Message from the USENIX ATC '23 Program Co-Chairs

Introduction

Welcome to the 2023 USENIX Annual Technical Conference (USENIX ATC '23). We are excited to be holding an in-person event with minimal visa issues requiring remote participation. Similar to last year, USENIX ATC '23 is co-located with OSDI. We very much look forward to meeting everyone in the systems community whether they attend USENIX ATC, OSDI, or both. The rest of this document provides some insights into the submission and selection process that culminated in 65 accepted works that will be presented at the conference.

Submissions

As in previous years, USENIX ATC '23 solicited three types of papers. In addition to full length, 11-page research papers, authors could submit 5-page short research papers that describe complete and properly evaluated ideas using fewer pages. Finally, to align with the USENIX mission of bringing together researchers in academia and systems practitioners, we continued the practice of soliciting papers describing the design, implementation, analysis, and experience with real-world deployment of systems and networks in a deployed systems track. These "Deployed Systems" papers had different criteria for acceptance from research papers, not needing to present new ideas or results to be accepted, but needing to convey practical insights.

A submission to USENIX ATC '23 involved more than a single PDF file. On the HotCRP submission system, each submission also contained an artifact description that included further details about the experimental environment. Optionally, authors could include a textual description of changes from previous submissions to help in the case where reviewers may have seen prior iterations of the paper while on other PCs. Finally, if on the deployed systems track, authors were required to specify a justification for why the paper belonged in that track.

Program Committee Selection Process

We assembled a program committee with many goals in mind: good coverage across diverse computer-systems topics, balance between academia and industry, a mix of veterans of prior USENIX ATC PCs with individuals in early stages of their professional careers, geographic diversity, and adherence to the USENIX diversity and inclusion principles. The assembled PC had 107 members from 19 countries, including 44% from North America, 33% from EMEA and 21% from APAC. 70% of the PC was from academia and 30% from industry, though some PC members from academia were also affiliated with industry. 55% of our PC were veteran PC members who had served USENIX ATC at least once in the past 4 years. Our PC had 26% female representation, which is higher than recent years (e.g., 18% for USENIX ATC '22). The main areas of expertise of PC members were Storage (24%), Distributed Systems (25%), Operating Systems (26%), Security (15%), Networking (12%), and Machine Learning (17%).

For the PC selection process, which was done well in advance of the submission deadline, we drew from a pool of experienced PC members who had served at least once in the prior 4 iterations of USENIX ATC, removing those who had served 4 times in a row and those who were concurrently serving for OSDI. In making our invitations, we prioritized several factors, including the following: reviewers flagged in HotCRP as producing good reviews for previous conferences; recommendations of researchers (usually early career) from invitees who were unable to serve; topic matches, trying to anticipate the need for Machine Learning expertise based on topic ratios from last year; and female representation, as it has been low in the USENIX ATC community.

During the review process, there were a few cases in which we needed expertise for a paper in which all reviewers identified low levels of expertise. For these, we solicited recommendations from the PC and invited external reviewers.

On January 9th, 2023, we held a synchronous online PC pre-review meeting to go over the unique aspects of USENIX ATC '23 submissions, and an overview of the duties and processes involving PC members, including bidding, reviewing rounds, online discussions, the author rebuttal, the PC meeting, and shepherding. Although attended by both veteran and new PC members, we hoped the meeting helped to welcome new PC members and provide opportunities for questions about the process. We held the meeting twice (7 hours apart) in an attempt to accommodate the various timezones of our international PC.

Review Process

USENIX ATC '23 received 353 submissions across all tracks, which was 10% fewer than USENIX ATC '22. Of these, 22 (6%) were deployed systems papers and 19 (5%) were short papers. The most popular topics for submissions, as specified by

authors were: Clouds, clusters, data centers (29%); ML/AI (24%); Storage, file systems (23%); Parallel and Distributed Systems (22%); Operating Systems, Kernels (14%); and Networking (14%).

We adopted a double-blind review process to minimize bias with strict anonymity rules. Four papers were ultimately rejected due to including author names, directly identifying or sharing a name or title with an existing technical report, or directly linking to a github repository under the author's name or institution. We identified one of these cases prior to reviewing, but the others were detected during the reviewing process.

We rejected three other submissions without review due to violations of the formatting guidelines, two papers for exceeding the length limits, and one that was too short and did not contain sufficient detail. Of particular note was the misuse of appendices, including very long appendices and appendices that contain information that is integral to the paper.

In order to increase the quality and relevance of reviews, we ran a bidding process in which PC members had 8 days to bid on which papers they felt were in their competency/expertise area and for which they could provide knowledgeable reviews. PC members also updated their topic preferences in HotCRP, which along with bid values were used by the HotCRP algorithm to assign papers. We took care to ensure that PC members requesting a lighter workload were assigned fewer papers in each round. Especially in the second round, we manually adjusted reviewers in cases where reviewer confidence was low, based mainly on PC members' bid values.

USENIX ATC '23 had two double-blind rounds of reviews. The goal of the first round was to identify early rejections and also identify for which papers the round 1 reviewers lacked sufficient expertise. In the first round we assigned 3 reviewers per paper, resulting in 1044 reviews. The reviewers had 5 weeks to review papers and 2 weeks for asynchronous online discussion. We notified authors of papers rejected in round 1 (216/353 = 61%) early (sent on March 22nd) to give these authors more time to prepare a future submission.

In the second round, we assigned at least two additional reviewers to the 132 submissions not rejected in round 1, amounting to 284 additional reviews, bringing the total number of reviews for round 2 papers to 5. The reviewers had 3.5 weeks to review these additional papers followed by 3 days of asynchronous online discussion to identify the most important questions for authors to respond to. Authors had 3 days to write a recommended 500 word response with a limit of 1000 words. Almost all authors wrote responses within this range. The reviewers continued the asynchronous online discussion for 1.5 weeks, converging to pre-accept, pre-reject, and pc-discussion decisions on papers. 48 papers were pre-accepted, leaving more discussion time for controversial papers at the synchronous virtual PC meeting. 37 papers were selected for discussion at the PC meeting, of which (22/37 = 59%) of papers were accepted.

We held a two-day synchronous virtual PC meeting with the goals of providing a high-bandwidth channel to resolve discussions, exposing all PC reviewers to a broader set of papers to level-set on quality, raising broader issues that may span multiple submissions and ultimately selecting the final program. We used Zoom, managing conflicts with breakout rooms and HotCRP to manage the discussion order. To manage timezones, we split the paper discussions into 2-hour blocks based on a Doodle poll of timezone availability for the specific reviewers on each paper. PC members were encouraged to attend all sessions regardless of whether one of their papers was being discussed. While it remains a challenge to have full PC participation for the entire meeting due to the wide range of timezones, we found the discussions to be lively and effective.

The PC selected 65 papers for an 18% acceptance rate. 11 were deployed systems papers, 3 were short, and the other 51 were full length research papers. Acceptance was based on the quality of the submissions; in-person conference constraints had no bearing on our decisions. After selecting the program, the program chairs selected two best papers based on nominations from the PC.

Artifact Evaluation Process

USENIX ATC '23 continued to run a joint artifact evaluation process with OSDI, led this year by Jianyu Jiang, Nathan Rutherford, and Cesar A. Stuardo. The artifact evaluation committee chairs assembled a committee consisting of 106 members. The authors of all accepted papers were invited to submit an artifact for an evaluation. 41 out of the 65 USENIX ATC papers (63%) did so. 98% of artifacts received an "Available" badge, 85% received a "Functional" badge, and 63% received a "Reproduced" badge. 61% of papers received all three badges (some artifacts were reproduced, but are not available).

Daniel Porto, researcher at INESC-ID in Lisbon, Portugal, passed away on April 29, 2023. He was a very talented and dedicated researcher, and a recognized expert in the areas of distributed systems and Byzantine consensus. His research led to several impactful publications in venues like EuroSys, OSDI, or DSN, and he served with a sense of community in several committees including the 2023 USENIX ATC/OSDI artifact evaluation committee. As a human being, Daniel will be remembered as an extraordinary person with an endless desire to help others. He touched the lives of many with his incredible generosity and kindness.

Acknowledgements

More than 200 people have contributed to the organization of the USENIX ATC '23, most of them in a voluntary capacity. We would like to thank each and every one of them. We are tremendously grateful to the program committee members for a job extremely well done, and for their personal sacrifices. We thank the Artifact Evaluation committee and the Artifact Evaluation Committee Chairs for their work and contribution, which improves our community and enables future research. Last, we thank the USENIX organization, the USENIX ATC steering committee and OSDI '23 co-chairs. The amount of work and preparation that goes into organizing a conference is immense, and we were astounded by the help and support provided by everyone involved.

Abstract

Existing confidential VMs (CVMs) experience notable network performance overhead compared to traditional VMs. We present the first thorough performance analysis of various network-intensive applications in CVMs and find that the *CVM-IO tax*, which mainly comprises the bounce buffer mechanism and the packet processing in CVMs, has a significant impact on network I/O performance. Specifically, the *CVM-IO tax* squeezes out virtual CPU (vCPU) resources of performance-critical application workloads and may occupy more than 50% of CPU cycles. To minimize the *CVM-IO tax*, this paper proposes Bifrost, a novel para-virtualized I/O design that 1) eliminates the I/O payload bouncing tax by removing redundant encryption and 2) reduces the packet processing tax via pre-receiver packet reassembly, while still ensuring the same level of security guarantees. We have implemented a Bifrost prototype with only minor modifications to the guest Linux kernel and the userspace network I/O backend. Evaluation results on both AMD and Intel servers demonstrate that Bifrost significantly improves the performance of I/O-intensive applications in CVMs, and even outperforms the traditional VM by up to 21.50%.

1 Introduction

As more and more data-processing applications [9, 13, 14, 57] embrace the cloud, widespread concerns are being raised about the security and privacy of data in-use on the cloud. To address these concerns, various confidential computing solutions have been proposed to safeguard data from unauthorized parties. Among them, confidential virtual machine (CVM) solutions, such as AMD SEV [2, 3], Intel TDX [32] and ARM CCA [8], run guest operating systems (OSes) in hardware-isolated environments. In these environments, the complex virtualization stack, such as hypervisor and host OS, is no longer trusted and cannot access data in guest OSes arbitrarily, while still providing resource management functions. This CVM abstraction transparently protects user workloads without requiring any modifications and integrates easily into the existing cloud infrastructure. Therefore, it has gained popularity and is increasingly deployed in data centers.

Unfortunately, while the speed of modern network devices continues to grow (Terabit Ethernet [60] like NVIDIA 400Gbps NIC [51]), the security protections introduced by existing CVM solutions have a significant negative impact on network performance. This paper first conducts a series of experiments to thoroughly analyze the network I/O performance of CVMs. We evaluate widely-deployed network-intensive applications in an AMD SEV-ES/SNP server and a simulated Intel TDX server. The results demonstrate that CVM's security protections significantly increase the *CVM-IO tax*, which we define as the CPU resources used during CVM's I/O procedure, resulting in up to 29% overhead over a traditional VM that does not use any CVM protections. The *CVM-IO tax* is caused by both security protections and intrinsic network I/O procedures in CVMs, draining substantial CPU resources from diverse application workloads.

Concretely, there are three common components in the CVM-IO tax: ① **VM exits** consume up to 11.54% more CPU cycles than the traditional VM. The time consumption of VM exits is greatly increased due to the security checks and protections from the trusted modules (e.g., AMD-SP [3], Intel TDX module [31]) and making the guest aware of emulation events (e.g., AMD #VC [3], Intel #VE [29]). ② The **bounce buffer mechanism**, an I/O staging memory shared between the CVM and hypervisor, takes up to 19.45% CPU cycles for bouncing packets (including headers and payload). I/O operations that could previously be done directly by the hypervisor to the traditional VMs must now be assisted by the bounce buffer mechanism in guest OSes. For example, to emulate a virtual NIC, the hypervisor in traditional VM systems can forward packets between the guest OS and the host network stack by directly copying I/O data to/from the guest private memory. But hypervisors in CVM systems require the guest OS to bounce packets to/from a hypervisor-visible shared memory region due to the memory encryption, introducing I/O data copy overhead. ③ The **packet processing** also spends up to 36.14% CPU cycles preparing payloads from massive network packets for application workloads. The

✉Corresponding author: Zeyu Mi (yzmizeyu@sjtu.edu.cn).

higher the number of packets transferred to the network stack, the more vCPU resources a CVM requires to process their headers. Fortunately, the cost of VM exits becomes negligible when the posted interrupt [59] feature is supported by the hardware, leaving the bounce buffer mechanism and packet processing as the main components of the CVM-IO tax.

This paper aims to **reduce as much CVM-IO tax as possible** for I/O-intensive applications in CVMs by bypassing the bounce buffer mechanism and offloading the packet processing. A straightforward design to bypass the bounce buffer mechanism is to keep the packet content in place by dynamically adjusting the accessibility of the same memory region to the hypervisor. However, this approach is limited by the memory encryption hardware support [34], which does not allow the plaintext contents of a memory region to be preserved when modifying the accessibility of the memory region [29]. To reduce network packet processing cost, the existing design is to pass fewer packets to the network stack by reassembling multiple small packets into a large one in the guest device driver. But the guest device driver still has to process a large number of packets, consuming substantial CPU resources.

Fortunately, there are three observations that can help us address the challenges mentioned above. We observe that either end-to-end encryption or a CVM's private memory alone can protect data security, while applying both protections to the payload is redundant. Additionally, we notice that end-to-end encryption/decryption can also change the payload's memory location, which is functionally equivalent to bouncing between two memory regions. As a result, bypassing payload bouncing can be achieved by directly encrypting/decrypting the payload into/from the guest-host shared memory. Another observation is that the network I/O backend typically has plenty of residual CPU resources. Given the bottleneck experienced by the saturated vCPUs of network-intensive CVMs, an opportunity arises to offload packet processing to the network I/O backend. This approach effectively utilizes the available CPU resources, alleviating the strain on vCPUs and resulting in improved performance.

Based on these observations, this paper proposes **Bifrost**[1] to improve the paravirtual network performance of the CVM with three techniques: ① The *zero-copy encryption deduplication* eliminates payload bouncing by leveraging dedicated guest-host shared memory to remove redundant encryptions on the payload in a zero-copy way. When receiving packets, the end-to-end encrypted payload is directly decrypted from the shared memory. When sending packets, the payload is directly encrypted into the shared memory. To minimize modifications, the shared memory is in the form of dedicated non-uniform memory access (NUMA) [37] nodes, allowing memory allocators in the guest kernel to be reused. ② The *one-time trusted read* mechanism protects guest OSes from time of check to time of use (TOCTTOU) attacks while accessing packets in the dedicated shared memory. With these two techniques, the bouncing of the end-to-end encrypted payload, which takes up much CPU resources of CVMs, is securely bypassed. ③ The *pre-receiver packet reassembly* reduces vCPU resources utilized by the device driver by offloading the task of reassembling received packets to the network I/O backend. Thus, CVMs are able to process fewer packets with larger payload, reducing the packet processing cost on vCPUs.

We have implemented a Bifrost prototype by modifying the guest OS kernel and host user-level software. The prototype extends the Linux v6.0-rc1 kernel in the guest OS with 815 lines of code, and adds 175 lines to OpenvSwitch v2.17.3 and 541 lines to DPDK v21.1.2, both of which run in the host user mode. We have also evaluated Bifrost's performance on both AMD and Intel platforms. The results show that, with advanced posted interrupt support, Bifrost enhances the performance of I/O-intensive applications in CVMs, surpassing traditional VMs by up to 21.50%.

In summary, this paper makes the following contributions:

- The first thorough performance analysis of I/O-intensive applications in CVMs on existing and next-generation hardware platforms, revealing their bottlenecks and overhead sources compared to traditional VMs.
- A secure paravirtual I/O design that greatly reduces the CVM-IO tax, significantly improving the performance of I/O-intensive applications in CVMs.
- A Bifrost prototype and a comprehensive evaluation on AMD and Intel platforms, demonstrating improvements on existing and future CVM hardware. The prototype is available at `https://github.com/IPADS-Bifrost`.

2 Background

2.1 Confidential VMs (CVMs)

There are different CVM solutions based on specialized hardware extensions. All of these solutions leverage hardware memory encryption and integrity checking [30, 34] to enforce confidentiality and integrity. They share the same CVM abstraction that excludes the entire virtualization stack from the trusted computing base (TCB). As shown in Figure 1, the trusted firmware, which is the unique software TCB, isolates the CVM from untrusted hypervisors and traditional VMs.

Existing CVM systems typically divide the physical memory of a VM into two major security types: private memory and shared memory. The private memory is encrypted by hardware and cannot be accessed or modified by any untrusted entities outside the VM, while the shared memory holding plaintext data can be accessed by the hypervisor. The CVM systems also allow the hypervisor to switch private memory and shared memory to each other at runtime. However, the data content of the memory page cannot be preserved before and after the security type switch [29]. Hence, the guest must

[1] Bifrost, the rainbow bridge from Norse mythology, metaphorically represents the secure and rapid transfer of CVM's I/O data (Asgard's gods) to and from the untrusted hypervisor (Midgard).

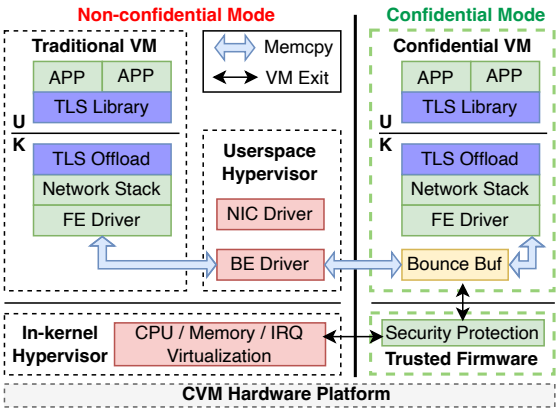

Figure 1: The paravirtual I/O networking architecture of traditional VMs and CVMs atop the CVM hardware platform. The black arrows represent the path of VM exits and VM enters. The light blue arrows indicate memory copies that consume CPU resources. The FE Driver and the BE Driver in the figure represent drivers in frontend and backend, respectively.

move data outside of private memory before the security type switch, and then copy it back to the new shared memory. Besides, it takes much effort to finish the security type switch. The guest OS has to cooperate with the host hypervisor to alter address translation data structures and maintain CPU micro-architectures, requiring multiple VM exits and interprocessor communications [4, 29]. As a result, the security type switch is unsuitable to occur frequently in CVMs.

2.2 Paravirtual I/O Networking in CVM

Paravirtual I/O has become a primary I/O virtualization choice for modern cloud providers owing to its high performance and excellent compatibility. There are two cooperative drivers in paravirtual I/O, a frontend driver in the guest VM and a backend driver in the hypervisor, which communicate with each other through shared memory. To provide maximum network performance, the backend driver can be deployed in the host userspace, for instance, using vhost-user [46, 53], to directly control the device in a busy-polling mode [16].

An example of paravirtual I/O networking of the traditional VM is shown in the left part of Figure 1. The applications in the userspace deal with payload, while the network stack and the frontend driver in the kernel handle packet processing. The packet processing includes network functions that handle conversions between payload and packets. For example, in the transmission (TX) direction, the payload from applications and the headers from the network stack are encapsulated into network packets, after which the backend driver is notified to send them out. Because the hypervisor can access the entire memory space of a traditional VM, the backend driver can copy the packets freely from the guest memory to its own memory and forwards them to the NIC driver.

Memory pages in CVMs, including those containing packets, are set to private by default. However, the host OS is untrusted and cannot access the private memory of CVMs (see § 2.1). To allow the host OS to transfer packets, CVMs utilize a bounce buffer mechanism that sets up a guest-host shared memory as an intermediary. As shown in the right part of Figure 1, the guest OS reserves a shared memory region with the host OS as the bounce buffer and copies the outgoing packets to it. Afterwards, the backend driver can copy the packets to the hypervisor as normal. As a result, the bounce buffer leads to excessive memory copies for I/O virtualization.

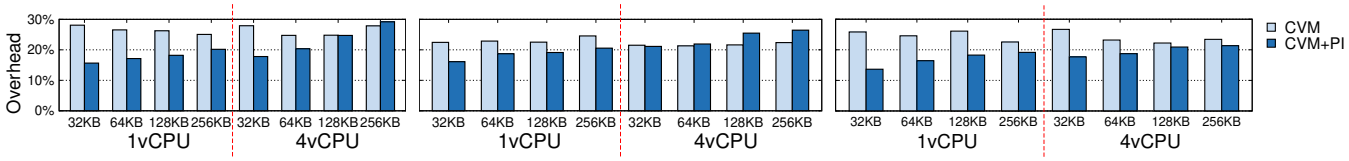
2.3 Transport Layer Security (TLS)

TLS is an end-to-end security protocol designed to protect data in transit by leveraging cryptography. It has been commonly used by modern applications to secure their I/O payload in transit [6, 17, 49, 55, 61]. CVM solutions have made it a mandatory requirement for their applications [22, 26, 54]. Moreover, today's OSes, such as Linux, provide in-kernel TLS support, enabling userspace applications to offload TLS to the kernel for enhanced performance and expanded features [19]. As shown in Figure 1, in-kernel TLS allows the payload from the page cache to be encrypted without going through the userspace.

The industry currently implements the TLS protocol based on encryption algorithms such as AES-GCM [18] to assure the confidentiality and integrity of data simultaneously. The output of these encryption algorithms consists of encrypted ciphertext for confidentiality, and an authentication tag generated from the ciphertext for integrity. To provide complete data security protection, the correctness of both the ciphertext and its authentication tag must be guaranteed during encryption, and vice versa.

2.4 Exitless Interrupt Virtualization

In the paravirtual I/O networking scenario, when a virtual NIC (i.e., network backend) receives some network packets, it notifies the guest VM with a virtual interrupt. The guest VM then needs to interact with the virtual interrupt controller to perform Acknowledgment (ACK) and End of Interrupt (EOI). Traditional techniques rely on the hypervisor to emulate interrupt delivery and interrupt controller access of guest VMs using trap-and-emulate approaches. However, virtualizing interrupts in this way can be a significant source of overhead, as each virtual interrupt's completion necessitates multiple VM exits and entries. To address this issue, modern hardware platforms have introduced the posted interrupt technique to enable exitless virtual interrupt delivery. They have also extended their interrupt controllers with specialized virtualization support to eliminate VM exits caused by ACK and EOI. Interrupt controllers with virtualization extensions are currently in production by all mainstream hardware vendors such as Intel, AMD, and ARM. Full-featured posted interrupt is available on the Intel platform, and it will soon be supported on other platforms (e.g., next-generation products with AMD AVIC [4] and ARM GICv4 [7]).



(a) Memcached **(b)** Nginx **(c)** Redis

Figure 2: Normalized overhead compared with traditional VM in I/O-intensive applications. The Y-axis is the normalized overhead compared to the baseline of each group. CVM+PI represents CVM + Posted Interrupt.

3 Analysis of CVM-IO Tax

In this section, we quantify the performance impact of the CVM-IO tax by comparing the I/O performance of existing CVMs with that of traditional VMs. The CPU execution time of I/O-intensive applications running in a CVM can be divided into two parts: 1) *Application workloads*: the time spent on executing application workloads, including business logic and payload processing. 2) The *CVM-IO tax*: the time spent on CVM-specific security protections and intrinsic network I/O procedures. It consists of VM exits, the bounce buffer mechanism, and the packet processing during the payload preparation for application workloads.

All experiments are conducted on a 128-core AMD SEV-ES/SNP server and a 24-core Intel server with 200Gbps NICs. The AMD server is used to evaluate the I/O performance of real CVMs, referred to as ***CVM***. However, the AMD server does not support posted interrupt, resulting in degraded performance due to numerous VM exits during virtual interrupt deliveries. Therefore, we simulate next-generation CVMs using the Intel server that supports posted interrupt, named ***CVM+PI***. More detailed testbed and simulation configurations are described in § 7.1. For fair performance comparison, *CVM*'s baseline is the vanilla AMD traditional VM, while *CVM+PI*'s baseline is the vanilla Intel traditional VM.

To achieve optimal network performance, we choose vhost-user as the network backend in follow-up experiments. We still use the SEV-ES VM because the SEV-SNP VM does not support vhost-user due to its lack of huge page support. Theoretically, the security protections introduced by SEV-SNP do not further increase the CVM-IO tax.

3.1 CVM-IO Tax Breakdown

We first evaluate the overall performance using three representative network-intensive applications: Memcached and Redis for key/value stores, and Nginx for web servers. All applications and benchmarks enable the in-kernel TLS support for end-to-end protection. Figure 2 depicts the normalized performance overhead of CVMs compared to their respective baselines. In all three benchmarks, *CVM* incurs 21%-28% overhead, while *CVM+PI* exhibits 13%-29% performance degradation. As a result, the performance impact of CVM-IO tax results in significant overhead over baselines.

We further take the Memcached benchmark with the 4vCPU-256KB test cases as an example to break down the time cost of the CVM-IO tax of CVMs, as shown in Figure 3. In the left subfigure, the *VM Exit*, *Bouncing* and *Pkt Processing* denote the three corresponding parts of the *CVM-IO tax* mentioned earlier. Because all vCPUs are fully utilized during the benchmark, the impact on overall performance becomes more significant as the percentage of CPU time consumed by the CVM-IO tax grows. The CVM-IO tax consumes over 50% of the total CPU time in all CVMs during the benchmark. For *CVM*, VM exits taking up more than 20% CPU time have more impact than the bounce buffer. For *CVM+PI*, the bounce buffer cost occupies more than 19% CPU time, while VM exits take up a tiny percentage of the total time in both *CVM+PI* (less than 1.2%) and its baseline (less than 0.5%). Packet processing in all the above cases accounts for about 30% of CPU time and thus has a considerable impact.

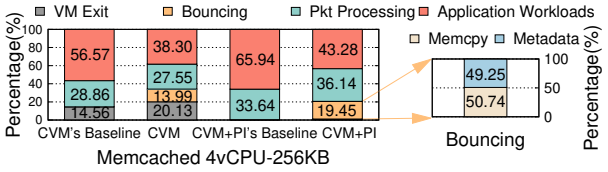


Figure 3: CPU time breakdown of the Memcached 4vCPU-256KB case in CVMs. The left subfigure shows the CPU time breakdown of *CVM*, *CVM+PI* and their baselines in the Memcached 4vCPU-256KB case. The right subfigure shows the CPU time breakdown of the bounce buffer part in *CVM+PI*.

The overhead over baselines can be attributed to the reduction in CPU time of application workloads due to the CVM-IO tax. For example, in the 4vCPU-256KB case of *CVM+PI*, the CVM-IO tax leaves 34.35% fewer cycles for application workloads than the baseline, explaining the 27.44% overhead. Since packet processing in both CVMs and their baselines consumes a similar portion (about 30%) of CPU time, VM exits and the bounce buffer in CVMs contribute the most to the overhead.

Take-away I

> *The CVM-IO tax that occupies more than half of total CPU time incurs a substantial performance impact on CVMs. VM exits and the bounce buffer are the primary sources of overhead over baselines.*

Lengthy VM Exits The AMD SEV-ES hardware introduces protection for CPU states (e.g., registers) of each CVM against the untrusted hypervisor during VM exits. In contrast

to traditional VMs, this protection adds thousands of cycles to each VM exit. We first break down the VM exit handling cost during every virtual interrupt delivery, finding that, on average, *CVM* spends 7,476 cycles on guest-host world switches, whereas a traditional VM only spends 1,643 cycles. We then collect the number of VM exits per second during the Memcached 4vCPU-256KB benchmark for different CVMs. *CVM* averagely triggers 41,615 VM exits per second on each vCPU, while *CVM+PI* only triggers 2,803 VM exits per second on each vCPU, an order of magnitude less than *CVM*.

The results indicate that frequent VM exits taking up more than 20% of total CPU time have a significant impact on *CVM*. However, with posted interrupt support (*CVM+PI*), the impact of VM exits is almost negligible. Fortunately, all next-generation CVM platforms, including AMD SEV, Intel TDX and ARM CCA, support posted interrupt, so that the performance impact of VM exits can become minimal.

Take-away II

> *VM exits may take up a large portion of the CPU time of CVM due to their high frequency and latency, but their performance impacts can become minimal with the posted interrupt support on next-generation hardware.*

Bounce Buffer To analyze the overhead of bounce buffers, we break down the CPU time spent on bounce buffers in the 4vCPU-256KB case of *CVM+PI* into two parts: copying I/O data (packets in this case) and maintaining metadata for buffer allocation and freeing. The breakdown result shown in the right subfigure of Figure 3 indicates that I/O data copy (corresponding to the *Memcpy*) consumes 50.74% of the bounce buffer time, while the metadata maintenance (corresponding to the *Metadata*) spends 49.25% of the bounce buffer time. Besides, the experimental results of small and large data sizes reflect that the performance impact of the bounce buffer rises as the data size increases.

Take-away III

> *The bounce buffer consumes a large percentage of CPU resources due to I/O data copying and metadata maintenance. It is necessary to avoid bouncing large-size I/O data to minimize the bounce buffer's performance impact.*

Packet Processing Packet processing in both the frontend driver and the network stack consumes up to 36.14% of CPU time in Memcached 4vCPU-256KB cases. Since the packet processing time cost is proportional to the number of packets processed, the large number of packets in I/O-intensive scenarios can demand a significant amount of CPU resources.

Take-away IV

> *Packet processing occupies a large fraction of CPU time due to the large number of packets to be processed. Reducing the number of packets to be processed can mitigate its performance impact.*

3.2 Summary

To sum up, our experiments have demonstrated that CVMs incur up to 29% overhead in I/O-intensive applications compared with traditional VMs. On the next-generation hardware with posted interrupt support, the tax of VM exits becomes negligible while the bounce buffer tax has a more significant impact on CVMs. Additionally, the packet processing tax consumes a great portion of CVMs' vCPU resources due to the large number of packets, which is also the case for traditional VMs. Therefore, it is essential to reduce the cost of the bounce buffer as well as the packet processing in CVMs to minimize the CVM-IO tax and achieve high network performance.

4 Overview

4.1 Design Goals

The primary goal of Bifrost is to reduce the paravirtual I/O network tax of existing CVM solutions while maintaining the same level of security guarantees. Besides, the design of Bifrost should be general enough to be easily applied to CVM solutions on various platforms, such as x86, ARM and RISC-V, and to support different host and guest OSes, including Linux, FreeBSD and Windows. Further, it is demanding that Bifrost should avoid intrusive modifications to existing software stacks and keep transparent to userspace applications in CVMs to make it practical for real-world scenarios.

4.2 Challenges

To reduce the CVM-IO tax, Bifrost should optimize the bounce buffer mechanism and the packet processing procedure. However, it is not easy to implement these optimizations due to the following two technical challenges:

C1: Out-of-place hardware encryption and decryption. The ideal way to eliminate the bounce buffer mechanism for a network packet is to enable zero copy by maintaining the packet within the same memory region throughout its entire lifecycle. In addition, either the guest or the host should have exclusive access to the packet's memory region while processing it to ensure data security, necessitating memory security type switches at runtime. However, as mentioned in § 2.1, when a private page containing a packet is converted to a shared page (and vice versa), the packet in this page is lost and unable to be correctly passed to the hypervisor. Moreover, changing the security type of guest memory pages is too expensive to be a frequent operation on the I/O critical path.

C2: Costly packet pre-processing in the device driver. Packet processing primarily operates on packet headers rather than payloads. To minimize the cost of packet processing, a commonly employed technique is to pre-process multiple small packets within the same flow into larger packets before submitting them to the network stack. Nonetheless, the virtual NIC driver still has to occupy large quantities of vCPU resources to handle massive small packets coming from the high-speed NIC.

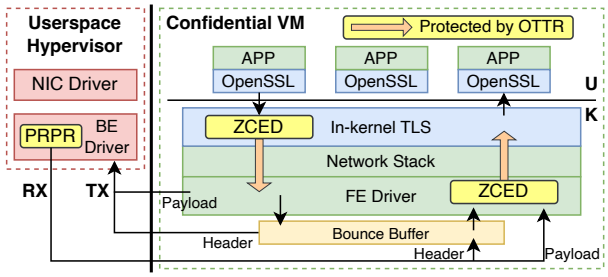

Figure 4: The overall architecture of Bifrost.

4.3 Observations and Insights

We observe three characteristics of existing CVM systems, allowing us to propose new designs that are appropriate for CVM scenarios to address the above challenges.

O1: Either private memory or end-to-end encryption alone is sufficient to assure data security. Data security can be ensured by either private memory protection or end-to-end encryption. Besides, it is not always better to apply multiple security protections to a piece of data at the same time, especially for performance-critical I/O data. Specifically, the guest OS in current CVM solutions initially encrypts the payload into private memory. But private memory protection is a redundant security mechanism for data that has already been encrypted. As a result, the payload bouncing tax can be eliminated by retaining existing end-to-end encryption while removing private memory protection at the same time.

O2: End-to-end encryption has the side effect of moving the memory location of the payload. The procedure of adding end-to-end encryption allows CVM to relocate payloads to a different memory location. Hence, end-to-end encryption at the in-kernel TLS layer provides an opportune moment to also remove private memory protection on the payload for userspace applications. In particular, the generated ciphertext during encryption can be directly written to the target shared memory with the host, ensuring data security while eliminating unnecessary copies and bouncing overhead.

O3: I/O backends usually have plenty of residual CPU resources available. Modern virtualization systems usually leverage dedicated CPUs to run I/O backends of VMs for high and predictable I/O performance [16, 45]. Unlike CPUs running CVMs' vCPUs, which are likely to be fully loaded due to complex in-guest logic, those running I/O backends have less work to do and thus have plenty of free CPU resources. As a result, I/O backends with adequate residual CPU resources can be utilized to release the burden of vCPUs by pre-processing packets before passing them to CVMs.

4.4 Architecture and High-Level Design

Based on the above observations, Bifrost leverages the side effect of end-to-end encryption and the residual CPU resources of network I/O backends to eliminate payload bouncing and reduce packet processing cost in CVMs in an application-transparent way. Figure 4 shows the architecture of Bifrost.

To address challenge **C1**, Bifrost proposes two designs to enable zero-copy transparently and securely for the end-to-end encrypted payload in the CVM. **D1:** *zero-copy encryption deduplication* (§ 5.1) eliminates payload bouncing by keeping the end-to-end protected payload in the same shared memory during its lifetime. Specifically, Bifrost directly stores output from the in-kernel TLS layer to the guest-host shared memory without copying any payload, and vice versa. To minimize modifications, Bifrost creates dedicated NUMA nodes to serve as shared memory for this design, so that memory allocators in the guest kernel can be reused. However, concurrent memory accesses to plaintext data in shared memory may lead to TOCTTOU attacks. A malicious host can tamper with data that has passed the security checks of the guest OS, such as altering a packet header after it has passed the checksum check. To defend against this attack, Bifrost introduces **D2:** *one-time trusted read* (§ 5.2), which ensures that the guest OS can only read and trust the target data content from shared memory once, as additional reads from the same memory may lead to host-tainted data content. The guest must process data after it has been read into registers or private memory to defend against host tampering during guest processing, thus eliminating TOCTTOU issues.

To address challenge **C2**, Bifrost proposes another design to complete pre-processing network packets before they reach the CVM. **D3:** *pre-receiver packet reassembly* (§ 5.3) makes use of the network backend's free CPU resources to pre-process multiple small incoming packets into a large one before transmitting them to the guest OS.

As mentioned in § 3.2, while **D1** and **D2** are designed to optimize payload bouncing issues that are specific to CVMs, **D3** can also be leveraged to reduce packet processing cost in traditional VMs.

We explain the Bifrost architecture and its design points by describing the high-level workflows of packet receiving and sending. **Packet receiving workflow:** When a network packet carrying an end-to-end encrypted payload arrives at the network I/O backend, Bifrost attempts to merge it with other same-flow packets, if possible, by pre-processing the packet with PRPR (**D3**). Then Bifrost flushes those pre-processed network packets to the frontend driver through virtual network queues of the CVM. The zero-copy aware TOCTTOU defense (**D2**) in the frontend driver only copies small metadata such as packet headers to private memory for security, while keeping the end-to-end encrypted payload in the shared memory allocated from dedicated NUMA nodes (**D1**). Next, the frontend driver constructs basic data structures (e.g., *skbuff* in Linux) for these pre-processed incoming packets before passing them to the network stack. Afterwards, Bifrost utilizes the in-kernel TLS support to decrypt the end-to-end encrypted payload directly from shared memory into the application's private memory. As a result, the packet receiving workflow experiences no end-to-end encrypted payload bouncing and less packet processing cost in the CVM.

Packet sending workflow: When an application begins to

send out a payload from the guest OS, Bifrost first leverages the in-kernel TLS support to encrypt plaintext from either application memory or kernel page cache in private memory and places the encrypted result directly into the guest-host shared memory allocated from dedicated NUMA nodes (**D1**). The memory copy of the end-to-end encrypted payload from private memory to the shared bounce buffers is removed at this step. For small metadata that is not protected by end-to-end encryption, the zero-copy aware TOCTTOU defense (**D2**) enforces Bifrost to fall back to the bounce buffer mechanism. Consequently, there is no end-to-end encrypted payload bouncing in its sending workflow.

4.5 Threat Model and Assumptions

The threat model of Bifrost is the same as that of existing CVM solutions. The TCB only comprises the CPU hardware and minimized trusted monitor firmware or software, if any. Attackers can control any untrusted software entities or hardware devices to launch attacks on CVMs. Therefore, for a specific CVM, all software outside it, including the hypervisor and other CVMs, and hardware devices, are untrusted. We assume that a CVM does not voluntarily reveal its sensitive data and protects its I/O data with end-to-end encryption. Denial-of-Service (DoS) attacks [11] are out of scope. Although CVM implementations may have bugs [5, 41] and are subject to side-channel attacks [12, 39, 40, 47], we do not consider them because they are orthogonal to this paper.

5 Design and Implementation Details

5.1 Zero-Copy Encryption Deduplication (ZCED)

Bifrost reserves a contiguous shared memory region for paravirtual I/O networking in the guest physical address (GPA) space. This shared memory appears as NUMA nodes dedicated for ZCED (hereinafter called ZCED NUMA), allowing Bifrost to utilize mature memory management mechanisms in existing guest OSes. Moreover, the location and size of ZCED NUMA memory are fixed at the boot time of a CVM for optimal performance.

Boot-time initialization: The memory range of a ZCED NUMA node can be configured by setting the base GPA and total length via the kernel command line. As shown in § 7.4, ZCED NUMA nodes of 200MB can satisfy the demands of all network-intensive benchmarks in our experiments. Bifrost parses the number of ZCED NUMA nodes and adds the specified guest memory range to each node. All ZCED NUMA nodes are created with no associated vCPU. Before a ZCED NUMA node is available for memory allocations, Bifrost sets its memory security type to shared. To achieve optimal performance, proper distances should be specified between NUMA nodes to assist the guest kernel in allocating memory [36]. The distances between ZCED NUMA nodes are the same as those between normal NUMA nodes to which their memory ranges originally belonged, while each ZCED NUMA node is zero distance from its original NUMA node.

Runtime allocation: To prevent data leakage caused by unintentional data store into the ZCED NUMA memory, Bifrost adjusts the memory allocation policies of the guest OS to only allow explicit allocation to acquire ZCED NUMA memory. Hence, the original memory allocations in the system do not allocate from ZCED NUMA nodes, avoiding the security issue of inadvertently exposing sensitive data. Guest kernel components are merely able to allocate memory from ZCED NUMA nodes by assigning a special allocation flag (e.g., a *GFP* flag in Linux) provided by Bifrost to parameters of memory allocation invocations. The allocator will first try to acquire memory from the closest ZCED NUMA node to the vCPU running this component. In the frontend driver, Bifrost checks the memory location in which the payload resides, and if it belongs to a ZCED NUMA node, Bifrost will bypass the bounce buffer mechanism.

In the TX direction, Bifrost modifies the in-kernel TLS layer to transparently intercept communications between upper applications and the lower network stack. The payload in the TX direction must go through *sendmsg* and *sendpage* functions of the existing in-kernel TLS layer before entering the network stack. *sendmsg* is the most often used function for sending payload from userspace, whereas *sendpage* is specialized for transferring payload from the storage (e.g., page cache). Bifrost just adds the special allocation flag to the parameters of memory allocation invocations in these two functions to allocate memory from ZCED NUMA nodes for storing encrypted payload.

In the RX direction, the guest memory regions used to accept incoming packets are allocated and assigned by the frontend driver (i.e., virtio-net in our case). Bifrost modifies the memory allocation invocations for these regions by adding the allocation flag as well. When an application attempts to receive payload, Bifrost decrypts the ciphertext directly from the ZCED NUMA memory to private memory.

5.2 One-Time Trusted Read (OTTR)

To defend against TOCTTOU attacks, Bifrost only trusts the data obtained from the first read of the ZCED NUMA memory during the guest OS's handling of packet headers and end-to-end encrypted payload.

Packet header handling: The content of each packet header should only be used after it has been validated by the guest OS's packet processing functions. However, if a malicious host modifies the header after the guest OS's validation, the guest OS may encounter problems due to the invalid header. For instance, buffer-overflow problems can happen if the guest OS uses a modified length to extract payload from packets.

To prevent this, Bifrost must read a packet header from the ZCED NUMA memory into a private memory region before further processing it. This read only happens once for each packet header, and Bifrost will never read the header from

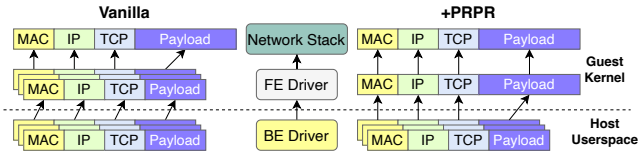

Figure 5: Comparison of the packet reassembly workflow of the vanilla CVM and the CVM with PRPR.

the ZCED NUMA memory again to prevent the host from subsequently tampering with the content of packet headers. In the TX direction, unlike the end-to-end encrypted payload that is stored in the ZCED NUMA memory, network packet headers are placed in private memory. The frontend driver still leverages the bounce buffer mechanism to copy packet headers to the guest-host shared memory before transmitting them to the backend driver. It has a very small impact on performance due to the small size of packet headers.

End-to-end encrypted payload handling: For end-to-end encrypted payload, as mentioned in § 2.3, data security protection requires that the encryption must generate both correct ciphertext (i.e., encrypted payload) and authenticated tag, and the decryption must correctly verify the ciphertext integrity with the authenticated tag. Both the authenticated tag generation and the integrity verification take the ciphertext as input, which exists in ZCED NUMA memory and may be tampered with by the host, resulting in compromised payload integrity. For instance, in the context of zero-copy I/O, the current Linux AES-GCM implementation on the x86-64 platform double reads the ciphertext from the same ZCED NUMA memory in the last phase of parallel decryption, suffering from TOCTTOU attacks on the ciphertext.

To prevent payload TOCTTOU attacks, in the decryption procedure, Bifrost reads only once from the ZCED NUMA memory to load the ciphertext value into CPU registers and always uses the correct ciphertext in the registers afterwards, avoiding reading a potentially compromised ciphertext. Similarly, during the encryption procedure, the ciphertext for each payload is guaranteed to remain valid from the moment it is generated in the register until it exits the register. Thus, Bifrost calculates the authentication tag using the correct ciphertext that is still in the CPU registers.

5.3 Pre-receiver Packet Reassembly (PRPR)

Large packets are split into smaller ones before sending out due to transmission size limit. To save CPU resources consumed by packet handling, prior work [33, 52] has decreased the number of packets passed to the network stack by reassembling small packets into large ones in advance. Modern OSes support small packets coalescing at the device driver layer using GRO [15]. However, packet reassembly in the guest device driver can still consume significant vCPU resources, severely affecting the application performance when handling large numbers of packets. While modern NICs enable hardware coalescing without engaging CPU using LRO [23], it is hard for hardware to dynamically adjust reassembly rules and support new packet formats. Inappropriate coalescing even causes metadata loss and network connection disruptions [15].

In comparison to prior approaches, Bifrost offloads the packet reassembly to the hypervisor backend driver which has sufficient CPU time, freeing up precious vCPU resources for CVMs without sacrificing flexibility. The packet reassembly logic in Bifrost is similar to that of previous work [15] since network packets share the same format.

Overall procedure: When a network packet arrives at the network backend, some packets may be cached in the backend and waiting for reassembly. Bifrost first parses the current packet header to determine if any cached packets from the same flow exist. If present, Bifrost tries to merge the current packet with the cached same-flow ones. Eventually, based on the status information in the currently cached packets in the network I/O backend, Bifrost decides whether it is time to flush them to the frontend driver in the guest OS.

Same-flow packet detection: Same-flow packets are network packets that share the same source, destination and sequence number. As our current implementation focuses on TCP/IP packets, Bifrost first recognizes headers that have the same MAC address, IP address and TCP port in both source and destination directions as same-flow candidates. Then Bifrost regards these candidates with an identical TCP acknowledgment (ACK) number as same-flow packets.

Flexible per-VM flush rules: It is essential to flush packets to the guest OS at an appropriate time since the network performance is highly sensitive to packet latency. When a newly received packet has a cached same-flow packet, Bifrost first checks whether these two packets have consistent status information, such as the time to live (TTL) field. If not, Bifrost flushes the old cached packet to the frontend driver. Otherwise, Bifrost reassembles these two packets into a new one. Finally, Bifrost flushes the new packet if it contains an immediate-flush flag (e.g., the TCP PSH flag). For a received packet that has no same-flow packet, Bifrost directly determines whether to flush it by checking its immediate-flush flag.

In addition to the above basic rules, Bifrost also allows each guest OS to customize flush rules. Bifrost provides paravirtual interfaces for receiver CVMs to install their own rules to disable reassembly, adjust the maximum number and timeout of cached packets.

Packet reassembly: Among the cached same-flow packets, the currently received packet can only be reassembled with the packet whose payload is contiguous with it. Bifrost finds neighbors of the received packet for reassembly by comparing their TCP sequence (SEQ) numbers. As depicted in Figure 5, duplicate packet headers are merged during reassembly.

6 Implementation Complexity

We implement a Bifrost prototype using Linux as the guest kernel and OpenvSwitch-DPDK as the network I/O backend.

In the Linux v6.0-rc1, we introduce 815 lines of code to support ZCED and OTTR. These changes include initializing

ZCED NUMA nodes during memory subsystem bootstrapping, replacing memory allocation invocations, and defending against TOCTTOU risks in AES-GCM assembly.

In the DPDK v21.11.2, we add 541 lines of code to implement PRPR, which primarily consists of two parts: 1) Reorganization of network packets, including header trimming during packet reassembly, flag resetting, etc. 2) Flush rules, which mainly focus on deciding whether to cache or immediately flush an incoming packet. Our implementation also adds 175 lines of code to OpenvSwitch v2.17.3, which preprocesses the network packets by parsing headers in advance, and invokes the interfaces provided by the DPDK.

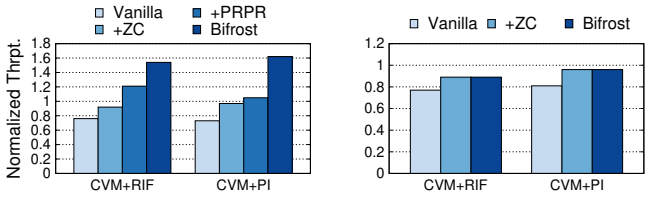
7 Evaluation

7.1 Experimental Setup

Testbed: Our testbed remains the same as in § 3, consisting of an AMD server and an Intel server running Ubuntu 20.04.4 LTS. The AMD server has two 64-core AMD EPYC 7T83 CPUs at 2.45GHz (128 cores in total) and 500GB DDR4 DRAM. The Intel server has two 12-core Intel Xeon Gold 5317 CPU at 3.00GHz (24 cores in total) and 188GB DDR4 DRAM. Both machines are equipped with one single-port Mellanox Connect-X6 200Gbps NIC and are back-to-back connected with a fabric cable. We disable CPU frequency boost features to lessen performance data fluctuation. The AMD server's host kernel is Linux v5.19.0-rc6 with SEV-ES and SEV-SNP support, while the Intel server's host kernel is Linux v5.4.0. The guest kernel version of all CVMs and their baseline VMs is Linux v6.0-rc1. Each guest OS is assigned with either 1 vCPU or 4 vCPUs, 16GB memory and a 2-virtqueue virtio-net device backed by the vhost-user backend based on OpenvSwitch v2.17.3 and DPDK v21.11.2. For each benchmark, the server side runs in the guest OS while the client side runs in the host OS on the other server.

To avoid the interference of unintended scheduling or interrupts, we isolate 6 cores on each server. The CPU isolation is achieved by the *isolcpus* function in the Linux kernel, and the binding is done by the *qemu-affinity* command for vCPUs and *pmd-cpu-mask* parameter for the OpenvSwitch-DPDK-based vhost-user backend. Each thread of vCPUs and the vhost-user backend is pinned to a different isolated CPU. IOMMUs of both machines are set to passthrough mode.

Naming Convention and Configurations: As mentioned in § 3, ***CVM*** represents real SEV-ES/SNP CVMs on the AMD server, while ***CVM+PI*** represents simulated TDX CVMs with posted interrupt enabled on the Intel server. The simulation is based on a vanilla Intel traditional VM, which further enables bounce buffer (i.e., Linux SWIOTLB [62]) for virtio devices and adds an additional 10,000 cycles to each VM exit to simulate the cost of guest-host world switches. The simulated world switches consume 2,524 more cycles than that of the SEV-ES/SNP VM. To the best of our knowledge, SEV-ES/SNP's lengthy VM exits primarily result from uncore co-processor (i.e., AMD-SP) intervention, whereas TDX's VM exits solely involve in-core firmware, leading to lower latency. As a result, though the increased VM exit latency does not guarantee identical performance to real Intel TDX hardware, the simulated VM exit overhead should be no less than that of real TDX VMs.



(a) RX **(b)** TX

Figure 6: TLS normalized throughput on both AMD and Intel server. The Y-axis is the normalized throughput compared with the baseline. *+PRPR* is not shown in (b) because it does not provide benefits for TX performance.

To get the performance of *CVM* close to the SEV-ES VM with posted interrupt, we optimize AMD *CVM* with reduced VM exit frequency by modifying the network backend to lower its notification frequency to the guest OS. We call the optimized version ***CVM+RIF***, signifying *CVM + Reduced Interrupt Frequency*. *CVM+RIF*'s baseline is the vanilla AMD traditional VM with reduced VM exit frequency, while *CVM+PI*'s baseline is the vanilla Intel traditional VM. To show the individual contribution of Bifrost's each technique, ***+ZC*** denotes only applying the ZCED as well as the OTTR, while ***+PRPR*** indicates adding the PRPR alone. The PRPR is configured to cache up to 1024 TCP flows for 2 virtqueues. Each flow can hold up to 1024 packets, and at most 32 packets can be submitted to the I/O frontend simultaneously.

7.2 Performance Improvement

In this section, we focus on the performance improvement of *CVM+RIF* and *CVM+PI*. We first build a microbenchmark to investigate the upper bound on the performance improvement that Bifrost can bring to I/O-intensive applications and then study the performance gains of real-world applications from Bifrost's design. Since the posted interrupt hardware has been able to minimize the performance impact of VM exits, we concentrate on Bifrost's effect on CVMs atop such hardware.

7.2.1 Microbenchmark

We develop a TCP-based TLS client/server pair to evaluate the network throughput. They simply contain simple code for single-threaded I/O data sending and receiving. This minimizes the time cost of business logic, demonstrating the maximum possible application performance improvement. To fully saturate the vCPU like an I/O-intensive application, we run 4 TLS server instances in a 1-vCPU VM.

RX Throughput: Figure 6a shows the network throughput comparisons in the RX direction. *CVM+RIF* attains 5.26 Gb/s, which is 24.10% slower than its baseline's 6.93 Gb/s. With the ZCED, *+ZC* alone (6.38 Gb/s) can reduce the slowdown to

7.81%. With the PRPR, *+PRPR* itself (8.39 Gb/s) can outperform the baseline by 21.10%. By combining both techniques, Bifrost reaches 10.64 Gb/s, which is 53.55% higher than the baseline. For *CVM+PI* (7.48 Gb/s), it incurs 27.03% overhead than its baseline (10.26 Gb/s). The throughput is increased to 9.99 Gb/s in *+ZC* (2.59% overhead) and grows to 10.76 Gb/s in *+PRPR* (4.95% better). Integrating both techniques makes Bifrost reach 16.64 Gb/s, which is 62.20% higher than the baseline. Therefore, Bifrost can boost performance by up to 89.23% (from 27.03% overhead to 62.20% better than the baseline) for applications experiencing high RX traffic in existing CVMs.

TX Throughput: Figure 6b shows the throughput comparisons in the TX direction. *CVM+RIF* attains 9.59 Gb/s, which is 23.03% slower than its baseline's 12.45 Gb/s. *+ZC* (11.04 Gb/s) reduces the slowdown to 11.37%. Bifrost has 10.79% overhead (11.11 Gb/s), slightly better than *+ZC*. Experiments of *CVM+PI* yield similar results. Therefore, Bifrost can have up to 12.24% (*CVM+RIF*) and 15.00% (*CVM+PI*) performance improvement for applications with high TX traffic.

Combining *+ZC* and *+PRPR* in the RX direction shows a greater performance improvement than the sum of each technique's individual improvement (explained in § 7.2.2). The TX improvement is less significant because PRPR only optimizes RX traffic. Limited CPU resources on a single vCPU for both packet processing and TLS operations result in a large gap from reaching the NIC's maximum bandwidth.

7.2.2 Applications

We utilize the same network-intensive applications as in § 3 to evaluate and break down the performance improvement of Bifrost. TLS/SSL is enabled in all the applications. We run each benchmark for 30 seconds and report the average value of the results from 10 rounds. To save space, we only present and analyze the results of the 32KB and the 256KB data sizes in detail, and provide an overview of the results for other data sizes. The detailed benchmark configurations and results are shown below.

Memcached [20] is a popular multi-threaded in-memory key-value store application. We use the *memtier_benchmark* [56] tool to measure throughput and average latency. The *Memcached* server is configured with either 1 or 4 threads for VM with 1 or 4 vCPUs respectively, and 4096MB memory. We set up 4 clients, 16 concurrent requests for 1-thread server and 8 clients, 32 concurrent requests for 4-thread server.

Figure 7a and Figure 8a show the throughput and latency overhead, respectively, of Memcached in *CVM+RIF*. Both throughput and latency improve as a result of alleviating the vCPU bottleneck. In 32KB cases, Bifrost cuts down more than half of *CVM+RIF*'s overhead over its baseline. Either *+ZC* or *+PRPR* alone slightly mitigates the overhead. In 256KB cases, Bifrost performs about 10% better than its baseline. Either *+ZC* or *+PRPR* alone reduces the overhead by more than half. With the same number of vCPUs, Bifrost's performance improvement increases as the data size grows. This is primarily because the performance impact of the CVM-IO tax, especially the bounce buffer tax, becomes more pronounced with the growth of data size, providing more room for improvement.

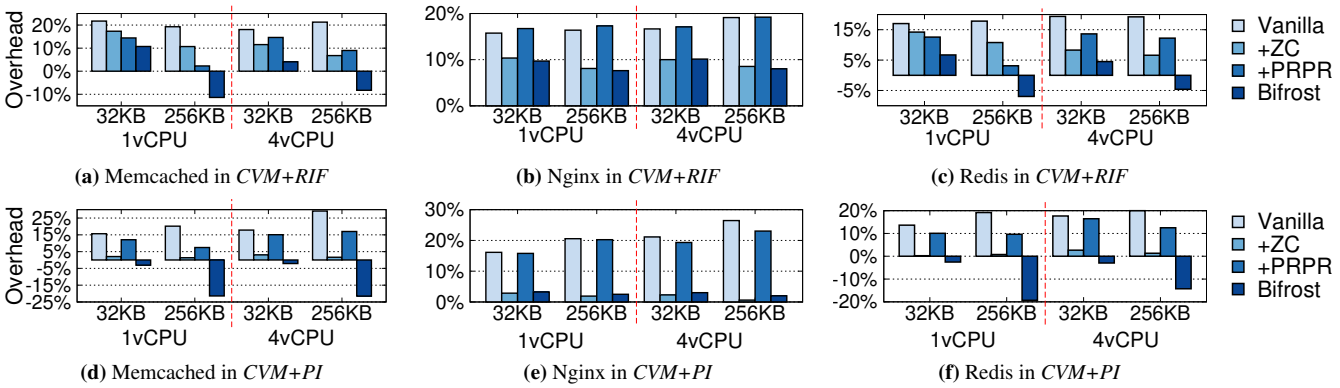
Figure 9a displays the time breakdown and backend utilization of CPUs in 4vCPU-256KB cases. The ZCED reduces the total timeshare of the bounce buffer tax from 15.67% to less than 2.50%. It cannot completely eliminate the bounce buffer cost because some small I/O data (e.g., TCP handshake packets) still falls back to the bounce buffer. The PRPR reduces the timeshare of the packet processing tax from 28.73% to 21.88%. Bifrost spends 2.39% more time on application workloads than the baseline and has more than 10% speed gain on the TLS processing in application workloads, which explains the 8.26% improvement over the baseline. Due to the higher throughput and PRPR cost, Bifrost's backend CPU utilization increases by 8.75% compared to the baseline.

Figure 7d and Figure 8b show the throughput and latency overhead, respectively, of Memcached in *CVM+PI*. Bifrost outperforms the baseline in all cases. The throughput acceleration over the baseline can reach 3.06% in 32KB cases and 21.50% in 256KB cases. The latency overhead is almost eliminated in 32KB cases and can outperform the baseline by 17.45% in 256KB cases. *+ZC* obtains more individual performance gain than *+PRPR*, and their combined improvement is larger than the sum of their individual gains. This is because applying both techniques can provide more available CPU cycles to application workloads than applying only one of them. As shown in Figure 9a, when only applying PRPR, part of the released CPU cycles will be occupied by bouncing packets.

Figure 9b depicts the breakdown and backend utilization of CPUs in 4vCPU-256KB cases. The ZCED reduces the total timeshare of the bounce buffer tax from 19.45% to less than 2.77%. The PRPR reduces the timeshare of the packet processing tax from 36.14% to 26.83%. Compared to the baseline, Bifrost provides application workloads with 11.53% more CPU time and more than 10% speedup in TLS processing. This can explain the 21.50% improvement over the baseline. Due to the higher throughput and PRPR cost, Bifrost's backend CPU utilization is 19.05% more than the baseline.

Nginx [50] is a well-known high-performance HTTP(S) web server. We run the *wrk* [21] benchmark tool to measure the throughput represented by requests per second (RPS). The client configurations are similar to the other two applications.

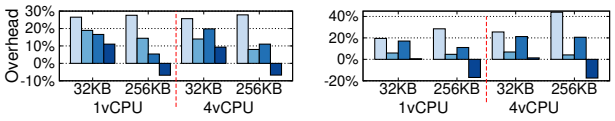
Figure 7b illustrates the Nginx throughput overhead of *CVM+RIF*. Since the traffic type of the Nginx benchmark is mainly in the TX direction, the majority of Bifrost's performance improvement comes from the ZCED, as analyzed in § 7.2.1. *+ZC* reduces the overhead by less than half because lengthy VM exits still significantly impact performance. The PRPR even increases the overhead for a little bit in the 1vCPU-256KB case, because there are more VM exits after



(a) Memcached in *CVM+RIF* **(b)** Nginx in *CVM+RIF* **(c)** Redis in *CVM+RIF*

(d) Memcached in *CVM+PI* **(e)** Nginx in *CVM+PI* **(f)** Redis in *CVM+PI*

Figure 7: Application performance comparisons when applying some or all of Bifrost's techniques. The Y-axis indicates relative overhead compared with baseline VMs, negative overhead represents performance improvement. (a), (b) and (c) compare throughput of *CVM+RIF* on the AMD server. (d), (e) and (f) compare throughput of *CVM+PI* on the Intel server.



(a) Latency in *CVM+RIF* **(b)** Latency in *CVM+PI*

Figure 8: Memcached average latency comparisons when applying some or all of Bifrost's techniques. The Y-axis indicates relative overhead compared with baseline VMs, negative overhead represents performance improvement.

the PRPR is applied. Figure 7e shows the Nginx throughput overhead of *CVM+PI*. Bifrost brings the overhead to less than 2.8% in all cases, thanks to the ZCED. The PRPR no longer impacts the performance negatively because VM exits cost is trivial when posted interrupt is enabled.

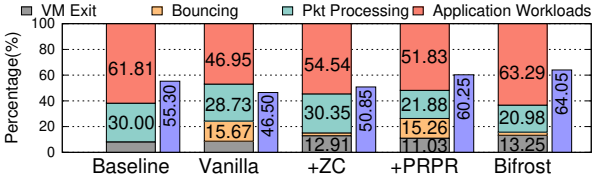
Redis [28] is a single-threaded in-memory key-value store application widely deployed in production environments. We also use the *memtier_benchmark* tool to measure the throughput. The *Redis* server is configured with 4096MB memory. The *memtier_benchmark* uses the same configurations as *Memcached*. To fully utilize vCPU resources in 4vCPU cases, we use *redis-cli* to build a *Redis* cluster with 4 instances.

Figure 7c and Figure 7f present the Redis throughput overhead, which have similar patterns to those of Memcached.

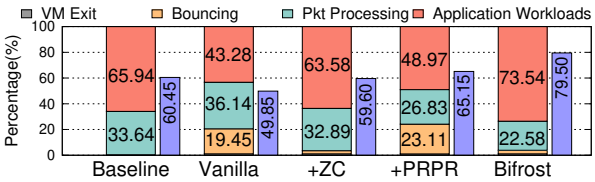
VM Scalability: To show Bifrost is scalable as the number of VM grows, we evaluate applications in 1, 2 and 4 Bifrost-enabled 4-vCPU 2-virtqueue *CVM+RIF*s. We conduct experiments on the AMD server because it has sufficient CPU cores on a single NUMA node. Figure 10 demonstrates that in multi-VM cases, Bifrost can always achieve comparable performance improvements to that of the single VM scenario. Bifrost's good VM scalability comes naturally because ZCED uses Linux's scalable memory allocator and PRPR is applied to each virtqueue without contention.

7.3 TOCTTOU Protection Overhead

Bifrost defends the guest OS against TOCTTOU attacks with OTTR by copying packet headers into private memory and keeping end-to-end encrypted payload in registers during

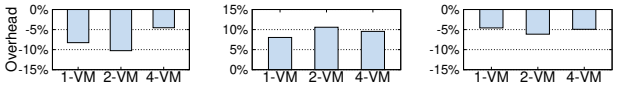


(a) Breakdown of *CVM+RIF* and its baseline & Backend CPU utilization



(b) Breakdown of *CVM+PI* and its baseline & Backend CPU utilization

Figure 9: VM CPU time breakdown and backend CPU utilization in Memcached 4vCPU-256KB experiments on AMD and Intel servers. The Y-axis represents the percentage of CPU cycles. In each case, the left side shows the breakdown of CPUs that run VMs, while the right side presents the utilization of backend CPUs.



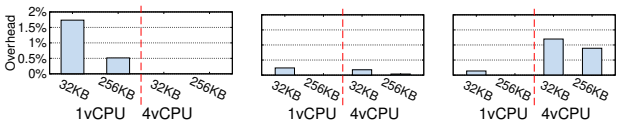
(a) Memcached **(b)** Nginx **(c)** Redis

Figure 10: Performance comparisons of Bifrost in 1, 2 and 4 *CVM+RIF* VMs using Memcached 4vCPU-256KB experiments. The Y-axis indicates relative overhead compared with baseline VMs, negative overhead represents performance improvement.

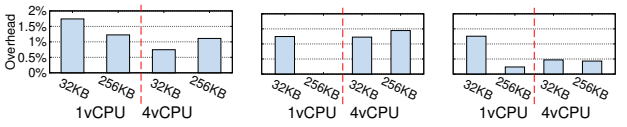
their processing. To evaluate the performance impact of these operations, we implement a prototype of Bifrost without applying OTTR, called Bifrost-noprot. We repeat application benchmarks to compare Bifrost's performance with that of Bifrost-noprot. The overhead of Bifrost in different benchmarks is shown in Figure 11, indicating no more than 2.0% overhead caused by TOCTTOU protections in all cases.

7.4 Memory Footprint

Bifrost must utilize memory efficiently to avoid unavailability due to the depletion of the ZCED NUMA memory. We first



(a) Memcached in *CVM+RIF* **(b)** Nginx in *CVM+RIF* **(c)** Redis in *CVM+RIF*



(d) Memcached in *CVM+PI* **(e)** Nginx in *CVM+PI* **(f)** Redis in *CVM+PI*

Figure 11: Application performance overhead of TOCTTOU protection. (a), (b) and (c) compare Bifrost with Bifrost-noprot (i.e., w/o OTTR) on the AMD server. (d), (e) and (f) compare Bifrost with Bifrost-noprot on the Intel server.

measure the ZCED NUMA's memory consumption via the *numastat* tool. Among all of our benchmarks, Bifrost consumes no more than 200MB out of the 512MB capacity of the ZCED NUMA memory. This amount does not exceed the default 1GB size of the bounce buffer area in the 16GB *CVM+RIF* VM. As for the footprint in the network backend, PRPR maintains a packet cache list in the backend memory for each virtqueue. Each cache list contains at most 8 network flows, each caching at most 1024 network packets. The maximum memory cost of one cache list is 1,088KB. In our benchmarks, we enable 2 virtqueues, consuming only 2.125MB memory.

8 Security Analysis

Bifrost introduces three major techniques to existing CVMs, in which only the ZCED and the OTTR retrofit the guest kernel and may have an impact on the network I/O data security. The only difference between the network I/O of Bifrost and a vanilla CVM is that Bifrost needs to process packets in the guest-host shared memory, while a vanilla CVM handles packets in private memory. Thus, we only need to analyze the security risks caused by TOCTTOU attacks on network packets during network I/O.

Headers: In the RX direction, a header is received in the guest-host shared memory. Bifrost copies the header into private memory, and subsequent header processing only uses the private copy, which does not suffer from TOCTTOU attacks. In the TX direction, each header is born in private memory and sent out through the bounce buffer mechanism, which is the same as in the existing CVMs.

Encrypted payload: In the RX direction, the in-kernel TLS layer decrypts the encrypted payload from the guest-host shared memory into private memory. Bifrost ensures that the decryption code has a consistent view of the encrypted payload by reading from shared memory only once and keeping it in CPU registers. In the TX direction, the in-kernel TLS layer encrypts the plaintext payload directly into shared memory. Bifrost ensures that the encryption code always refers to the correct ciphertext in CPU registers, which is isolated by CVM platforms and immune to TOCTTOU attacks.

Plaintext payload: There are also packets carrying plaintext payload due to procedures such as handshaking. In the RX direction, the plaintext payload is not accessed until the guest kernel copies it from shared memory to private memory. In the TX direction, the plaintext payload is no longer accessed once the guest kernel copies it from private memory to shared memory. Avoiding shared memory access eliminates the risks of TOCTTOU vulnerability.

Therefore, Bifrost does not expose guest OS's network processing to TOCTTOU attacks, achieving the same level of security guarantees as vanilla CVMs.

9 Related Work

Secure Virtualized Systems. A long line of research works and commercial products have been proposed to build secure virtualized systems [3, 8, 10, 11, 26, 32, 38, 48]. AMD SEV [2, 3], Intel TDX [29, 32] and ARM CCA [8] enable the CVM abstraction with hardware extensions, especially memory encryption and integrity protection [30, 34]. While AMD SEV relies on a secure processor [1], Intel TDX and ARM CCA employ trusted firmware [31] to manage CVMs. TwinVisor [38] provides an TrustZone-based alternative to ARM CCA by retrofitting the virtualization extension on existing ARM platforms. The design of Bifrost is not restricted to AMD or Intel and can be applied to other CVM systems.

Zero Copy I/O. Prior research works have proposed various techniques to eliminate data copies for better I/O performance [24,27,35,42–44]. For user-level applications, zIO [58] can transparently remove redundant I/O copies. For the I/O stack in the kernel, DAMN [44] and Demikernel [63] eliminate I/O memory copies by directly allocating buffers from the I/O memory pool. PASTE [25] performs DMA directly into non-volatile memory to avoid copies. Unlike these systems that target traditional scenarios and/or require intrusive software modifications, Bifrost focuses on eliminating unnecessary I/O data copies in CVMs with minor modifications.

10 Conclusion

This paper presents the first systematic analysis of the CVM-IO tax for network-intensive workloads in CVMs. To optimize the I/O performance of CVMs, we propose a new paravirtual I/O design called Bifrost. Bifrost eliminates redundant packet bounces and greatly reduces packet processing cost, while maintaining the same level of security guarantees as existing CVMs. Evaluation results show that Bifrost significantly improves the I/O performance of CVMs, and even outperforms traditional VMs by up to 21.50%.

SecretFlow-SPU: A Performant and User-Friendly Framework for Privacy-Preserving Machine Learning

Junming Ma, Yancheng Zheng,* Jun Feng, Derun Zhao, Haoqi Wu
Wenjing Fang, Jin Tan,† Chaofan Yu, Benyu Zhang, Lei Wang

Ant Group

Abstract

With the increasing public attention to data security and privacy protection, privacy-preserving machine learning (PPML) has become a research hotspot in recent years. Secure multi-party computation (MPC) that allows multiple parties to jointly compute a function without leaking sensitive data provides a feasible solution to PPML. However, developing efficient PPML programs with MPC techniques is a great challenge for users without cryptography backgrounds.

Existing solutions require users to make efforts to port machine learning (ML) programs by mechanically replacing APIs with PPML versions or rewriting the entire program. Different from the existing works, we propose SecretFlow-SPU, a performant and user-friendly PPML framework compatible with existing ML programs. SecretFlow-SPU consists of a frontend compiler and a backend runtime. The frontend compiler accepts an ML program as input and converts it into an MPC-specific intermediate representation. After a series of delicate code optimizations, programs will be executed by a performant backend runtime as MPC protocols. Based on SecretFlow-SPU, we can run ML programs of different frameworks with minor modifications in a privacy-preserving manner.

We evaluate SecretFlow-SPU with state-of-the-art MPC-enabled PPML frameworks on a series of ML training tasks. SecretFlow-SPU outperforms these works for almost all experimental settings (23 out of 24). Especially under the wide area network, SecretFlow-SPU is up to 4.1× faster than MP-SPDZ and up to 2.3× faster than TF Encrypted.

1 Introduction

Privacy-preserving machine learning (PPML) [24, 27, 34, 43, 44, 47, 49, 56, 57] has been gaining popularity due to the pervasive usage of machine learning (ML) and attendant privacy problems. Secure multi-party computation (MPC) [39], a cryptographic technique that enables multiple parties to jointly compute a function without leaking each party's private inputs, brings a provable and practical solution to ML users with strong privacy concerns. For example, financial and medical data analysts can collaboratively train a model on private datasets that contain sensitive information.

However, incorporating MPC techniques in ML applications introduces great challenges due to the natural differences between these two fields. MPC experts mainly focus on designing performant cryptographic protocols for low-level computation primitives. In contrast, ML practitioners are more accustomed to constructing high-level ML models using user-friendly frameworks that encapsulates commonly-used ML building blocks. Consequently, it poses a massive obstacle for ML users without cryptography expertise to achieve complex PPML tasks efficiently in real-world scenarios.

A series of works have been proposed to eliminate this obstacle. EzPc [9], ABY [15], MP-SPDZ [29], etc. [18] design domain-specific languages (or use high-level languages) to provide general purpose MPC compilers and support arbitrary computations upon MPC. These works significantly reduce the difficulty of developing MPC programs and allow for MPC-specific compilation optimizations. Whereas, these works remain a significant gap from mainstream ML frameworks on API designs, thus lacking user-friendliness to develop complex ML programs.

TF Encrypted [14] and CrypTen [33] take a step further in this direction by providing general ML interfaces with MPC implementations. These works mimic the existing ML frameworks' API designs (e.g., TensorFlow [5] and PyTorch [45]) to hide the underlying MPC cryptographic details and gain further user-friendliness. However, efforts still need to be made to port ML programs from TensorFlow/PyTorch by substituting PPML version APIs mechanically. Take CrypTen as an example: given a pre-defined PyTorch model, the user must manually re-write the model training/prediction programs by replacing PyTorch tensors, loss function, and optimizer with CrypTen counterparts. Besides, these frameworks rely on TensorFlow or PyTorch as their underlying runtime, which lacks

MPC domain-specific knowledge for compilation optimizations.

A question then arises: *can we efficiently run ML programs of mainstream frameworks in a privacy-preserving manner?* As an attempt to answer this question, we propose SecretFlow-SPU in this paper. For simplicity, we will refer to it as SPU throughout the rest of this paper. SPU is a general-purpose PPML framework designed to bridge the gap between ML and MPC communities more naturally. The core components of SPU include a frontend compiler and a backend MPC runtime. SPU provides users with Python APIs to accept an ML program (with minor modifications to specify protected data) as input, and the frontend compiler emits a customized intermediate representation (IR) named PPHLO (short for **P**rivacy-**P**reserving **H**igh-**L**evel **O**perations) as output. The backend runtime is a virtual device built on multiple connected computing nodes, which receives PPHLO and executes it as MPC protocol implementations among nodes to complete private ML training or prediction.

SPU's architecture makes it friendly to both ML and MPC developers. On the one hand, ML developers can conveniently run ML applications developed through mainstream ML frameworks in a privacy-preserving manner on SPU (Section 3.3) without the cryptographic knowledge of MPC. Besides, SPU is not bound to one specific ML framework. Diverse frameworks and libraries can be supported in SPU if there is a path from ML source code to PPHLO. On the other hand, SPU provides great extensibility to MPC protocol developers, who only need to focus on designing fundamental MPC primitives and implementing corresponding APIs defined by SPU. New MPC protocol supports can be easily supplemented without caring about high-level ML workflows (Section 3.6.1).

Besides user-friendliness, PPHLO enables us to propose and implement MPC-specific optimizations at both frontend and backend to achieve high performance. At the frontend, we observe that traditional ML frameworks usually generate a computation graph that is not optimal for MPC computations. The reason behind the observation is that MPC computations have a rather different cost model than plaintext computations due to additional communication overhead. Based on PPHLO, we design and implement several compiler passes to generate more efficient IR (Section 3.5). At the backend, we implement strategies such as vectorization and streaming to reduce MPC communication overhead. Meanwhile, SPU backend runtime employs inter- and intra-operation concurrency to execute PPHLO efficiently (Section 3.6.2).

We develop SPU frontend and backend in C++ and provide PPML developers with Python APIs to run applications. We mainly use ML programs written in JAX [8] to evaluate SPU's performance and user-friendliness. For performance, we use three state-of-the-art MPC-enabled PPML frameworks (i.e., MP-SPDZ [29], TF Encrypted [14], and CrypTen [33]) as the baseline. We train four common-evaluated neural networks on the MNIST [37] dataset for image classification under both local area network (LAN) and wide area network (WAN) settings. SPU achieves comparable classification accuracy and superior training speed. Concretely, SPU outperforms the state-of-the-art works for almost all the settings (23 out of 24). Especially under the WAN setting, SPU is up to 4.1× faster than MP-SPDZ and up to 2.3× faster than TF Encrypted.

Regarding user-friendliness, we evaluate SPU by running JAX programs from popular open-source JAX projects' official examples. We only need to modify a few lines of code to make these examples run seamlessly on SPU. Experimental results show that SPU can be easily applied to other models such as Long Short-Term Memory [23] and Variational Auto-Encoder [32]. This compatibility is hard to achieve for existing MPC-enabled frameworks. Moreover, we also validate SPU's feasibility in supporting different ML frameworks by running TensorFlow and PyTorch programs.

The contributions we make in this paper are summarized as follows:

- We design and implement SPU as the first MPC-enabled PPML framework to support ML programs (with minor modifications) from different mainstream ML frameworks, significantly accelerating the development, testing, debugging, and deployment of PPML applications.
- We design an MPC-specific IR, i.e., PPHLO, which connects ML and MPC worlds. Besides, we propose/implement a series of compilation optimizations and develop a high-performance runtime to execute PPHLO.
- We validate SPU with a series of experiments on performance and user-friendliness. The experimental results demonstrate SPU's efficiency and ease of use.
- We open-source SPU to bolster the advancement of PPML for academic and industry communities. The code is available at https://github.com/secretflow/spu.

The remainder of this paper is organized as follows. Section 2 gives a brief introduction to the background of ML compilers and MPC. We describe the design details of SPU in Section 3. Section 4 describes the system implementation and evaluation results. Section 5 describes SPU's limitations. Related work is discussed in Section 6. Finally, we conclude this paper in Section 7.

2 Background

SPU is an interdisciplinary work of ML compiler and MPC. In order to better understand the motivation and design of SPU, we give a more detailed description of the background of ML compiler and MPC in this section.

2.1 Machine Learning Compilers

In the past decade, artificial intelligence technologies driven by ML have made numerous breakthroughs in many fields, such as natural language processing [55], computer vision [19], and drug discovery [26]. As the key infrastructure for implementing ML algorithms, an easy-to-use and efficient ML framework is crucial. A large number of ML frameworks (and libraries) are currently on the market, including TensorFlow [5], PyTorch [45], JAX [8], and MxNet [11], providing developers with similar capabilities to train and serve models.

Meanwhile, in addition to traditional CPU and GPU, many application-specific integrated circuits for ML workloads have been developed to accelerate program execution. Typical representatives are Google TPU [25] and Hisilicon NPU [38]. Generating machine code for different ML frameworks to adapt to different types of hardware requires substantial engineering efforts, especially when the number of ML frameworks and hardware devices keeps increasing. ML compilers are proposed as the solution to this problem. Usually, the compiler frontend will transform source code written with the existing frameworks into hardware-independent IR, and the compiler backend will further transform IR into hardware-dependent machine code. With ML compilers, frontend frameworks only need to focus on generating IR, and backend hardware vendors only need to pay attention to supporting IR instructions.

The IR used in ML compilers is typically expressed as a computation graph (i.e., a directed acyclic graph). Graph nodes are ML operations (such as matrix multiplication and convolution) whose input and output are tensors (i.e., multi-dimensional arrays). Graph edges show the data dependencies between operations. One widely-used ML compiler is Google's XLA [4]. XLA defines its IR as HLO (High-Level Operations) to represent computation graphs. A series of frontends, including TensorFlow, PyTorch, and JAX, support XLA. ML programs written in these frameworks can be compiled into HLO. After performing hardware-independent and hardware-dependent optimizations, HLO is finally lowered to machine code by the XLA backend to run on the CPU, GPU, or TPU.

2.2 Secure Multiparty Computation

MPC originates from the Yao's Millionaires' problem [59] in the 1980s, where two rich people want to compare their wealth without giving away the exact value. Beyond this, MPC has shifted from an academic theory to practical usage in more complicated tasks, such as training ML models [30, 44, 56].

One fundamental technique used in MPC is secret sharing [6, 51]. A secret value is divided into multiple random shares and distributed to several parties. Each party only gets a subset of the shares and cannot reconstruct the original value independently. These parties jointly compute pre-defined computations (e.g., ML training) without leaking any sensitive information of the inputs or intermediate computation results. Usually, the final computation result (e.g., the trained model) are revealed to some designated parties. At that time, all parties put together their holding shares to reconstruct the result.

The private inputs, including integer and boolean values, are typically encoded over an algebraic ring or finite field. For integers, arithmetic secret sharing encrypts a secret over the ring $\mathbb{Z}_{2^k}$ and supports efficient arithmetic operations, including additions and multiplications. Correspondingly for boolean values, binary secret sharing provides a scheme to encrypt a secret over the ring $\mathbb{Z}_2$ and supports more efficient boolean operations, including XOR and AND computations. Addition (resp., XOR) operation of two arithmetic (resp., boolean) secret shares is equal to add (resp., XOR) the share of the two secrets locally. Operations with similar local-computation properties include a secret value adding a public value and a secret value multiplying a public value. In contrast, the multiplication (resp., AND) of two secret values is more complicated, which requires additional communication among the participating parties to exchange extra information. The heavy communication overhead has weakened the performance of MPC, especially in handling complex computations in real-world scenarios.

To improve the efficiency, mixed-protocols [15, 43, 46] that use arithmetic and binary secret sharing interchangeably shed light on MPC. With dedicated protocols, arithmetic and binary secret shares can be transformed back and forth to handle complex computations, including both arithmetic and non-arithmetic computations. However, these conversions also need communication. Despite the great efforts that have been made, the performance of MPC operations is still heavily communication-bound and sensitive to the network environment. Such characteristic makes MPC significantly different from traditional plaintext computations over CPU.

Besides integer and boolean operations, MPC also supports decimal computations, which are common in ML. It is more common and efficient to encode decimals as fixed-point numbers, which can be interpreted as the integer value multiplying a scaling factor. This factor is configurable and indicates how many bits represent the fractional part, and the remaining bits (except the sign bit) represent the integer part. When a fixed-pointed value multiplies another fixed-pointed value, the fractional bits double. In order to maintain that the result has consistent fractional bits with the input, a truncation operation is required.

The addition and multiplication of integers, fixed-point numbers, and boolean logic operations constitute MPC's most fundamental building blocks. ML scenarios require more complex and high-level operations. For linear operations such as matrix multiplication and convolution, a combination of those basic building blocks can accomplish them. For non-linear operations such as activation functions, we can approximate these functions using mathematical algorithms like Newton-

Raphson method [60]. Based on the linear and non-linear operations, complex ML tasks can be completed.

3 System Design

We describe the detailed system design of SPU in this section. The threat model of SPU is given first, followed by an overview of SPU's architecture and individual descriptions of SPU's main components, including programming interfaces, PPHLO, frontend, and backend.

3.1 Threat Model

SPU follows a standard MPC threat model and runs predefined programs among multiple parties, protecting input data and all intermediate results, typically only revealing the final results to some designated parties. Taking ML model training as an example, MPC can protect participating parties' training datasets and intermediate results like gradients, and reveal the trained model weights as the final results.

Furthermore, as an MPC computing engine, SPU is not restricted to any specific MPC threat models, such as the number of participating parties or if participants behave honestly [39]. The underlying MPC protocol used in SPU is configurable, allowing the threat model of the entire SPU system to be determined by the selected MPC protocol at runtime. For instance, using the semi-honest (with honest majority) ABY3 [43] protocol in SPU indicates SPU inherits ABY3's threat model, i.e., all participants follow the protocol honestly but may attempt to gain additional information from exchanged messages.

3.2 Architecture Overview

The goal of SPU is to run ML programs in a privacy-preserving manner. To complete this goal, we propose SPU's architecture, as illustrated in Figure 1. In the rest of this section, we use JAX as an example ML framework to describe SPU's design although SPU is not limited to JAX. We give evaluations on SPU's support to other frameworks in Section 4.2.3. Given an ML program written in JAX, our programming interfaces will implicitly call JAX API to convert this program into HLO (Section 2.1). This HLO graph and data visibility defined by users will be passed to SPU frontend, which compiles HLO to SPU's customized IR, i.e., PPHLO. After generating PPHLO, the frontend will further perform MPC-specific optimizations. The optimized PPHLO will then be sent to SPU backend, a virtual device built on multiple networked computing nodes. These nodes host SPU runtime responsible for executing MPC operations, and their number should match the supported parties of the configured MPC protocol.

SPU employs the SPMD (Single-Program-Multiple-Data) programming model. All nodes receive the same PPHLO to execute. The data consumed by each node are secret shares

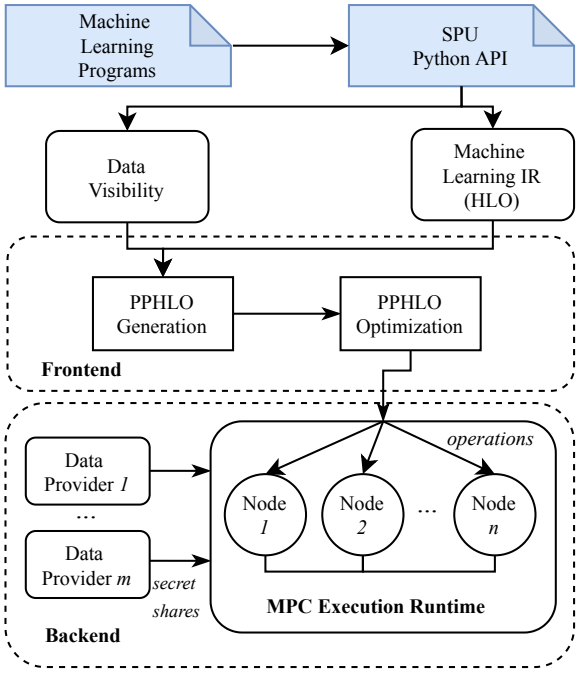

Figure 1: SPU architecture.

derived from original data held by data providers. Following the workflow described above, sensitive data from different sources can be jointly used to finish a PPML job by simply running a JAX program on SPU.

The design of SPU has the following advantages:

- By supporting ML programs of mainstream ML frameworks, SPU is extremely easy to use. SPU does not require users to learn a new library or language, or have MPC expertise.
- SPU frontend consumes HLO generated by ML programs rather than the source code. This design choice makes SPU can support a series of existing frameworks that have a lowering path to HLO directly. Moreover, SPU can benefits from platform-independent optimizations from existing ML compilers.
- SPU backend is also extensible. We can implement multiple pluggable MPC protocols in the backend without modifying PPHLO and frontend programs.
- PPHLO allows SPU to do systematic optimizations at the granularity of the high-level computational graph, which enables it to generate high-performance code for MPC execution.

3.3 Programming Interface

In order to achieve ease of use, we provide simple Python APIs so that developers can run ML programs on SPU with

```
1  import jax.numpy as jnp
2  import numpy as np
3  import spu.binding.util.distributed as ppd
4
5  # init SPU backend nodes
6  with open("/path/to/config", 'r') as file:
7      conf = json.load(file)
8  ppd.init(conf["nodes"], conf["devices"])
9
10 # specify data visibility
11 @ppd.device("P1")
12 def data_from_alice():
13     return np.random.randint(100, size=(4,))
14
15 # specify data visibility
16 @ppd.device("P2")
17 def data_from_bob():
18     return np.random.randint(100, size=(4,))
19
20 # specify a private function
21 @ppd.device("SPU")
22 def compare(x, y):
23     return jnp.maximum(x, y)
24
25 # x & y will be automatically
26 # fetched by SPU (as secret shares)
27 x = data_from_alice()
28 y = data_from_bob()
29
30 # compare will be evaluated privately by SPU
31 z = compare(x, y)
32
33 # reveal the real value of z
34 print(f"z = {ppd.get(z)}")
```

Figure 2: A demonstration of how to use SPU's API run JAX programs privately. Developers use decorators to specify data visibility and functions to be protected.

a few lines of code modifications. An example is given in Figure 2. We use SPU to solve Yao's Millionaires' problem as a simple demonstration.

We assume the two participants are called Alice and Bob. In line 3, at the start of this code, we import SPU's APIs as module *ppd*. In lines 6 to 8, we initialize the backend SPU nodes and data providers (i.e., P1 and P2 are to represent Alice and Bob). The decorators in lines 11 and 16 are data visibility marks that specify these data come from P1 and P2, which means that the two functions can only be evaluated locally on P1 and P2. The derived results are private data to be protected on SPU. The decorator on line 21 is a private function mark that specifies the function *compare* is private and should be evaluated on SPU. Lines 27 to 31 compare Alice and Bob's data. Variables x and y will be automatically fetched by SPU as secret shares, and the compared result z is also secret shares. To get the plaintext result of z, developers should use *ppd.get()* to reconstruct z as shown in line 34.

As we can see, the most crucial part of SPU's APIs is the decorator *@ppd.device()*, which is used to specify protected data and private functions. In the example demonstrated in Figure 2, the private function is a JAX *maximum* function. In fact, this can be extended to more complex JAX functions, such as an ML model training function from JAX libraries. Decorator *@ppd.device()* is the entry point for using SPU as the workflow described in Section 3.2, which will trigger HLO generation, compilation to PPHLO, and PPHLO execution. We can have SPU do all the stuff in the background by putting the decorator on top of a JAX function.

3.4 Privacy-Preserving High-Level Operations

We design PPHLO based on HLO as a customized IR for SPU because HLO lacks MPC-related semantics for optimization and efficient execution. In general, PPHLO represents a computational graph consisting of a series of operations. Each operation's input and output are tensors. The tensor type system is the most significant difference between PPHLO and other ML counterparts. A tensor's type in PPHLO can be represented by a triple <*Shape, Data Type, Visibility*>. Shape is a tensor's dimensionality. As for data type, PPHLO currently supports boolean, integer, and fixed-point numbers. Visibility is a unique tensor attribute in PPHLO. It can be either secret or public. Secret means that the tensor needs to be protected, and its real value is not visible to any node in SPU backend nodes. In contrast, public means that the tensor does not need to be protected, and any backend node can get its value.

Application developers specify the visibility of PPHLO's initial input tensors. As we described in Section 3.3, the variables generated by functions with decorator *@ppd.device()* are secret tensors, such as x and y in Figure 2. Otherwise, variables are public tensors. For each operation in PPHLO, we use the following rules to determine the output's type according to the input's type (shape is not considered here as it is determined by operation semantics). 1) **Data Type Promotion:** if one of the operands is a fixed-point number, the result is also a fixed-point number; 2) **Visibility Narrowing:** if one of the operands is a secret, the result is also a secret. Based on the two rules, we can deduce the types of all tensors in PPHLO.

Figure 3 gives an example of PPHLO in static single assignment form [50]. This code snippet corresponds to the JAX *maximum* function in Figure 2. The symbol *@main* is the program entry point. Lines 1 and 2 represent the program has two input arguments and one return value. The symbol *tensor<4x!pphlo.sec<i32>>* describes a tensor whose shape is 4, and that is a 32-bit integer secret value. Inside the braces is the program body, which contains two operations, i.e., *pphlo.greater* and *pphlo.select* (lines 3 to 6). An operation's output is assigned to the symbol on the left, which can be used as the operand of subsequent operations. When all operations

```
1  func.func @main(%arg0: tensor<4x!pphlo.sec<i32>>, %arg1: tensor<4x!pphlo.sec<i32>>)
2        -> tensor<4x!pphlo.sec<i32>> {
3    %0 = "pphlo.greater"(%arg0, %arg1) : (tensor<4x!pphlo.sec<i32>>, tensor<4x!pphlo.sec<i32>>)
4        -> tensor<4x!pphlo.sec<i1>>
5    %1 = "pphlo.select"(%0, %arg0, %arg1) : (tensor<4x!pphlo.sec<i1>>, tensor<4x!pphlo.sec<i32>>,
6        tensor<4x!pphlo.sec<i32>>) -> tensor<4x!pphlo.sec<i32>>
7    return %1 : tensor<4x!pphlo.sec<i32>>
8  }
```

Figure 3: An example of PPHLO. Generated from JAX *maximum* function shown in Figure 2.

are finished, the return value is given at line 7. PPHLO operations are extended from HLO operations [3][1]. An operation can accept public or secret tensors as its operands and has corresponding plaintext or MPC computation implementations on SPU backend runtime.

3.5 Frontend

SPU frontend is responsible for PPHLO generation and optimization. The frontend first receives an ML program's HLO and initial data visibilities as inputs and applies rules proposed in Section 3.4 to deduce the entire graph's data types and visibilities. After this step, a legal PPHLO representation is generated. The frontend will further perform code optimizations to modify PPHLO. PPHLO optimizations come from this insight: *an ML computational graph generated for non-MPC hardware may not be optimal in the MPC scenario.* We propose/implement the following compilation optimizations based on analyzing initially-generated PPHLO and our MPC expertise.

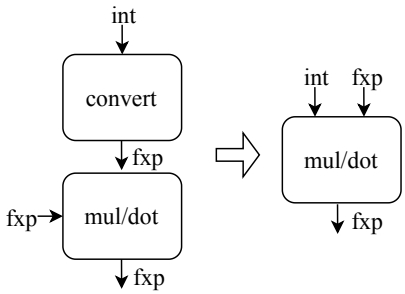

Figure 4: Mixed-data-type multiplication fusion.

Mixed-data-type multiplication fusion. In regular ML computations, when multiplying an integer to a decimal number, a *convert* operation will be called first to convert this integer to a floating-point number. Then the *multiply* operation can be dispatched to the floating-point multiplication kernel. A computation graph is illustrated in Figure 4. If we use this graph directly in SPU, an integer will be converted to a fixed-point number first, followed by a fixed-point multiplication which requires a truncation to maintain fractional bits (Section 2.2). However, an integer can directly multiply with a fixed-point number. Therefore, we can fuse the two operations into one *multiply* operation to reduce redundant truncation and conversion. This optimization applies to other similar operations like *dot*.

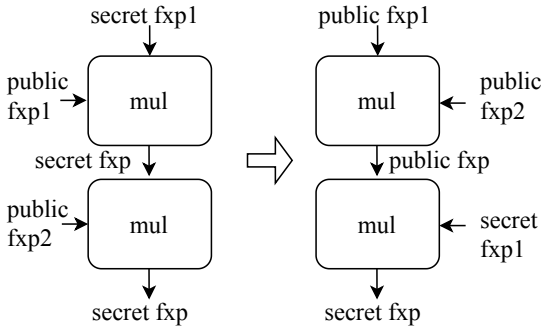

Figure 5: Mixed-visibility multiplication operands reorder.

Mixed-visibility multiplication operands reorder. Another scenario where truncation can be optimized is multiplying consecutive fixed-point numbers with mixed visibilities. As shown in Figure 5, a secret fixed-point number multiplying two public fixed-point numbers involves two *multiplication* operations. Each operation generates a secret product requiring a truncation that have a high communication overhead under some MPC protocols [24, 43]. However, we can reorder the operands without affecting the correctness. The multiplication of two public fixed-point numbers can be calculated first. The product is also public, so we can truncate the result by shifting bits locally. Then the result is used to multiply the secret fixed-point number. By reordering multiplication operands, one expensive truncation can be saved.

Inverse square root transformation. This optimization is demonstrated in Figure 6. When SPU frontend detects a computation of $y/(\sqrt{x}+u)$ where u is a tiny constant to prevent a division-by-zero problem, it will transform the computation to $y*rsqrt(x+eps())$. In the transformed computation, *eps* is

[1] Supported PPHLO operations can be found at https://github.com/secretflow/spu/blob/main/docs/reference/pphlo_op_doc.md

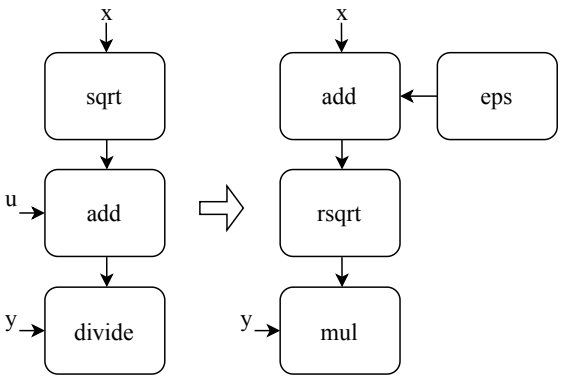

Figure 6: Inverse square root transformation.

a unique operation that will generate a minimum fixed-point number. The reason behind this transformation is that the inverse square root *rsqrt* operation has a fast MPC implementation than computing the reciprocal of the *sqrt* result (an approximation is needed). This computation pattern is observed in state-of-the-art optimizers such as Adam [31] and AMSGrad [48] when they update weights in each learning step. This optimization technique was first used by Lu et al. [41] and applied in related systems like MP-SPDZ [30] and TF Encrypted [14]. These frameworks must re-implement customized Adam and AMSGrad optimizers to employ this optimization. However, as we do the optimization at the PPHLO level, original Adam and AMSGrad optimizers in the existing JAX libraries can be directly reused.

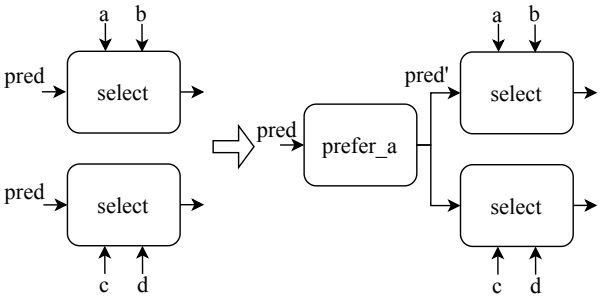

Figure 7: Select predicate reuse.

Select predicate reuse. *Select* is a commonly-used ML operation that receives a predicate and a pair of values *a* and *b*. If the predicate is true, then a is returned. Otherwise, b is returned. The predicate usually is generated with a previous comparison or logical operations and is represented as a binary secret sharing. The secret *select* operation works as a computation listed in Equation 1, where the predicate is transformed into 0 (false) and 1 (true) as a multiplier that demands converting binary secret sharing to arithmetic secret sharing. The conversion requires communication and is expensive [15]. We observe that a predicate may be used by multiple *select* operations when training some convolutional neural networks. Once SPU frontend detects this pattern, a *prefer_a* operation that explicitly converts binary secret sharing to arithmetic secret sharing will be inserted before the first select operation to reduce redundant conversions (as shown in Figure 7).

$$Select(pred, a, b) = b + pred * (a - b) \tag{1}$$

Max-pooling transformation. Max-pooling is a widely-used layer in convolutional neural networks, usually connected behind the convolutional layer for downsampling input features. In the forward propagation stage, max-pooling needs to find the maximum value in a window of values. In the backpropagation stage, max-pooling needs to replace the maximum value with its gradient while other values are set to zeros. We observe that the two stages are computed by two independent operations (i.e., *reduce_windows* and *select_and_scatter* in Figure 8) when ML frameworks train models. Although the *reduce_window* operation has found the maximum value in a window, *select_and_scatter* will do the same to find the index of the maximum value. Redundant and expensive comparisons would be called in both operations. Therefore, SPU frontend transforms this computation pattern to two new operations we proposed in PPHLO, i.e., *argmax* and *maxpool_scatter*. In the *argmax* operation, we will get the maximum value and its index in the window. The index can be directly reused by *maxpool_scatter* operation. We use a one-hot vector to represent the index. The maximum value can be updated by multiplying the index by the gradient.

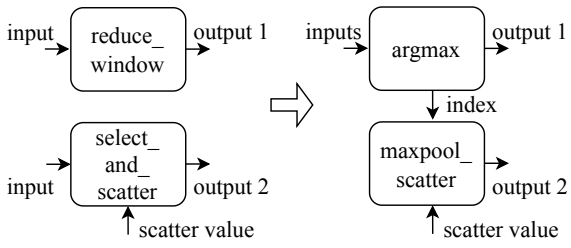

Figure 8: Max-pooling transformation.

In this section, we share observations on generated PPHLO from the ML computation graph and operation optimization strategies we implemented. Optimization techniques for ML computational graphs are much more mature with the efforts of countless experts and engineers. However, MPC computations introduce a different cost model compared to CPU or GPU computing, which enables us to adopt novel optimization techniques on PPHLO. We believe that more optimization opportunities are waiting to be discovered in this new interdisciplinary field.

3.6 Backend

SPU backend consists of multiple computing nodes, and each node contains a runtime to execute PPHLO operations. The number of nodes should match the parties of the underlying MPC protocol. The design goal of SPU backend is scalable to support different MPC protocols with a pluggable experience and efficiently execute PPHLO operations as MPC protocols. This section describes the operation dispatching mechanism and runtime optimizations used in SPU backend.

3.6.1 Operation Dispatching

We design the layered dispatching mechanism to achieve extensibility to different MPC protocols, as shown in Figure 9. For each PPHLO operation, the SPU runtime will first dispatch it to the PPHLO layer, which has a one-to-one mapping function acting as the operation entrance. The PPHLO mapping function will further dispatch the operation to fine-grained HAL (Hardware Abstraction Layer) functions. We borrow the concept of HAL from traditional operating system implementation which is mean to eliminate the boundary between hardware and software. We use HAL to hide the MPC implementation details from PPHLO operations. Specifically, at the HAL level, the SPU runtime will decompose an operation into a set of MPC-primitive functions according to the data type and visibility of operands. As the example in Figure 9, a secret fixed-point number multiplication will be decomposed to a secret integer multiplication function and a truncation function. Each MPC-primitive function will be finally dispatched to the MPC layer, corresponding to a specific implementation of fundamental MPC protocols. Adding a new MPC protocol in SPU only needs to implement the MPC-primitive function set. When users configure a new backend protocol, SPU's runtime will dispatch PPHLO operations to the new MPC implementation.

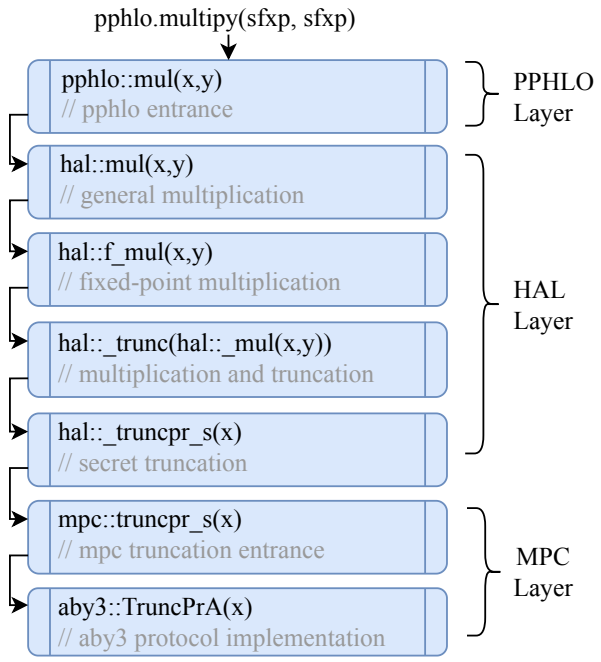

Figure 9: The dispatching path from a PPHLO operation to an MPC protocol in SPU. Different protocols can reuse the same PPHLO/HAL layer code and diverge at the final MPC layer.

3.6.2 Runtime Optimizations

We employ the following techniques in SPU runtime to achieve high performance.

Vectorization. Vectorization is a standard technique used on CPUs supported by SIMD (Single Instruction, Multiple Data) instructions. Applying one instruction to multiple data enables parallelism and improves program execution efficiency. SPU implements a similar vectorization mechanism by running one operation on a list of data to reduce the number of executed operations. For example, there are two operations *mul(a,b)* and *mul(c,d)* where *mul* stands for an element-wise multiplication operation and a, b, c, d are tensors. SPU will pack a, b, and c, d together and execute one *mul* operation on these tensors. As MPC multiplication needs communications, SPU can reduce the number of communication rounds through vectorization.

Streaming. Many MPC operations involve both intensive network I/O activities and local computations. If such an MPC operation processes a very large tensor, a more efficient method is to tile the tensor into sub-tensors and use multiple operations to process them concurrently. We illustrate this problem with the toy model in Figure 10. An ML model training stage consists of many iterations. When a processed tensor is enormous, the processing operations repeatedly block network I/O and local computing, affecting the overall execution efficiency. Suppose we tile the tensor into two small tensors and execute them concurrently. In that case, multiple sub-tensors and sub-operations can significantly improve network

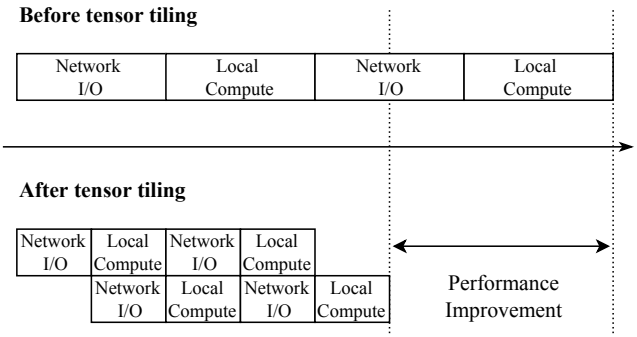

Figure 10: Streaming for MPC operations.

and computing resource utilization, thereby shortening execution time.

Concurrency. SPU supports both intra- and inter-operation concurrency to gain performance benefits. For intra-operation concurrency, most PPHLO operations consist of more than one HAL function. We implement these operations with well-established engineering experience and execute multiple functions without data dependencies in different threads. Taking the implementation of *rsqrt* operation as an example, we follow the protocol proposed by Lu et al. [41] to compute the inverse square root of a tensor x. The calculation consists of a fractional part computation and an exponential part computation which can be computed independently in two threads.

For inter-operation concurrency, SPU uses an aggressive strategy at the PPHLO graph granularity to prevent operations with communications blocking the use of computing resources. When executing PPHLO computation graph, SPU runtime launches as many operations as possible asynchronously. Once an operation's dependencies are completed, this operation will be scheduled for execution.

4 Implementation and Evaluation

We implement SPU frontend compiler based on MLIR (Multi-Level Intermediate Representation) [36], a compiler infrastructure for domain-specific computations. PPHLO is implemented as a new MLIR dialect for MPC computations. Frontend optimizations are implemented as compiler passes. We develop SPU backend with modern standard C++, and its computing nodes communicate through a high-performance RPC library, bRPC [1]. The SPU C++ library is binding to Python interfaces exposed to application developers as a Python module (Section 3.3). Currently, we provide users with three built-in MPC protocols, i.e., the semi-honest implementations of a three-party protocol ABY3 [43] and a N-party protocol SPDZ2k [13], and a two-party protocol Cheetah [24]. Our overall code base contains more than 50k LOC of C++ and 3k LOC of Python.

In the rest of this section, we evaluate SPU on performance and user-friendliness. Evaluations are done on three Alibaba Cloud *ecs.g7.xlarge* instances with 4 vCPU and 16GB RAM each. We complete evaluations under local area network (LAN, 10.1Gbps bandwidth and 0.1ms round-trip time) and wide area network (WAN, 300Mbps bandwidth and 40ms round-trip time) settings.

4.1 Performance

To evaluate SPU's performance, we compare SPU to general MPC-enabled PPML frameworks rather than some specific protocol implementations. We use SPU and three optimized frameworks (i.e., MP-SPDZ [29], TF Encrypted [14], and CrypTen [33]) to train four neural network models for image classification on the MNIST dataset. The models are trained privately with the encrypted training dataset and revealed to evaluate on the plaintext validation dataset. All frameworks train models with three ML optimizers, i.e., SGD, Adam [31], and AMSGrad [48] (except CrypTen which does not support Adam and AMSGrad). Using different optimizers to train models results in distinct computation graphs, causing varying computation costs that are noticeably divergent between MPC scenarios and plaintext training. Consequently, evaluating diverse optimizers showcases SPU's performance extensibility.

The selected four models have been widely used in related literature for evaluations [30, 40, 44, 49, 56, 57], and their detailed architectures are listed in Appendix A.1 (Table 2, 3, 4, and 5). We follow the numbering (from A to D) given by Wagh et al. [56] to refer to these models. All training experiments use a semi-honest three-party MPC (3PC) protocol, which is widely used and supported by all frameworks.

Table 1 reports the classification accuracy and seconds per batch when training 5 epochs with a batch size of 128. MP-SPDZ data is collected by running scripts provided by its author Keller [30] (commit 0f7020d). TF Encrypted data is collected by directly running scripts provided in its code repository (commit 51de98f). CrypTen data is collected by running an adaption of its official example *mpc_autograd_cnn* (commit 909df45). For SPU, we write JAX programs to train models and run these programs on SPU to collect data.

In Table 1, CrypTen has a significant gap with the other three frameworks in terms of both training speed and classification accuracy. One possible reason for this may be that CrypTen is primarily implemented in Python. Besides, CrypTen differs from the other three works in that it does not strictly employ a standard semi-honest 3PC protocol based on replicated secret sharing [6]. The protocol CrypTen uses can support any number of participants ($N \geq 2$), and we evaluate its performance in the three-party scenario.

Therefore, in order to ensure fairness, our comparisons in this section will mainly focus on SPU, MP-SPDZ, and TF Encrypted. For accuracy, the three frameworks all get high and close results. These is no single framework can achieve optimal results in every configurations. For training time, MP-SPDZ has better results under LAN while losing its advantages under WAN compared to TF Encrypted . The possible reason is that MP-SPDZ implements a more efficient multi-threaded kernel for operation execution, so it benefits from the intensive local computations under LAN. However, when network I/O communications become the bottleneck under WAN, TF Encrypted which relies on the underlying TensorFlow for graph scheduling works better.

Compared with MP-SPDZ and TF Encrypted, SPU achieves the fastest training on 11 out of 12 configurations under LAN and all configurations under WAN. Under LAN, SPU's advantage over MP-SPDZ is minor but achieves 1.4-4.6× faster training than TF Encrypted. Under WAN, SPU achieves up to 4.1× faster training than MP-SPDZ and up to

Table 1: The accuracy and seconds per batch of training four neural network models on the MNIST dataset with SGD/Adam/AMSGrad optimizer in four MPC-enabled PPML frameworks. M, T, C, and S are abbreviations of MP-SPDZ [29], TF Encrypted [14], CrypTen [33], and our SPU, respectively. CrypTen does not support Adam and AMSGrad as of the time we write this paper.

2.3× faster training than TF Encrypted. Overall, the evaluation results demonstrate that SPU achieves state-of-the-art performance by combining the two aspects of WAN and LAN.

We further analyze the performance benefits of SPU. Although we implement a series of compiler passes to optimize the computation graph, it should be noted that these optimizations are workload-dependent, and not all optimizations will be effective for a specific workload. Taking training Network C with the Adam optimizer, which has the most complex computation graph, as an example. We find that when all compiler passes are disabled, the training time is 2.0× slower under LAN (4.63 versus 2.37 seconds) and is 1.9× slower under WAN (43.49 versus 22.87 seconds). Additionally, we find that nearly all performance benefits come from two frontend optimizations, i.e., max-pooling transformation and inverse square root transformation. This phenomenon does not mean that other implemented optimizations are meaningless, as we observe that those compiler passes are more effective on other workloads with corresponding computational patterns, such as training decision tree models.

Another conclusion we can draw is that the backend runtime also plays a significant role in contributing to SPU's performance improvement. Network A does not have a max-pooling layer and the SGD optimizer also does not involve the *rsqrt* operation. As a result, the two optimizations mentioned above do not apply to training Network A with SGD. However, SPU also achieves state-of-the-art in this experimental setting. Therefore, we believe SPU's high-performance benefits from collaborative frontend/backend implementations.

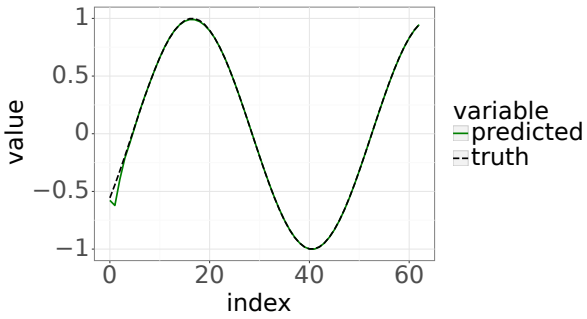
4.2 User-friendliness

This section evaluates SPU's user-friendliness through its compatibility with ML applications from different mainstream ML frameworks. We select two ML training programs from well-known open-source JAX projects and run them on SPU to train models privately. We found that only minor modifications to these programs are required to run them on SPU with acceptable overhead and achieve results comparable to plaintext training on CPUs. Besides, we test SPU's feasibility to run TensorFlow and PyTorch programs. These experiments show that SPU can be easily extended to other ML models and frameworks. The evaluations for SPU also use the same setting (a semi-honest 3PC protocol) as in Section 4.1 under LAN. The evaluations for plaintext training and prediction on CPUs run on a single cloud server.

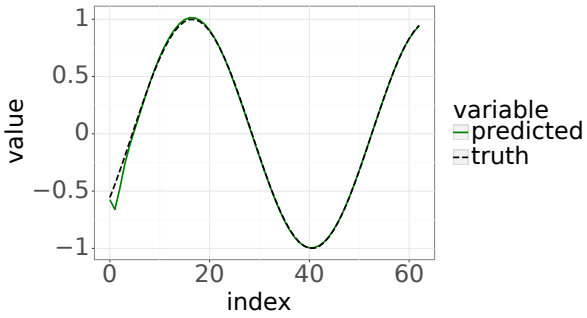
4.2.1 Long Short-Term Memory

This example of training a Long Short-Term Memory (LSTM) model [23] comes from Haiku [21], a JAX neural network library developed by DeepMind. LSTM is a recurrent neural network model for processing sequential data such as text or speech. This example trains an LSTM model to predict time series, using the data generated from a sine wave for training and validation. The model is trained privately with the encrypted training dataset and revealed to evaluate on the plaintext validation dataset. We modify about 8 lines of the example's source code to enable SPU to run the training program.

The vanilla JAX program takes 3.01 seconds to train 2001



(a) JAX.



(b) SPU.

Figure 11: Predictions with LSTM models trained by JAX and SPU.

steps, reducing the training loss from 0.45737 to 0.00067. SPU takes 7177.83 seconds (2384.7× slowdown) to reduce the training loss to 0.00099. Figure 11 shows that we use JAX and SPU-trained models to predict validation data with ground truth. The SPU-trained model achieves similar prediction results with high accuracy compared to the JAX model that is trained in plaintext.

4.2.2 Variational Auto-Encoder

This section describes a Variational Auto-Encoder [32] (VAE) model training example from Flax [20], a JAX neural network library developed by Google. VAE is a generative model which can map high-dimensional input space into low-dimensional latent space and regenerate the input from the latent representation. This example trains a VAE model to compress and regenerate images from the MNIST dataset. The model is trained privately with the encrypted training images and revealed to evaluate on the plaintext testing images. We modify about 22 lines of code to enable SPU to run the training program.

It takes JAX and SPU 214 and 9131 seconds (42.7× slowdown) to train 5 epochs with a batch size of 128,[2] reducing the training loss from 535 to 106. Figure 12 shows that using the model trained by SPU to reconstruct MNIST digits has a comparable result to JAX.

[2]The times include an extra evaluation on testing dataset in each iteration.

(a) JAX.

(b) SPU.

Figure 12: Reconstruct MNIST digits with VAE models trained by JAX and SPU. The digits above are original inputs.

4.2.3 Beyond JAX

Technically, SPU is able to support any ML frameworks that can be translated to HLO. In this section, we validate SPU's feasibility to support TensorFlow and PyTorch as frontend ML frameworks. For TensorFlow programs, SPU Python APIs can also be used directly on ML training or prediction functions made of TensorFlow functions. SPU will call *tf.function* API provided by TensorFlow to compile these composite functions into HLO as SPU frontend inputs. For PyTorch programs, SPU relies on the Torch-MLIR [2] project to convert them into HLO, which SPU can further consume.

We train a TensorFlow logistic regression model with the diagnostic Wisconsin breast cancer dataset [52]. The model is trained privately on SPU with the encrypted training dataset and revealed to evaluate on the plaintext testing dataset. SPU achieves the same ROC-AUC (Area Under the Receiver Operating Characteristic Curve) [16] of 0.99 as the plaintext training result on CPU. Training times on CPU and SPU are 0.067 and 1.121 seconds (16.7× slowdown).

As for PyTorch, we use the same dataset to train a linear classification model on the plaintext data and run predictions with jointly encrypted features on SPU (the model weights are not protected in this example). Experimental results show that compared to plaintext prediction on vanilla PyTorch, SPU achieves the same ROC-AUC of 0.97 with a 345.7× speed slowdown (0.05186 versus 0.00015 seconds). Overall, these results demonstrate SPU is feasible to support different ML frameworks.

5 Limitations and Discussion

This section discusses some known issues of SPU. SPU uses the fixed-point representation to encode decimal numbers like other MPC-based ML systems, which leads to two limitations. First, fixed-point numbers have limited precision and range compared to floating-point numbers. This problem will cause running some ML programs on SPU to get incorrect results. We can mitigate this problem by using more fractional bits to

encode fixed-point numbers in SPU. Second, some function implementations rely on floating-point number representations (such as JAX *random.normal*), which will cause SPU to compute these functions with unexpected results. We will try to provide a library overwriting these functions in the future.

Besides, SPU currently does not support secret conditions as some operations (such as *while*) may use. In most cases, these tensors are not data that need to be protected. Developers can implement these values as public tensors.

6 Related Work

In recent years, there has been a line of works studying applying MPC techniques for PPML [9,24,27,34,43,44,49,56,57]. Most of these works focus on protocol optimizations and innovations, improving MPC-enabled PPML's performance and making it a practical solution. These works diverge on security models (malicious or semi-honest adversaries, honest-majority or dishonest-majority), secret sharing schemas, the number of supported parties, and implementation details of basic operations. These protocol innovations are orthogonal to SPU, which can implement them as the underlying protocols.

Another bunch of works try to reduce MPC usage difficulty for non-MPC experts by implementing general-purpose MPC compilers. These compilers convert functions written in high-level or domain-specific languages to MPC circuits, which are later executed by backend runtime in an MPC manner. Hastings et al. [18] have a detailed survey on these compilers. However, these works are not tailored-made for ML scenarios. Using them to develop complex and efficient ML programs takes significant work.

The most relevant works to SPU are TF Encrypted [14], CrypTen [33], and MP-SPDZ [29]. TF Encrypted and CrypTen provide programming interfaces similar to TensorFlow and PyTorch in their Python modules. Refactoring an ML program into the PPML version must replace original ML APIs with TF Encrypted/CrypTen APIs corresponding to MPC implementations. The frontend of MP-SPDZ is Python. Users write ML programs based on Python APIs provided by MP-SPDZ, which compiles programs to byte code and runs in an MPC manner. Compared with these frameworks, SPU runs programs written in existing ML frameworks. Besides, SPU can support more than one ML framework.

There are other PPML frameworks developed based on Trusted Execution Environments (TEE) [47] or federated learning (FL) [28]. TEE-based solutions require special hardware and are vulnerable to side-channel attacks [10,54]. FL also enables multiple participants to jointly and privately train a model. In the classic FL scenario, each participant performs local gradient computations on the plaintext datasets, and then a centralized server aggregates the model parameters from participants. As the original input data remains within the owner's domain throughout the training process, FL can be considered as a PPML solution. However, some works have already shown that even only exchanging model parameters may also threaten the original input data [35,42,61].

Compared with FL frameworks, SPU provides end-to-end privacy protection based on provable MPC techniques. MPC does not necessarily require an independent server responsible for model aggregation. Participants' data is first encrypted and then fed into SPU. SPU then performs computations on the encrypted data (such as gradient updates) and trains a model, which is also kept in encryption. Finally, the model is reconstructed to plaintext and revealed to some designated parties. In addition to model training, another use case for SPU is private model inference, in which one party protects the input data, and the other protects the model parameters.

More advanced FL frameworks have been proposed in recent years to improve FL's security. Chen et al. [12] introduce MPC techniques into model aggregation to resist generative adversarial network attacks [22]. HybridAlpha [58] uses functional encryption [7] to prevent curious aggregators and colluding participants from inferring private data. Both approaches require a model aggregator and an additional trusted third party, which are not necessarily required in SPU. Besides, Chen et al. [12] mainly target convolutional neural networks, while SPU is not limited to specific model types. Triastcyn et al. [53] propose FedGP to replace participants' original data with artificial data by training generative adversarial networks [17]. However, their approach is limited to protecting image data and lacks a theoretical security guarantee. Compared with FedGP, SPU has no restrictions on the protected data types, and its security guarantee is based on provable MPC techniques.

7 Conclusion

In this paper, we propose SPU, a compiler and runtime suite, which converts ML programs into an MPC-specific IR and executes the IR in an MPC manner. Using the Python APIs provided by SPU, users can achieve privacy-preserving ML training and prediction by writing programs in mainstream ML frameworks. We believe that using SPU can significantly lower the threshold for users to achieve privacy protection and promote the development of the entire PPML community.

Acknowledgments

We would like to thank our shepherd, Sara Bouchenak, and the anonymous reviewers for their invaluable comments. We would also like to acknowledge the insightful feedback provided by Yu Luo on the early version of our paper. We extend our appreciation to Wen-jie Lu, Zhicong Huang, and Cheng Hong for their significant contributions to SPU. Lastly, we thank all members of the SecretFlow team for their support throughout this project.

A Supplementary Materials

A.1 Evaluated Neural Network Models

This section describes models used in Section 4.1. Network A is defined in [44]. Network B is defined in [40]. Network C is defined in [37]. Network D is defined in [49].

Table 2: Architecture of Network A (SecureML [44] model).

Layer	Input	Description	Output
Fully Connected	784	784×128 matrix multiplication	128
ReLU	128	Element-wise ReLU on input	128
Fully Connected	128	128×128 matrix multiplication	128
ReLU	128	Element-wise ReLU on input	128
Fully Connected	128	128×10 matrix multiplication	10

Table 3: Architecture of Network B (MiniONN [40] model).

Layer	Input	Description	Output
Convolution	$1 \times 28 \times 28$	5×5 kernel, 1×1 stride	$16 \times 24 \times 24$
MaxPooling	$16 \times 24 \times 24$	2×2 kernel	$16 \times 12 \times 12$
ReLU	$16 \times 12 \times 12$	Element-wise ReLU on input	$16 \times 12 \times 12$
Convolution	$16 \times 12 \times 12$	5×5 kernel, 1×1 stride	$16 \times 8 \times 8$
MaxPooling	$16 \times 8 \times 8$	2×2 kernel	$16 \times 4 \times 4$
ReLU	$16 \times 4 \times 4$	Element-wise ReLU on input	$16 \times 4 \times 4$
Fully Connected	256	256×100 matrix multiplication	100
ReLU	100	Element-wise ReLU on input	100
Fully Connected	100	100×10 matrix multiplication	10

Table 4: Architecture of Network C (LeNet [37] model).

Layer	Input	Description	Output
Convolution	$1 \times 28 \times 28$	5×5 kernel, 1×1 stride	$20 \times 24 \times 24$
MaxPooling	$20 \times 24 \times 24$	2×2 kernel	$20 \times 12 \times 12$
ReLU	$20 \times 12 \times 12$	Element-wise ReLU on input	$20 \times 12 \times 12$
Convolution	$20 \times 12 \times 12$	5×5 kernel, 1×1 stride	$50 \times 8 \times 8$
MaxPooling	$50 \times 8 \times 8$	2×2 kernel	$50 \times 4 \times 4$
ReLU	$50 \times 4 \times 4$	Element-wise ReLU on input	$50 \times 4 \times 4$

ReLU	500	Element-wise ReLU on input	500
Fully Connected	500	500×10 matrix multiplication	10

Table 5: Architecture of Network D (Chameleon [49] model).

Layer	Input	Description	Output
Convolution	$1 \times 28 \times 28$	5×5 kernel, 2×2 stride	$5 \times 14 \times 14$
ReLU	$5 \times 14 \times 14$	Element-wise ReLU on input	$5 \times 14 \times 14$
Fully Connected	980	980×100 matrix multiplication	100
ReLU	100	Element-wise ReLU on input	100
Fully Connected	100	100×10 matrix multiplication	10

B Artifact Appendix

B.1 Abstract

SecretFlow-SPU is an open-source framework designed for privacy-preserving machine learning. This artifact contains

the source code of SecretFlow-SPU, along with documentation for reproducing the experiments reported in this paper. Additionally, we provide scripts and a Docker container image to quickly build the experimental settings.

B.2 Scope

The artifact includes experiments for secure neural network training, secure Variational Auto-Encoder (VAE) training, and secure Long Short-Term Memory (LSTM) training using JAX. We also provide two simple TensorFlow and PyTorch demos. These experiments cover all we reported results in the paper.

B.3 Contents

README.md describes the artifact and provides a road map for evaluation. For more details on the SecretFlow-SPU repo's directory layout, please refer to *REPO_LAYOUT.md* under the base directory.

B.4 Hosting

The artifact is available at https://github.com/secretflow/spu (branch *atc23_ae*).

B.5 Requirements

SecretFlow-SPU has no special hardware requirements. To reproduce our results, users should have at least three servers that are connected within a high-performance network. We have done our evaluations on three Alibaba Cloud ecs.g7.xlarge cloud servers with 4 vCPU and 16GB RAM each. The CPU model is Intel(R) Xeon(R) Platinum 8369B CPU @ 2.70GHz. We evaluated SecretFlow-SPU on Ubuntu 20.04.5 LTS with Linux kernel 5.4.0-125-generic. Technically, SecretFlow-SPU is supported to run on any Linux servers with software requirements described in *CONTRIBUTING.md*.

Portunus: Re-imagining Access Control in Distributed Systems

Abstract

TLS termination, which is essential to network and security infrastructure providers, is an extremely latency-sensitive operation that benefits from access to sensitive key material close to the edge. However, increasing regulatory concerns prompt customers to demand sophisticated controls on where their keys may be accessed. While traditional access-control solutions rely on a highly-available centralized process to enforce access, the round-trip latency and decreased fault tolerance make this approach unappealing. Furthermore, the desired level of customer control is at odds with the homogeneity of the distribution process for each key.

To solve this dilemma, we have designed and implemented Portunus, a cryptographic storage and access control system built using a variant of public-key cryptography called attribute-based encryption (ABE). Using Portunus, TLS keys are protected using ABE under a policy chosen by the customer. Each server is issued unique ABE keys based on its attributes, allowing it to decrypt only the TLS keys for which it satisfies the policy. Thus, the encrypted keys can be stored at the edge, with access control enforced passively through ABE. If a server receives a TLS connection but is not authorized to decrypt the necessary TLS key, the request is forwarded directly to the nearest authorized server, further avoiding the need for a centralized coordinator. In comparison, a trivial instantiation of this system using standard public-key cryptography might wrap each TLS key with the key of every authorized data center. This strategy, however, multiplies the storage overhead by the number of data centers. Deployed across Cloudflare's 400+ global data centers, Portunus handles millions of requests per second globally, making it one of the largest deployments of ABE.

1 Introduction

Transport Layer Security (TLS) is a cryptographic protocol widely used to secure communication and protect data integrity between clients, such as browsers, and servers, who host the websites. In a TLS handshake, the server presents a certificate—containing its public key—to the client, and uses the associated private signing key to create a digital signature. This verifies the website's authenticity and creates a secure connection.

Seeking enhanced performance and security, website operators often enlist the services of infrastructure providers like Content Delivery Networks (CDNs). These providers—offering services such as DDoS protection, load balancing, and caching—run on globally distributed data centers to ensure low latency and high performance, and to maintain availability. They also need to be able to inspect the TLS connection between clients, who are the end users of their customer's websites, and their customer's servers. This process of intercepting a TLS connection at an intermediary point in the network is called TLS termination. To handle TLS termination on behalf of their customers, service providers require access to the private signing key for their respective websites.

However, customers utilizing these services have different degrees of comfort concerning the use of their key material across data centers. For example, European customers may stipulate key storage exclusively within the European Union. Another might demand key storage only in data centers secured with bulletproof glass and laser alarm systems. These customers would like providers to control access to their key material based on geographical and security properties. Given that the TLS handshake is in the critical path of establishing a connection to a website, any latency introduced by key access control methods could significantly disrupt service quality. Additionally, for larger infrastructure providers handling millions of TLS terminations per second, minimizing computational overhead from the access control method is essential to scalability.

Unfortunately, traditional access control mechanisms fall short in this endeavor. Centralized methods of access control [41] require edge data centers to communicate with the network's control plane to access specific keys, leading to an expensive round-trip which adds latency and reduces reliability. Alternately, access control using standard public-key encryption provides low latency by assigning

[*] Equal contribution
[†] Work done while at Cloudflare

unique encryption keys to each data center and encrypting the customer's private signing key with the keys of each data center that complies with the access policy. This encrypted data can then be disseminated across all edge data centers in advance of connection requests, reducing latency. However, this strategy becomes rather complex to manage in the face of heterogeneous policies and large scale. The ciphertext size grows in proportion to the number of data centers, creating large overheads. Newly added centers cannot participate in establishing TLS connections unless the customer's signing key is re-encrypted with their newly issued encryption keys.

To address these issues, we required a more direct way to enforce access control through cryptography. Our first attempt [52, 53] combined identity-based encryption [11, 51] and broadcast encryption [25], but ultimately was too inflexible and limited in the types of access policies it could support. Spurred by these restrictions, we created Portunus. Portunus uses a variant of traditional public key cryptography called ciphertext-policy attribute-based encryption (CP-ABE) [9], which can implement fine-grained access control on a cryptographic level. CP-ABE is a a variant of the more general notion of attribute-based encryption (ABE), which was first proposed by Sahai and Waters [46] as a type of public-key encryption in which the keys and ciphertexts are associated with attributes instead of individual users. Concretely, CP-ABE links the secret keys to the attribute set of the key holders, and the ciphertexts to access policies that govern which key holders can decrypt them. Those policies are determined by the encryptor, who can therefore manage access to their data in the spirit of attribute-based access control (ABAC) [38].

We have adopted Portunus at scale. Using Portunus, TLS keys are encrypted using an X25519 key that serves as a data encryption key, which we call the *policy key*. This policy key is further encrypted using ABE under a policy chosen by the customer. Both the encrypted customer keys and policy keys are stored in a globally replicated database present on every machine at Cloudflare. Each edge machine has attributes determined by a database mapping its core cryptographic identity to a set of attributes, e.g., country and region. Edge machines are issued unique ABE secret keys by a key generation authority run in the control plane, allowing them to decrypt only the policy keys that they are authorized to access based on their attributes. Thus, both the encrypted customer keys and policy keys can be stored at the edge, with access control enforced passively through ABE. If a server receives a TLS connection but is not authorized to decrypt the necessary TLS key, the request is forwarded directly to the nearest authorized server, further avoiding the need for a centralized coordinator. As new machines are added, they automatically have access to the keys to which they are permitted by the policy.

While decryption in ABE is more computationally expensive than its equivalent in traditional public key cryptography, we are able to significantly mitigate its impact through session resumption and caching decrypted policy keys.

Adopting CP-ABE as a storage-layer access control solution means that all nodes share the same data, simplifying the distribution process. It also makes it easy for newly added nodes to take up the burden of satisfying requests. Furthermore there are no centralized components whose failure would lead to breaks in the availability of the system. Cryptographically enforced access control is inherently less coupled and more fault tolerant than a centralized system would be.

Our core contributions are:

1. Portunus, a real-world deployment of an ABE-based access control system for key management. Although several works have shown interest in using ABE [22, 23, 32, 48], few have resulted in large-scale real-world deployments.

2. A discussion of the practical costs and benefits of such a scheme, concluding that it is effective in solving distributed access control

3. Lessons learned for future use of CP-ABE by engineers and for ABE researchers about real-world requirements

2 Requirements

In the design process for Portunus, we identified a series of requirements arising from customer needs, internal engineering demands, and the experience of operating the predecessor of Portunus, Geo Key Manager [52, 53].

Low computational overhead: As TLS handshakes can happen at extremely high volumes for legitimate reasons, it is essential that we not add significant computational overhead to the responding process.

Rotation capable: It should be easy to rotate encryption keys used in the system. Key rotation is the practice of systematically replacing cryptographic keys with new ones periodically, to limit the amount of data exposed by the compromise of a particular key. A rotation ensures that newly-uploaded TLS signing keys are not decryptable by machines that have not been updated with new key material.

Recovery from strong attackers: We assume an attacker that is capable of compromising multiple edge machines and reading the database of certificates and associated signing keys. We would like this attacker to be unable to continue impersonating sites after their access is removed, unless the site's certificate was decryptable on the machines they compromised. We also want subsequent certificates not to be decryptable by the attacker after key rotation.

Flexible attributes: Historically, the set of attributes customers want changes over time, such as when a new compliance standard is introduced. Accommodating these changes in the prior system, Geo Key Manager, took considerable work.

Flexible policies: From experience, we know that customers and internal services would need a wide range of policies. Even

if the eventual product did not expose the full expressiveness, future developments would be difficult to anticipate.

Limited storage: Quicksilver, Cloudflare's configuration management system [43], has limited space because it duplicates all data across all machines globally. To preserve fault tolerance and the ability to serve requests quickly from all machines, our system needs to minimize storage overhead.

Uniformity of data: Quicksilver employs a homogeneous tree replication strategy: data centers around the world are organized into a tree and writes at the root are replicated downward. As a response to server failure, the tree is reorganized: such reorganization requires all nodes in the tree to be accessing the new data. Therefore, the system must accommodate a consistent data view across all edge machines.

3 Cryptographic Building Blocks

This section describes the various components of the ABE scheme implemented in Portunus. We start by describing the language to specify policies and attributes. Next, we define CP-ABE and its security property, collusion resistance. After that, we delve into pairings, a mathematical operation used to build many ABE schemes. This includes the scheme of our choice, TKN20, which uniquely satisfies all of our requirements. Presented informally and intuitively, we strive to make this complex scheme accessible to a broad audience. We further discuss necessary aspects for achieving strong security guarantees. Finally, we conclude by discussing the software implementation of this scheme and a usage example of the ABE library API.

3.1 Policy Specification Language

In Portunus, the set of attributes assigned to data centers is an injective map from labels to values, both represented as strings, e.g., `country: Japan`. The policies that are enforced on the wrapped private keys are non-monotone Boolean formulas (consisting of AND, OR and NOT operators) over statements that demand that a label has a value, or that it does not have a certain value, e.g., `country: Japan` or `country: not Japan`. Table 1 shows some example policies and corresponding semantics.

For the negations (i.e., NOT operators), we put the NOT operator on the attribute value rather than on the entire attribute. This means that, to satisfy a negation, e.g., `country: not Japan`, the attribute set must have an attribute with the same label, i.e., `country`, and it must differ from the value i.e., `Japan`. In contrast, many schemes put the NOT on the entire attribute, e.g., `not country: Japan` [40]. In these schemes, the attribute set satisfies the negation if it does not contain the attribute `country: Japan`. However, the problem with this type of negation is that attribute sets that do not have any attributes with this label trivially satisfy this negation. This is especially problematic when new labels are added. Then, all previously issued keys automatically satisfy the negation, regardless of whether they may have the negated value or not.

To express and represent policies, we implement a simple language that parses strings from the API and converts them into the structures that are consumed by the ABE scheme (Section 3.2.7). This means the front end of our policy language is composed of Boolean expressions as strings, such as `country: JP or (not region: EU)`, while the back end is a monotonic Boolean circuit consisting of wires and gates.

Monotonic Boolean circuits only include AND and OR gates. In order to handle NOT gates, we assign positive or negative values to the wires. Every NOT gate can be placed directly on a wire because of De Morgan's Law, which allows the conversion of a formula like `not (X and Y)` into `not X or not Y`, and similarly for disjunction.

3.2 Attribute-Based Encryption

Attribute-based encryption (ABE) is a variant of public-key cryptography in which the key pairs are associated with attributes rather than individual users [46]. Unlike traditional public-key encryption, ABE allows users to enforce a more fine-grained access control to the encrypted data [3, 9, 27, 42, 59]. There are two variants of ABE: key-policy ABE (KP-ABE) [27], and ciphertext-policy ABE (CP-ABE) [9].

3.2.1 Key-Policy ABE (KP-ABE)

In KP-ABE, users' secret keys are generated based on an access policy that defines the privileges scope of the concerned user, and data are encrypted over a set of attributes. For example, consider a military setting. A confidential document about nukes is encrypted under the attributes `type: nuclear, clearance: top-secret`. Then a user with a key defined over the access policy `(type: nuclear or type: laser) and clearance: top-secret` can decrypt the document, but a user with a key `clearance: top-secret` cannot.

3.2.2 Ciphertext-Policy ABE (CP-ABE)

In CP-ABE, encrypting users specify access policies that determine who is allowed to decrypt the data. Users' secret keys are generated over a set of attributes. For example, consider a hospital setting in which a doctor has attributes `role: doctor` and `region: US`, while a nurse has attributes `role: nurse` and `region: EU`. A document encrypted under the policy `role: doctor or region: EU` can be decrypted by both the doctor and nurse.

We restrict our discussion to CP-ABE in this paper, because it is a more natural fit to the desired semantics of Portunus: our fleet of servers have natural attributes like location and compliance standards, and our customers choose their policies.

Table 1: Example Policies and Semantics

Example Policy	Semantics
`country: US or region: EU`	Decrypt only in US or European Union
`NOT (country: RU or country: US)`	Do not decrypt in Russia and US
`country: US and security: high`	Decrypt only in US data centers with a high level of security

3.2.3 Formal Definition of CP-ABE

A ciphertext-policy ABE (CP-ABE) scheme consists of four algorithms [9]:

- Setup(λ) $\rightarrow$ (MPK, MSK): The setup takes as input a security parameter λ, it outputs the master public-secret key pair (MPK,MSK).
- KeyGen(MSK,S) $\rightarrow$ SK_S: The key generation takes as input a set of attributes S and the master secret key MSK, and outputs a secret key SK_S.
- Encrypt(MPK, $\mathbb{A}$, M) $\rightarrow$ $CT_{\mathbb{A}}$: The encryption takes as input a plaintext message M, an access policy $\mathbb{A}$ and the master public key MPK. It outputs a ciphertext $CT_{\mathbb{A}}$.
- Decrypt(SK_S,$CT_{\mathbb{A}}$) $\rightarrow M'$: The decryption takes as input the ciphertext $CT_{\mathbb{A}}$ that was encrypted under an access policy $\mathbb{A}$, and a secret key SK_S associated with a set of attributes S. It succeeds and outputs the plaintext message M' if S satisfies $\mathbb{A}$. Otherwise, it aborts.

A scheme is called correct if decryption of a ciphertext with secret key yields the original plaintext message.

3.2.4 Collusion Resistance

The security models for ABE schemes consider their security against chosen-plaintext (CPA) and chosen-ciphertext attacks (CCA), as well as their collusion resistance. Informally, collusion resistance ensures that multiple users with secret keys cannot join forces and decrypt a ciphertext that they could not decrypt individually. For example, a ciphertext encrypted under the policy `role: doctor and region: EU` cannot be decrypted by a user with the attributes `role: doctor` and `region: US`, and another user with the attributes `role: nurse` and `region: EU`. To capture this type of security, the security models allow the attacker to request multiple secret keys for attributes that are not authorized to decrypt the challenge ciphertext. Furthermore, the models capture security against chosen-plaintext attacks or chosen-ciphertext attacks. We define these security models more formally in Appendix A.

3.2.5 Pairing-Based ABE

A popular type of ABE is pairing-based ABE, because it is efficient and can support many desirable properties [59]. A pairing—also known as a bilinear map—is a map $e: \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_T$ defined over three groups $\mathbb{G}_1$,$\mathbb{G}_2$ and $\mathbb{G}_T$ of prime order p with generators $g_1 \in \mathbb{G}_1$,$g_2 \in \mathbb{G}_2$ such that (i) $e(g_1^a, g_2^b) = e(g_1, g_2)^{ab}$ for all $a,b \in \mathbb{Z}_p$ (bilinearity), (ii) $e(g_1, g_2)$ is not the identity in $\mathbb{G}_T$ (non-degeneracy) and (iii) e is efficiently computable. Note that $\mathbb{Z}_p$ denotes the ring of integers modulo p.

Intuitively, pairings are used to ensure that we can achieve security guarantees for both the keys and the ciphertexts. We need those guarantees, because we require ABE schemes to be secure against collusion, meaning that users should not be able to combine their keys and obtain better decryption powers. In contrast, traditional public-key encryption typically only provides security guarantees for the ciphertexts. Therefore, we can use discrete-log based assumptions such as the Diffie-Hellman assumption [19] to create secure encryption schemes such as the ElGamal encryption scheme [26]. In such encryption schemes, the public key and ciphertext typically live in a group in which the discrete-log problem is believed to be hard, while the associated secret key is an integer. By exponentiating a part of the ciphertext with the secret key, we can obtain the message. To ensure that we can achieve similar security assumptions for the keys in ABE, we also place the keys in a group in which the discrete-log problem is believed to be hard. To recover the message, we perform a pairing operation instead of exponentiating, which can be seen as an exponentiation with a "hidden" integer.

Most ABE implementations rely on open-source libraries for the pairing-based arithmetic, e.g., MIRACL [49], RELIC [4] or our own library, CIRCL [1]. In this way, ABE can be implemented in a highly optimized fashion without requiring all the details about the inner workings of pairings. Furthermore, using pairings in a black-box way also allows us to efficiently update the underlying pairing-friendly curves, should the old ones be broken or more efficient ones be found [18].

3.2.6 The TKN20 Scheme

We are using a fully CCA-secure hybrid encryption scheme based on the scheme by Tomida, Kawahara and Nishimaki (TKN20) [54–56]. We have open-sourced this code as part of our cryptographic library, CIRCL [1]. We chose TKN20 because it is currently the only ABE scheme that has a full description and satisfies the following properties simultaneously [59]:

1. **Expressivity:** support for AND, OR and NOT operators. Many schemes exist that support monotone formulas, i.e., formulas with AND and OR only. Few of these also

support NOT operators[1].

2. **(Almost) completely unbounded:** any string can be used as an attribute, and there are no bounds on the policy lengths and attribute sets. Note, however, that it is bounded in the number of label occurrences in the secret key, i.e., each label may occur only once.

3. **Multi-use of attributes:** support for repeated use of the same attribute in a Boolean formula.

4. **Strong security guarantees:** full security against chosen-plaintext attacks under standard assumptions[2].

3.2.7 Representation of Monotone Access Policies

In the mathematical description of the scheme, the (monotone) access policies are represented as linear secret-sharing scheme (LSSS) matrices [28]. In such matrices, the rows of the matrix are associated with the attributes used in the policy. To determine whether a set of attributes S satisfies the policy, the subset of rows associated with the attributes that also occur in the set can be considered. If the vector $(1,0,...,0)$ is in the span of those rows, then the set satisfies the policy matrix.

More formally, an access policy can be represented as a pair $\mathbb{A} = (\mathbf{A}, \rho)$ such that $\mathbf{A} \in \mathbb{Z}_p^{n_1 \times n_2}$ is an LSSS matrix, where $n_1, n_2 \in \mathbb{N}$, and ρ is a function that maps its rows to attribute values. Then, for some vector with randomly generated entries $\mathbf{v} = (s, v_2, ..., v_{n_2}) \in \mathbb{Z}_p^{n_2}$, the i-th share of secret s generated by this matrix is $\lambda_i = \mathbf{A}_i \mathbf{v}^\intercal = A_{i,1} s + \sum_{j \in \{2,...,n_2\}} A_{i,j} v_j$, where $\mathbf{A}_i$ denotes the i-th row of $\mathbf{A}$. In particular, if S satisfies $\mathbb{A}$, then there exist a set of rows $\Upsilon = \{i \in \{1,...,n_1\} \mid \rho(i) \in S\}$ and coefficients $\varepsilon_i \in \mathbb{Z}_p$ for all $i \in \Upsilon$ such that $\sum_{i \in \Upsilon} \varepsilon_i \mathbf{A}_i = (1,0,...,0)$, and by extension $\sum_{i \in \Upsilon} \varepsilon_i \lambda_i = s$, holds.

An efficient method to convert a Boolean formula to an LSSS-matrix representation was proposed by Lewko and Waters [36]. For example, the policy `role: doctor and region: EU` is represented as $(\mathbf{A}, \rho)$ where $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$ and ρ maps the first row to `doctor` and the second row to `EU`. The vector $(1,0)$ can only be recovered from both rows, i.e., by adding them. Note that this algorithm yields the same shares of the secret s as the secret-sharing algorithm in the TKN20 paper.

3.2.8 Representing NOTs and Labels

To represent NOT operators and labels in the policy, we define two additional maps, $\bar{\rho}$ and ρ_{lab}. The map $\bar{\rho}: \{1,...,n_1\} \to \{0,1\}$ maps the rows of the matrix (which each correspond to an attribute in the policy) to 0 if the attribute is not negated, and to 1 if the attribute is negated, e.g., `not region: EU`. The map $\rho_{\text{lab}}: \{1,...,n_1\} \to \{0,1\}^*$ maps the rows of the matrix to labels (represented as strings), e.g., `region`.

3.2.9 High-Level Overview of the TKN20 Scheme

Before we give a description of a simplified version of the TKN20 scheme, we first give an overview of the scheme. By doing this, we aim to demystify the many components of the scheme and highlight the techniques used to construct it.

First, we consider the general form of the scheme's master public key, the secret keys and the ciphertexts. In general, the ciphertext consists of one element in $\mathbb{G}_T$ that hides the message, i.e., $M \cdot A^s$, where $A = e(g_1, g_2)^\alpha$ is part of the public key, and further, elements in $\mathbb{G}_1$ and $\mathbb{G}_2$. The secret keys consists of elements in $\mathbb{G}_1$ and $\mathbb{G}_2$, where at least one contains α "in the exponent", e.g., $g_1^{\alpha + rb}$. To decrypt, the appropriate key and ciphertext components need to be paired (with e) to recover $A^s = e(g_1, g_2)^{\alpha s}$, and thus, the message M.

To embed the attribute sets and policies in the secret keys and ciphertexts, we use appropriate representations of these in $\mathbb{G}_1$ and $\mathbb{G}_2$. To represent the policies, we use the shares λ_i generated with the matrix representation in Section 3.2.7. In the scheme, these shares occur as B^{λ_i} in the ciphertext, where B is part of the master public key. To represent the attribute label-value pairs, we use two techniques: the hash-based [28] and the polynomial-based [10] approaches. The hash-based approach simply takes as input the attribute string, e.g., `role: doctor`, and hashes it directly into $\mathbb{G}_1$ or $\mathbb{G}_2$. The polynomial-based approach takes as input the string and first hashes it to an element x in $\mathbb{Z}_p$, and then maps it into $\mathbb{G}_1$ or $\mathbb{G}_2$ with an implicit polynomial, e.g., $B_0 \cdot B_1^x = g_1^{b_0 + x b_1}$. In TKN20, these two approaches are combined: a hash is used to map the attribute-label string directly into the group $\mathbb{G}_1$, and the implicit polynomial is used to map the attribute-value string into the group. More specifically, this combination computes $H_0(\text{lab}) \cdot H_1(\text{lab})^x$, where lab denotes the label, e.g., `role`, and x denotes the representation of the associated value, e.g., `doctor`, in $\mathbb{Z}_p$.

The reason why TKN20 maps the attribute values into the group using the polynomial-based approach is that it can support NOT operators. To support these, TKN20 uses the high-level approach introduced by Ostrovsky et al. [40], which exploits the structure of the polynomial-based map. Roughly, this approach uses the fact that two distinct points on a 1-degree polynomial can be used to reconstruct the polynomial with Lagrange interpolation[3]. More concretely, this means that the secret can be reconstructed if the attribute value in the key does not match the attribute value in the ciphertext, i.e., when they represent two distinct points on the polynomial.

3.2.10 Simplified Description of the TKN20 Scheme

We provide a simplified version of the scheme below, and explain then how the real version of the scheme—which can

[1] NOT operators can be supported in three ways [5]. TKN20 supports the most efficient variant proposed by Okamoto and Takashima [39]. This variant requires that the attribute set uses each label at most once.

[2] We do, however, require the use of the random oracle model [7]

[3] This approach is also used in Shamir's secret sharing scheme [50].

be found in the TKN20 paper [55, 56]—can be constructed from the simplified version.

- Setup(λ) $\rightarrow$ (MPK, MSK): The setup outputs the master public-secret key pair (MPK, MSK), where $H_i\colon \{0,1\}^* \rightarrow \mathbb{G}_1$ with $i \in \{0,1\}$ are two hash functions (modeled as random oracles), MSK $= (\alpha, b)$, and

$$\text{MPK} = (p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e, g_1, g_2, H_0, H_1,$$
$$A = e(g_1, g_2)^{\alpha}, B = g_1^b).$$

- KeyGen(MSK, (S, ψ_{lab})) $\rightarrow \text{SK}_S$: On input a set of attribute values S and the associated labeling map $\psi_{\text{lab}}\colon S \rightarrow \{0,1\}^*$, which maps the attributes in the set S to labels (represented as strings), it outputs the secret key SK_S as

$$\text{SK}_S = (S, K_1 = g_1^{\alpha + rb}, K_2 = g_2^r,$$
$$\{K_{3,\text{att}} = (H_0(\psi_{\text{lab}}(\text{att})) \cdot H_1(\psi_{\text{lab}}(\text{att}))^{x_{\text{att}}})^r\}_{\text{att} \in S}),$$

  where $r \in_R \mathbb{Z}_p$ is a randomly generated element in $\mathbb{Z}_p$ and x_{att} denotes the representation of att in $\mathbb{Z}_p$.

- Encrypt(MPK, $\mathbb{A}, M$) $\rightarrow \text{CT}_{\mathbb{A}}$: On input a plaintext message $M \in \mathbb{G}_T$ and an access policy $\mathbb{A} = (\mathbf{A}, \rho, \rho_{\text{lab}}, \overline{\rho}, \tau)$—where $\tau\colon \{1,\ldots,n_1\} \rightarrow \{1,\ldots,m\}$ is a function that maps each row that is associated with the same label to a different integer in $\{1,\ldots,m\}$, with m being the maximum number of times that a label occurs in the policy—it outputs a ciphertext $\text{CT}_{\mathbb{A}}$ as

$$\text{CT}_{\mathbb{A}} = (\mathbb{A}, C = M \cdot A^s, C_1 = g_2^s, \{C_{2,l} = g_2^{s_l}\}_{l \in \{1,\ldots,m\}},$$
$$\left\{C_{3,j} = B^{\lambda_j} \cdot (H_0(\rho_{\text{lab}}(j)) \cdot H_1(\rho_{\text{lab}}(j))^{x_{\rho(j)}})^{s_{\tau(j)}}\right\}_{j \in \chi_0},$$
$$\left\{C_{3,j} = B^{-\lambda_j} \cdot H_0(\rho_{\text{lab}}(j))^{s_{\tau(j)}},\right.$$
$$\left. C_{4,j} = B^{x_{\rho(j)}\lambda_j} \cdot H_1(\rho_{\text{lab}}(j))^{s_{\tau(j)}}\right\}_{j \in \chi_1}),$$

  where $s, s_1, \ldots, s_m, v_2, \ldots, v_{n_2} \in_R \mathbb{Z}_p$ are randomly generated elements in $\mathbb{Z}_p$, $\lambda_j = A_{j,1}s + \sum_{k \in \{2,\ldots,n_2\}} A_{j,k}v_k$, and $\chi_i = \{j \in \{1,\ldots,n_1\} \mid \overline{\rho}(j) = i\}$ for $i \in \{0,1\}$.

- Decrypt($\text{SK}_S, \text{CT}_{\mathbb{A}}$) $\rightarrow M'$: On input the ciphertext $\text{CT}_{\mathbb{A}}$, and a secret key SK_S, it checks whether S satisfies $\mathbb{A}$. If not, then it aborts. Otherwise, it computes the message by first determining $\Upsilon_0 = \{j \in \chi_0 \mid \rho(j) \in S\}$, $\Upsilon_1 = \{j \in \chi_1 \mid \rho(j) \notin S \wedge \rho_{\text{lab}}(j) \in \psi_{\text{lab}}(S)\}$, $\Upsilon = \Upsilon_0 \cup \Upsilon_1$ and $\{\varepsilon_j\}_{j \in \Upsilon}$ such that $\sum_{j \in \Upsilon} \varepsilon_j \mathbf{A}_j = (1,0,\ldots,0)$, then computing

$$e(g_1, g_2)^{\alpha s} = e(K_1, C_1)$$
$$\cdot \left(\prod_{j \in \Upsilon_0} \left(e(K_{3,\rho(j)}, C_{2,\tau(j)}) / e(C_{3,j}, K_2)\right)\right.$$
$$\left. \cdot \prod_{j \in \Upsilon_1} \left(e(K_{3,\rho(j)}, C_{2,\tau(j)}) / e(C_{3,j}^{y_j} \cdot C_{4,j}, K_2)^{\frac{1}{x_{\rho(j)} - y_j}} \right) \right),$$

  where $y_j = x_{\psi_{\text{lab}}^{-1}(\rho_{\text{lab}}(j))}$. Then, $M = C / e(g_1, g_2)^{\alpha s}$.

3.2.11 Description of the Fully Secure Variant

The structure of the actual TKN20 scheme [55] is much more advanced. This is because the scheme is fully secure under well-studied assumptions, in particular, a variant of the matrix decisional Diffie-Hellman assumption [21]. This assumption is closely related to the decisional Diffie-Hellman assumption [19, 21]. The main technique that is used to achieve this level of security is the dual-system encryption technique [62]. Currently, the most advanced and efficient techniques [16, 35] in this paradigm use matrix structures "in the exponent", e.g., mapping the key component $K_1 = g_1^{\alpha + rb}$ to $g_1^{\mathbf{a} + \mathbf{W}\mathbf{r}}$, where $\mathbf{a}$ and $\mathbf{r}$ are vectors of length 3 and $\mathbf{W}$ is a (3×3)-matrix [35].

3.2.12 Support for Wildcards

To support CCA-security more efficiently than e.g., [64], we use wildcards in the secret keys (as also proposed in the journal version of TKN20, i.e., [56]). A wildcard is represented by an asterisk $*$, e.g., `region: *`, and means that all values for the associated label are accepted, e.g., `region: EU`. In other words, it always matches any occurrence of an attribute with the same label in the policy. The keys for asterisks have the following form:

$$(K_{3,1,\text{att}}, K_{3,2,\text{att}}) = (H_0(\psi_{\text{lab}}(\text{att}))^r, H_1(\psi_{\text{lab}}(\text{att}))^r).$$

Tomida et al. [56] show that the variant of the scheme using wildcards is provably fully secure as well. Note that we use this functionality only to achieve CCA-security, because this functionality seems less intuitive to use for other purposes. In particular, handing out a wildcarded attribute for some label gives the user much power: it always satisfies any occurrence of that specific attribute label in the policy, regardless of what the policy dictates that the user should have.

3.2.13 Key Encapsulation and Symmetric Encryption

We use the TKN20 scheme to encapsulate a symmetric key to be used to encrypt the data, and use a one-time secure symmetric encryption scheme to encapsulate the data. More accurately, we first derive a symmetric key from the ABE ciphertext. In particular, instead of encrypting some message $M \in \mathbb{G}_T$, we directly derive the symmetric key from $e(g_1, g_2)^{\alpha s}$ by applying a key derivation function [17]. Because $e(g_1, g_2)^{\alpha s}$ is indistinguishable from a random element in $\mathbb{G}_T$, the derived key is also indistinguishable from a random key [31, 33]. Then, we use this random key to symmetrically encrypt the data. For this, we use a symmetric encryption scheme that is one-time secure, which means that no attackers can distinguish between the encryptions of any two messages (see Appendix B for a more formal definition). This "hybrid encryption" variant—where we use ABE to encapsulate a key and symmetric encryption to encapsulate the data—is provably secure against chosen-plaintext attacks, see e.g., [34, §A]. To encrypt symmetrically, we use the same approach as Boneh and Katz [12]. We

use a pseudo-random generator to generate a key stream that has the same length as the message, and XOR it to the message. In Portunus, we use an extendable output function to generate a sufficiently-long key stream, i.e., BLAKE2b [45], which is believed to be indistinguishable from pseudo-random generator.

3.2.14 CCA-Security via the BK-Transform

Finally, to achieve CCA-security, we apply the Boneh-Katz transform [12]. With this transform, we combine the hybrid encryption scheme with a message authentication code (MAC) function and a special commitment scheme[4], for which formal definitions and security models can be found in Appendix B. Informally, the special commitment scheme that we use consists of two independent hash functions. The first hash is used to generate a public commitment to a secret random value, and the second hash uses the secret random value to derive a key K'. Subsequently, this secret random value is included in the encryption of the message with the hybrid encryption scheme. We compute a MAC with the key K' over the resulting ciphertext to ensure authenticity of the ciphertext. Furthermore, the public commitment to the secret random value is included in the access policy with an AND operator applied to the original policy, and also in plain in the resulting ciphertext. To decrypt, one first recovers the message and secret random value by decrypting the ciphertext. Then, one verifies whether the public commitment is equal to the hash over the secret random value, and then if the MAC verifies correctly given the key derived from the secret random value. We give a full description of the CCA-secure construction (using the simplified version of TKN20) in Appendix C. It follows from [12] and [60] that this construction is CCA-secure.

3.3 Software Implementation

We implemented our scheme as part of the CIRCL library [1] in Go. The particular instantiation of the pairing-friendly groups $\mathbb{G}_1$,$\mathbb{G}_2$ and $\mathbb{G}_T$ that our implementation uses is the BLS12-381 curve [6, 13]. We generated the code for the arithmetic in $\mathbb{Z}_p$ with the Fiat Cryptography tool [20], which formally verifies the correctness of the produced code. We have also optimized the arithmetic for the groups $\mathbb{G}_1$,$\mathbb{G}_2$ and $\mathbb{G}_T$ through judicious choice of representation. Our implementation uses the fast subgroup checks via Bowe's method [14], which allow us to check whether any given point is in the group, e.g., $\mathbb{G}_1$. To hash into groups, we followed the relevant IETF specification [24]. To optimize the decryption algorithm, we use two common tricks that are often used to speed up computing a product of pairings, i.e., by reordering the computations [42] and by sharing the final step of the pairing operations [29]. Figure 1 presents a reproducible program showing the usage of our code.

[4]Boneh and Katz [12] call this an "encapsulation" scheme, but to distinguish it more clearly from key and data encapsulation, we call it "special commitment scheme" in this paper.

4 Design

Armed with the above scheme, we now must construct services to encrypt customer keys, and make them available to those who should have them. Cloudflare logically has four components. The first is a set of edge machines located in geographically spread and distant data centers. These edge machines run a homogeneous mixture of services that terminate TLS and serve HTTP. The actual signing of TLS handshakes takes place in a system called Gokeyless in all relevant cases.

The second component is a centralized set of services in the control-plane responsible for the API that customers interact with to configure their website. One of these services, the certificate manager, handles all configuration relating to TLS.

The third component is a small number of very tightly controlled machines that handle certificate issuance for internal certificates. All machines at Cloudflare have a machine identity based on RSA keys: our key issuance service uses that identity to determine the attributes a machine shall have. We call this service the Key Generation Authority (KGA).

The fourth component is a globally synchronized key-value store, Quicksilver. This is a global gossip tree for customer configurations, such as certificates, that is designed to ensure extremely fast replication, at the cost of constrained bandwidth and storage. Every edge machine stores a local copy of the data in Quicksilver.

4.1 Encrypting Customer Keys

When a customer uploads a certificate and the associated private signing key to Cloudflare, and indicates it is to be protected under an access policy, the certificate manager in the control-plane takes the private key and encrypts it with the required policy. However, the customer's private key is not encrypted with the ABE master public key directly. Rather, it is encrypted with an X25519 key pair, the private key of which is encrypted under the ABE scheme. These key pairs are indexed by the policy and the epoch they are under. At any time, there may be several of these key pairs, called *policy keys*, present in the database for a given policy. The certificate manager will use the most recent one for encryption. This permits gradual rotation of the key pairs. Note that the only encryption happening in Portunus is done by the certificate manager.

4.2 Accessing Customer Keys

On receipt of a connection to a site, such as `alice.test.com`, Gokeyless carries out a lookup for the certificate in Quicksilver. If that certificate has a key protected by Portunus, the metadata for that certificate will have a pointer to the relevant policy key together with a ciphertext that decrypts to the private key. Gokeyless then loads the policy key and determines if it is decryptable by the machine. If not, it consults a table that maps each policy to a list of satisfying data centers to find a

Listing 1: Example usage of the ABE library API

```
masterPubKey, masterSecKey := Setup() // Initialize the master public and master secret key
accessPolicy := new(Policy)
accessPolicy.FromString("country: US or region: EU") // Create new policy from given string
// Encrypt the secret message using the master public key and policy
encryptedMsg := masterPubKey.Encrypt(accessPolicy, []byte{"long live ABE"})
parisDCAttributes := new(Attributes) // Create attributes for the Paris data center
parisDCAttributes.FromMap(map[string]string{ "country": "FR", "region": "EU"})
// Generate an attribute secret key for the Paris data center using the master secret key
parisDCSecKey := masterSecKey.KeyGen(parisDCAttributes)
// Decrypt the ciphertext using the attribute secret key of the Paris data center
decryptedMsg := parisDCSecKey.Decrypt(encryptedMsg)
assertEquals(decryptedMsg, []byte{"long live ABE"})
```

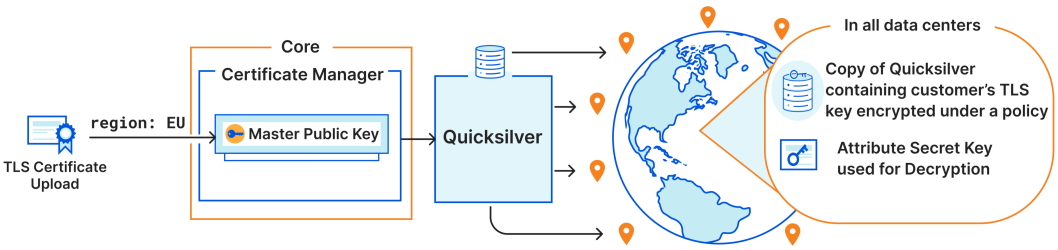

Figure 1: Encryption under a policy

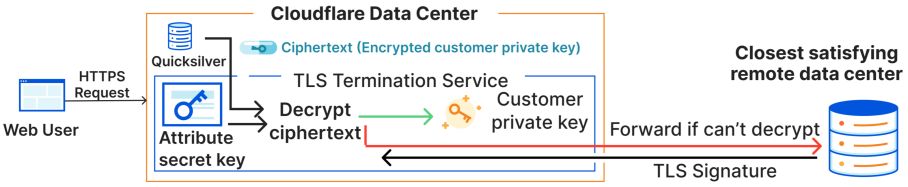

Figure 2: Decryption using Attribute Secret Key

neighboring one, and forwards the request there. Gokeyless on this machine then decrypts the policy key and uses the result to decrypt the certificate's private key, performing the signature and completing the TLS handshake. The decrypted policy keys are cached in memory, so the computationally burdensome ABE decryption only happens once for commonly used policies. This is an important optimization to avoid excessive CPU consumption during attack scenarios when many handshakes are arriving.

4.3 Key Distribution

The key generation authority (KGA) holds the ABE master secret key. It also has access to the unique cryptographic identity for every machine in the fleet, as well as a map of machines to attributes. This map is largely synchronized with the machine's own view. Key issuance for the machine's attribute-based secret key is managed by the service configuration management system, Salt [2]. Salt uses the RSA identity key of the machine to authenticate to the CA, which generates the machine's attribute secret key using the master secret key and the attributes of the machine. The map of machines to attributes is configured in the same database that drives machine identity for Salt.

4.4 Key Rotation

Over time, it is necessary to change the key material in the system so that an attacker who has access to old key material can no longer decrypt newly uploaded customer TLS private keys. However, the lifetime of a customer certificate can extend beyond a rotation period and it must be possible to continue to decrypt the customer TLS key for that duration.

The key generation authority generates a new *generation* of the master key pair. To preserve the ability to decrypt old TLS private keys, the CA re-encrypts the existing policy keys on behalf of the certificate manager. During this process,

machines will have both the old and new generation of the attribute secret key, ensuring that availability is not impacted as the old key material is phased out.

Newly uploaded certificate private keys are encrypted under the same policy key. This means that an attacker who has access to a policy key can continue to to decrypt new TLS keys, but it is possible to generate new policy keys for a policy. This does however guard against an attacker who obtains the attribute secret keys for a machine from being able to access the TLS keys after rotation.

To detect accidental or malicious usage of expired key generations and have end-to-end visibility into the status of key rotation, we have logging and metrics for key generation held and used in each part of the system.

4.5 Attribute Changes

From time to time, the attributes associated with a set of data centers may change. Introducing new labels that have not been used by existing policies is straightforward, since the set of data centers that can decrypt a given TLS private key remains unchanged. However, when the attributes of the data centers that can decrypt a key are changing, certain changes are needed to maintain system functionality [5, 59]. We split the act of "changing an attribute" in two steps: removal of the old label and value, and the re-addition of the label with the new value. The former results in loss of decryption capabilities for associated data centers, because they no longer satisfy the policies that required the presence of this label. Note that the removal does not increase the decryption capabilities yet, because to satisfy a negated attribute, the set of attributes of the data center must have an attribute with the same label, regardless of the value. Adding a new label can only increase the number of policies satisfied due to negation semantics.

Carrying out this transition requires three steps. First, the affected label is removed from the forwarding information of the involved data center, so that other data centers stop sending requests that require its presence. Second, the key is re-issued with the new attribute. Third, the new attribute is re-added to the forwarding information so requests are handled by the data center again. Throughout this, the affected data center handles end-user requests as usual: those requests that cannot be satisfied locally are forwarded to other data centers that can satisfy them, whose forwarding information is not affected by the transition. This process can be difficult to carry out at scale and requires careful planning and should be done in stages. Lastly, a key rotation is required to ensure that any retained copies of the older key are not used.

4.6 Networking and Resiliency

Gokeyless uses an RPC protocol to forward TLS signing requests to the closest satisfying data center, which on arrival leverage a network layer load balancer [63] to determine an appropriate machine to handle the connection. Since the computational load of handling a request forwarded for Portunus is merely an X25519 decryption and an RSA/ECDSA signature, even high levels of request volume have not led to failures due to load balancing issues.

Because maintaining connections to all other machines can be expensive, machines within one data center will elect among themselves a machine to forward requests to specific close foreign data centers. This reduces the number of TCP connections being used.

Resiliency is negatively impacted for customers who apply overly restrictive policies. It is possible for data centers to be taken offline or become overwhelmed for a variety of reasons. If all data centers a customer's key is decryptable in are offline, then the customer's website will be rendered inaccessible. To prevent this, we require customer keys be decryptable in at least two large-capacity data centers.

We have found that typically customers will store their certificates in regions where the majority of their users are found. This unsurprising pattern puts low demands on the remote execution capabilities. Unfortunately, events such as DDoS attacks can add significant load. Operation under normal conditions is not a guide to operation under adverse conditions. This led us to expend significant effort to integrate distributed tracing in addition to metrics to track system performance and quickly diagnose and reproduce scaling issues.

5 Evaluation

While Portunus was launched to customers in 2022, the older version of the system based on similar principles (Geo Key Manager) has been in production since 2017. Over the years, the number of customers and end-users relying on this product has steadily increased. This section is an evaluation of the various components of Portunus.

During a sample week in December 2022, we observed 100k requests per second being served between Portunus and Geo Key Manager. As most customers restrict key access to the region where they typically have the most users, approximately 80% of these requests are handled locally. The remaining 20% are forwarded to their closest satisfying neighbor.

5.1 Cryptography

We evaluate our underlying cryptography library against RSA-2048 and X25519, utilizing Go libraries `crypto/rsa` and `x/crypto/nacl/box` as reference implementations. These comparative algorithms were chosen because they are standard public-key cryptography. We conduct our measurements on an Apple M1 Mac.

We characterize our library's performance using measures inspired by ECRYPT [8]. In all comparisons involving ABE, we set the attribute set size to 50 and consider policy formulas over 50 attributes. This attribute set size is significantly higher

Table 2: Space Overheads (bytes)

Scheme	Secret key[5]	Public key	Encrypt 23 B	Encrypt 10 KB
RSA-2048	1190	256	233	496
X25519	32	32	48	48
Our scheme	23546	3282	19475	19475

Table 3: Operation times (ms)

Scheme	Key Gen.	Encrypt 23 B	Decrypt 23 B
RSA-2048	180	0.209	1.47
X25519	0.061	0.096	0.046
Our scheme	701	364	30.1

than necessary for any of Portunus' applications, as most policies are typically limited to a combination of geographic properties. Nevertheless, it serves as an extreme worst-case scenario for benchmarking purposes.

Table 2 shows the space consumed by the various operations. For our system, the ciphertext overhead is of particular concern since it is replicated on every machine. Unfortunately, this overhead is significantly larger than in traditional public-key cryptography. However, the good news is that this overhead is constant with respect to message length for a given policy size, and can be reduced by relying on a small handful of policy keys (defined in Section 4.1) rather than encrypting every customer key using ABE. Importantly, the ciphertexts in our system can be decrypted by multiple decryptors, whereas standard public-key cryptography benchmarks only consider a ciphertext that can be decrypted by a single decryptor. The size of the attribute secret key is less relevant, as a single copy is stored per machine. The size of the master public key is of even less concern, as it is only used by the certificate manager in the control plane.

Table 3 shows the average time required to perform different key operations. Key generation refers to the process of generating attribute secret keys from the master secret key, which can be performed out-of-band of user handshakes and is therefore of marginal relevance in this context. Encryption latency can also largely be ignored, as it is acceptable for encryption to take a few extra cycles before a certificate is considered deployed. But once it is deployed, HTTPS requests to the website should complete quickly. Since decryption is in the critical path of every request, it is the most pertinent in our situation. While session resumption and caching policy keys can amortize the number of ABE decryptions across TLS handshakes to a small fraction, improvements to decryption latency will still affect overall baseline performance. It is therefore important to further optimize the decryption process.

[5]For ABE, this is the Attribute-Based Secret Key.

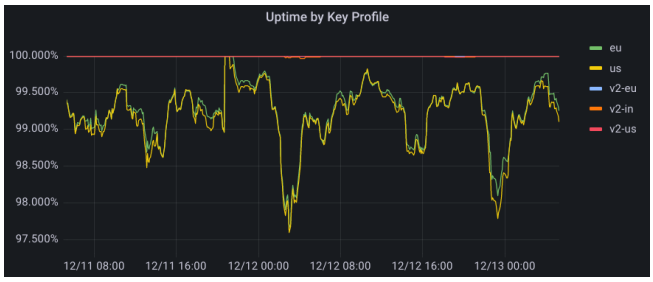

Figure 3: Uptime by policy; this shows that Portunus (v2) has consistently better uptime than Geo Key Manager (v1)

5.1.1 Request Latency

The overall performance of Portunus includes the impact of cryptography, networking and geographic location based on the type of Portunus request: handshakes processed locally, and those forwarded to a remote data center. The vast majority of local requests only perform an X25519 decryption because of policy keys. The remainder incur the overhead of an ABE decryption. For remote requests, network latency largely dominates.

5.2 Availability

Figure 3 shows the uptime of our system by policy vs the previous system. This graph was produced using synthetic probes spanning every machine across our fleet. It demonstrates that dynamically selecting all possible machines to decrypt rather than a pre-determined handful as in our previous release, produces significant improvements to real-world reliability.

6 Discussion

We want to reiterate why an access-control solution based on novel cryptography makes the most sense for our system.

The TLS key management system is responsible for ensuring that edge machines can access customer signing keys when customers upload their TLS certificates (and associated signing keys) to Cloudflare. To ensure availability and low latency, the key manager relies on an internal globally synchronized key-value store, Quicksilver [43] to distribute user configurations to all edge data centers within seconds. A copy of the entire Quicksilver data set is replicated on every edge machine for fault tolerance, allowing requests to be served even if disconnected from the central synchronizing server.

However, augmenting the key management system to support policy-based access restrictions required us to rethink our approach of storing the same data on all edge machines. Using a central server to enforce access would reduce fault tolerance and add additional latency, undermining the advantages of a distributed edge. Alternatively, we could ensure that only data centers that satisfy a given policy receive those policy-restricted keys. However, this would require

modifying Quicksilver's replication strategy to store only a subset of the key set, which challenges core design decisions Cloudflare has made over the years that assume the entire data set is replicated on every machine.

We considered a third option of issuing unique keys for each data center: wrapping each TLS signing key with the key of every authorized data center and adding them all to Quicksilver. Although this approach would have permitted access to the key only in certain locations while letting TLS be terminated where possible, it would also significantly increase the storage space requirements on every machine proportional to the number of datacenters.

This encouraged us to explore alternative cryptographic solutions. Our first attempt, Geo Key Manager, was developed back in 2016, when there was only one ABE scheme that supported all properties [59], but in a rather inefficient way. In particular, at the time, supporting negations led to significant efficiency penalties in the decryption algorithm [58]. Only recently, the community started addressing these efficiency issues [5, 55, 58]. To get around this limitation, we initially used a combination of identity-based encryption and broadcast encryption to simulate an ABE-like scheme. Unfortunately, this scheme was not collusion resistant (Section 3.2.4). As a result we were eager to switch to a more theoretically satisfying solution once practical ABE schemes became available.

During the implemention of our ABE scheme, while we performed much optimization (Section 3.3), the implementation has larger overheads compared to the mature implementations for traditional cryptographic schemes. We mitigated some of these costs by using policy keys (Section 4.1). This approach is similar to hybrid encryption, where public-key cryptography is used to establish a shared symmetric key used to encrypt data. Policy keys are public key encryption keys to permit the central service to encrypt user's certificates without access to the key. While not as efficient as symmetric cryptography this still reduces the overhead.

The performance and reliability improvements of the deployed system are due to side-effects of the new cryptographic scheme. The original system only supported one kind of attribute, a region. Unfortunately, this did not support customers who wanted to specify countries, and so a hard-coded list of cities was used on upload. This list was rarely updated, so new datacenters were not used. Migration was an extremely difficult prospect. Switching to the new system meant that country could be used directly, and additional attributes could be added. This immediately increased the available set of data centers for many common policies, and directly improved reliability.

Although ABE employs a highly trusted key generation authority to issue the secret keys, we argue that this authority does not need to be more trusted than an authority enforcing traditional access control. Specifically, in Portunus, the role of the key generation authority is integrated with a certificate authority that is used to secure all critical services within Cloudflare's internal network. If this authority were to be corrupted, the consequences would be much worse than simply breaking the security of ABE. If, however, a similar setting would require that the trust in the authority is mitigated by distributing the trust across multiple authorities, one could also deploy multi-authority ABE [15, 37].

A policy conundrum may also arise in certain situations: the encrypted data still resides in restricted regions. This can potentially cause concern among those without a comprehensive understanding of the system. Assuaging these concerns will vary between organizations, but a big part involves spreading awareness of how policy-based encryption works.

7 Future Work

Although ABE can support all properties required by our particular application, it does present minor limitations that may be critical in other contexts. For instance, our scheme doesn't support policies with wildcards of the form `country: *`, meaning any country can satisfy this policy. It likewise doesn't permit an attribute set with multiple values for a single attribute label, such as `{group: fiddlers, group: percussionists}`.

It is unclear what post-quantum ABE schemes will have the combination of performance, implementation simplicity, and expressivity required. Likewise, the use of pairing-based cryptography creates some challenges in acceptance, as decision makers may be unfamiliar with it and it is not standardized, despite ongoing efforts towards standardization at IETF [47].

8 Lessons Learned

In the course of operating Portunus and its predecessor Geo Key Manager, we have learnt several lessons.

Even after more practical ABE schemes became available, the difficulty in translating a scheme from an ABE paper to practice, as well as in selecting an appropriate scheme, should not be underestimated. Typically, there are some parameters that must be chosen, with little indication of the strength of the various assumptions the parameters create. In addition, the notation can require a formidable amount of translation, sometimes concealing significant computational steps.

There persists a prevalent notion in the cryptography community that ABE is still unreasonably slow to be useful. We believe this is no longer true. Just like traditional public key cryptography is not used independently to encrypt large amounts of data, but rather in concert with symmetric encryption, we believe many applications can enjoy the benefits of ABE using it with a hybrid encryption strategy.

Complicated cryptographic schemes in services, particularly ones as critical as TLS termination, can elicit operational apprehensions amongst SREs and other teams that depend on the service. Cryptography can end up being scapegoated when issues arise, despite the problems originating from other system components. We believe when designing such a system, it is prudent

to prioritize simplicity in every other aspect. This makes failures outside the cryptography straightforward to diagnose and conserves the complexity budget for the cryptography.

We have certainly faced the consequences of not adhering to this principle, in the form of delayed rollout due to difficulty garnering operational confidence. Geo Key Manager's complexity extended beyond just the cryptographic components, such as the use of a custom RPC protocol - an artifact of the parent system's (which Geo Key Manager was integrated into) development before the existence of gRPC. This custom protocol, despite resolving most of its quirks as part of Portunus's development, continued to present challenges in specific edge cases. We are presently transitioning to gRPC to alleviate these issues and preempt future related issues. Another example of reducing complexity was replacing a complex thread-pool architecture based on outdated assumptions, with a simple and scalable architecture of one goroutine per request, capitalizing on the lightweight concurrency model offered by Go. Our ongoing efforts aim to simplify various other components, with the ultimate goal of improving system maintainability and fostering enthusiastic buy-in from other stakeholders, as well as encouraging other teams to consider applying ABE-based access control for their own use cases, armed with the reassurance of Portunus's successful deployment.

9 Related Work

Prior work has considered CP-ABE for enforcing access control. Oftentimes, the design of new ABE schemes is justified by their new capabilities based on use in access control [9,44,65], but without many details on potential system design. However, as Venema and Alpár demonstrate [57], there have been various attacks on some of these constructions [44,65], particularly those that do not rely on pairings [30,66]. It is therefore important that care is taken in choosing an established scheme that has the necessary properties and is secure.

Although there are many schemes with various properties [59], our chosen scheme is unique in satisfying our desired properties 3.2.6, making comparisons with alternative ABE schemes difficult. Likewise, comparing cryptographic operation benchmarks with potentially sub-optimized research implementations of ABE schemes is not in scope and we refer the reader to more comprehensive analyses [18].

In contrast to most works about systems that use ABE, Sieve [61] dives deeper into the details of the system. The authors discuss how key management, ABE overhead, and key deletion have to be addressed in a deployed system. In this system, applications can interact with user data stored in the cloud, while users maintain control over which applications have access to their data. Because Sieve is built for a different setting than Portunus, it makes different choices in how ABE is applied. Most notably, it uses key-policy ABE, where the keys are associated with policies and the ciphertexts are associated with attribute sets, to apply a "tag-based" access control like described in Section 3.2.1. In particular, the encrypted data objects that are stored in the cloud are associated with attribute sets. Once an application requests access to the user's data, the user can specify a policy stating which data can be accessed.

Excalibur [48] is perhaps the most similar to our work, because it also uses CP-ABE to enforce access control in the spirit of attribute-based access control. The authors designed and implemented a system for customers to make data accessible on certain machines, and integrated it into a cloud environment. Because their use case is different, the challenges that their system overcomes also differ. Importantly, like Sieve, Excalibur did not progress beyond a lab setting and was never actually deployed in a large-scale real-world setting.

Finally, most existing access-control applications separate the cryptographic and access-control aspects. Cryptography is used to protect sensitive data (in transit, but sometimes, also at rest), while access control is enforced more traditionally. In traditional models, a central authority typically enforces policies by validating an entity's authorization prior to granting data access. When access is granted, a decryption key is shared with the requesting entity, who can then access the data by decrypting it. However, this approach introduces significant latency to the access request. Furthermore, a single central authority makes the system vulnerable to denial-of-service attacks. In contrast, using ABE allows access control on a cryptographic level, achieving both protection of the data whilst allowing the enforcement of access control. By extension, it removes this extra latency and mitigates the availability issues of the central authority. It also allows data to be freely transmitted between nodes, removing the risk of accidental data leakage as long as the target node's secret key is not compromised.

10 Conclusion

For several months, Portunus has seen real-world usage protecting customer keys. It has succeeded in supplanting the capabilities of the legacy system and setting a foundation for future product development. This required multiple person-years of effort by a small team, as well as accepting a fairly novel scheme as the foundation of its security. This effort brought about increases in reliability and enhanced performance.

Acknowledgements

We are grateful for the assistance of the Security Engineering team, particularly Mihir Jham and Nicky Semenza, in explaining their software and letting us make some rather audacious proposals to redesign a significant system. We would also like to thank the Research team. Finally, Mike Rosulek helped us solve the hardest problem in Computer Science by suggesting the name Portunus[6].

A Security Model for CP-ABE

We define the security game IND-CCA(λ) between challenger and attacker as follows:

- **Setup phase:** The challenger runs Setup(λ) to obtain MPK and MSK, and sends the master public key MPK to the attacker.
- **First query phase:** The attacker can make two types of queries:
  - **Key query:** The attacker queries secret keys for sets of attributes S, and obtains $\mathrm{SK}_S \leftarrow \mathrm{KeyGen}(\mathrm{MSK}, S)$ in response.
  - **Decryption query:** The attacker sends a ciphertext $\mathrm{CT}_{\mathbb{A}}$ for access policy $\mathbb{A}$ and some set S that satisfies $\mathbb{A}$ to the challenger, who returns the message $M \leftarrow \mathrm{Decrypt}(\mathrm{MPK}, \mathrm{SK}_S, \mathrm{CT}_{\mathbb{A}})$ (where $\mathrm{SK}_S \leftarrow \mathrm{KeyGen}(\mathrm{MSK}, S)$).
- **Challenge phase:** The attacker specifies some access policy $\mathbb{A}^*$ such that none of the sets S in the first key query phase satisfies $\mathbb{A}^*$, generates two equal-length messages M_0 and M_1, and sends these to the challenger. The challenger flips a coin, i.e., $\beta \in_R \{0,1\}$, encrypts M_β under $\mathbb{A}^*$, i.e., $\mathrm{CT}_{\mathbb{A}^*} \leftarrow \mathrm{Encrypt}(\mathrm{MPK}, \mathbb{A}^*, M_\beta)$, and sends the resulting ciphertext $\mathrm{CT}^*_{\mathbb{A}^*}$ to the attacker.
- **Second query phase:** This phase is identical to the first query phase, with the additional restriction that the attacker cannot query keys for sets of attributes S that satisfy the policy $\mathbb{A}^*$ or make a decryption query for $\mathrm{CT}^*_{\mathbb{A}^*}$.
- **Decision phase:** The attacker outputs a guess β' for β.

The advantage of the attacker is defined as

$$\mathsf{Adv}_{\text{IND-CCA}} = \left| \Pr[\beta' = \beta] - \frac{1}{2} \right|.$$

A scheme is fully secure against chosen-ciphertext attacks if all polynomial-time attackers have at most a negligible advantage in this security game.

In the model for security against chosen-plaintext attacks, the attacker is not allowed to make decryption queries in the first and second query phase—only key queries.

B Other Definitions

B.1 Symmetric Encryption

B.1.1 Formal Definition

We define symmetric encryption as follows. Let λ be the security parameter. A symmetric encryption scheme $\mathrm{SE} = (\mathrm{Enc}, \mathrm{Dec})$, with symmetric key $\mathrm{K} \in \{0,1\}^\lambda$, is defined as

- $\mathrm{Enc}_\mathrm{K}(M)$: On input message $M \in \{0,1\}^*$, encryption returns a ciphertext $\mathrm{CT}_{\mathrm{sym}}$.
- $\mathrm{Dec}_\mathrm{K}(\mathrm{CT}_{\mathrm{sym}})$: On input ciphertext $\mathrm{CT}_{\mathrm{sym}}$, decryption returns a message M or an error message $\perp$.

The scheme is correct if for all keys $\mathrm{K} \in \{0,1\}^\lambda$ and all messages $M \in \{0,1\}^*$, we have $\mathrm{Dec}_\mathrm{K}(\mathrm{Enc}_\mathrm{K}(M)) = M$.

B.1.2 Security Model

For symmetric encryption, we use the same security notion as in [33], i.e., ciphertext indistinguishability. Informally, ciphertext indistinguishability ensures that an attacker cannot distinguish between encryptions of any two messages. More formally, it is defined as follows. Let λ be a security parameter and let $\mathrm{SE} = (\mathrm{Enc}, \mathrm{Dec})$ be a symmetric encryption scheme. Consider the following game between a challenger and attacker. The challenger first picks a key $\mathrm{K} \in \{0,1\}^\lambda$. Then, the attacker specifies two messages M_0, M_1 and gives these to the challenger, who flips a coin $\beta \in_R \{0,1\}$ and returns $\mathrm{CT}_{\mathrm{sym}} \leftarrow \mathrm{Enc}_\mathrm{K}(M_\beta)$ to the attacker. The attacker outputs a guess β' for β. Then, $\mathrm{SE} = (\mathrm{Enc}, \mathrm{Dec})$ has indistinguishable ciphertexts if for all polynomial-time attackers in the game above holds that the advantage $\left| \Pr[\beta' = \beta] - \frac{1}{2} \right|$ is negligible

B.2 MAC Function

B.2.1 Formal Definition

We formally define a MAC function as follows. Let λ be the security parameter. A message authentication code (MAC) $(\mathrm{MAC}_{\mathrm{K_{MAC}}}, \mathrm{Vrfy}_{\mathrm{K_{MAC}}})$, where $\mathrm{K_{MAC}} \in \{0,1\}^\lambda$ is the MAC key, is defined by

- $\mathrm{MAC}_{\mathrm{K_{MAC}}}(M)$: On input message $M \in \{0,1\}^*$, this algorithm outputs a tag T.
- $\mathrm{Vrfy}_{\mathrm{K_{MAC}}}(M, \mathrm{T})$: On input message M and tag T, the algorithm returns 0 ("reject") or 1 ("accept").

The MAC is correct if for all keys $\mathrm{K_{MAC}} \in \{0,1\}^\lambda$ and all messages $M \in \{0,1\}^*$ it holds that if $\mathrm{T} \leftarrow \mathrm{MAC}_{\mathrm{K_{MAC}}}(M)$, then $\mathrm{Vrfy}_{\mathrm{K_{MAC}}}(M, \mathrm{T}) = 1$.

B.2.2 Security Model

For MACs, we use the notion of security against one-time chosen-message attacks. Let λ be the security parameter, and let $(\mathrm{MAC}_{\mathrm{K_{MAC}}}, \mathrm{Vrfy}_{\mathrm{K_{MAC}}})$ be a message authentication code. Consider the following game between challenger and attacker. The challenger first picks a key $\mathrm{K_{MAC}} \in \{0,1\}^{\lambda}$. The attacker sends a message M to the challenger, who returns a tag $\mathrm{T} \leftarrow \mathrm{MAC}_{\mathrm{K_{MAC}}}(M)$. Then, the attacker outputs a pair (M', T'). The attacker succeeds if $(M, \mathrm{T}) \neq (M', \mathrm{T}')$ and $\mathrm{Vrfy}(M', \mathrm{T}') = 1$.

B.3 Special Commitment Scheme

B.3.1 Formal Definition

The special commitment scheme that we use is defined as follows. Let λ be the security parameter.

- $\mathrm{ESetup}(\lambda) \rightarrow \mathrm{pub}$: Define hashes $h_1 \colon \{0,1\}^{448} \rightarrow \mathbb{Z}_p$ and $h_2 \colon \{0,1\}^{448} \rightarrow \{0,1\}^{\lambda}$, and set $\mathrm{pub} = (h_1, h_2)$.
- $\mathrm{ES}(\lambda, \mathrm{pub}) \rightarrow (\mathrm{rand}, \mathrm{com}, \mathrm{dec})$: Generate $\mathrm{dec} \in_R \{0,1\}^{448}$, and compute $\mathrm{com} = h_1(\mathrm{dec})$ and $\mathrm{rand} = h_2(\mathrm{dec})$.
- $\mathrm{ER}(\mathrm{pub}, \mathrm{com}, \mathrm{dec}) \rightarrow \mathrm{rand}$: Generate $\mathrm{rand} \leftarrow h_2(\mathrm{dec})$.

The special commitment scheme is correct if for all $(\mathrm{rand}, \mathrm{com}, \mathrm{dec}) \leftarrow \mathrm{ES}(\lambda, \mathrm{pub})$ holds that $\mathrm{ER}(\mathrm{pub}, \mathrm{com}, \mathrm{dec}) = \mathrm{rand}$.

B.3.2 Security Model

A special commitment scheme $(\mathrm{ESetup}, \mathrm{ES}, \mathrm{ER})$ is secure if it is hiding and binding.

- **Hiding:** Consider an attacker and a challenger. Then, the challenger runs $\mathrm{pub} \leftarrow \mathrm{ESetup}(\lambda)$ and flips a coin $\beta \in_R \{0,1\}$. If $\beta = 0$, then $\mathcal{C}$ generates a random $\mathrm{rand} \in_R \{0,1\}^{\lambda}$, and otherwise, it runs $(\mathrm{rand}, \mathrm{com}, \mathrm{dec}) \leftarrow \mathrm{ES}(\lambda, \mathrm{pub})$. It shares $(\lambda, \mathrm{pub}, \mathrm{rand}, \mathrm{com})$ with the attacker, who then outputs a guess β' for β. The scheme is hiding if for all such attackers, it holds that the advantage $\left|\Pr[\beta = \beta'] - \frac{1}{2}\right|$ is negligible.
- **Binding:** Consider an attacker and a challenger. Then, the challenger runs $\mathrm{pub} \leftarrow \mathrm{ESetup}(\lambda)$, and shares $(\mathrm{rand}, \mathrm{com}, \mathrm{dec}) \leftarrow \mathrm{ES}(\lambda, \mathrm{pub})$ with the attacker. Then, it is computationally infeasible for the attacker to find $\mathrm{dec}' \neq \mathrm{dec}$ such that $\mathrm{ER}(\mathrm{pub}, \mathrm{com}, \mathrm{dec}') = \mathrm{rand}$, i.e., for output $\mathrm{dec}' \neq \mathrm{dec}$ of the attacker, it holds that the success probability $\Pr[\mathrm{ER}(\mathrm{pub}, \mathrm{com}, \mathrm{dec}') = \mathrm{rand}]$ is negligible. The scheme is binding if this holds for all such attackers.

C Description of Our CCA-Secure Scheme

We give a simplified description (using the simplified description of TKN20 in Section 3.2.10) of our CCA-secure scheme below.

- $\mathrm{Setup}(\lambda) \rightarrow (\mathrm{MPK}, \mathrm{MSK})$: The setup outputs the master public-secret key pair (MPK, MSK), where $H_i \colon \{0,1\}^* \rightarrow \mathbb{G}_1$ with $i \in \{0,1\}$ are two hash functions (modeled as random oracles), $\mathrm{KDF} : \mathbb{G}_T \rightarrow \{0,1\}^{\lambda}$ is a key derivation function [17], $\mathrm{SE} = (\mathrm{Enc}, \mathrm{Dec})$ is a symmetric encryption scheme, pub are the public parameters generated with the setup ESetup of a special commitment scheme, $\mathrm{MSK} = (\alpha, b)$, and

$$\mathrm{MPK} = (\mathrm{SE}, \mathrm{pub}, p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e, g_1, g_2, H_0, H_1, A = e(g_1, g_2)^{\alpha}, B = g_1^b).$$

- $\mathrm{KeyGen}(\mathrm{MSK}, (S, \psi_{\mathrm{lab}})) \rightarrow \mathrm{SK}_S$: On input a set of attribute values S and the associated labeling map $\psi_{\mathrm{lab}} \colon S \rightarrow \{0,1\}^*$, which maps the attributes in the set S to labels (represented as strings), it outputs the secret key SK_S as

$$\mathrm{SK}_S = (S, K_1 = g_1^{\alpha + rb}, K_2 = g_2^r,$$
$$\{K_{3,\mathrm{att}} = (H_0(\psi_{\mathrm{lab}}(\mathrm{att})) \cdot H_1(\psi_{\mathrm{lab}}(\mathrm{att}))^{x_{\mathrm{att}}})^r\}_{\mathrm{att} \in S},$$
$$K_{3,\mathrm{CCA}} = H_0(\mathrm{CCA})^r, K_{4,\mathrm{CCA}} = H_1(\mathrm{CCA})^r),$$

  where $r \in_R \mathbb{Z}_p$ is a randomly generated element in $\mathbb{Z}_p$ and x_{att} denotes the representation of att in $\mathbb{Z}_p$.

- $\mathrm{Encrypt}(\mathrm{MPK}, \mathbb{A}, M) \rightarrow \mathrm{CT}_{\mathbb{A}}$: On input a plaintext message $M \in \{0,1\}^*$ and an access policy $\mathbb{A} = (\mathbf{A}, \rho, \rho_{\mathrm{lab}}, \overline{\rho}, \tau)$—where $\tau \colon \{1, \ldots, n_1\} \rightarrow \{1, \ldots, m\}$ is a function that maps each row that is associated with the same label to a different integer in $\{1, \ldots, m\}$, with m being the maximum number of times that a label occurs in the policy—it first extends the policy $\mathbb{A}$ to $\mathbb{A}'$ such that it applies an AND operator to $\mathbb{A}$ and the attribute label-value pair `CCA: com` (where com is defined as below), and outputs a ciphertext $\mathrm{CT}'_{\mathbb{A}'}$ as

$$\mathrm{CT}'_{\mathbb{A}'} = (\mathbb{A}, \mathrm{com} \leftarrow h_2(\mathrm{dec}), C \leftarrow \mathrm{Enc}_{\mathrm{K}}(\mathrm{dec} \| M), \mathrm{CT}_{\mathbb{A}'},$$
$$\mathrm{T} = \mathrm{MAC}_{\mathrm{K}'}(\mathbb{A} \| \mathrm{com} \| C \| \mathrm{CT}_{\mathbb{A}'})),$$

  so that

$$\mathrm{CT}_{\mathbb{A}} = (C_1 = g_2^s, \{C_{2,l} = g_2^{s_l}\}_{l \in \{1, \ldots, m\}},$$
$$\left\{C_{3,j} = B^{\lambda_j} \cdot (H_0(\rho_{\mathrm{lab}}(j)) \cdot H_1(\rho_{\mathrm{lab}}(j))^{x_{\rho(j)}})^{s_{\tau(j)}}\right\}_{j \in \chi_0},$$
$$\left\{C_{3,j} = B^{-\lambda_j} \cdot H_0(\rho_{\mathrm{lab}}(j))^{s_{\tau(j)}},\right.$$
$$\left. C_{4,j} = B^{x_{\rho(j)} \lambda_j} \cdot H_1(\rho_{\mathrm{lab}}(j))^{s_{\tau(j)}}\right\}_{j \in \chi_1}),$$

  where $s, s_1, \ldots, s_m, v_2, \ldots, v_{n_2+1} \in_R \mathbb{Z}_p$ are randomly generated elements in $\mathbb{Z}_p$, $\lambda_j = A_{j,1} s + \sum_{k \in \{2, \ldots, n_2+1\}} A_{j,k} v_k$, $\chi_i = \{j \in \{1, \ldots, n_1 + 1\} \mid \overline{\rho}(j) = i\}$ for $i \in \{0,1\}$, $\mathrm{K} \leftarrow \mathrm{KDF}(A^s)$, $\mathrm{dec} \in_R \{0,1\}^{448}$ and $\mathrm{K}' \leftarrow h_1(\mathrm{dec})$.

- Decrypt($\mathrm{SK}_S, \mathrm{CT}_{\mathbb{A}'}$) $\rightarrow M'$: On input the ciphertext $\mathrm{CT}_{\mathbb{A}'}$ (where $\mathbb{A}'$ is an AND-composition of policy $\mathbb{A}$ and `CCA: com`), and a secret key SK_S, it first checks whether S satisfies the $\mathbb{A}$. If not, then it aborts. Otherwise, it first determines $\Upsilon_0 = \{j \in \chi_0 \mid \rho(j) \in S\}$, $\Upsilon_1 = \{j \in \chi_1 \mid \rho(j) \notin S \wedge \rho_{\mathrm{lab}}(j) \in \psi_{\mathrm{lab}}(S)\}$, $\Upsilon = \Upsilon_0 \cup \Upsilon_1$ and $\{\varepsilon_j\}_{j\in\Upsilon}$ such that $\sum_{j\in\Upsilon} \varepsilon_j \mathbf{A}_j = (1, 0, ..., 0)$, then computes $e(g_1, g_2)^{\alpha s}$ as in the decryption of TKN20 (Section 3.2.10), where a key can be generated for `CCA : com` by computing $K_{3,\mathrm{CCA}} \cdot K_{4,\mathrm{CCA}}^{x_{\mathrm{com}}}$, then retrieves:

$$\begin{aligned} \mathrm{K} &\leftarrow \mathrm{KDF}(e(g_1,g_2)^{\alpha s}) \\ \mathrm{dec} \| M &\leftarrow \mathrm{Dec}_{\mathrm{K}}(C) \\ \mathrm{K}' &\leftarrow h_1(\mathrm{dec}), \end{aligned}$$

and verifies:

$$\begin{aligned} h_2(\mathrm{dec}) &\stackrel{?}{=} \mathrm{com} \\ \mathrm{Vrfy}(\mathbb{A} \| \mathrm{com} \| C \| \mathrm{CT}_{\mathbb{A}'}, \mathrm{T}) &\stackrel{?}{=} 1. \end{aligned}$$

If both checks pass, then the decryption returns M, and if not, it returns an error message.

Abstract

Interactive GPM (iGPM) is becoming increasingly important, where a series of graph pattern matching (GPM) queries are created and submitted in an interactive manner based on the insights provided by the prior queries. To solve the iGPM problem, three key considerations must be taken into account: performance, usability and scalability, namely if results can be returned in a timely manner, if queries can be written in a declarative way without the need of imperative fine-tune, and if it can work on large graphs. In this paper, we propose the GLogS system that allows users to interactively submit queries using a declarative language. The system will compile and compute optimal execution plans for the queries, and execute them on an existing distributed dataflow engine. In the evaluation, we compare GLogS with the alternatives systems Neo4j and TigerGraph. GLogS outperforms Neo4j by 51× on a single machine due to better execution plans. Additionally, GLogS can scale to processing large graphs with distributed capability. While compared to TigerGraph, GLogS is superior in usability, featuring an optimizer that can automatically compute optimal execution plans, eliminating the need of manual query tuning as required in TigerGraph.

1 Introduction

Graph pattern matching (GPM) aims to compute the mappings in a data graph that match a given small pattern graph, and it plays an important role in a variety of applications covering bioinformatics [3, 24, 37], chemistry [17, 23], social/web network analysis [20, 26], and recently in enhancing the expressive power of graph neural network [15, 53, 55].

Increasingly, interactive GPM (iGPM) is becoming critical for data scientists to mine relationships, identify frauds or detect intrusions from a variety of large graphs in real life. In these scenarios, data scientists create and submit a series of GPM queries in an interactive manner based on the insights provided by the results of prior queries. For example, we demonstrate a simplified application scenario as follows.

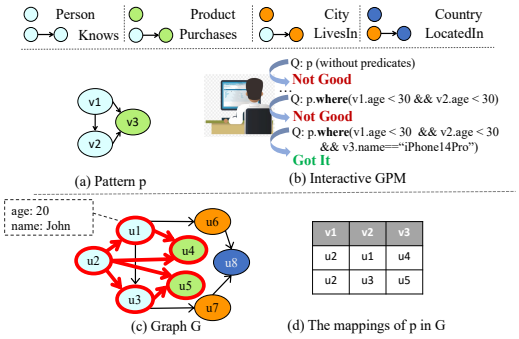

Figure 1: Example of interactive graph pattern matching, where a user will interactively submit graph pattern matching queries (see Example 2.1) to explore the graph.

Example 1.1. In Figure 1, a user is exploring recommendation rules in an e-commerce graph, which maintains relationships such as "Purchases" between persons and products. The user is specifically looking at a pattern (Figure 1(a)) of co-purchasing among pairs of people who are acquainted. If such co-purchasing occurs very frequently among these pairs in historical data, a recommendation rule may be created to recommend the product that has been purchased by one person to his/her friends who have not yet purchased it. The user tries different patterns and constraints (using predicates) through a series of interactive queries. In Figure 1(b), the user decides to create a rule suggesting that young people ("*age* < 30") tend to co-purchasing the "iPhone 14 Pro", rather than an arbitrary product.

In the above scenario of iGPM, it is necessary to consider the requirements of *performance*, *scalability* and *usability* simultaneously. Performance allows users to quickly obtain useful insights from the "trial-and-error"

*Equal Contribution.

process. Usability enables users to easily present arbitrary GPM queries. Scalability is also crucial as it is now common to handle large-scale graphs. Due to the computation-intensiveness of GPM queries [14, 29], it is already difficult for a graph expert to tune the execution [13, 25, 54]. The problem becomes even more complex in iGPM, where users may not be experts and the queries can involve intricate patterns and optional predicates. Therefore, the following features are essential to meet the above requirements.

Declarative Language. A declarative query language can provide users convenience and flexibility to express complex GPM queries.

Automatic Optimization. Automatic optimization allows non-expert users to focus on exploring valuable patterns without having to worry about the challenging task of performance tuning.

Distributed Execution. With the graph partitioned across the cluster, distributed execution is expected to spread the workloads accordingly.

However, the systems that are potentially usable for iGPM, including Neo4j [33] and TigerGraph [18], all fall short in providing one or more above features (Section 2). In this paper, we propose the GLogS (name after GLogue, see Section 5.3) system to fill in the gap. Our goal is to give the users the convenience and flexibility of presenting GPM queries interactively, and to have the system deal with the complexities that arise from compilation, query optimization, and distributed execution. We mainly make the following technical contributions.

(1) A compilation stack that compiles declarative GPM queries into distributed programs. We adopt Gremlin's declarative `match` step, an industrial-strength query language, for expressing GPM queries. The `match` step, after compilation and optimization, will be transformed into a program that can be executed on a distributed dataflow engine.

(2) An optimizer that can automatically derive optimal execution plans for GPM queries. While analyzing the execution plans of Neo4j, we have identified two critical impact factors of deriving good execution plans for GPM: worst-case optimal execution plan [4] and high-order statistics [12]. We take into considerations both factors to design and implement the optimizer for GLogS.

(3) A system that allows users to interactively submit and efficiently execute GPM queries at large scale. We build the GLogS system upon the existing distributed dataflow engine GAIA [38] to leverage its optimization for graph queries. In the evaluation based on the LDBC benchmark, we compare GLogS with Neo4j and TigerGraph. GLogS outperforms Neo4j by 51× on a single machine due to better execution plans. Additionally, GLogS can scale to handle large graphs with distributed capability. While compared to TigerGraph, GLogS is superior in usability, featuring an optimizer that can automatically compute optimal execution plans, eliminating the need of manual query tuning as required in TigerGraph.

2 Background and Challenges

2.1 The Problem of iGPM

We adopt the property graph model [6] for usability. A property graph $G(V_G, E_G)$ is a directed labelled graph, as shown in Figure 1, in which each vertex $u \in V_G$ models an entity, and each edge $(u_s, u_t) \in E_G$ models the relationship from a source vertex u_s to a target vertex u_t. We call the edge (u_s, u_t) the adjacent edge of u_s and u_t, and u_s (resp. u_t) is an in neighbor (resp. out neighbor) of u_t (resp. u_s). A vertex u (an edge is analogously defined) is assigned a globally unique identifier (Id) and a label (Label) to indicate is type. Moreover, it can carry a collection of key-value pairs as the properties. We use u.key to denote accessing u's property of given key.

A pattern $p(V_p, E_p)$ is a small *connected* graph. Given a pattern p and graph G, the graph pattern matching (GPM) problem aims to compute all mappings $Q_G(p)$ of the pattern in the graph G, where each mapping $f \in Q_G(p)$ matches the pattern vertices[1] to a set of non-duplicate graph vertices one by one, so that if there is a pattern edge between two pattern vertices, there must be a graph edge between the two matched graph vertices. For a pattern vertex v, we use $f(v) = u$ to obtain the matched graph vertex u. The number of mappings is called the frequency of the pattern in the graph, denoted as $\mathscr{F}_G(p)$. When the context is clear, the subscript of G in above notations may be omitted (i.e. $Q(p)$). Predicates can be specified, while we mostly omit predicates to focus on the pattern in the paper. Details of how we handle predicates are in our open-source page [46].

Example 2.1. In Figure 1, there are two mappings of the triangle pattern p in the graph as shown, and thus the frequency of p is 2. Specifically, a mapping f matches v_1 to u_2 and v_2 to u_1, namely $f(v_1) = u_2$ and $f(v_2) = u_1$. Obviously, there is a graph edge (u_2, u_1) corresponding to the pattern edge (v_1, v_2). The predicate "$v_1.age < 30$ && $v_2.age < 30$" in Figure 1(b), constrains that the vertices matching v_1 and v_2 must have "age" smaller than 30.

We target the iGPM scenario to process GPM queries on large-scale property graphs in an interactive context.

2.2 Solving iGPM using Existing Systems

Graph databases [2, 8, 18, 27, 33] allow users to interactively query the graph using declarative query languages,

[1] The details of matching edges are not discussed as they are similar to matching vertices.

and thus have the most potential to be deployed for iGPM. However, they often lack support for automatic optimization or distributed execution, and thus cannot meet performance, usability and scalability at the same time. We discuss Neo4j and TigerGraph as representatives. Other related systems are surveyed in Section 8. Neo4j [33] is one of the most popular graph databases, but is limited by its single-machine design and insufficient optimizer, leading to poor scalability and performance as reported in previous studies [38, 44, 48]. TigerGraph [18], on the other hand, is a distributed system that can scale well but lacks an automatic optimizer, requiring users to manually tune the plan for good performance, which significantly limits its usability. In addition, users need to pre-install the queries before they can be executed on TigerGraph. The pre-installation involves native code generation and compilation, which can take 1 to 3 minutes per query in our evaluation and may not be tolerable in the interactive context.

2.3 Challenges of Solving iGPM

It's challenging to develop an iGPM system with performance, usability and scalability. Here, we discuss the issues arise from query compilation and optimization.

Compilation. Compiling a declarative query language itself is non-trivial, and the interactive context introduces extra difficulties. Due to the timeliness of iGPM, it's infeasible to generate native codes from the queries and process a time-consuming online compilation like TigerGraph [18]. Preparing store procedurals for a set of queries offline is not possible, as the useful patterns remain unknown in advance.

Optimization. The automatic optimization of GPM lies at the core of an iGPM system, but it's difficult to design such an optimizer for real-life queries. To see this, in Figure 2, we've demonstrated the execution plans Plan_G and Plan_N of a benchmark query derived by the optimizers of GLogS and Neo4j, respectively. For now, one only needs to know that a better execution plan typically, if not definitely, produces less intermediate results, which are a collective of the mappings of all intermediate patterns that must be computed during the execution. We mark in Figure 2 the corresponding intermediate pattern frequencies in the benchmark graph G_1 (Table 1). Obviously, Plan_N produces much larger intermediate results than Plan_G. We execute the two plans in our system, and Plan_N not only runs orders of magnitude slower, but also consumes significantly larger memory, than Plan_G. This demonstrates that Neo4j's optimizer is insufficient to handle such complex GPM queries.

There are two main reasons for this. Firstly, the execution plan given by Neo4j cannot guarantee *worst-case optimality*. Secondly, it uses only *low-order statistics* to estimate the cost of a plan, which can cause the resulting plan to have small estimated cost even though it actually costs heavily. We elaborate in details.

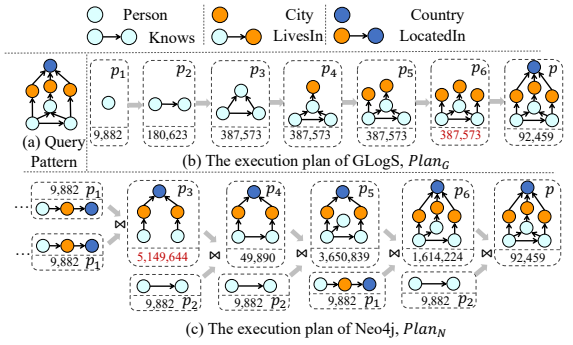

Figure 2: Execution plans of GPM. Certain trivial steps in the plans are not shown for clarity.

Worst-case optimality. An execution plan for computing a pattern p is worst-case optimal, if the frequency of any *intermediate pattern* in the plan does not exceed $\mathscr{F}(p)$ in the worst case. Here, an intermediate pattern in an execution plan refers to a subgraph (or sub-pattern, interchangeably) of the queried pattern whose mappings must be computed during the execution. For instance, the patterns p_1-p_6 in Plan_G (all plans in this section are referred to Figure 2) are intermediate patterns of p. The process of solving GPM typically involves operations of binary join and vertex expansion. Briefly, binary join involves performing a hash join on the mappings of two input patterns in order to produce the results of the output pattern. For example, in Plan_N, p_2 is joined with p_3 to produce p_4. Execution plans that rely *solely* on binary joins, such as Plan_N, are called binary-join plans. However, these plans may not guarantee worst-case optimality [29]. Neo4j's plan actually falls into this category, which is a dominant factor of its poor performance [48].

Alternatively, Ammar et al.[4] have looked into Ngo's algorithm[35] for GPM optimization. The key operation to this algorithm is vertex expansion, which involves expanding a base pattern by adding one more vertex to it. In Plan_G, for instance, p_2 is expanded to p_3 in this way. Begin with a base pattern that is a vertex, the algorithm processes vertex expansions iteratively until the desired pattern is obtained. According to Ngo's algorithm, we can obtain an execution plan that is worst-case optimal, such as Plan_G for GPM.

Recent research [1, 32, 54] has shown that the best possible execution plans for GPM must incorporate both binary joins and vertex expansions. Consequently, our optimizer must be capable of handling this hybrid strategies. It's crucial to note that to achieve worst-case optimality, such hybrid plans must carefully consider the use of binary joins, as will be explained in Section 5.4.

High-order statistics. An optimal execution plan for a GPM query is the plan that has the smallest cost. The pattern frequencies are essential for evaluating the cost of an execution plan. In large-scale graphs, it is more feasible to estimate these frequencies, rather than trying to exactly compute them. Neo4j uses Low-order statistics such as the number of vertices and edges (of each type) to estimate pattern frequencies by assuming independent existence of graph edges [34]. However, this assumption is too idealistic and can lead to inaccurate cost estimation and poor execution plans in practice. To address this issue, we follow Mhedhbi et al. [32] to exploit the *high-order statistics* [12] of the graph.

Definition 2.1. The high-order statistics of a graph refer to the frequencies of a series of small patterns (also known as motifs [3]), from the smallest single-vertex patterns to the largest patterns that are *complete* graphs of k vertices. Here, k is called the high-order *level*, and must be at least 3 to avoid degrading to low-order.

Mhedhbi et al. [32] and us have both demonstrated the effectiveness of the high-order statistics. However, their computation is at least as costly as the widely recognized computation-intensive workload of graph pattern mining [45]. To reduce the computation cost, Mhedhbi et al. [32] have proposed using a sampling technique that matches a randomly selected portion of data vertices and edges at runtime. Nevertheless, the sampling technique is difficult to apply to large-scale graphs that are partitioned in the cluster.

3 System Overview

We've built the GLogS system for iGPM, as shown in Figure 3, to address the challenges in Section 2.3. The system allows users to interactively submit their GPM queries using Gremlin's declarative `match()` step [7]. An example of the Gremlin code for the triangle pattern is presented. Because GPM is computationally intractable [28], users can optionally specify a timeout to prevent the query from running for an unreasonable amount of time. It is worth noting that relational operations, including projection, ordering and grouping, may also be applied in iGPM. However, for queries that involve these operations, GLogS processes them only after the execution of GPM. Therefore, their computation complexity is dominated by that of GPM, and will not be further discussed in this paper.

Frontend Module. The frontend machine runs the processors of a *pattern parser*, a *plan optimizer* and a GLogue *manager* for parsing and optimizing the GPM queries. The pattern parser parses a Gremlin query into a *language-agnostic* structure called `PatternDesc`. The

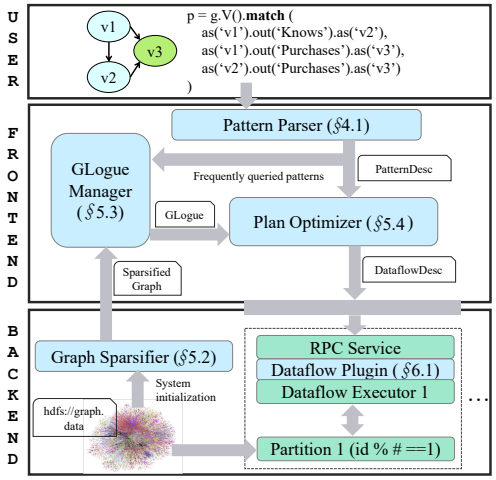

Figure 3: System overview. Blue components are the focus of this paper, with the paper's sections indicated.

key objective of designing `PatternDesc` is to decouple the query language and the optimizer. This enables easy integration with other query languages such as Neo4j's Cypher [16]. For given `PatternDesc`, the plan optimizer aims to produce an execution plan that has the smallest-possible cost based on a generic cost model. The cost model considers the high-order statistics of the graph, which are maintained in a novel graph-based structure called GLogue. The GLogue manager handles the construction of the GLogue by computing the frequencies on the sparsified graph for patterns up to k vertices (i.e. with high-order level k) when the system is initiated. It also buffers the frequently queried patterns whose frequencies are missing from the GLogue, and launches a procedural periodically to append these frequencies to the GLogue.

Backend Module. The backend module consists of a *distributed dataflow engine*, a *graph store* and a *graph sparsifier*, spreading across a cluster of n computing nodes. We have built the GLogS system on an existing dataflow engine, which organizes n executors, each corresponding to a computing node in the cluster. A declarative `DataflowDesc` is constructed from the execution plan produced by the plan optimizer, which embeds the computing instructions of GPM in a dataflow that is a directed acyclic diagram (DAG). The `DataflowDesc` is then distributed to all executors via RPC services to launch the computation in parallel. To make the `DataflowDesc` executable, a library of dataflow plugin is implemented that contains the generated code and a job assembler to assemble the distributed program. The dataflow plugin is required to co-compile offline with the underlying dataflow engine, which bypasses a costly online native-code compilation as TigerGraph [18].

The graph store manages the partitioned graph data in the cluster. As it is not the main focus of this paper, for

simplicity, we adopt in-memory and immutable graph store, where the graph data is partitioned using a hash partition strategy, namely the vertex u will be placed on the partition of "u.Id % # partitions", together with all its properties and adjacent (both in and out) edges. Such a simple yet widely used partition strategy[4, 29, 38] may lead to load skew, which can potentially impact query performance. Nonetheless, a well-optimized execution plan is still the key to the efficiency and scalability of GPM. Therefore, rather than exploring alternative partition strategies [52], we employ the simple strategy and focus on query optimization in this work. The i[-th] partition of the graph is co-located with the i[-th] executor of the dataflow engine. Moreover, The raw graph data are pre-partitioned, encoded and stored in a distributed file system such as *HDFS*. Each dataflow executor loads its partition into the main memory while starting up the system. During system initialization, a graph sparsifier will be simultaneously launched as loading graph data, which is responsible for sparsifying the large-scale graph into a small graph that can fit into the main memory of the frontend machine. The sparsified graph will be serialized to a persistent store to prevent the need for re-sparsification when the system is restarted.

4 Compiling Declarative GPM Queries

We demonstrate in Figure 4 the process of compiling the declarative Gremlin's `match()` step for a GPM query into distributed dataflow program.

4.1 The Pattern Parser

As shown in Figure 4(a), in Gremlin's `match()` step, a pattern is described as a collection of clauses in the form of "`as().[in|out]().as()`", in which the start and end `as()` steps identify the two vertices with tags that are unique in the pattern, and the `in()` or `out()` step in between expresses the edge that connects the two vertices. In this simplest[2] form of a `match()`, each clause expresses an edge in the pattern. Given a Gremlin's `match()` step, the pattern parser utilizes the ANTLR tool [21] (officially provided by Gremlin) to parse a query into an Abstract Syntax Tree, from which a `PatternDesc` is built, as illustrated in Figure 4(b).

We first define two *computing primitives* called `GetV` and `GetE` for describing GPM queries. A `GetV` primitive is a 4-tuple (eTag, tag, label, [Source|Target]) that encodes the semantics of matching the vertex with "tag" as the source or target vertex of an "eTag" edge. A `GetE`(vTag, tag, label, [In|Out]) encodes matching the edge with "tag" as the in or out edge of a "vTag" vertex.

A sentence that is an ordered sequence of `GetV` and `GetE` is then used to encode the semantics of a clause in `match()`, and a `PatternDesc` is composed of a collection of sentences. The semantics are self-explanatory, and we just discuss some special use cases in the first sentence of Figure 4(b). Observe that the first `GetV` has the "eTag" field unspecified (`NA`), which means that the vertex may not be bound to any prior edge and should match all vertices in the graph. In the `GetE`, the "tag" field is specified as an empty `String`. This tells the runtime that the matched edge (also applied for `GetV`) should not be kept in the results, which is useful when only a part of the matched instances are needed in practice. Following the `GetE`, a `GetV` has an empty "eTag", which means the vertex must be obtained directly from this "previous" edge.

Observe that we include the label information in `GetV` that is not actually given in the Gremlin query. In GLogS, while loading the graph data, we can meanwhile extract the *meta connections* that maintain the possible types of source and target vertices of each edge type. For example, a Purchases edge can only connect a Person to a Product. Such meta connections not only help us validate user queries, but also reduce the number of patterns stored in the GLogue (Section 5.3).

4.2 The Dataflow Embedding

In the plan optimizer (Section 5.4), an optimized execution plan will be computed for the `PatternDesc`, which will be further embedded into a `DataflowDesc` that describes how to compute the pattern in a dataflow engine.

In a dataflow engine, a dataflow is a directed acyclic graph (DAG) that abstracts the computation, in which a vertex stands for an operator that defines the computing logic, and an edge between two operators o_1 and o_2 represents the data channel such that the output of o_1 is the input of o_2. In the task of GPM, the input and output data of each operator in a dataflow are mappings of the patterns. We introduce five operators in this paper:

- `Source(udf)`: A `Source` operator specifies the input data of the dataflow program, which are a collection of vertices in the graph.
- `Sink(udf)`: The `Sink` operator (only one allowed) writes the results to the output channel (e.g. an RPC port) that users can access.
- `Map(udf)`: For each input item, a `Map` operator computes *exactly* one data item using the given user-defined function (udf).
- `FlatMap(udf)`: For each input item, a `FlatMap` operator can produce *arbitrary* (none, single or multiple) number of data items via the udf.
- `Join(key1, key2, udf)`: A `Join` operator consumes two input data, extracts the corresponding

[2] The other more complex forms only bring in engineering details.

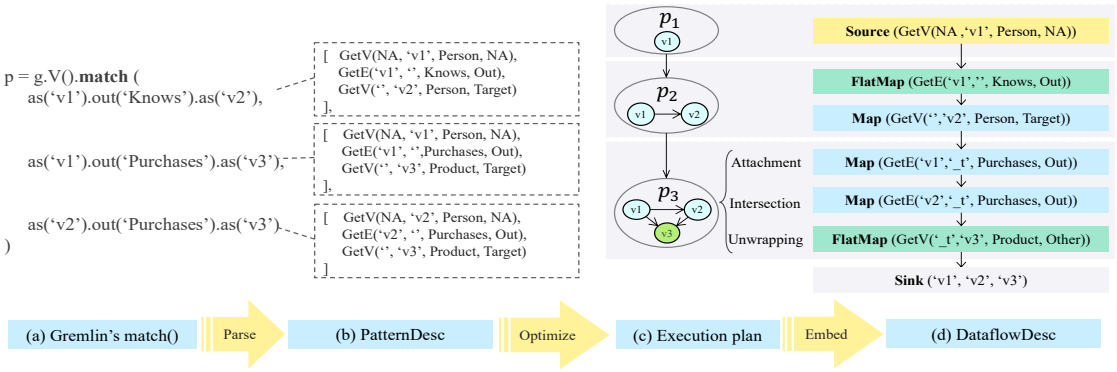

Figure 4: The process of compiling a Gremlin's `match` step into a `DataflowDesc`.

keys, and conducts a join via the `joinFunc` on the two input data.

In a nutshell, a `DataflowDesc` for GPM is a dataflow that embeds the GPM primitives of such as `GetV` and `GetE` in the above operators as the udfs. Figure 4(d) illustrates a `DataflowDesc` for computing the triangle pattern. We look into the first three operators for now, which describe the computation of the mappings for v_1 and v_2. First, v_1 is matched in a `Source` operator that consumes all Person vertices from the graph. Then for each vertex that matches v_1, a `FlatMap` operator is assigned to traverse its out edges, which is reasonable as a vertex typically has more than one adjacent edges in the graph. The last `Map` operator extracts the target vertex from each edge to match v_2. More details of how we compute the given `DataflowDesc` will be discussed in the next section.

5 Automatic Optimization

This section covers the automatic optimization of GPM queries, which is a collaboration of the system components of graph sparsifer, GLogue manager, and plan optimizer. For a graph vertex u, we denote $\mathsf{Nbr}[elabel](u)$ as the neighbors[3] of u in the graph G subject to the edge label constraint. Given two graphs G_1 and G_2, G_2 is a subgraph of G_1, denoted as $G_2 \subseteq G_1$, if $V_{G_2} \subseteq V_{G_1}$ and $E_{G_2} \subseteq E_{G_1}$. Furthermore, G_2 is an induced subgraph of G_1, if it contains *all* edges in G_1 among V_{G_2}. For two sets S_1 and S_2, we denote $S_1 \setminus S_2$ as the set of elements in S_1 but not in S_2.

5.1 Execution Plan and Cost Model

We first introduce the execution plan for GPM and define its cost, which allows us to search for the optimal execution plan as the one with the smallest cost.

[3]Note that the edges can be in out, in or even both directions, but we omit the direction in the notation for simplicity.

Execution Plan. To allow the optimizer to derive hybrid execution plans as mentioned in Section 2.3, we consider two basic operations: the *binary join* and *vertex expansion* that are critical to fulfil the binary joins and worst-case optimal joins, respectively. A binary join, denoted as $\mathsf{Join}(\{p_{s_1}, p_{s_2}\} \to p_t)$, conducts hash join operation for $Q(p_{s_1})$ and $Q(p_{s_2})$ on the join key of $V_{p_{s_1}} \cap V_{p_{s_2}}$ to compute the results of $Q(p_t)$. The operation of vertex expansion needs further explanation.

Definition 5.1. Consider two patterns, p_s and p_t with $V_{p_t} \setminus V_{p_s} = \{v\}$, and $E_{p_t} \setminus E_{p_s} = \{e_1 = (v_1, v), e_2 = (v_2, v), \ldots, e_k = (v_k, v)\}$ without loss of generality. A vertex-expansion operation, denoted as $\mathsf{Expand}(p_s \to p_t)$, extends each mapping f of p_s by one more graph vertex corresponding to v. The newly matched graph vertex must be in the common neighbors of all $f(v_i)$ for $1 \le i \le k$, namely $\bigcap_{i=1}^{k} \mathsf{Nbr}[e_i.\mathsf{Label}](f(v_i))$.

Example 5.1. In Figure 4(c), it's clear that $V_{p_3} \setminus V_{p_2} = \{v_3\}$. This allows us to perform a vertex expansion $\mathsf{Expand}(p_2 \to p_3)$. We use the graph in Figure 1 to illustrate the process. For a given mapping $f = \{u_2, u_1\}$ of p_2, we can expand it to the mapping $\{u_2, u_1, u_4\}$ for p_3. Here, v_3 is matched to $\{u_4\}$, which is obtained by intersecting $\mathsf{Nbr}[\mathsf{Purchases}](u_2)$ and $\mathsf{Nbr}[\mathsf{Purchases}](u_1)$. We can similarly perform this process for the other mappings $\{u_1, u_3\}$ and $\{u_2, u_3\}$.

Given a queried pattern p, we denote an execution plan for computing p as $\mathsf{Plan}(p) = (\Phi = \{p_1, p_2, \ldots, p_n = p\}, \Gamma = [\tau_1, \tau_2, \ldots, \tau_m])$, where Φ represents a set of intermediate patterns and Γ is an ordered sequence of operations that can be either binary join or vertex expansion. For example, we have the execution plan in Figure 4(c) as $(\Phi = \{p_1, p_2, p_3\}, \Gamma = [\mathsf{Expand}(p_1 \to p_2), \mathsf{Expand}(p_2 \to p_3)])$.

Cost Model. With the execution plan $\mathsf{Plan}(p) = (\Phi, \Gamma)$, we propose the cost model as

$$\mathsf{Cost}(\mathsf{Plan}(p)) = \sum_{p' \in \Phi} \mathscr{F}(p') + \sum_{\tau \in \Gamma} \mathsf{Cost}(\tau). \quad (1)$$

The first part refers to the cost of accessing the intermediate results from the memory, which can be considered as the commmunication cost, namely, the cost of accessing remote memory. This is because the intermediate results are a collection of the output from all executors in the cluster, and the cost of accessing remote data is much greater than that of accessing local data. The second part stands for the cost of the operations, also known as the computation cost.

As any join algorithm must go through the data of both participants, the cost of a binary join is computed as

$$\mathsf{Cost}(\mathsf{Join}(\{p_{s_1}, p_{s_2}\} \to p_t)) = \alpha_j(\mathscr{F}(p_{s_1}) + \mathscr{F}(p_{s_2})), \tag{2}$$

where α_j is a normalized factor. We do not consider the joined results in Equation 2 because it must have been considered as the communication cost in Equation 1.

Consider a vertex expansion $\mathsf{Expand}(p_s \to p_t)$ in Definition 5.1, and let f be one mapping of p_s. The cost of the vertex expansion of f is dominated by intersecting the neighbors of $f(v_i)$ for $1 \le i \le k$, which has the complexity of $\sum_{i=1}^{k} |\mathsf{Nbr}[e_i.\mathsf{Label}](f(v_i))|$. Regarding e_i, let $\sigma_{e_i}(f) = |\mathsf{Nbr}[e_i.\mathsf{Label}](f(v_i))|$ be the vertex-expansion factor of the mapping f, and $\overline{\sigma_{e_i}}$ the average factor of all mappings. We have the cost of vertex expansion as

$$\begin{aligned}\mathsf{Cost}(\mathsf{Expand}(p_s \to p_t)) &= \alpha_{ve} \sum_{f \in Q(p_s)} \sum_{i=1}^{k} \sigma_{e_i}(f) \\ &= \alpha_{ve} \mathscr{F}(p_s) \sum_{i=1}^{k} \overline{\sigma_{e_i}},\end{aligned} \tag{3}$$

where α_{ve} is a normalized factor that, along with α_j in Equation 2, aligns the differences in computation cost of vertex expansion and binary join, as well as the communication cost and the computation cost.

5.2 Graph Sparsifier

While it is necessary to compute $\mathscr{F}(p)$ of any pattern p for Equation 1, it's cost-prohibitive to do so directly. The sampling technique proposed in [32] cannot be applied to large-scale graphs (see Section 2.3). Therefore, we explore the technique of graph sparsification [40, 49]. Specifically, during system initialization, the graph sparsifier will conduct sparsification on each partition of the graph to randomly preserve a subset of edges, and aggregate them at the frontend machine to form the sparsified graph G^*. It is obviously more feasible to compute the pattern frequencies on G^* than on the original graph G. Thus, we use $\mathscr{F}_{G^*}(p)$ (with normalization) as an estimation of $\mathscr{F}_G(p)$ for cost evaluation.

However, it's non-trivial to sparsify real-life graphs that can contain many different types of edges. A naive uniform sparsification [40, 49] adopts a uniform *sparsification ratio* (the probability of keeping an edge) for all edges during sparsification. Although such a naive approach can obtain unbiased estimation of $\mathscr{F}_G(p)$, but it still works poorly in our evaluation (Section 7). The main reason is that different types of edges can appear in rather skewed frequencies in real-life graphs. A less frequent type of edge, such as the LocatedIn edge in Figure 1 that appears in thousands compared to the Purchases edge in billions, is more likely to get eliminated during sparsification, causing the estimation to have large variance.

We also notice that there are sparsification [11, 42] and coarsening [31] algorithms based on spectral graph theory, aiming to offer a superior approximation via biased sampling. However, these algorithms emphasize preserving global statistics such as edge cut, rather than counting subgraphs that are local information. As a result, they may not be suitable for our task.

Regarding our task, we adopt the stratified sparsification [19] that treats each type of edges as an independent stratum, and assign each stratum an individual sparsification ratio. The stratified sparsification provides the flexibility in choosing the sparsification ratio, and we propose an optimization problem that aims to minimize the estimation variance through tuning the ratio. Before proposing our optimization problem, we first introduce the norm factors and discuss its unbiasedness. Let the sparsification ratios be $\Omega = \{\rho_1, \rho_2, \ldots, \rho_l\}$, where ρ_i denotes the ratio for the stratum of edges with label i without loss of generality. The following lemma holds.

Lemma 5.1. *Let* $\widetilde{\mathscr{F}(p)} = \prod_{e \in E_p} \frac{1}{\rho_{e.\mathsf{Label}}} \mathscr{F}_{G^*}(p)$. *We have* $\mathbb{E}[\widetilde{\mathscr{F}(p)}] = \mathscr{F}_G(p)$, *where* $\mathbb{E}[X]$ *denotes the expected value of a random variable* X.

Proof is in Section A.1.1. In the following, when we write $\mathscr{F}(p)$, we by default mean $\widetilde{\mathscr{F}(p)}$ if not otherwise specified.

The next question is how to specify the sparsification ratios. Given that the sparsified graph must reside in the frontend machine, we model an optimization problem subject to the memory constraint M, that minimizes the variance of the frequency estimation regarding a forged pattern p^* formed by all types of edges in the graph, as:

$$\begin{aligned}&\arg\min_{\Omega} \mathrm{Var}[\widetilde{\mathscr{F}(p^*)}] \\ &\text{s.t.} \sum_{i=1}^{l} s_i \rho_i \le M,\end{aligned} \tag{4}$$

where s_i denotes the frequency of the edges that have label i. The optimization problem achieves its optimum under the following condition:

$$\rho_i = \min(1, \frac{M}{l} \times \frac{1}{s_i}),$$

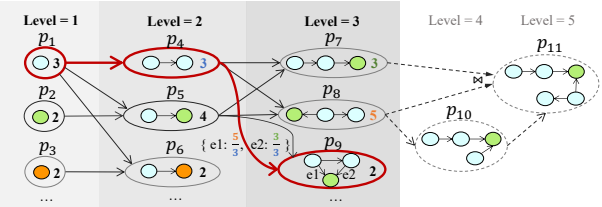

Figure 5: A fragment of GLogue. The value aside the pattern indicates its frequency in the graph in Figure 1(c). Note that the patterns in "Level=4/5" do not actually present in the GLogue.

Detailed derivation can be found in Section A.1.2. Interestingly, if $s_i \ll M$, ρ_i must be set to 1, which means that a very infrequent type of edge, such as the above LocatedIn edges, must not be ruled out during sparsification.

5.3 GLogue Manager

Our system aims to automatically derive the optimal execution plan for any arbitrary pattern. To do so, we follow the methodology presented in [32] to calculate the high-order statistics (Definition 2.1) of the graph. However, the approach in [32], which employs a table-based *catalogue* for retaining the high-order statistics, is not only expensive to construct but also challenging to apply when there are numerous complex pattern relationships in real-world graphs that need to be recorded, thereby making plan searching a difficult task. Instead, we have recognized the intrinsic suitability of graph structure for retaining complex relationships of this sort, and thus, we have proposed GLogue as a graph-based catalogue.

The GLogue is a hierarchical property graph as shown in Figure 5, in which each vertex is a pattern p at level $|V_p|$ with its frequency $\mathscr{F}(p)$ as the property. To ease lookup, the pattern will be encoded as a `String` using the technique of canonical labelling [10]. We say that the GLogue has k levels, if it maintains the high-order statistics up to level k. There're two types of edges in GLogue. The first type connects p_s and p_t in GLogue, if p_s can be expanded to p_t via vertex expansion. Regarding $\mathsf{Expand}(p_s \to p_t)$, the edge (p_s, p_t) records the vertex-expansion factors $\overline{\sigma_e}$ for all $e \in E_{p_t} \setminus E_{p_s}$. The second type corresponds to a binary join $\mathsf{Join}(\{p_{s_1}, p_{s_2}\} \to p_t)$, which introduces one edge from p_{s_1} to p_t with $(p_{s_2}, \mathscr{F}(p_{s_2}))$ as the property.

We deploy the GLogue manager in GLogS for the construction and maintenance of GLogue. When the system is initiated, with a threshold of level k, GLogue will be constructed from scratch to include all valid patterns with up to k vertices that satisfy the meta connections (see Section 4). While processing queries, the GLogue manager will buffer the incoming patterns (patterns only without predicates) from the users, and will launch a procedure to update the GLogue from the buffered patterns periodically.

Algorithm 1: The Plan Optimizer.

```
1  Function PlanOptimizer (GLogue, PatternDesc)
2      Construct a pattern p from the PatternDesc;
3      Let QSet organize all induced subgraphs of p by level;
4      Initialize a PlanMap to record {p : (plan, cost)} with
         patterns in level 1 and 2 pre-computed;
5      for 3 ≤ level ≤ |V_p| do
6          for p ∈ QSet[level] do
7              searchPlan (p, PlanMap, GLogue);
8      return PlanMap.get(p);
9  Function searchPlan (p, PlanMap, GLogue)
10     Initialize Plan(p) and Cost(Plan(p)) ← ∞;
11     for edge = (p_{s_1}, p) ∈ GLogue.getEdges(p) do
12         (plan1, cost1) ← PlanMap.get(p_{s_1});
13         if edge is a vertex extension then
14             Compute a new plan' by merging plan1 and
                 Expand(p_{s_1} → p);
15         else if edge{(p_{s_2}, F(p_{s_2}))} is binary join then
16             (plan2, cost2) ← PlanMap.get(p_{s_2});
17             Compute a new plan' by merging plan1, plan2
                 and Join({p_{s_1}, p_{s_2}} → p);
18         Compute a new cost' of plan' by Equation 1;
19         if cost' < Cost(Plan(p)) then
20             Update Plan(p) as plan' and the cost as cost';
21     PlanMap.insert(p, (Plan(p), Cost(Plan(p))));
```

5.4 Plan optimizer

Another benefit of the graph-based GLogue is that the searching of an optimal plan can be reduced to a variant of shortest path problem: the optimal plan of p is a shortest "path" that has the smallest cost regarding Equation 1, from the base pattern (a single vertex) to p. An example is highlighted in Figure 5. We first assume that the queried pattern and all its sub-patterns are present in the GLogue. The process is shown in Algorithm 1.

The optimizer first builds the pattern from the `PatternDesc` that is compiled from a Gremlin query (line 2), and then organizes all *induced* subgraphs of the queried pattern by levels (line 3). Note that the use of induced subgraphs is key to ensuring worst-case optimality of the computed plan [29]. The `searchPlan` function is then launched for each pattern (line 7). We now consider processing a pattern p in the `searchPlan` function. Before searching for the plan for p, the optimal plans for all its subgraphs in the lower level must have already been computed in the `PlanMap` (line 12,16). We use the graph interface of `getEdges` in line 11 to obtain all sub-patterns in the lower level that connect to the current pattern p. Depending on whether the edge stands for a vertex expansion or binary join, the new plan will be accordingly computed in line 14 and 17. As long as

the new cost (line 18) is smaller than a previous value, the plan and its cost will be updated. The optimal plan in the GLogue can be cached to avoid re-computation. For example, in Figure 5, the cached optimal plan for computing p_9 is highlighted in red, which is the worst-case optimal plan in Figure 4(c).

Handling Pattern Miss. We discuss how to process the queried pattern p when it has not yet been recorded in the GLogue. First of all, given two *induced* subgraphs p_1, p_2 of p with $E_p = E_{p_1} \cup E_{p_2}$, by assuming the independent presence of p_1 and p_2 in the graph, we can compute the frequency of p as follows

$$\mathscr{F}(p) = \text{Avg}_{p_1,p_2} \frac{\mathscr{F}(p_1) \times \mathscr{F}(p_2)}{\mathscr{F}(p_1 \cap p_2)}, \tag{5}$$

where $p_1 \cup p_2$ denotes a pattern formed by the common parts of p_1 and p_2. Equation 5 can be recursively called in case p_1 and p_2 are not present. Then in line 11, instead of calling `getEdges` of the GLogue, we simply enumerate all p_s that can potentially expand to p, either via vertex expansion or binary join. The remaining process naturally follows Algorithm 1. In Figure 5, p_{11} is a pattern missing from the GLogue, which can either be expanded from p_{10}, or joined from p_7 and p_8. Thus, p_7, p_8 and p_{10} can all be p_s in line 11.

5.5 Dataflow Embedding

Given the optimal execution plan $\mathsf{Plan}(p)$, one last step is to embed the execution plan into a `DataflowDesc`. Following the operations of $\mathsf{Plan}(p)$, there must be some base patterns (single vertex) that are not target patterns in any operation. We encode these base patterns as `GetV` and then embed them into `Source` operators. For $\mathsf{Join}(\{p_{s_1}, p_{s_2}\} \to p_t)$, a `Join` operator is installed, which are connected by the operators that computes p_{s_1} and p_{s_2}, and the keys of the `Join` operator are set to the vertex tags of $V_{p_{s_1}} \cap V_{p_{s_2}}$.

There are two cases for hanlding a vertex expansion $\mathsf{Expand}(p_s \to p_t)$. If p_t has only one more edge than p_s, the vertex expansion will be transformed into a pair of `FlatMap(GetE)` and `Map(GetV)`, which has been discussed in Section 4.2. Otherwise, suppose p_t has $k > 1$ more edges than p_s. The execution will be decomposed into three phases, namely *attachment*, *intersection* and *unwrapping*, as shown in Figure 4(c). In the attachment phase, a `Map(GetE)` operator is installed, which tells the runtime to attach the adjacent edges of the given vertex as a *set*. The intersection phase handles $k-1$ consecutive intersection operations, while each intersection is achieved by a `Map(GetE)` that instructs computing the common edges between the existing set and the current adjacent edges. The last unwrapping phase uses a `FlatMap(GetV)` to unwrap the neighbors into discrete elements.

```
impl MapFunction for GetE { vtag,tag,label,dir } {
  fn map(&self, mut datum: GRecord) -> GRecord {
    let v = datum.get(self.vtag)?;
    // edge tag already present, do intersection
    if let Some(set) = dataum.get_mut(self.tag) {
        set.intersect(to_set(
          G.get_edges(  // G is a graph handle
            v.get_id(), self.label, self.dir))
        );
    } else { // not present, do attachment
        datum.insert(self.tag, to_set(
          G.get_edges(
            v.get_id(), self.label, self.dir));
        );
    }
    return datum;
  }
}
```

Figure 6: Code generation of `Map(GetE)`.

Example 5.2. In Figure 4(c), let's consider a mapping f that matches (v_1, v_2) before entering the process of vertex expansion. The attachment phase first maps f into $(f \mid set := \mathsf{Nbr}(f(v_1)))$ by directly attaching the adjacent edges (we reuse the notation of neighbors) as a set. In the phase of intersection, the set is updated by intersecting with the current neighbors of $f(v_2)$, as $(f \mid set := set \cap \mathsf{Nbr}(f(v_2)))$. Finally, the *set* is unwrapped into discrete vertices to match v_3.

6 System Implementation

We have implemented the frontend components including pattern parser, plan optimizer and GLogue manager in Java, to easily connect with Tinkerpop's Java runtime. The backend components are implemented in Rust to be compatible with the underlying dataflow engine, GAIA [38]. The GAIA engine runs n executors in the cluster, and each executor further forks working threads for parallel processing. The frontend and backend components of the system are bridged via the RPC services.

We implement `GRecord` to record a mapping of a pattern, which is essentially a `Map` with the key as pattern's tag (Section 4), and the value that is an `Object` to either encode a vertex, an edge, or a set of vertices/edges. Consequently, a collection of `GRecords` serve as the input and output data of all operators of the GAIA engine. Initially, the executors will load corresponding vertices as `GRecords` according to the graph partition. In the following computation, we can use the `Repartition` primitive of GAIA to reshuffle the data as needed. For example, a vertex v will be loaded by the executor numbered as "v.Id % #partitions". Moreover, in order to get adjacent edges from the matched vertices tagged as v, we can `Repartition` the `GRecords` according to the field of v.

6.1 The Dataflow Plugin

The dataflow plugin is key to making the `DataflowDesc` executable (Section 4) on the dataflow engine, which is

a native library consisted of the generated code for operators in `DataflowDesc` and a job assembler for assembling the GAIA job.

We perform code generation for all possible operators in `DataflowDesc`, and co-compile the generated code with GAIA. In Figure 6, we show the generated code of `Map(GetE)` that fulfils the phases of attachment and intersection for vertex expansion (Section 5.4). Note that in the `Map` operator for attachment in Figure 4(c), the system assigns a "_t" (as temporary) tag in the `GetE`, which will cause the adjacent edges maintaining as a set in the "_t" field of a `GRecord`. In the `Map` operator for intersection, as the "_t" field must present, it does an intersection between the existing set and the current adjacent edges.

The job assembler, after receiving the `DataflowDesc`, attempts to assemble the GAIA job. Basically, it will install the corresponding GAIA operator for each operator in the `DataflowDesc`. For example, a `Map(GetE)` will be installed as a `Map` operator with the generated code in Figure 6. The job assembler is also responsible for installing the `Repartition` primitive in case that data shuffling is needed.

7 Evaluation

7.1 Setup

Datasets. We base the evaluation on Linked Data Benchmark Council (LDBC)'s social network benchmark [30], which is the only publicly available resource that provides the scale we target in this work. As shown in Table 1, 5 datasets are generated using LDBC data generator, where G_{sf} denotes the graph generated with scale factor sf. The largest graph G_{1000} consumes around 2TB on disk and roughly 6TB aggregated memory in the cluster. The default sparsifying rate $\gamma = 100\frac{|E_{G^*}|}{|E_G|}\%$ is given for each graph. With γ, we set the memory constraint $M = \gamma|E_G|$ (Section 5.2) for graph sparsification. We by default construct the GLogue with level = 3 using the corresponding sparsified graph.

Table 1: The LDBC datasets.

Graph	$\|V\|$	$\|E\|$	Size	γ
G_1	3M	17M	1.5GB	100%
G_{30}	89M	541M	40GB	1%
G_{100}	283M	1,754M	156GB	0.1%
G_{300}	817M	5,269M	597GB	0.1%
G_{1000}	2,687M	17,789M	1,960GB	0.03%

Queries. On the basis of the business intelligence (BI) workloads from LDBC benchmark, we've manually constructed 10 queries, denoted as p_1 to p_{10}, for evaluation. Details of the construction of these queries and their execution plans are in Section A.2. These queries have sufficient variance, ranging from simple triangle patterns to complex patterns like p_9 that contains 7 vertices and 9 edges. We will specify predicates corresponding to the BI workloads for p_4 to p_{10} on G_{100}, G_{300} and G_{1000}, to prevent the tests from running unnecessarily long. The LDBC benchmark driver has been modified to run each queries 5 times from a set of randomly selected parameters. Average query latency is reported.

Systems. We compare GLogS with Neo4j [33] and TigerGraph [18], two potential systems for iGPM (Section 2). We directly use the execution plans of Neo4j. By default, GLogS runs the optimal execution plan of a query p, which are derived from the GLogue (on each sparsified graph) specifically constructed from p. As TigerGraph does not have an optimizer, on the one hand, we used the queries generated by its graph studio [47], on the other hand, we manually wrote the queries according to the optimal plans of GLogS. Note that we did not include the results of our base system, GAIA [38], as it could not terminate in reasonable time in most of our large-scale tests. On the one hand, GAIA has optimized graph workloads by utilizing a breadth-first/depth-first hybrid scheduling and memory-bounded execution model, enabling it to handle considerable amounts of data without overflowing the memory. In fact, our GLogS has benefited from GAIA in handling large-scale data (Section 7.3). On the other hand, GAIA lacks proficiency in executing GPM queries efficiently, primarily due to the fact that GAIA must comply with Gremlin's imperative traversal which conforms to a sub-optimal EdgeJoin execution plan [29] that sequentially joins edges.

We use the default system configurations of Neo4j and TigerGraph. For GLogS, we have measured the differences in the operations of vertex expansion and binary join, as well as the communication and computation cost, which allows us to set $\alpha_j = 60$ and $\alpha_{ve} = 1$ in Equations 2 and 3, respectively. We deploy a cluster for the evaluation that contains one frontend server and up to 16 backend servers. Each server configures two 24-core Intel(R) Xeon(R) Platinum 8163 CPUs at 2.50GHz and a 512GB RAM. The servers are connected to an EDR 25 Gbps InfiniBand network, which can scale deterministically and achieve full bisection bandwidth. If not mentioned, we will use 32 threads on each server for GLogS (some threads are reserved for communication and system calls) as suggested by GAIA authors [38]. TigerGraph will use all threads as recommended.

7.2 Compare with Alternative Systems

We first compare GLogS with Neo4j on a single machine, using the smallest graph G_1 to allow Neo4j processing all queries in a reasonable time. The query latencies of both systems are shown in Figure 7a. GLogS with a single thread still performs better than Neo4j for most queries, with 4.4× speedup. After using 32 threads, GLogS out-

(c) Scale-Up: Group1 (d) Scale-Up: Group2

(e) Data-Scale: Group1 (f) Data-Scale: Group2

Figure 8: Scalability Experiments

performs Neo4j by an average of 51× for all queries.

The tests against TigerGraph are performed on G_{300} using 16 machines. While benefiting from the optimal execution plans of GLogS, TigerGraph still performs 59% slower on average. Note that the results obtained from TigerGraph's graph studio are not reported as they exceed the time limit (one hour) in all tests. Additionally, TigerGraph requires the installation of queries via native-code compilation before they can be run, with installation times ranging from 1 to 3 minutes. In contrast, GLogS does not have this overhead because of the design of dataflow plugin (see Section 6.1). The time required to compile and optimize all queries in GLogS is less than 1 millisecond, which is insignificant compared to the query execution time. This demonstrates GLogS's advantage in usability for iGPM.

7.3 Scalability

It's important to test the scalability on GPM workload given its nature of irregularity [14, 29, 54]. The results are in Figure 8, where the queries are split into two groups based on their latency for clear illustration.

Scale-Out. We vary the server number as 1, 2, 4, 8, 16 and run all queries on G_{100}. Note that G_{100} is the largest graph that can reside in the main memory of a single server. The results are reported in Figure 8a and Figure 8b. Most queries scale well, with up to 15× (average 6×) performance gain from one machine to 16.

Scale-Up We use 16 servers and vary the number of working threads on each server from 1 to 32. The results on G_{300} are shown in Figure 8c and Figure 8d. We see an improvement in runtime of up to 23× (average of 10×) when increasing the number of threads from 1 to 32. A common trend in both scale-out and scale-up tests is that some queries, such as p_2 and p_{10}, scale less significantly when using more working threads. This phenomenon is not unique to our system [14, 38] and is mostly due to the sensitivity of GPM workloads to data skew [14]. It's a future work to further address this issue.

Data-Scale Using 16 servers, we run all queries on the graphs of G_{30}, G_{100}, G_{300} and G_{1000}. The results are reported in Figure 8e and Figure 8f. As the graphs become larger, most queries demonstrate an almost linear trend in performance degradation, except for p_6 and p_{10}. As for p_6, its execution time only tripled from G_{30} to G_{1000}, because it is a short-running query that visits a small part of the graph. However, for p_{10}, its performance degrades by 100× from G_{30} to G_{1000}. This is likely because the execution plan for p_{10} is the only plan that involves a join operator, which maintains a hashmap for the "build" component of the join. When processing a large volume of data, a hashmap lookup can become slower because many entries may have been mapped to the same bucket. Despite this, the plan with the join operator still performs much better than the one without it.

In summary, GLogS exhibits excellent scalability in the test, which we attribute to both the well-designed optimizer and GAIA's graph-specific optimizations.

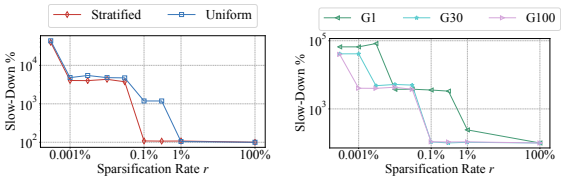
7.4 Plan Optimization

In this experiment, we will study the impact of high-order statistics and graph sparsification on plan optimization for all queries. While running a query, we obtain the time t using the optimal execution plan, and the time t' using the computed execution plan in a certain context. We report the slow-down rate as $100\frac{t'}{t}\%$. For convenience, we run all tests in a single server.

Table 2: The effectiveness of high-order statistics.

	level=2	level=3	level=4
Slow-down (%)	966	245	243
Generation Time(s)	6	55	1664
Memory Usage(GB)	2	3	105
# Patterns	34	248	4164

High-Order v.s. Low-Order. To study the effectiveness of high-order statistics, we construct the GLogue of level 2, 3 and 4 for G_1, and try to evaluate the average slow-down rate of all queries while using the execution plans



(a) Uniform v.s. Stratified (b) Vary graphs.

Figure 9: Impact of sparsification on plan optimization.

computed from these GLogue. Here, we use the unsparsified G_1 to rule out potential impact from sparsification. The results are shown in Table 2. When increasing the level of GLogue from 2 (low-order statistics only) to 3, the performance of queries improves by 4× on average. The shows that high-order statistics can contribute to deriving better execution plans for GPM queries. Moreover, the performance of queries remains almost unchanged when we increase GLogue's level from 3 to 4, but the time and memory consumption for constructing the 4-level GLogue increase significantly. Given that the GLogue will be further updated from frequently queried patterns, we suggest that the initial construction of 3-level GLogue is sufficient.

Uniform v.s. Stratified. This test verifies the advantage of the proposed stratified sparsification over the uniform alternative. As shown in Figure 9a, we apply both methods on G_{100}, and report the average slow-down rate for all queries using the execution plans computed from the sparsified graphs of various sparsifying rate ranging from 0.001% to 100%. Stratified sparsification performs much better than the uniform alternative, as it has resulted in a better execution plan at a lower sparsifying rate and, at the same sparsifying rate, it has achieved a lower slow-down. With statified sparsification, the graph can be sparsified 10× more edges, on which the optimizer can still derive the optimal execution plans.

Vary Graphs. To verify whether we can use larger sparsifying rate on larger graph, we sparsify three graphs G_1, G_{30} and G_{100} (G_{300} and G_{1000} are too large to process in a single server) using different rates, and report the average slow-down of all queries from the resulting plans in Figure 9b. Clearly, larger graphs can be sparsified at a lower rate, while still rendering good execution plans. For example, the performance of queries on G_{100} and G_{30} only notably downgrades when $\gamma < 0.1\%$. In comparison, the downgrading point of G_1 are $\gamma < 1\%$. Furthermore, while sparsified to 0.001%, the resulting plans from G_{100} slow down by roughly 50×, but those from G_{30} and G_1 downgrade by over 500×.

8 Related Work

GPM Algorithms. Ullmann proposed the first backtracking algorithm [50] for GPM, based on which many optimizations have been proposed, such as tree indexing [41], symmetry breaking [25] and compression [13]. As it's hard to parallelize the backtracking algorithm, join-based algorithms, such as binary-join algorithms [28, 29, 43], have been developed in the distributed context. Aware that binary-join algorithms cannot guarantee worst-case optimality, [4] implemented the worst-case-optimal join algorithm [35] for solving GPM. A hybrid mechanism [1, 32, 54] has been further explored to combine the advantage of binary join and worst-case optimal join. The above algorithms all rely on low-order statistics to devise execution plans. In order to improve cost estimation, [32] proposed to leverage the high-order statistics of the graph to compute execution plans for GPM. These algorithmic approaches are lacking essential system components needed to solve iGPM.

Query Languages and Graph Databases. GPM lies at the core of the query languages of Gremlin [39], Cypher [22], G-Core [5], PGQL [51] and GSQL [18]. These languages have been widely adopted in graph databases and systems. Tinkerpop [7] uses the Gremlin language to express graph traversal and pattern matching. Neo4j [33] is one of the most popular graph databases that uses Cypher as the query language. Gremlin-enabled JanusGraph [27], Orient DB [36] and Neptune [9] store graph data in distribution, but they adopt a sequential computing engine and can still suffer from scalability issue [38]. Targeting large scale, GAIA [38] has been developed to compile Gremlin traversal queries into a distributed dataflow program. However, the imperative Gremlin traversal cannot guarantee worst-case optimality, and it requires users to manually tune the execution. TigerGraph [18] is a distributed graph database, that uses the GSQL query language. However, the lack of an automatic optimizer greatly limits its usability for iGPM.

9 Conclusion

We've presented the GLogS system in this paper to solve the iGPM, meeting the requirements of performance, usability and scalability. GLogS allows users to interactively submit declarative GPM queries. With the worst-case optimality and high-order statistics, we've implemented an optimizer in GLogS that can automatically derive optimal execution plans for arbitrary GPM queries. Furthermore, on top of an existing distributed dataflow engine, GLogS is capable of being deployed in a large cluster to handle large-scale real-life graphs.

A Appendix

A.1 Graph Sparsification

In the paper, we adopt the stratified sparsification [19] that treats each type of edges as an independent stratum, and assign each stratum an individual sparsification ratio. For clarity, we use v (or e) and u (or ε) to denote a vertex (or edge) in the pattern and graph, respectively. Moreover, given an edge e (or ε), we denote its label as $L(e)$. Let $\{1,2,\ldots,l\} \subset \mathbb{N}^+$ be the domain of edge labels without loss of generality, and $\{s_1,s_2,\ldots,s_l\}$ be the frequencies of the edges with the given label in the graph G. Then we define the sparsification ratios as $\Omega = \{\rho_1,\rho_2,\ldots,\rho_l\}$, where ρ_i denotes the ratio for the stratum of edges with label i.

For two random variables X, X', we denote $\mathbb{E}[X], \mathrm{Var}[X]$ as the expected value and variance of X, and $\mathrm{Cov}[X,X']$ the covariance of X and X'. Given that we only eliminate edges in the sparsification process, we assume that the vertex set retains after sparsification, namely $V_G = V_{G^*}$.

A.1.1 The Proof of Lemma 6.1

Proof. Let $E_G(u_1,u_2)=1$ indicate the existence of edge (u_1,u_2) in the graph G and 0 otherwise. We formulate that

$$\mathscr{F}_{G^*}(p)=\underbrace{\sum_{(u_1,u_2,\ldots,u_{|V_p|})\in V_{G^*}^{|V_p|}}}_{\text{For each possible subgraph,}}\underbrace{\prod_{\substack{e\in E_p,\\ e=(v_j,v_k)}}E_{G^*}(u_j,u_k)}_{\text{verify the existence}}, \tag{6}$$

and obtain

$$\begin{aligned}&\mathbb{E}[\mathscr{F}_{G^*}(p)]\\ =&\sum_{(u_1,u_2,\ldots,u_{|V_p|})\in V_{G^*}^{|V_p|}}\prod_{\substack{e\in E_p,\\ e=(v_j,v_k)}}\rho_{L(e)}\times E_G(u_j,u_k)\\ =&\prod_{e\in E_p}\rho_{L(e)}\sum_{(u_1,u_2,\ldots,u_{|V_p|})\in V_{G^*}^{|V_p|}}\prod_{\substack{e\in E_p,\\ e=(v_j,v_k)}}E_G(u_j,u_k),\end{aligned}$$

Since $V_G=V_{G^*}$, we have

$$\mathbb{E}[\mathscr{F}_{G^*}(p)]=\prod_{e\in E_p}\rho_{L(e)}\mathscr{F}_G(p).$$

Thus, the lemma holds.

A.1.2 The Optimization Problem for the Stratified Sparsification

Let M denote a memory constraint to ensure that the sparsified graph can reside in the frontend machine. We first consider a specific pattern p, and later generalize to an arbitrary pattern. We formulate the stratified sparsification as an optimization problem as:

$$\begin{aligned}&\arg\min_{\Omega}\mathrm{Var}[\widetilde{\mathscr{F}(p)}]\\ &\text{s.t.}\sum_{i=1}^{l}s_i\rho_i\le M.\end{aligned} \tag{7}$$

Given an ordered set of vertices $S=(u_1,u_2,\ldots,u_{|V_p|})\in V_G^{|V_p|}$ from the graph G, we denote $\mathbb{1}(f_G(p)|S)$ to indicate whether there is a subgraph with S in G that can match the pattern p. If $\mathbb{1}(f_G(p)|S)=1$, in other words, S must be mapping of p in G, we directly use $f_G(p)|S$ to represent the matched subgraph regarding S. Note that the notations will be applied to both the eMap and G^* in the following. For example, given a vertex set S (same vertex set in both eMap and G^*), if $\mathbb{1}(f_G(p)|S)=1$ but $\mathbb{1}(f_{G^*}(p)|S)=0$, we know that some edge in the matched subgraph has been eliminated during sparsification. With the indicator, we have

$$\mathscr{F}_{G^*}(p)=\sum_{S\in V_{\texttt{eMap}}^{|V_p|}}\mathbb{1}(f_{G^*}(p)|S).$$

Therefore,

$$\begin{aligned}&\mathrm{Var}[\mathscr{F}_{G^*}(p)]\\ =&\sum_{S_1,S_2\in V_G^{|V_p|}}\mathrm{Cov}\left[\mathbb{1}(f_{G^*}(p)|S_1),\mathbb{1}(f_{G^*}(p)|S_2)\right]\\ =&\sum_{S_1,S_2\in V_G^{|V_p|}}(\mathbb{E}[\mathbb{1}(f_{G^*}(p)|S_1)\mathbb{1}(f_{G^*}(p)|S_2]\\ &-\mathbb{E}[\mathbb{1}(f_{G^*}(p)|S_1)]\times\mathbb{E}[\mathbb{1}(f_{G^*}(p)|S_2)].\end{aligned} \tag{8}$$

We observe that the covariance in Equation 8 must be zero in either of the following case.

- S_1 or S_2 cannot form a mapping of p in G, i.e., $\mathbb{1}(f_{\texttt{eMap}}(p)|S_1)=0$ or $\mathbb{1}(f_{\texttt{eMap}}(p)|S_2)=0$. In this case, the matched subgraph must not exist in G^*, leading to $\mathbb{E}[\mathbb{1}(f_{G^*}(p)|S_1)]=0$ or $\mathbb{E}[\mathbb{1}(f_{G^*}(p)|S_2)]=0$.
- $S_1\cap S_2=\emptyset$, namely the two sets are disjoint.

Therefore, we only need to study the two sets S_1 and S_2, such that $\mathbb{1}(f_{\texttt{eMap}}(p)|S_1)=1$ and $\mathbb{1}(f_{\texttt{eMap}}(p)|S_2)=1$, and $S_1\cap S_2\neq\emptyset$. In this case, $f_{\texttt{eMap}}(p)|S_1$ and $f_{\texttt{eMap}}(p)|S_2$ may share either none, one, or more than one common edges. The trivial case of sharing no edge results in zero variance. For other cases, we empirically studied their occurrences while matching all benchmark queries on G_1. We found that the case of sharing one single edge occurs much more frequently than that of sharing multiple edges. Let the common edge be ε, which must be matched by a pattern edge $e'\in E_p$. According to Equation 8, the covariance becomes

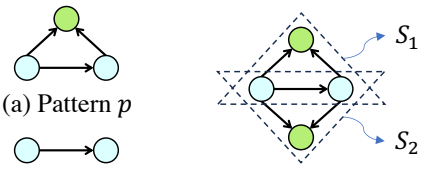
$$\begin{aligned}&\mathrm{Cov}\left[\mathbb{1}(f_{\texttt{eMap}}(p)|S_1),\mathbb{1}(f_{\texttt{eMap}}(p)|S_2)\right]\\ =&\left(\prod_{e\in E_p}\rho_{L(e)}\right)^2*\left(\rho_{L(e')}^{-1}-1\right).\end{aligned} \tag{9}$$

We then group these pairs by the labels of e', which eliminates e' in Equation 9 and transforms Equation 8 into

$$\begin{aligned}&\mathrm{Var}[\mathscr{F}_{G^*}(p)]\\ \approx&\left(\prod_{e\in E_p}\rho_{L(e)}\right)^2*\sum_{e\in E_p}\left(\rho_{L(e)}^{-1}-1\right)\lambda_{\texttt{eMap}}(p|e),\end{aligned} \tag{10}$$

where $\lambda_{\texttt{eMap}}(p|e)$ denotes the number of pairs of S_1 and S_2 in eMap whose common edge is matched by e in pattern p.

Figure 10 demonstrates a pair of S_1 and S_2 that matches a triangle pattern, as an example. In addition, matched subgraphs $f_{\texttt{eMap}}(p|S_1)$ and $f_{\texttt{eMap}}(p|S_2)$ share a common edge in the example. We observe that $f_{\texttt{eMap}}(p|S_1)$ and $f_{\texttt{eMap}}(p|S_2)$ together form a new pattern,



(a) Pattern p

(b) Common edge e (c) A pair of S_1 and S_2

Figure 10: Example of a pair of S_1 and S_2 with shared edge e.

which is a mirror symmetric structure with respect to the common edge. In terms of an edge $e \in E_p$, we denote such a mirror pattern as p_e^+. It's clear that $\lambda_{\texttt{eMap}}(p|e)$ is equal to the frequency of pattern p_e^+ in eMap, namely $\lambda_{\texttt{eMap}}(p|e) = \mathscr{F}_G(p_e^+)$. Combining with the Equation 4 in the paper, we have

$$\lambda_{\texttt{eMap}}(p|e) = \mathscr{F}_G(p_e^+) \approx \frac{\mathscr{F}_G(p) \times \mathscr{F}_G(p)}{\mathscr{F}_G(e)} = \frac{\mathscr{F}_G(p)^2}{s_{L(e)}}, \tag{11}$$

Combining the definition of $\widetilde{\mathscr{F}(p)}$, Equation 10, and Equation 11, we obtain

$$\text{Var}[\widetilde{\mathscr{F}(p)}] \approx \sum_{e \in E_p} \left(\rho_{L(e)}^{-1} - 1\right) \frac{\mathscr{F}_G(p)^2}{s_{L(e)}},$$

Note that $\mathscr{F}_G(p)$ can be treated as a constant value in the optimization problem. Consequently, we can rephrase the optimization problem in Equation 7 as

$$\begin{aligned} &\arg\min_{\Omega} \sum_{e \in E_p} \left(\rho_{L(e)} s_{L(e)}\right)^{-1}, \\ &\text{s.t.} \sum_{i=1}^{l} s_i \rho_i \leq M. \end{aligned} \tag{12}$$

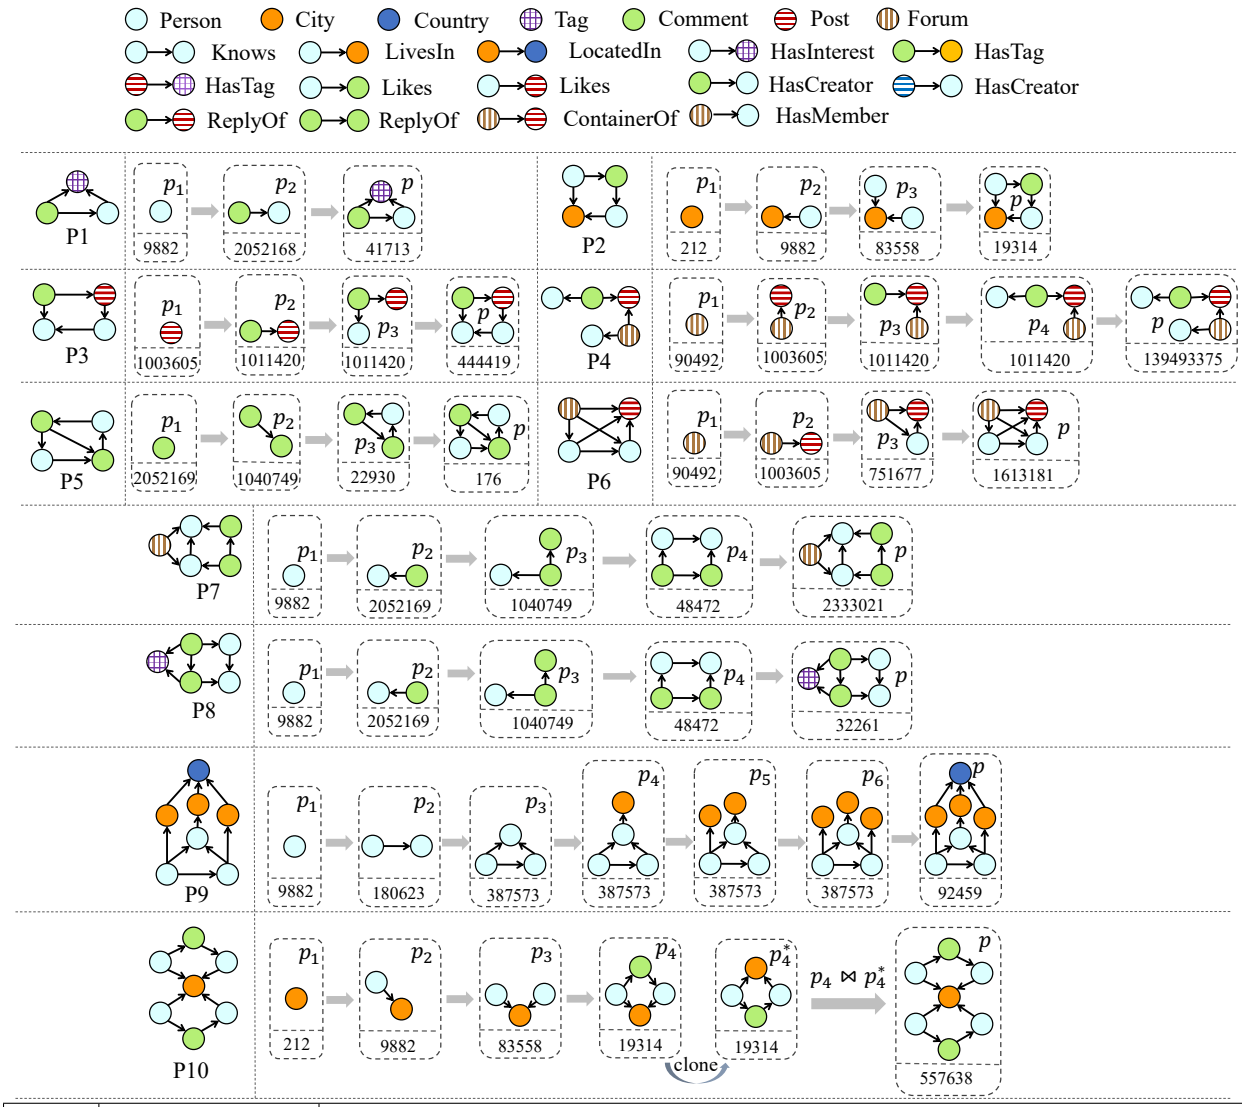
Till now, the optimization problem only considers a specific pattern p. For generalizing to an arbitrary pattern, we construct a pattern p that is formed by all types of edges in the graph, and in Equation 12, we enumerate all labels rather than those in the pattern p, which becomes

$$\begin{aligned} &\arg\min_{\Omega} \sum_{i=1}^{l} \left(s_i \rho_i\right)^{-1}, \\ &\text{s.t.} \sum_{i=1}^{l} s_i \rho_i \leq M. \end{aligned}$$

The minimal variance is achieved when $\rho_i = \frac{M}{l} \times \frac{1}{s_i}$. Since the sparsification ratio ρ_i has a upper bound 1, i.e., all edges with label i are preserved, we have $\rho_i = \min(1, \frac{M}{l} \times \frac{1}{s_i})$.

A.2 Queries and Execution Plans

We reported all queries used in the experiments, along with their execution plans generated by the optimizer of GLogS, in Figure 11. In the execution plans, we also marked the corresponding intermediate pattern frequencies in the benchmark graph G_1 for the evaluation of their performance. The table in Figure 11 explains how the queries are constructed. Specifically, their main structures of all queries are extracted from LDBC [30] Business Intelligence (BI) workloads, and then modified to cover more test scenarios. Overall, the queries contains Long-Chain, Triangle, Square, 4-Clique, House that are commonly used for benchmarking GPM queries [29, 32]. Their execution plans cover both Expand and Join operators.



Query	Source	Explanation
p_1	BI-8	p_1 is extracted from BI-8
p_2	BI-5	Wedge Person → Comment → Person is extracted from BI-5. Additionally, a City vertex and two LivesIn edges are added to form a Square
p_3	BI-15	p_3 is extracted from BI-15
p_4	BI-17	p_4 is extracted from BI-17
p_5	BI-17	p_5 is extracted from BI-17
p_6	BI-4, BI-15	Some subgraphs are extracted from BI-4 and BI-15 to form a 4-Clique
p_7	BI-19, BI-4	Its right square is extracted from BI-19. In addition, a Forum hat is extracted from BI-4 and added to the square to form a House
p_8	BI-19, BI-17	Its right square is extracted from BI-19. In addition, a Tag hat is extracted from BI-17 and added to the square to form a House
p_9	BI-11	p_9 is the main structure of BI-11
p_{10}	BI-5	p_{10} consists of two p_2 by joining on the City vertex. This is designed to verify whether GLogue can generate a plan with join

Abstract

Graph pattern mining is an essential task in many fields, which explores all the instances of user-interested patterns in a data graph. Pattern-centric mining systems transform the patterns into a series of set operations to guide the exploration and substantially outperform the embedding-centric counterparts that exhaustively enumerate all subgraphs. These systems provide novel specializations to achieve optimum search space, but the inherent redundancies caused by recurrent set intersections on the same or different subgraph instances remain and are difficult to trace, significantly degrading the performance.

In this paper, we propose a dataflow-based graph pattern mining framework named Cyclosa to eliminate the above redundancies by utilizing the concept of computation similarity. Cyclosa is characterized by three features. First, it reorganizes the set operations for a pattern into a set dataflow representation which can elegantly indicate the possibility of redundancies while sustaining the optimal scheduling for high performance. Second, the dataflow-guided parallel execution engine decouples data access and computations to enable efficient results sharing. Third, the memory-friendly data management substrate can automatically manage the computation results with high reuse possibility. Evaluation of different patterns demonstrates that Cyclosa outperforms state-of-the-art pattern-centric systems GraphPi and SumPA by up to 16.28× and 5.52×, respectively.

1 Introduction

Graphs are the *de facto* paths to explore useful information in various fields, including social media analysis [1, 2], financial networks [3, 4], and bioinformatics [5]. Graph pattern mining aims to explore interesting subgraph structures according to the user-given constraints. Typical graph pattern mining applications include subgraph matching [6, 7], clique finding [8, 9], and motifs counting [10–12]. Despite the prevalence of graph pattern mining applications, they have high computational complexity and usually need hours or even days to complete [13–15].

Graph pattern mining systems have emerged in recent years to provide high performance and programmability [16–18]. A common approach is to enumerate all the subgraphs, usually under a certain depth, to check whether the subgraphs satisfy the pattern constraints, which is called the embedding-centric paradigm [16, 19]. This approach is easy to develop and parallelize. However, it results in high memory consumption and wasted computing resources due to a large number of intermediate partial instances [17, 20]. Recently, advanced graph pattern mining systems have adopted a pattern-centric paradigm to overcome inefficiencies [17]. The main idea is to use the structure information of graph patterns to filter intermediates that will not lead to a correct final match. This is achieved by transforming the graph patterns into a series of set operations and executing them in a nested loop following a matching order of pattern vertices. Each loop computes the candidates of corresponding pattern vertex, where the computation is represented as a formula of set intersections on the neighboring lists of previously matched pattern vertices based on the structural connectivity, e.g., $Cand(v_2) = N(v_0) \cap N(v_1)$ for a triangle pattern after matching an edge (v_0, v_1). In this way, only valid partial instances are produced in each loop.

Prior works propose many novel techniques to reduce the search space also the number of partial instances to be explored. AutoMine [17] provides a convenient compiler to generate optimized matching orders automatically (also the order of computations), which will significantly influence the search space. Peregrine [20] and GraphZero [21] introduce a symmetry-breaking method that filters the partial instances leading to the same final mapping by comparing vertex IDs of symmetric vertices. GraphPi [22] further explores an optimal combination of different symmetry-breaking rules and matching orders to minimize the search space. The above systems mainly optimize the mining of a single pattern. SumPA [23] further proposed an abstraction approach to reduce workloads for mining multiple patterns simultaneously.

However, a large number of intrinsic redundant computations remain in the execution of set operations even in an optimized search space, the same set intersection, e.g.,

$N(v_0) \cap N(v_1)$, repeats throughout the processing. Specifically, the redundancies can be classified into two categories, the *explicit redundancy* and *implicit redundancy*, based on whether they rely on the same subgraph instance. In explicit redundancies, one set intersection can be repeatedly used for computing different pattern vertices connected to the same subgraph instances. In implicit redundancies, the same intersection appears in computing on different subgraph instances. The redundant computations usually cost more than 80% of the runtime and severely degrade the performance. Furthermore, these explicit and implicit redundancies spread over the runtime when mining a single pattern or multiple patterns, making it difficult to trace and reuse. Existing systems follow the principle of structural equality and rewrite the exact same set formulas of different vertices into a single one to reduce part of the explicit redundancies [21–23]. However, there are still more than 60% of the redundancies remaining unsolved.

We observe two kinds of computation similarity in the set operations providing the opportunity to help identify and reuse both explicit and implicit redundancies. The first one is the static similarity which reveals the structural similarity among the operands of the set operations in a pattern, that one input operand can be reused in two operators, and the output results of these operators may have latent redundancies. The static similarity can be analyzed before execution. We propose to decouple the operands and operators of all set operations and organize them into a directed flow oriented by the connections among the inputs and outputs, which is called a *set dataflow*, to efficiently exploit the static similarity. Each node in the set dataflow is a set operand or a set operator. The explicit redundancies can be removed by keeping only unique operands in the dataflow, while the implicit redundancies between different operators can be indicated by the overlapped input source nodes of the dataflow.

The second one is the dynamic similarity which reveals the similarity among the inputs of all occurred set intersections during runtime, which can only be analyzed after execution. Specifically, we observe that a small number of high-degree vertices participate in most of the computations, which means redundant computations are concentrated in these vertices. This allows us to cache and reuse implicit redundant results by tracing these high-degree vertices. However, maintaining correctness and efficiency in the execution of the dataflow is challenging. How to manage the intermediate computation results in limited memory space is also a main difficulty.

In this paper, we present Cyclosa, a novel dataflow-based graph pattern mining system to eliminate both explicit and implicit redundancies in the pattern-centric paradigm. Specifically, Cyclosa is characterized by the following key features. First, we propose a novel set dataflow representation and an efficient constructing approach to generate the set dataflow for arbitrary patterns. It maintains optimized cost through a lightweight cost estimation model and introduces the redundancy probability to guide the appropriate reusing of results. Second, we develop a dataflow-based execution model to expose the possibility of capturing and reusing redundancies during runtime. Through the dataflow execution, the data accesses and computations are decoupled, providing the ability to maximize data reuse in parallel. Third, we design a memory-friendly data management substrate to automatically store the computation results with a high possibility of redundancy. It implements smart cache strategies according to the reuse probability of results evaluated, thus achieving a controlled memory consumption. Furthermore, the substrate can efficiently cooperate with the dataflow execution engine to provide the results requested by repeated computations. We implement a prototype of Cyclosa and achieve significant performance improvement over state-of-the-art pattern-centric graph pattern mining systems.

The key contributions of this paper are as follows:

- It introduces a set dataflow representation to explore the fine-grained computation similarity in set operations of pattern-centric graph mining for reducing both explicit and implicit redundancies.
- It proposes a dataflow-guided execution model and a self-managed redundancy storage substrate to efficiently share results among computations, overcoming the challenges of managing and reusing the results.
- It develops Cyclosa, a high-performance graph pattern mining system that eliminates redundant computations for various pattern settings. Experimental results show that Cyclosa outperforms GraphPi and SumPA by up to 16.28× and 5.52×, respectively.

2 Background and Motivation

2.1 Definition of Graph Pattern Mining

Given a data graph $G = \langle V, E \rangle$, where V is the vertex set and E represents the edges, and an input graph pattern p which can be arbitrary graphs, the basic graph pattern mining problem aims to find all the subgraphs of G that are isomorphic to p [20–22]. Each isomorphic subgraph is called an *embedding* of p, and the vertices and edges form an one-to-one mapping between the embedding and p. For example, Figure 1 shows a data graph and a diamond pattern. The subgraphs connected by (2, 3, 0, 4) and (2, 3, 1, 4) are two embeddings of the diamond pattern, and the vertices are mapped correspondingly. As in prior studies, this work focuses on graph pattern mining on the undirected graphs.

Graph pattern mining applications have many variants which may require either a single pattern or multiple patterns to be mined. For example, *subgraph listing* outputs all the instances of a given pattern [24]. The *k-clique finding* counts the complete subgraphs with a certain number of vertices [25]. The *k-motifs counting* counts the number of instances for all

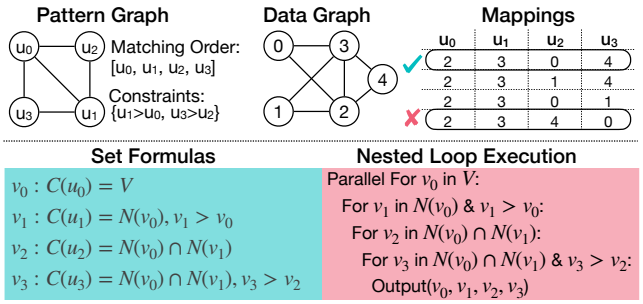

Figure 1: The example of mining a diamond pattern in a pattern-centric system

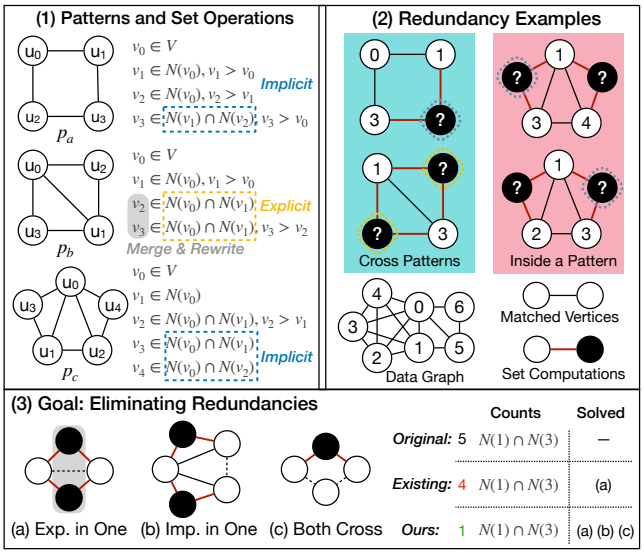

Figure 2: An example of redundant computations in graph pattern mining. The black vertices in dashed cycles represent redundant computations $N(1) \cap N(3)$ in different situations.

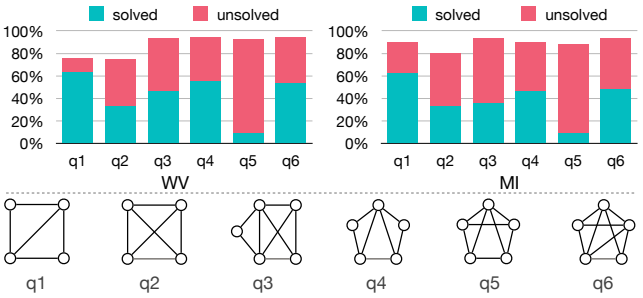

Figure 3: The ratio of redundancy as repeated set intersections for different patterns on *Wiki-Vote* (WV) and *MiCo* (MI) graphs. Solved: the redundancy amount that can be addressed by SumPA against a naïve nested loop execution. Unsolved: the number of remaining redundancies in SumPA.

2.2 Procedure of Graph Pattern Mining

In pattern-centric systems, the mining procedure is typically performed as a series of nested set operations in three steps [17, 22, 27]. Firstly, the graph pattern is analyzed to generate a matching order of pattern vertices. The vertices in the data graph will be computed and mapped to the pattern following the order. Secondly, the set operations required for computing each pattern vertex will be generated based on its prior neighbors in the matching order. Lastly, the set operations will be executed in a nested loop that starts from each data graph vertex. The end of each loop represents that a subgraph instance is found. Usually, the outer loop is executed in parallel. Existing systems focus on minimizing the branches that need to be accessed in the search tree by generating optimized matching orders. In order to further reduce the search space, the symmetry-breaking method is also applied by adding comparison constraints to filter computed results that will lead to an automorphic instance.

For instance, Figure 1 shows how to find the subgraphs of a diamond pattern. In the pattern analysis phase, the matching order of the diamond is defined as $[u_0, u_1, u_2, u_3]$. There are comparison constraints between vertex pairs $<u_1, u_0>$ and $<u_2, u_3>$ because they are symmetric. Following the matching order, we can formulate the set operations for each pattern vertex. Initially, u_0 can be mapped to any of the data graph vertices while u_1 is represented as finding a neighbor of u_0. For vertices u_2 and u_3, they are common neighbors of u_0 and u_1, so that a set intersection is defined respectively. The constraints are checked when $<u_1, u_0>$ and $<u_2, u_3>$ are involved in the computations. These set operations are organized into a nested loop of 4 depths for execution. The first two loops map edges of the data graph to (u_0, u_1). Assuming that the edge (2, 3) has been assigned, the candidates for u_2 and u_3 will be {0, 1, 4}. Due to the symmetry-breaking constraints, we can safely filter (2, 3, 4, 0) and avoid mapping (2, 3, 0, 4) twice because they are the same subgraph.

Our work incorporates existing optimizations of reducing the size of explored search space while enabling high efficiency on computations by eliminating redundancies.

2.3 Problem: Redundant Computations

Despite the pattern-centric mining procedure providing good optimizations on the search space, time-consuming explicit and implicit redundancies exist in the procedure of mining single or multiple patterns. This problem is detailed in Figure 2. The set operations for each vertex corresponding to the matching order and constraints of patterns P_a, P_b, and P_c are given. Following the matching order, consider that a part of

the substructures of these patterns have been mapped to the data graph, which is denoted as white vertices. Next, we will explain the explicit and implicit redundancies in detail.

Explicit Redundancy: A set of intersections that are repeatedly operated upon the neighboring lists of the same vertices from the *same* subgraph instance. For pattern P_b, (1, 3) is partially assigned to (u_0, u_1). In order to compute u_2 and u_3, $N(1) \cap N(3)$ is performed twice. For pattern P_c, the computation $N(1) \cap N(3)$ must be performed in order to map (1, 3, 4) to u_2. To this end, the explicit redundant computation $N(1) \cap N(3)$ is conducted based on the same edge instance (1, 3) inside single pattern P_b and also in the pattern P_c.

Implicit Redundancy: A set of intersections that are repeatedly operated upon the neighboring lists of the same vertices from the *different* subgraph instances. In single pattern P_c, consider two subgraph instances (1, 3, 4) and (1, 2, 3) are already mapped to (u_0, u_1, u_2). The repeated set intersections $N(1) \cap N(3)$ exist for computing u_3 and u_4. They are induced from different subgraph instances. For multiple patterns, when (0, 1, 3) is partially matched to P_a, the computation of $N(1) \cap N(3)$ is induced from different subgraph instances of all three patterns.

These redundancies can be aggravated in a nested loop of set operations as in Figure 1, e.g., resulting in more than twice the number of redundancies for computing u_3 of P_b. As profiled in Figure 3, more than 80% of total computations are redundant in different patterns. However, existing systems can only explore parts of the explicit redundancies because they view each set formula (or a pattern vertex) as a whole in each loop and all follow the principle of structural equality to merge equal set formulas. For example, in Figure 4, GraphPi [22] and GraphZero [21] will merge and rewrite the formulas S_3 and S_4 into one loop. SumPA [23] will reduce v_2 and v_3 into an abstract pattern vertex and then generate a single set formula for two vertices. However, the implicit redundancies remain because they cannot be exposed as structural equality in set formulas. Besides, in parallel execution, explicit redundancies on a reverted edge such as $N(1) \cap N(3)$ and $N(3) \cap N(1)$ will be omitted. As profiled in Figure 3, existing work can only solve less than 40% redundancies. Our work aims to eliminate both explicit and implicit redundancies.

2.4 Insights: Computation Similarity

In order to detect and reuse both the explicit and implicit redundancies, we must explore finer-grained computation similarity rather than the structural equality as in existing work. If the similarity of computations can be identified before the execution, then we can use it to guide the reusing of results. The computation similarity comes from two folds:

- *Static Similarity.* The static similarity originates from the operands level of the set operations for a pattern, exposing the reuse possibility of both inputs and outputs of different computations. Figure 4 presents the set formulas of P_c in Figure 2, other than the formula equality of S_3 and S_4, the input operand $N(v_0)$ is also getting involved in S_2 and S_5. $N(v_0)$ can be shared as inputs for four formulas, and it also results in the implicit redundancies between S_4 and S_5.

- *Dynamic Similarity.* The dynamic similarity lies in the runtime characteristics of the inputs of occurred computations, reflecting which vertices are more likely to be requested for computation. Specifically, we observe *most of the computations are concentrated in a small part of high-degree vertices.* We make an analysis of 4-motifs counting on two graphs as shown in Figure 5. The vertices of the graphs are reordered by a decreasing degree. More than 85% of the computations lie in about 15% of the first high-degree vertices, where the redundancies also concentrate.

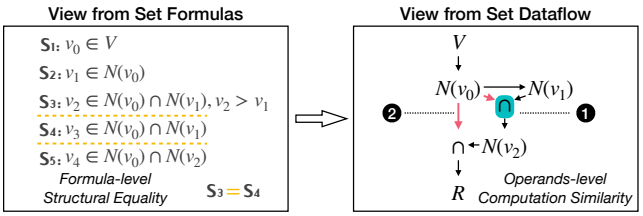

Figure 4: The dataflow view for analyzing the mining procedure of p_c in Figure 2. ❶ S_3 and S_4 are reduced. ❷ Results of $N(v_0)$ are reused in two ∩.

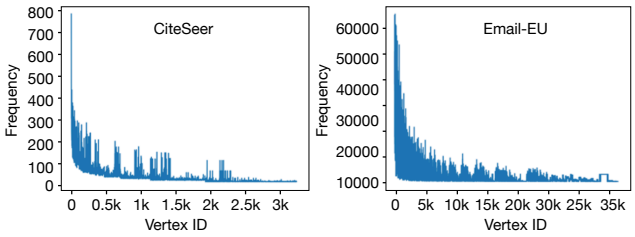

Figure 5: The frequency of vertices getting involved in computations for size-4 motifs counting on two graphs

In this work, we propose a *set dataflow* to use the computation similarity for redundancy elimination, as shown in Figure 4. The set dataflow is a directed graph indicating the procedure of how sets are transferred and computed. The set dataflow decouples the set formulas into individual operands and operators, and the directed edges represent the transfer relation of the input/output data between different operators. It removes explicit and implicit redundancies as follows: ❶ The explicit redundancies can be removed by cutting and maintaining unique operators, e.g., only single $N(v_0)$ and $N(v_1)$ exist. Original two $N(v_0) \cap N(v_1)$ are thus reduced to one, and the set operands are fully shared. ❷ The implicit redundancies between operators are indicated by overlapped inputs, e.g., the results of $N(v_0) \cap N(v_1)$ and $N(v_0) \cap N(v_2)$. Based on the dynamic similarity, we can heuristically cache the computation results of high-degree vertices for reusing.

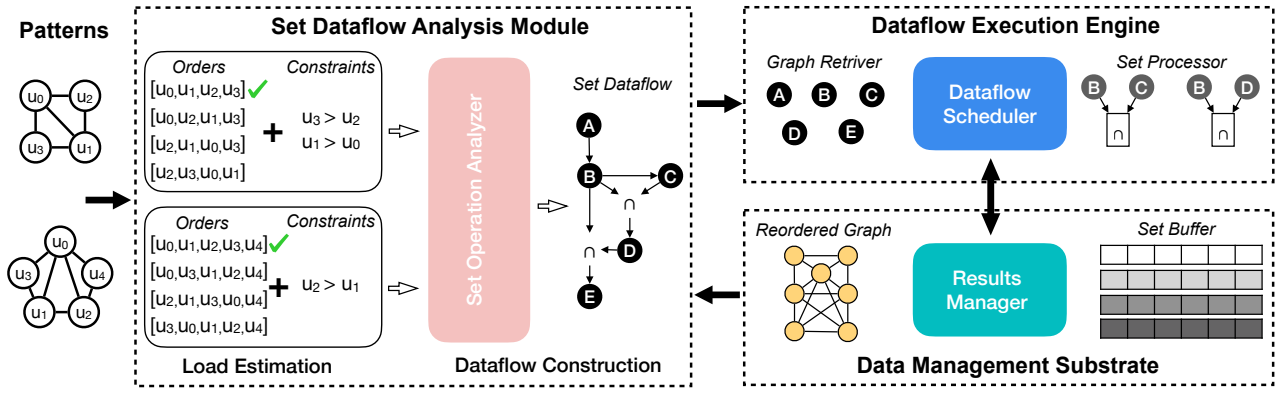

Figure 6: Overview of Cyclosa

Challenges. However, there are still several challenges in constructing an efficient redundancy-free graph pattern mining system. First, maintaining correctness and efficiency is difficult. The set dataflow is only aware of sets during execution, and we need to extract the results correctly while enabling maximum data sharing. Second, managing a large number of redundant results is challenging. Simply storing all the redundant results indicated by set dataflow is inefficient and may consume a large size of memory footprint.

3 System Overview

Cyclosa is architected to solve the above challenges and achieves a redundancy-free execution for graph pattern mining. Given arbitrary graph patterns, Cyclosa can fast analyze the computation similarity via the set dataflow and use the set dataflow to guide the sharing of computations with high parallelisms. Specifically, Cyclosa works with three main modules, as presented in Figure 6.

Set Dataflow Analysis Module. The set dataflow of input patterns is constructed in this module. Each pattern is first analyzed to generate a reuse-aware matching order and constraints with data graph properties. Then, based on the matching order, a set operation analyzer generates a redundancy-reduced set dataflow by keeping unique operands. Through the analysis, the generated set dataflow will maintain sufficient information for correct results and indicate the redundancy probability of different set operators.

Dataflow Execution Engine. The generated set dataflow is fed to the dataflow execution engine for processing. It keeps a decoupled view of the data access and computation that provides the opportunity to manage the results independently. Each node in the dataflow is assigned to a worker to process. The inputs and outputs are managed by the graph retriever communicating with the data management substrate. The set operators are assigned to redundancy-aware set processors that will request redundant results before the computation. A dataflow scheduler controls the processing order by directed edges of the set dataflow to ensure correctness.

Data Management Substrate. Computed results are automatically maintained in the substrate. Once received a result set, a results manager will implement smart cache strategies and maintain results with different reuse possibilities in a proper place of a multi-level set buffer. In this way, the memory footprint is under control. Furthermore, the results management can overlap with the execution engine for high parallelism. The substrate also provides a fast request to the data graph and cached results through efficient data layout.

4 Set Dataflow Analysis

This section first introduces the approach to generate a cost-efficient reuse-aware matching order and then describes the procedure for efficiently constructing a set dataflow.

4.1 Pattern Analysis

Existing approaches enumerate all possible orders and estimate the cost to find the order with the lowest workload [17, 20, 22], but they are oblivious to the redundant computations exposed in runtime characteristics. Besides, the overhead for enumerating all orders will increase when patterns get larger. In this work, we propose a degree-guided two phases analysis, as shown in Figure 7, to solve the above challenges. The main idea is to match the high-degree vertices in a *Depth-First-Search* (DFS) manner to raise the possibility of reusing the results on these vertices. At the same time, we design a lightweight and efficient cost model with graph information for the optimal cost.

DFS Order Enumeration. This phase will generate all degree-first DFS orders of a pattern. Firstly, the constraints of symmetric vertices are generated using the permutation group theory as in GraphPi [22], independent of the order of vertices. In the example of Figure 7, there are two equal constraints because each is sufficient to breaking symmetries, and the $u_0 < u_2$ is selected randomly. Secondly, it traverses

from the pattern vertices with the highest degree and follows a DFS style to get all valid matching orders, e.g., the order starting from u_1 with a degree by 4 is valid while the one from u_0 with a degree by 3 is discarded. These orders will then be estimated for the minimum cost.

Graph-Aware Cost Estimation. We estimate the total number of intermediate subgraph instances as the cost. Given a matching order, we can get the set formulas for computing each pattern vertex. Cyclosa then iteratively estimates the number of instances produced in a nested loop execution of the set formulas. Existing works typically use a fixed metric (i.e., average degree) to predicate the number of newly generated instances from each subgraph [17, 23]. However, this approach omits the filtering effect of set intersections and is inaccurate [28]. Cyclosa incorporates more graph information by combining the vertex degree and triangle-count-per-edge for estimation, because the triangle count enables capturing the reduction information on neighboring lists after an intersection on two or more vertices.

As shown in Figure 7, initially, $|V|$ vertices can be mapped to u_1 after `Loop0`. In `Loop1`, because only one $N(u_1)$ operator is used for matching u_0, we use the average degree deg to estimate the number of newly produced instances from each instance in the previous loop. The total instances in `Loop1` are $|V| * deg$. In `Loop2`, since the results are produced by an intersection on $N(u_0)$ and $N(u_1)$, we use the triangle-count-per-edge $ntri$, instead of deg, to estimate the number of newly generated instances. Note that the constraint $u_0 < u_2$ is applied to `Loop2` so that some produced instances will be filtered. We use a parameter α to reflect the reduction of instances. The cost estimated for subsequent loops is similar. Finally, the total cost of this order is calculated by summarizing the costs of all loops for selection.

Similar to Cyclosa, there is also research [28] considering the data graph properties and using the number of sub-patterns in a sampled graph to estimate the cost of the whole graph. However, it requires the extra sampling and matching phase to get the cost. Different from existing systems, Cyclosa precomputes triangle counts and degrees of the original graph to preserve accuracy without introducing extra steps. Additionally, Cyclosa also considers the factor of instances filtering by symmetry-breaking constraints.

4.2 Dataflow Construction

Given the matching order, a pattern can be transformed into a series of set formulas as in prior work. Based on the set operation, there are mainly two challenges for generating the set dataflow. First, the set dataflow must be aware of existing optimizations on symmetry-breaking. Second, we need a fast approach to save construction time when facing a large number of set operations.

We propose a novel abstraction for representing the set dataflow by introducing three kinds of set operators to provide

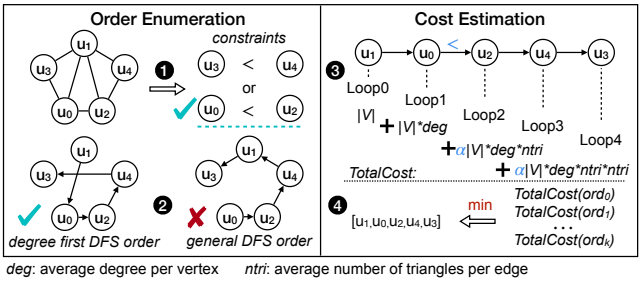

Figure 7: The procedure of finding an appropriate reuse-aware matching order for a pattern by ❶ generating constraints, ❷ enumerating valid DFS orders by degrees, ❸ estimating cost for each order with graph information, and ❹ selecting the order with minimum cost

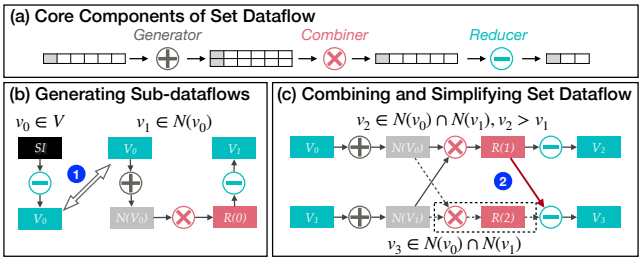

Figure 8: An example of constructing the set dataflow given four set formulas. The sub-dataflow of each set formula is first constructed with three operators, and the input/output sets of each operator are uniquely assigned and identified. The sub-dataflows are then combined into a final set dataflow by ❶ reducing inputs/outputs and ❷ simplifying set operators.

a uniform view and contain all information of set operations including the symmetry-breaking: `Generator`, `Combiner`, and `Reducer`. The `Generator` consumes a valid candidate set of a pattern vertex to generate the neighboring sets. The `Combiner` receives two sets and outputs a single set. The `Reducer` checks a result set and selects valid candidates following filtering rules to produce a new candidate set for certain pattern vertices. Based on these operators, we adopt the idea of divide-and-conquer by first generating the sub-dataflow of each set operation and then combining them to get the final set dataflow, as shown in Figure 8.

Generating Sub-Dataflows. The sub-dataflow of each formula must contain the `Generator`, `Combiner`, and `Reducer` at the same time, except of the initial one because there is no intersection required. In this way, the data required for computation and the operators performed are separated, which are represented in a unified style. For example, in Figure 8, the sub-flow of initial $v_0 \in V$ only contains one `Reducer`. For $v_1 \in N(v_0)$, the $N(v_0)$ is first transformed into a flow with a `Generator`, the output of the `Generator` is then sent to a `Combiner` and is finally checked by a `Reducer`. Similarly, the sub-dataflow for $v_2 \in N(v_0) \cap N(v_1)$ is given, and the con-

straints will be recorded in the metadata of the `Reducer`.

Combining and Simplifying Set Dataflow. Different sub-flows are first combined by connecting same inputs and outputs, e.g., the sub-flows of $v_1 \in N(v_0)$ and initial formula are combined by the output and input candidate sets denoted with V_0. Only one candidate set of V_0 will be maintained after the combination. After the combination, we then traverse the combined set dataflow in a BFS style to cut set operators with the same input nodes. Consider two `Combiners` used for computing the results of v_2 and v_3. They have the same input nodes so that only one `Combiner` remains. Thus, the explicit redundancies of these two operators are eliminated. After the simplification, the final set dataflow is generated.

4.3 Dataflow Evaluation

This evaluation aims to exploit the latent probability of redundant results among different *Combiners* in the set dataflow, which will guide the storing of results. However, providing an exact prediction of the probability before execution is difficult. Therefore, we propose to qualitatively analyze the latent probability of redundancy for different set operators through their depths and input information in the dataflow.

Generally, the operators with at least one shared input source and at the same depth have a higher possibility of producing similar results. Considering the view of pattern structure, this can be understood as they have similar substructures. In Figure 2, the computations for u_3 and u_4 have produced the same results during runtime because these two vertices have similar triangle structures and share the u_0. Figure 9 summarizes the reuse probability under different situations of the combinations of depth and shared input sets. The redundant probabilities of different `Combiners` are recorded in a table together with the set dataflow for execution.

5 Redundancy-Free Pattern Mining

This section introduces an efficient set-centric execution engine and a redundancy-aware data management substrate to enable high performance and optimal results reuse.

5.1 Set-Centric Dataflow Execution

The set formulas are processed in a nested loop in prior works. Despite of the convenience of parallelizing, it lacks the ability of fine-grained data management and reuse. In this work, we present a set-centric dataflow execution engine that decouples data management from computation to maximize results sharing. The core idea is to put the set instead of a subgraph as the basic processed element. The set operator in the set dataflow will start processing whenever the input sets from directed edges are ready. This discrete view enables sharing any results to any of the computations.

To realize the goal, we correspondingly design an executor for each `Generator`, `Combiner`, and `Reducer` together with a *Dataflow Monitor*, as shown in Figure 10(a). Each set contains two parts for identification: the set ID and the elements value, e.g., ID $< 3, -1 >$ for the neighboring set of vertex 3. Set operators coordinate through flow signals. The monitor identifies from the flow signals to know where to move the results and activates the next operator.

Generator Module. It traverses each vertex element from the input candidate set or the initial set to generate related neighboring sets. Each input set is assigned a signal consisting of an operator ID and an instance ID. The output will inherit the operator ID, and a new instance ID is produced to indicate a newly generated subgraph instance for correctness. In the case of Figure 10(a), the signal $nei < 3, -1, op, gid^*, value >$ is sent to the monitor. The monitor will then transfer the output set to a `Combiner` needed.

Combiner Module. In order to support reuse-aware computation, it introduces a *check unit* and a *compute unit*. The check unit first queries whether there are already computed results with the same ID, $req < 3, 5, op, gid >$ in Figure 10(a). The monitor will transfer the request to the data manager. If the request hits, then the computation is omitted. Otherwise, the compute unit is called to generate a new output. The new result $res < 3, 5, gid, value >$ is then transferred to the monitor for the next operator.

Reducer Module. Each input to this module will be a result directly computed from the `Combiner` or fetched from the cached results. The output is a set with valid candidates for a pattern vertex. The constraint information is checked by accessing the metadata of the set dataflow. Once an output set is generated, the related signal, i.e., $ret < op, gid, value >$, is sent to the monitor.

Dataflow Monitor. The monitor coordinates the movement of sets guided by the set dataflow. It has three components: 1) the *Flow Map* storing the metadata of a set dataflow by recording unique IDs for operators, 2) the *Activator* handling the signals of operators and scheduling the sets based on the flow map, and 3) the *Retriever* communicating with the data manager for accessing the graph data and cached results.

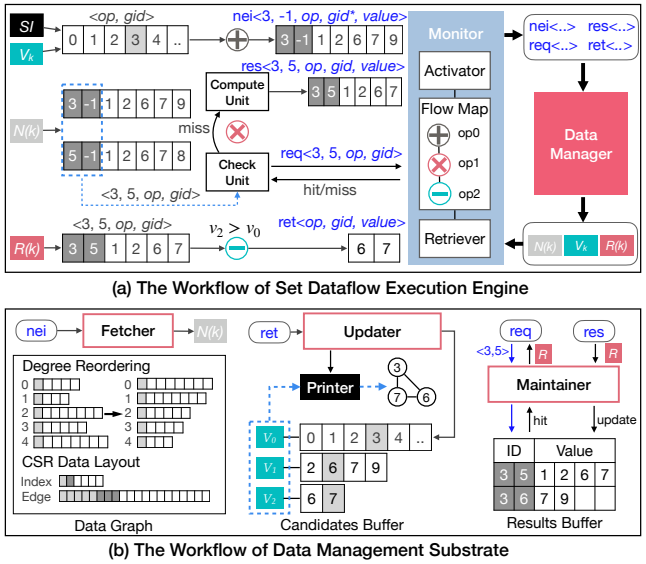

Figure 10: The workflows of set dataflow execution engine and data management substrate

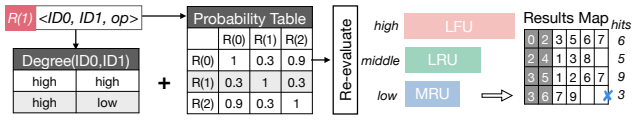

Figure 11: The caching strategy for result sets. The vertex degrees of result $R(1)$ are first checked, and only results with at least one high-degree vertex are maintained. The corresponding row of the probability table is then accessed to further decide the caching strategy.

5.2 Reuse-Aware Data Management Substrate

The dataflow execution engine will continuously produce new result sets. However, due to the large search space, maintaining the results in a limited memory space while maintaining high reuse ratio is challenging. We propose a memory-friendly data management substrate to solve this challenge. The main idea is to selectively store result sets with the highest reuse probability. It also overlaps with the computation phase to embrace correctness and efficiency. The substrate implements three main components: the results maintainer, the candidates updater, and the graph fetcher, as shown in Figure 10(b).

Results Maintainer. The cores of the results maintainer are three fixed-size result buffers under different caching strategies, i.e., the *Least Frequently Used* (LFU), the *Least Recently Used* (LRU), and the *Most Recently Used* (MRU) buffers storing results with high, middle, and low reuse probability, respectively. High reusable results come from high-degree vertices, which are more likely to be generated at the upper levels of the dataflow and are the most frequently requested. Middle reusable results are from parallel computations at the same middle level, yielding better time locality. Low reusable results occurs at the lower levels, which are often infrequently requested by low-degree vertices that are deferred to be processed in Cyclosa. This module dynamically maintains the computed results and responds to the *req* and *res* signals. The sets in the buffer are stored in a <key, value> manner. When a *req* signal arrives, it will search for results by the set ID, update the hit information, and respond to the dataflow monitor. When a *res* signal arrives, the maintainer will estimate the reuse probability with smart caching strategies and store the result in a proper buffer.

The strategy for identifying the reuse probability of a result set is demonstrated in Figure 11. It combines the static and dynamic computation similarities to estimate the reuse probability during runtime. Higher values in the probability table of the set dataflow analysis and higher degrees of the vertices by the result set ID, in particular, will result in a higher reuse probability evaluated. For instance, in Figure 11, the result has a low reuse probability. This is because there is a low degree vertex in the computation, which may not participate in other computations.

Candidates Updater. It is responsible for maintaining the candidate sets produced by the `Reducer` and extracting correct subgraph instances. Each candidate set is allocated with independent memory space. When a *ret* arrives, the *op* information is used for indicating the correct candidate sets. After each update, a *Printer* will consume the candidate sets using the *gid* information once all candidate sets are updated. The *Printer* records current pointers in the candidates set and produces exact subgraph instances. In order to overlap with the updating process, we use a double buffer for extracting the subgraph instances in the *Printer*.

Data Graph Fetcher. It reorganizes the data graph to improve the reuse efficiency and responds to the *nei* signal by returning the neighboring list as a set to the execution monitor. Specifically, based on the degree information, the vertices and edges are reordered so that the vertices with higher degrees will be assigned smaller IDs. In addition, the edges of the high-degree vertices are stored in a contiguous space to improve the cache efficiency because these edges will be frequently accessed during computation. It also conducts a triangle counting process to get the number of triangles of the data graph for pattern analysis.

Discussions. Through the above designs, Cyclosa enables efficient results sharing for redundant computations. In the case of operating intersections upon small sets, directly recomputing may be faster than reusing the results. However, this case rarely happens since most cached results are related to high-degree vertices that have large-size sets. We track the cached intersection results of size-4 motif counting on MiCo graph in Cyclosa and find that only 7.3% of results benefit from recomputations while most prefer the reuse method that can yield higher speedups against the former.

Currently, Cyclosa focuses on mining unlabeled patterns because they generally yield higher computation complex-

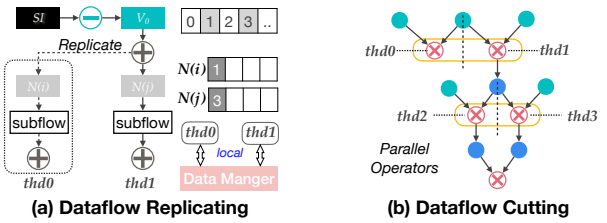

Figure 12: Parallel processing of the set dataflow that exploits multi-level parallelisms

Friendster (FR)	65.6M	1.8B	13.46GB

ity than the labeled ones. For handling labeled patterns, we can simply add label information as constraints in `Reducers`. During execution, the structural information of a pattern is first explored for set computation, and the label information is then used only for filtering elements in a set. The labels provide more filtering opportunities that help reduce the total workload amount with fewer redundancies. However, the proposed set dataflow can still benefit labeled patterns by exploring the explicit redundancies in the pattern topology. Note that the dynamic computation similarity may change when the high-degree vertices have different labels.

6 Implementations

Cyclosa is currently built with C++ as an in-memory system on a single machine. This section will introduce the parallel implementations in Cyclosa for mining flexible patterns.

Flexible Pattern Interpretation. Cyclosa provides a convenient interface, `PatternGraph()`, for users to construct flexible pattern graphs by providing exact structures or graph properties, e.g., the edge list of a triangle or clustering coefficient, through *EdgeList* and *Restriction* parameters. The above information will be automatically interpreted into possible patterns. Users only need to interact with the `PatternGraph()` while the underlying runtime is transparent.

Parallel Execution of Set Dataflow. We use OpenMP for parallel execution in Cyclosa. The set dataflow inherently provides multi-level parallelisms, as shown in Figure 12. First, the sub-parts of a dataflow can be replicated and assigned to different threads to exploit the data parallelism. The starting point of the replicas is divided by the `Generator`. Take Figure 12(a) for example. Two threads handle the neighboring sets of vertex 1 and 3, respectively. Second, the `Combiners` at the same depth can be conducted in parallel because there are no dependencies, as shown in Figure 12(b). Note that the thread-local memory maintains an input set and an output set for every dataflow node which are reused throughout the execution. Since the number of dataflow nodes is small and the input/output set size is limited to the maximum degree of the data graph, the thread-local memory is often small.

Load Balancing. The skewness in Cyclosa relates to different numbers of sets produced by `Generators`. We address it in two folds: 1) *Static task assignment.* The input of the first `Generator` is initialized by assigning the reordered graph vertices in a round-robin fashion. This makes the upper `Generators` in a dataflow for different threads produce similar workloads. 2) *Dynamic work stealing.* This can be safely realized by managing the independent thread-local set space. Specifically, Cyclosa identifies the input-set position in the dataflow of the busy thread and replicates its workloads and relevant local set states to idle threads, which launch their corresponding `Generators` with higher parallelism.

Parallel Data Management. The data management substrate maintains the data graph and computation results. The data graph is stored in the *Compressed Sparse Row* (CSR) format. For cliques, the graph is oriented by enforcing a direction between each pair of vertices to reduce workloads. The results buffers are implemented using a concurrent hash map with a fixed-size space. Each candidate set is independently allocated with the size of the maximum degree. In this way, we can keep a controlled memory consumption.

7 Evaluation

In this section, we evaluate the effectiveness of the set dataflow and present the efficiency of Cyclosa.

7.1 Methodology

Patterns and Graph Datasets. The real-world graph datasets in our experiments are shown in Table 1, which are from the Stanford SNAP collection of datasets [29]. They represent typical graphs from different domains and are widely used in previous works [21–23]. The graph pattern mining algorithms evaluated are classified into two categories: 1) single pattern query that includes mining the single non-clique patterns (SM) [24] and *cliques finding* (CF) [25], 2) multiple patterns query that includes mining all patterns with a certain number of vertices, i.e., counting *k-motifs* (*k*-MC) [30] and multiple patterns satisfying specific graph property like *pseudo cliques* (PC) which are constrained with the given density [31]. These applications cover different kinds of representatives of graph pattern mining algorithms in prior works [20–23, 32].

Baseline Systems. Cyclosa is compared with two state-of-the-art pattern-centric systems, GraphPi [22] and SumPA [23].

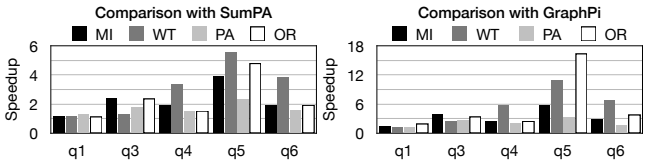

Figure 13: Performance comparison on listing single patterns

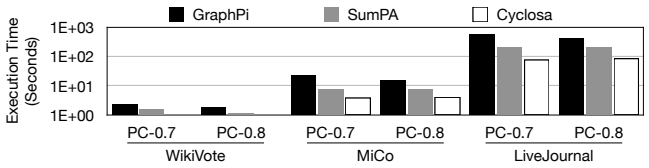

Figure 14: Performance on finding pseudo cliques

Table 2: Execution Time (Seconds) of Clique Finding

Systems	App.	MiCo	Patents	LiveJournal
Cyclosa	4-CF	0.23	0.11	2.27
	5-CF	21.82	0.29	463.02
SumPA	4-CF	1.21	0.37	5.98
	5-CF	50.77	0.45	1182.33
GraphPi	4-CF	1.64	0.44	12.14
	5-CF	60.51	0.52	1625.47

Table 3: Execution Time (Seconds) of Motifs Counting

Systems	App.	WikiVote	MiCo	Patents
Cyclosa	4-MC	1.25	9.56	6.81
	5-MC	257.34	1211.7	336.57
SumPA	4-MC	1.67	14.18	9.34
	5-MC	492.31	4789.5	662.03
GraphPi	4-MC	2.33	17.83	12.99
	5-MC	694.74	5803.97	803.55

Both systems are designed based on the mining procedure of Figure 1. GraphPi is a single pattern matching system that preserves the highest efficiency by finding an optimal combination of matching orders and symmetry constraints for an arbitrary pattern. SumPA is most related to our work and achieves higher performance on multiple patterns than prior works through a novel pattern abstraction.

Hardware Environments. All the experiments are conducted on a single server which is equipped with two 14-core Intel Xeon E5-2680v4 processors, 256GB RAM, and 512GB SSD. It runs a 64-bit Ubuntu 18.04 with kernel 5.4. We use gcc 7.3.0 to compile the applications with optimization under -O3. We use all the physical cores, and hyper-threading is enabled when the threads number exceeds 28.

7.2 Performance Comparison

Single Pattern Query. We first compare the performance of matching single non-clique patterns in Figure 3. These patterns are widely used in prior works [20, 21, 23]. Figure 13 shows the normalized speedups. Compared with GraphPi, Cyclosa achieves a speedup from 1.19× to 16.28×. The lowest speedup is for mining $q1$. Cyclosa can not only eliminate the explicit redundancies for $q1$ but also provide an efficient data graph layout. The highest speedup comes from $q5$ on Orkut. There are more implicit redundancies in $q5$ that cannot be removed by GraphPi, which can be explored in Cyclosa. Compared with SumPA, Cyclosa achieves a speedup from 1.13× to 5.52×. The pattern abstraction of SumPA can only expose parts of the explicit redundancies, while the set dataflow and smart cache in Cyclosa provide more opportunities for handling both explicit and implicit redundancies.

Table 2 shows the execution time for counting size-4 and size-5 cliques on different graphs. Overall, Cyclosa outperforms GraphPi by up to 7.13× and SumPA by up to 5.26× (4-CF on MiCo). GraphPi performs the lowest in all cases because all vertices in a clique are symmetric to each other, and the optimal matching order is unique. SumPA has limited improvement over GraphPi since the pattern abstraction will select a large sub-clique and omit opportunities for data reusing inside. In Cyclosa, the set dataflow can fully exploit the operands level redundancy for clique vertices, and the total workloads are reduced by graph orientation.

Multi-Pattern Query. We compare the performance of Cyclosa with SumPA and GraphPi on motifs counting and pseudo cliques. To support multiple patterns, we add a merging phase in GraphPi as in Automine [17]. Table 3 compares the execution time of counting size-4 and size-5 motifs on different graphs. With a larger size, the number of patterns increases (6 in 4-MC and 21 in 5-MC). Cyclosa outperforms SumPA and GraphPi by up to 3.95× and 4.79× for 5-MC on MiCo, respectively. The average speedups of Cyclosa on 4-MC and 5-MC of all cases are 1.64× and 2.95×. Note that Cyclosa achieves higher speedup when the pattern size and number increase. Existing approaches based on structural equality will face too many divergent branches when processing in-equal parts of these patterns. The set dataflow execution in Cyclosa can explore the computation similarity of both equal and in-equal parts.

Pseudo cliques (PC-k) algorithm finds patterns with a density greater than k. Figure 14 shows the results for mining all pseudo cliques with vertices less than six [23]. Notice that Cyclosa is superior to GraphPi and SumPA by 4.01× $\sim$ 7.52× and 1.48× $\sim$ 2.63×, respectively. Pseudo cliques are denser patterns, where one vertex is usually involved in most computations for other vertices. The set dataflow of Cyclosa can capture this similarity and fully reuse these operands as described in Section 2.4. Besides, the data management substrate can efficiently share results among different patterns.

Note that different mining algorithms can benefit from Cyclosa since the redundancies are highly related to the pattern topology and are independent of algorithm types. For larger patterns, more static similarity opportunities can be exploited. Also, an increased number of total computations amplifies the

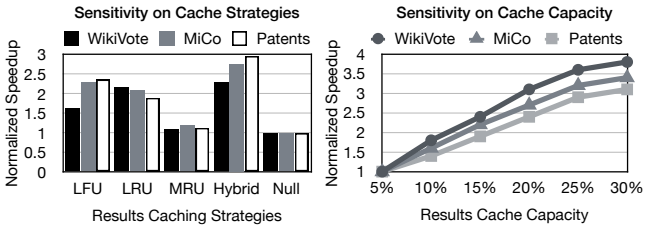

Figure 15: Normalized speedups under various settings of the cache capacity and caching strategy for 4-MC

Table 4: Execution Time (Seconds) on the Large Graph (FR)

App.	Cyclosa	SumPA	GraphPi
3-MC	94.26	143.38	281.42
4-CF	512.97	1491.72	1647.55

reusable computation amount arising from dynamic similarity. However, the size of set dataflow may increase and require more local memory space for parallel processing.

7.3 Sensitivity Study

Cache Strategy. The left chart in Figure 15 investigates the behaviors of different caching strategies for 4-MC. We fix the buffer capacity as 15% size of corresponding graphs. Notice that no single strategy can outperform others in all cases. Among all graphs, the LFU behaves better on Patents graph (2.36×), and the LRU behaves better on the WikiVote (2.17×). This is due to the diverse sparsity of the graphs, and the Patents graph is sparser than WikiVote. The MRU strategy is slowest in all cases, and this is because the results of high-degree vertices in the prior phase will be discarded even though they may be frequently reused. The hybrid strategy can combine the pattern and graph information to select the best buffer and thus achieves the highest performance.

Cache Capacity. The right chart in Figure 15 shows the normalized speedups with various buffer sizes. Initial buffer size is defined as the 5% size of a given data graph. Typically, larger cache capacity brings higher performance gains, e.g., 3.1× improvement from 5% to 20% on WikiVote, because more results can be cached and reused. However, the growth slows down gradually while increasing the buffer size. The main reason is that a larger buffer size induces higher latency in maintaining and querying the results.

7.4 Scalability

Figure 16 compares the performance of different systems by varying the number of threads. The results are normalized to GraphPi with a single thread. Hyperthreading is enabled when the number of threads exceeds 28. For GraphPi and SumPA, each thread is saturated with computations. More threads offer more compute parallelism but have to compete for computation resources. Thus, hyperthreading improves efficiency,

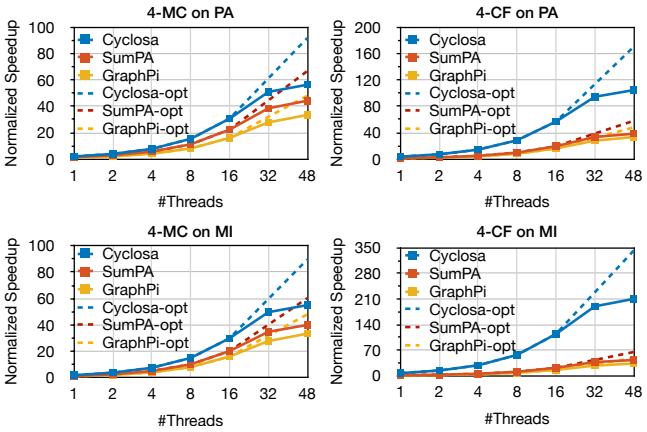

Figure 16: The normalized speedups with various number of threads for different applications

Table 5: Memory Consumption on Orkut with 28 Threads

Systems	4-CF	4-MC	5-MC	PC-0.8
Cyclosa	2.69GB	2.75GB	2.96GB	2.94GB
GraphPi	3.81GB	3.83GB	4.16GB	3.97GB

but the growth slows down gradually. Cyclosa resolves the redundant computation bottleneck, therefore offering more speedups against the above earlier systems. However, memory access contention becomes important when hyperthreading is used, incurring the increasingly-saturated performance improvement as shown in Figure 16. This is because Cyclosa has to maintain and query the results cache.

We also test the ability of Cyclosa to scale to large graphs with billion edges, as shown in Table 4. For size-3 motifs counting, Cyclosa gains 1.52× and 2.99× speedups over SumPA and GraphPi. Cyclosa outperforms SumPA and GraphPi on the Friendster graph for size-4 clique by 2.91× and 3.21×, respectively. Caching the results for large graphs is difficult because of the vast amount of intermediates. The performance improvement proves the efficiency of the set dataflow and caching strategies on larger graphs.

7.5 Overhead

Memory Consumption. Table 5 compares the memory consumption of Cyclosa and GraphPi on the Orkut graph. Cyclosa and GraphPi take an average of 2.84GB and 3.94GB of memory space in these cases. Although Cyclosa needs to maintain some of the results, the memory footprint is still kept small. This is because GraphPi maintains intermediate subgraph instances while Cyclosa shares the same result set for different vertices and executes the dataflow in a DFS style. Each thread in Cyclosa only maintains a local space for each set dataflow node. Besides, the smart caching strategies explore the trade-off between the space efficiency and reuse possibility. The memory space in the data management substrate is

Table 6: Time for Constructing Set Dataflow

App.	WikiVote	Patents	Orkut
5-CF	1.74ms	1.72ms	1.69ms
5-MC	9.32ms	9.44ms	9.37ms
PC-0.8	3.16ms	3.09ms	3.22ms

pre-allocated by a small fixed size.

Dataflow Construction. Table 6 presents the dataflow constructing time for different applications. This includes pattern analysis to get matching order, building the set dataflow, and evaluating redundancy probability. The triangle counting time is excluded because it is only conducted once and can be reused for different algorithms. Notice that the constructing time rises when the number of patterns increases. However, the dataflow construction is only executed once throughout processing and is negligible compared with the computation time. For example, it takes over 250s for 5-MC on WikiVote, while the dataflow construction only takes 9.32ms.

8 Related Work

Early graph pattern mining research focuses on customized improvements for specific given algorithms. For counting cliques, kClist [33] designs an efficient algorithm for processing sparse graphs based on the core value. To handle motifs effectively, G-tries [34] creates a novel tree-like data structure. PGD [26] counts all size-3 and size-4 motifs using partial patterns by some combinatorial rules. There have also been works that use GPUs to speed the subgraph isomorphism problem in finding network motifs and enumerating subgraphs [18, 35–37]. Cyclosa, as opposed to algorithm-specific improvements, focuses on tackling the common redundancy challenges in a more general situation. Prior optimizations can also be integrated into Cyclosa.

General-purpose graph pattern mining systems use expressive and efficient programming paradigms to automatically parallelize a variety of graph mining applications in a consistent manner [16, 38]. Early distributed systems, such as Arabesque [16] and Fractal [19], adopt the embedding-centric model to iteratively extend and enumerate all subgraphs size by size and verify the user-defined constraints for each intermediate embedding. RStream [39] and Kaleido [40] optimize the embedding-centric model in an out-of-core manner on a single machine to alleviate the data shuffling and communication cost. Pangolin [41] and Sandslash [42] provide flexible interfaces that integrate customized algorithmic optimizations to enhance the filtering of intermediate embeddings. Despite the expressiveness and massive parallelisms of these systems, managing a large number of intermediate embeddings becomes the main bottleneck, which suffers from high memory consumption and heavy I/Os [15].

Compared to the embedding-centric model, Cyclosa works in a pattern-aware manner, pioneered by AutoMine [17] and Peregrine [20], to avoid unnecessary storage and process of embeddings under the guide of pattern constraints. The cores of these systems are efficient matching engines that execute fast set operations [27]. AutoMine is a compilation-based system that automatically transforms graph patterns into set programs. GraphZero [21] is an enhanced version of AutoMine that removes explicit redundancies among multiple patterns by introducing the symmetry-breaking optimizations that define a partial order between symmetric vertices. GraphPi [22] further explores the optimal combination of matching orders and symmetry-breaking constraints to speed set programs. Despite the efficiency, the compilation method may induce non-negligible overhead while generating new set programs for newly coming patterns. Dryadic [43] proposes a flexible tree-structured intermediate representation to solve this problem, which supports both compilation and runtime optimizations. DecoMine [28] decomposes a large pattern into smaller ones for faster pattern counting. SumPA [23] merges multiple patterns in a pattern abstraction to minimize workloads. Cyclosa aims to eliminate the inherent computation redundancies, and the data management substrate can also be integrated into the above systems to reduce redundancies.

9 Conclusion

In this work, we present a redundancy-free framework, Cyclosa, that eliminates both explicit and implicit redundancies in pattern-centric graph mining systems. Cyclosa explores the computation similarity through a novel set dataflow representation, which exploits a finer-grained similarity at the operand level instead of the structural equality as in existing works, making it possible to indicate both explicit and implicit redundant computations. Based on the set dataflow, Cyclosa implements an efficient dataflow-guided execution model collaborated with a memory-friendly data management substrate to efficiently reuse computing results, embracing high performance and correctness. The proposed substrate may also be incorporated into the runtime of existing systems to reduce redundancies. Evaluation of a variety of patterns and real-world graphs shows that Cyclosa can significantly outperform state-of-the-art systems GraphPi by up to 16.28× and SumPA by up to 5.52× for various applications.

Abstract

Random walks serve as a powerful tool for extracting information that exists in a wide variety of real-world scenarios. Different from the traditional first-order random walk, the second-order random walk considers recent walk history in selecting the next stop, which facilitates to model higher-order structures in real-world data. To meet the scalability of random walks, researchers have developed many out-of-core graph processing systems based on a single machine. However, the main focus of out-of-core graph processing systems is to support first-order random walks, which no longer perform well for second-order random walks.

In this paper, we propose an I/O-optimized out-of-core graph processing system for second-order random walks, called SOWalker. First, we propose a walk matrix to avoid loading non-updatable walks and eliminate useless walk I/Os. Second, we develop a benefit-aware I/O model to load multiple blocks with the maximum accumulated updatable walks, so as to improve the I/O utilization. Finally, we adopt a block set-oriented walk updating scheme, which allows each walk to move as many steps as possible in the loaded block set, thus significantly boosting the walk updating rate. Compared with two state-of-the-art random walk systems, GraphWalker and GraSorw, SOWalker yields significant performance speedups (up to 10.2×).

1 Introduction

Random walks on graphs have received significant attention for their ability to extract meaningful insights in graph data analysis and machine learning [10–14]. Most existing random walk implementations are based on the first-order Markov model [15, 16], which assumes the transition probability only depends on the current vertex and is independent of the previous information. Although many encouraging results have been obtained under this assumption, the high-order information such as second-order properties is ignored, and thus some recent works have revealed the necessity of second-order random walks [17, 18]. Node2vec [14], one of the most popular network embedding methods, uses the second-order random walk to capture neighborhood information of vertices, which significantly outperforms the first-order methods like DeepWalk [13]. Similar findings have been found in graph proximity measurements. Wu et al. [19] developed the second-order PageRank and SimRank, and Liao et al. [20] proposed the second-order CoSimRank, which can explore cluster structures in the graph and better model real-world applications. In addition, the random walk has been widely used in social physics. Rosvall et al. [21] showed how the second-order random walk model constraints on dynamics influence community detection, ranking, and information spreading, while it is difficult for the first-order random walk in these scenarios.

Graphs with billions of edges are becoming more prevalent in many domains, and performing some tasks often requires tens of TB to several PB spaces. Although some vendors such as Amazon (AWS) [6], Oracle [7], and Microsoft [8] provide graph database services, striking a balance between low cost and high quality remains challenging. For example, when processing our largest graph, CrawlWeb (see Section 4.1), on Amazon Neptune [9], we use an Amazon Elastic Compute Cloud (EC2) instance, db.r5.4xlarge (8 cores, 16 virtual cores, 128 GB memory), and 3 TB of storage space. The monthly cost for this instance is up to $3, 000. As the size of the graph continues to grow, the storage requirements and computational resources needed would also increase. This would likely lead to higher costs in terms of storage space, computing resources, and potentially data transfer. In contrast, out-of-core graph processing systems are cheaper and easier, as they utilize external storage for processing large graphs [22–25]. These systems divide a large graph into several blocks (i.e., subgraphs) and store them on disks. During the graph processing, a block is loaded into memory and application-specific vertex or edge values in this block can be updated immediately. As expected, the significant performance bottleneck of out-of-core graph processing systems is the I/O between memory and disks, and developers can ill afford to ignore it. Recently, numerous works have been devoted to designing I/O-efficient graph processing systems for random walks.

DrunkardMob [26] is the first large-scale out-of-core graph processing system that allows massive random walks to be performed in parallel. The states of all walks are represented compactly in memory to minimize the memory footprint of each walk. GraphWalker [27] adopts a state-aware I/O model and an asynchronous walk updating scheme to further improve the I/O performance. Besides, it proposes a lightweight block-centric indexing scheme to reduce the memory requirement for storing walk states. However, these proposed solutions cannot be efficiently compatible with second-order random walks.

In this paper, we propose an I/O-optimized out-of-core graph processing system for second-order random walks, called SOWalker. First, to eliminate useless walk I/Os, we propose a *walk matrix* to represent the walks, so as to prevent loading non-updatable walks whose previous vertices are not in memory. Along with the proposed walk matrix, we design a succinct and compact data structure to provide an efficient representation of a walk. Second, to improve the I/O utilization, we develop a *benefit-aware I/O model*. Specifically, we load multiple blocks with the maximum accumulated updatable walks and only load walks whose previous and current vertices are both in the loaded blocks. For this purpose, we map the block scheduling problem into the maximum edge weight clique problem, and adopt a heuristic algorithm to provide comparable I/O performance but significantly reduce the computation time. Finally, to boost the walk updating rate, we adopt a *block set-oriented walk updating scheme*, which allows each walk can be updated as much as possible in the loaded block set, so as to accelerate the progress of random walks. To summarize, we make the following contributions.

- We propose a *walk matrix*, which prevents loading non-updatable walks, so as to eliminate useless walk I/Os.
- We develop a *benefit-aware I/O model*, which loads multiple blocks with the maximum accumulated updatable walks, so as to maximize the I/O utilization.
- We adopt a *block set-oriented walk updating scheme*, which allows each walk to move as many steps as possible in the loaded block set, so as to boost the walk updating rate.
- We conduct detailed experiments on a variety of real-world and synthetic graphs to evaluate SOWalker. Extensive evaluation results show that SOWalker can substantially reduce the I/O cost, achieving up to 10.2× speedup.

The rest of this paper is organized as follows. Section 2 presents the background and motivation. Section 3 describes the detailed system designs of SOWalker. Section 4 evaluates the system and compares it with two state-of-the-art systems. Section 5 gives an overview of related work, and finally, Section 6 concludes this paper.

2 Background and Motivation

Given a graph $G = (V, E)$, where V and E are the set of vertices and edges, respectively. Each edge $e \in E$ is an ordered pair $e = (u, v)$ and is associated with a weight w_{uv}. For each $u \in V$, the neighbor set of a vertex u is $N(u)$. For easy reference, we illustrate the frequently used notations in Table 1.

Notation	Description
$G = (V, E)$	graph G with vertex set V and edge set E
$e = (u, v)$	edge from u to v
w_{uv}	weight between vertex u and v
$N(u)$	set of neighbor vertices of vertex u
B	block set
$\|B\|$	number of blocks in B
m	maximum number of blocks cached in memory
B_L	loaded block set in a batch
$W(i, j)$	number of walks crossing between block i and j
AUW	accumulated updatable walks
CDG	complete directed graph
k	actual number of blocks to be loaded
β	a bitmap to represent whether the block is cached in memory
T_0, T_s	initial temperature and end temperature
γ	cooling coefficient of temperature
$iter_{max}$	maximum number of iterations

Table 1: Notations.

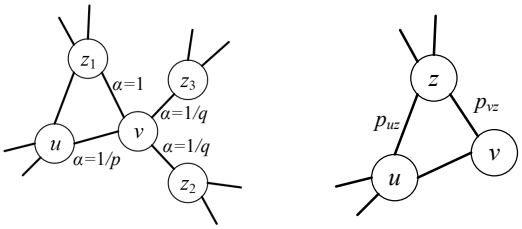
2.1 Second-order Random Walk

First-order random walk. Suppose a walk is visiting vertex v, in the next step, the walk will move to a neighbor of v with transition probability $p_{vz} = P(z|v) = w_{vz}/W_v$, where $W_v = \sum_{t \in N(v)} w_{vt}$.

Second-order random walk. Given that the walk is visiting vertex v at the current step and vertex u at the previous step, the second-order transition probability that moving to vertex z at the next step is $p_{uvz} = p(z|uv)$. Such transition probability can be interpreted as the edge-to-edge transition probability: let $\alpha = (u, v)$ be the edge from vertex u to v, and $\beta = (v, z)$ be the edge from vertex v to z, that is, $p_{uvz} = p_{\alpha\beta}$.

Below are two representative examples of second-order random walk-based algorithms.

Node2vec. Node2vec [14] is a popular network embedding method that introduces the second-order random walk. In order to combine Depth First Search (DFS) and Breadth First Search (BFS), two parameters p and q control the random walk strategy. Parameter p controls the probability of repeated access to the just visited vertex. Parameter q controls whether a walk moves inward or outward. Given that vertex u was visited at the previous step, the unnormalized transition probability p_{uvz} from the current vertex v to the



(a) Node2vec (b) Second-order PageRank

Figure 1: The transition probability computation in second-order random walk algorithms.

next vertex z depends on the edge weight w_{vz} and $\alpha_{pq}(u,v,z)$, i.e., $p_{uvz} = \alpha_{pq}(u,v,z) \cdot w_{vz}$. α_{pq} is calculated in the following formula (shown in Figure 1(a)):

$$\alpha_{pq}(u,v,z) = \begin{cases} \frac{1}{p}, & d_{uz} = 0 \\ 1, & d_{uz} = 1 \\ \frac{1}{q}, & d_{uz} = 2 \end{cases}$$

where d_{uz} denotes the shortest path distance between vertices u and z, and $d_{uz} \in \{0,1,2\}$.

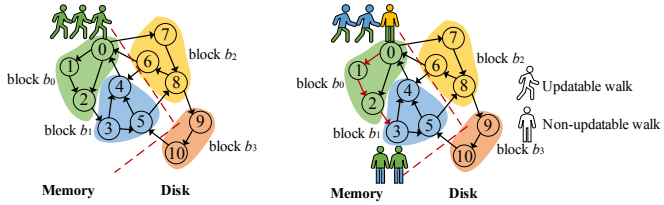
Second-order PageRank. Wu et al. [19] proposed a second-order PageRank and used an autoregressive model to compute the second-order influence probability, which is described as follows:

$$p_{uvz} = \frac{p'_{uvz}}{\sum_{t \in N(v)} p'_{uvt}}$$

where $p'_{uvz} = (1-\alpha)p_{vz} + \alpha p_{uz}$ (shown in Figure 1(b)). The parameter $\alpha \in [0,1)$ is a constant (e.g., 0.2) to control the strength of effect from the previous step.

2.2 Motivation

The out-of-core random walk systems divide a graph into several blocks and cache some of them in memory, the remainder blocks reside in disks temporarily. The total number of cached blocks is limited by the available memory and block size. During the random walk procedure, a block is loaded from disk into memory according to a scheduling model, which is called the *current block*. Walks that reside on the current block are also loaded into memory and can be updated as much as possible until they reach the boundary of the loaded block. However, the main focus of out-of-core random walk systems is to support first-order random walks, which are no longer effective for second-order random walks. In the following, we will discuss three major challenges that lead to poor I/O performance on existing systems.



(a) First-order random walks (b) Second-order random walks

Figure 2: Differences in updatable walks between (a) first-order random walks and (b) second-order random walks. All three first-order random walks are updatable as opposed to only two second-order random walks. View in color for optimal visualization.

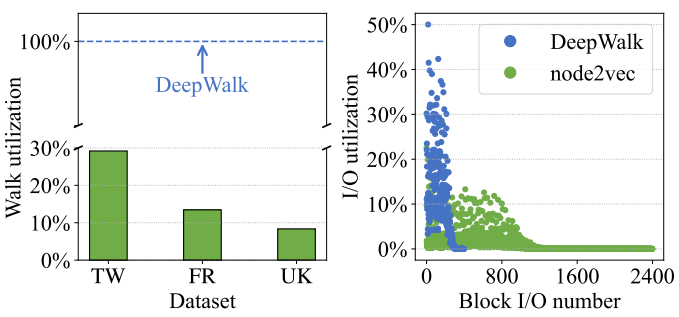
Non-updatable walks result in useless walk I/Os. The first-order random walk's transition probability only depends on the current vertex. As long as the current vertex is in memory, the walk can be immediately updated. Unlike the first-order random walk, the second-order random walk considers recent walk history in selecting the next stop. However, the previous vertex might belong to other blocks on slow disks. Consequently, due to the lack of previous vertex information, some loaded walks cannot be updated directly, resulting in *non-updatable walks*. As a result, these non-updatable walks lead to useless walk I/Os.

As an example, Figure 2 illustrates the differences in updatable walks between first-order and second-order random walks for a specific iteration, where block b_0 and b_1 are in memory, and block b_0 is the current block. Suppose that there are three walks residing on vertex 0. For first-order walks in Figure 2(a), all three walks are updatable. As a result, the walk utilization of first-order random walks is always 100%, which is defined as the ratio of updatable walks to the total loaded walks. For second-order walks in Figure 2(b), the color of the walk represents its state, with the upper and lower colors indicating the block that the previous and current vertex belongs to, respectively. Out of the three walks, one has its upper half-colored yellow, indicating that its previous vertex belongs to block b_2, which is not in memory. As a result, this walk is non-updatable, resulting in the walk utilization of only 2/3. In order to further quantitatively evaluate the walk utilization of node2vec on real-world graphs, we conducted experiments on three datasets (introduced in Section 4.1). As shown in Figure 3(a), the walk utilization of node2vec is less than 30%, and it decreases as the size of the graph increases.

In SOWalker, we propose a walk matrix, which prevents loading non-updatable walks to eliminate useless walk I/Os.

The non-optimal block scheduling model results in low I/O utilization. To update non-updatable walks, the existing block scheduling model [27, 28] iteratively loads ancillary blocks where previous vertices belong to, resulting in a large number of additional block I/Os. On the other hand, due to the irregular structure of graphs and the randomness inherent in random walks, previously visited vertices are unevenly scattered in different blocks.

To quantify the effect of the non-optimal block scheduling model on I/O utilization, we run DeepWalk (i.e., first-order) and node2vec (i.e., second-order) on a state-of-the-art system, GraphWalker [27]. The I/O utilization is defined as the num-



(a) Walk utilization (b) I/O utilization

Figure 3: Walk utilization and I/O utilization.

ber of walk steps divided by the number of edges in a loaded block. For Deepwalk, we use GraphWalker's state-aware I/O model to preferentially load the block with the most walks into memory. For node2vec, we also load a block with the most walks as the current block and iteratively load another block into memory as the ancillary block. Figure 3(b) shows the I/O utilization of DeepWalk and node2vec. We can see that the I/O utilization is significantly low in the second-order random walk application. Besides, running DeepWalk requires fewer than 400 block I/Os, while running node2vec requires over 2400 block I/O, which severely slows down the processing of random walks.

In SOWalker, we develop a benefit-aware I/O model, which loads multiple blocks with the maximum accumulated updatable walks to maximize the I/O utilization.

The block-oriented walk updating scheme brings low walk updating rate. Existing systems [27] manage walks at a block granularity and restrict walk updating to a block, which is called *block-oriented walk updating*. However, this hinders the walk updating and walks fail to utilize the vertex information in other blocks residing in memory, resulting in low walk updating rate. For example, in Figure 2(b), suppose that two updatable walks move along the red path toward vertex 3. Under the block-oriented walk updating scheme, block b_1, where vertex 3 belongs to, is not the current block, so the walks cannot continue to move, which leads to low walk updating rate. In fact, if a walk moves to any vertex belonging to the block in memory, it can further be updated, since the previous and current vertex information are both available.

In SOWalker, we adopt a block set-oriented walk updating scheme, which allows each walk to move as many steps as possible in the loaded block set to boost the walk updating rate.

3 Design of SOWalker

In this section, we first present the system overview of SOWalker. Then, we introduce the detailed designs including the walk matrix, benefit-aware I/O model, and block set-oriented walk updating scheme.

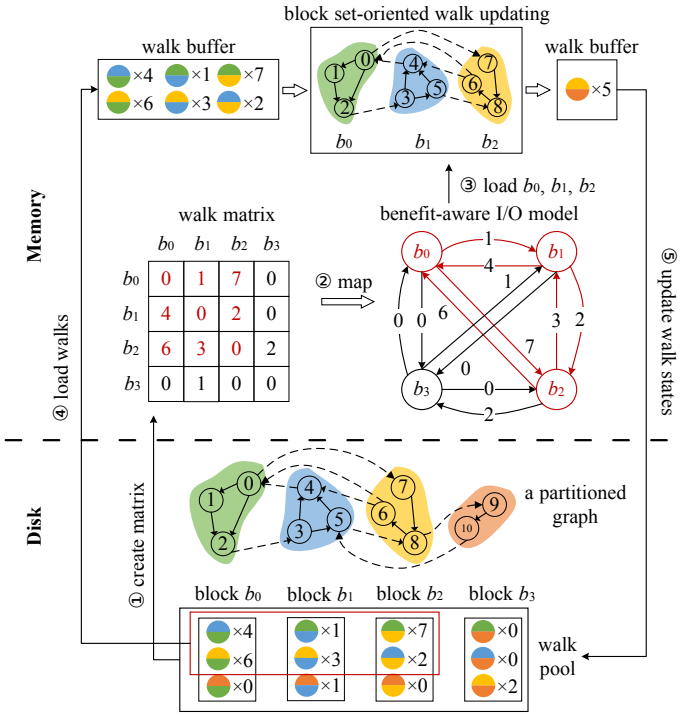


Figure 4: Overall design of SOWalker. View in color for optimal visualization.

3.1 System Overview

Figure 4 shows the overall design of SOWalker. To represent large graphs in the external memory setting, the graph is often partitioned into several blocks and stored on disks, and each block is associated with a walk pool storing the temporarily non-updatable walk states. A semi-circle in the walk pool is a vertex in a walk, with the color of the upper and lower semi-circle indicating the block that the previous and current vertices belong to, respectively. '$\times n$' means there are n walks of such state. Considering that the previous and current vertices may belong to two blocks, we propose a *walk matrix* to intuitively show the number of walks crossing between blocks. The values in the walk matrix are created and updated based on the walk states in the walk pool (①).

During the random walk procedure, we first load m blocks simultaneously to fit into memory, where m denotes the maximum number of blocks cached in memory. Suppose that $m = 3$ in Figure 4. We define loading a block as one *block I/O*, and scheduling and loading m blocks at the same time as a *batch*. To maximize accumulated updatable walks in a batch, we develop a *benefit-aware I/O model*. Specifically, relationships between blocks (i.e., the values in the walk matrix) can be mapped as a directed complete graph (②), and the block scheduling can be modeled into the maximum edge weight clique problem. Nodes in the clique are the blocks to be loaded. As an example in the figure, there are 23 updatable walks in block b_0, b_1, and b_2, which is the maximum

among all candidate block sets. Therefore, we load the three blocks into memory (③, shown as red nodes), and only load the walks whose previous and current vertices are both in the loaded blocks (④, walks in red box).

During the updating phase, we adopt a *block set-oriented walk updating scheme* that allows walks to access vertices in all loaded blocks since there are some edges connecting blocks (shown as arrows with dashed lines). That is to say, if the next vertex is still in memory, the walk can keep moving until it reaches a termination condition or visits a vertex belonging to a disk block. Here, 18 walks finish and the remaining 5 walks move to block b_3. When there are no more walks in memory, update the walk states in the walk pool (⑤). Repeat the process of block loading and walk updating until all random walks are finished.

3.2 Walk Matrix Representation

In order to skip loading non-updatable walks and eliminate useless walk I/Os, we use a walk matrix to represent the walks. The dimensionality of the matrix is the number of blocks. Each element (i, j) in this matrix represents the walks whose previous vertex belongs to block i, and the current vertex belongs to block j. The sum of all elements is the number of unfinished walks. The walk matrix is created and updated according to the walk states in the walk pool. In each batch, m blocks are selected based on the number of walks in the walk matrix, which will be discussed in Section 3.3. When all the walks in memory have been finished or have reached the boundary of the loaded block set, SOWalker checks the walk states to obtain the block IDs of the previous and current vertices. If the IDs are different, it means the walk is crossing blocks. Count the number of such walks that cross blocks and update the corresponding element of the walk matrix. Based on the walk matrix, SOWalker can readily check whether a walk can be updated, judging that both the previous vertex and the current vertex are in memory, thus skipping loading non-updatable walks and eliminating useless walk I/Os.

Figure 5 shows the detail of walk matrix W. The elements in W represent the number of walks crossing blocks at the current time. Suppose a graph is divided into 8 blocks, and the maximum number of blocks cached in memory is 3. If SOWalker selects blocks b_0, b_1, and b_2 to load into memory, then only the updatable walks, which are in the red box need to be loaded. Other walks do not need to be loaded because the blocks containing the previous or previous vertices are not in memory. Note that the number of walks in $W(i,i)$ is always 0 because the walk whose previous and current vertices are in the same block can be updated without additional block I/Os. Without the walk matrix, walks whose current vertices are in blocks b_0, b_1, and b_2 will be loaded (in the green box). However, the walks in the set difference of the green box and the red box are non-updatable walks.

In order to organize the walk data more compactly, we adopt a succinct data structure to encode each walk with 128 bits as shown in Figure 5 (on the right). *source*, *previous* and *current* is encoded in 29 bits, which represents the start vertex, previous vertex, and current vertex of a walk respectively. In this way, SOWalker can support starting random walks from 2^{29} source vertices simultaneously. Commonly, random walks are fed into downstream tasks, so it is necessary to save walk paths easily. In order to identify each walk quickly, we encode *walk ID* in 34 bits, which supports a maximum of 32 (i.e., $2^{34}/2^{29}$) walks starting from each vertex. Besides, *hop* indicates the number of steps the walk has already moved.

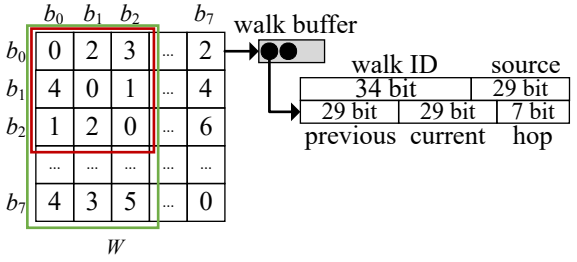

Figure 5: Walk matrix representation.

3.3 Benefit-Aware I/O Model

This section discusses how to efficiently schedule blocks. Since the previous and current vertices of a second-order random walk may belong to different blocks, we need to consider dependencies between blocks. Thus, we simultaneously schedule multiple blocks, instead of one block. Specifically, to improve the I/O utilization, we propose a benefit-aware I/O model to load multiple blocks with the maximum accumulated updatable walks. For this purpose, we formulate the block scheduling problem as the maximum edge weight clique problem. We also adopt an efficient heuristic algorithm to provide comparable I/O performance with a fraction of the cost.

Problem definition. Suppose the block set is B, $|B|$ is the number of blocks, and m is the maximum number of blocks cached in memory. $W(i, j)$ denotes the number of walks crossing between block i and j, that is, the values in the walk matrix. B_L is the loaded block set in a batch. The goal of block scheduling is to load multiple blocks with the maximum accumulated updatable walks, so the benefit is measured in terms of the *accumulated updatable walks* (*AUW*), defined as:

$$AUW(B_L) = \sum_{i \in B_L} \sum_{j \in B_L} W(i, j) \tag{1}$$

Problem mapping. Here, the relationship between blocks can be illustrated with a complete directed graph. The edge weight between two neighborhood blocks denotes the number of walks crossing between two blocks. For the block set B, the complete directed graph (*CDG*) is defined as:

$$CDG = (B, E) \tag{2}$$

$$E = \{e_{ij} = W(i,j) | i, j \in B\} \tag{3}$$

To maximize the accumulated updatable walks, we convert the block scheduling problem into the maximum edge weight clique problem, i.e., maximizing the sum of edge weights from all the feasible candidates.

Definition 1 (*Maximum Weighted Scheduling*, *MWS*): Given the complete directed graph $CDG = (B, E)$ along with the memory capacity requirements, MWS produces the loaded blocks, which satisfies that (1) the block scheduling problem is feasible according to the memory capacity requirements, i.e., the maximum number of blocks cached in memory; (2) the block scheduling problem produces the maximum sum of edge weights that maximizes the number of accumulated updatable walks in a batch.

Taking into account both the memory capacity and maximizing the sum of edge weights, the MWS is formulated as:

$$\max \sum_{i} \sum_{j} e_{ij} y_{ij} \tag{4}$$

$$\text{s.t.} \sum_{i=0}^{|B|-1} x_i = m \tag{5}$$

$$y_{ij} \leq x_i \tag{6}$$

$$y_{ij} \leq x_j \tag{7}$$

$$x_i, y_{ij} \in \{0, 1\} \tag{8}$$

where the variable x_i equals one if block i is loaded in memory. Constraint 5 guarantees that only m blocks can be chosen. By Constraints 6 and 7, for any edge (i, j), a binary variable $y_{ij} = 1$ if and only if both $x_i = 1$ and $x_j = 1$.

To maximizes $AUW(B_L)$, MWS must select m blocks for scheduling, but it ignores the contribution to block I/O reduction. In fact, the candidate block cached in memory does not yield block I/O but the walks in that block can be updated. Therefore, we aim to maximize the number of accumulated updatable walks in a block I/O. The objective function is redefined as:

$$\max_{B_L} S = \frac{AUW(B_L)}{k} \tag{9}$$

where k is the actual number of blocks to be loaded.

We use a bitmap β to record whether the block is cached in memory. If block i is in memory, the bit of block i is set to 1, i.e., $\beta_i = 1$. Otherwise, the bit is set to 0. By identifying which blocks are in memory, we can fully utilize the blocks in memory. Based on this consideration, we try to add the following constraint to the formulation:

$$\sum_{i=0}^{|B|-1} \beta_i \cdot x_i = m - k \tag{10}$$

where $m - k$ chosen blocks are already in memory. Constraint 10 ensures that the chosen block i does not need to be loaded, if and only if $\beta_i = 1$ and $x_i = 1$. We iterate over all $k \in [1, m]$ to find the optimal solution.

Algorithm 1: SA-based benefit-aware I/O model

Input: $CDG = (B, E)$, B_0: initial block set
Output: the loaded block set B_L

```
Function SelectBlocks(CDG=(B,E), B_0):
    B_L ← B_0                    // initial block set
    t ← T_0                      // initial temperature
    i ← 0                        // iteration counter
    while t ≥ T_s and i ≤ iter_max do
        B_c ← CHOOSENEWBLOCK(CDG, B_L)
        ΔS = S(B_c)-S(B_L)
        if ΔS>0 or e^(ΔS/t) > random(0,1) then
            B_L ← B_c
        t ← γt
        i ← i+1
    return B_L
```

The above linear programming method can guarantee the optimality of the solution obtained. However, the complexity of this problem is in order of 2^n [29]. As the scale of the problem is increasing, the complexity also soars. To settle the problem in a reasonable time, we adopt a heuristic algorithm to provide sub-optimal solutions, which is possible to solve large-scale problems within an acceptable time [30].

Solutions via heuristic algorithm. Since the maximum edge weight clique problem is NP-hard [31], many heuristic algorithms have been proposed to achieve a reasonable trade-off between computation time and solution quality. Simulated annealing (SA) is a local search procedure to find an efficient and feasible solution. In order to escape from local optima, a worse solution is accepted as the new solution with a probability that decreases as the computation proceeds. Despite its simpler structure and fewer parameters, SA has shown competitiveness in searching for optimal or near-optimal solutions and has been widely used to solve the maximum edge weight clique problem [32–35].

Inspired by Ernst et al. [35], we also use SA to select a loaded block set to maximize the number of accumulated updatable walks in a block I/O. The establishment of the objective function is described according to Equation 9. The detailed procedures of the SA-based benefit-aware I/O model is given as follows. Algorithm 1 illustrates the pseudo-code of this model.

Step 1: Initialize. Set initial temperature T_0, end temperature T_s, cooling coefficient γ of temperature, and the maximum number of iterations $iter_{max}$, where $iter_{max} = C^m_{|B|}$. Previous work has shown that a good initial solution results in faster convergence and improves the quality of the solution [36, 37]. In order to find a reasonably good initial block set, blocks appear in descending order of the number of walks in it. We

choose the top-m block as the initial block set B_0, meaning the block with more walks is more likely to be loaded into memory.

Step 2: Accept or reject the new solution. SA works iteratively by successively replacing the current solution with a random solution. In each iteration, randomly remove a selected block from the current block set B_L. Then, one of the remaining blocks is chosen randomly, and getting a new candidate block set B_c. Compute the difference between the new candidate block set B_c and the current block set B_L, i.e., the increment of the objective function $\Delta S = S(B_c) - S(B_L)$. If B_c is better, i.e., $\Delta S \geq 0$, then it will be accepted. Otherwise, it will be accepted with probability $p = e^{\Delta S/t}$, where t denotes the current temperature. Generate a random number ζ, where $\zeta \in [0,1]$. If $p > \zeta$, then B_c will be accepted. Otherwise, it will be rejected.

Step 3: Continue or end. Compute current temperature $t = \gamma t$ and the number of iterations $i = i + 1$. If $t < T_s$ or $i > iter_{max}$, end the algorithm. Otherwise, go back to step 2.

Compared to the exact but complicated linear programming method, SA provides an approximate solution but is much simpler, which yields orders of magnitude speedup and the computation time is only a small fraction of the total execution time (see Section 4.4.1).

3.4 Block Set-Oriented Walk Updating

Existing random walk systems partition a graph into several blocks. The block loading and walk management are at a block granularity, resulting in the walk updating being limited to a single block, called *block-oriented walk updating*. Once a walk reaches the boundary of the current block, the updating of a walk will be stopped. However, such a strategy hinders the walk updating and potentially increases the number of block I/Os.

To see this problem more concretely, we will consider a partitioned graph in Figure 4. The graph is partitioned into four blocks. Suppose two blocks are cached in memory and all walks start at vertex 0. We use the state-aware I/O model in GraphWalker [27] to load the block containing the largest number of walks as the current block, and iteratively load another block as the ancillary block. We skip loading the blocks without containing any previous vertex information. Figure 6(a) shows the process of block-oriented walk updating. (i, j) means the blocks cached in memory, where i is the current block, and j is the ancillary block. Only the walk in the current block can be updated. '+' means the lasted loaded block. As a result, 10 block I/Os are required and the walk steps per block I/O is 2.4.

We argue that although a graph is partitioned into several blocks, walks can move across blocks via the cut edges between these blocks. Thus, if a walk moves to any vertex belonging to the block in memory, it can further be updated, until it reaches the boundary of the block set in memory and moves to the block in disk. Such walk updating is called *block set-oriented walk updating*, which is illustrated in the example in Figure 6(b). In the first batch, blocks b_0 and b_1 are loaded into memory. Walk w_1 can be finished directly without extra block I/Os. While it needs 4 block I/Os in the block-oriented walk updating scheme. In the third batch, both walk w_0 and w_2 can be updated. In contrast, in the block-oriented walk updating scheme, only the walk in the current block can be updated. As a result, the number of block I/Os is reduced to 6 and the walk steps per block I/O increases to 4. The reason is that the block set-oriented walk updating allows walks to repeatedly visit the block in memory, which boosts the walk updating rate and accelerates the random walk process. Recently, GraSorw [28] also allows walks to be updated across the blocks. However, it limits the number of blocks in memory to 2, which is less flexible for different-scale graphs and random walks.

(i, j)	Walk paths
$(+b_0, +b_1)$	w_0: 0→7 w_1: 0→1→2→3 w_2: 0→2→3
(b_1, b_0)	w_1: 3→4→0 w_2: 3→5→8
$(+b_2, b_0)$	w_0: 7→8→6→4
$(b_2, +b_1)$	w_2: 8→6→0
$(+b_0, b_1)$	w_1: 0→2→3
$(b_0, +b_2)$	w_2: 0→1→2 (end)
$(+b_1, b_0)$	w_1: 3→4 (end)
$(b_1, +b_2)$	w_0: 4→0

4 Evaluation

In this section, we evaluate the effectiveness of SOWalker. First, we introduce our experimental setup. Then, we compare SOWalker with two state-of-the-art random walk systems, GraphWalker [27] and GraSorw [28], in terms of overall performance and I/O efficiency. Third, we evaluate the effect of different block scheduling models. Finally, we analyze the impact of block size.

4.1 Setup

Environment. The hardware platform used in our experiments is a commodity server equipped with a 32-core 2.10 GHz Intel Xeon CPU E5-2620 with 128GB main memory and a 3TB HDD, running Ubuntu 20.04 LTS. SOWalker is implemented in around 4, 000 lines of C++ code and compiled by g++ 9.4.0 with an optimization flag as -O3. We use OpenMP for parallel random walks, and the number of threads is set to 32 unless explicitly specified. The reported results were averaged over 5 runs, and the error bars have been omitted as the variance was negligible.

Datasets. Table 2 describes the statistics of our evaluated graphs. RANDOM (RND) is a synthetic graph where each vertex is connected to five randomly selected neighbors. The probability of two vertices being connected is inversely proportional to the difference in their IDs. RMAT-27 (RM27), RMAT-28 (RM28), and Kron30 (K30) are synthetic graphs generated with the Graph500 generator [5], exhibiting a power-law degree distribution. Twitter (TW) [1] and Friendster (FR) [2] are social graphs that show the relationship between users within each online social network. UK-Union (UK) [3] and CrawlWeb (CW) [4] are web graphs that consist of hyperlink relationships between web pages. *Graph Size* is the amount of data stored in text format as an edge list. *CSR Size* is the storage cost to store graphs in CSR format. Since systems are executed in an out-of-core environment, the memory limit is set to 2GB (for RND and RM27), 4GB (for RM28, Twitter, Friendster, and UK-Union), or 32GB (for Kron30 and CrawlWeb). *Block Size* is heuristically set to 1/4 of the memory size according to Section 4.4.3. $|B|$ is the number of blocks that a graph is partitioned into according to the block size.

Dataset	$\|V\|$	$\|E\|$	Graph Size	CSR Size	Block Size	$\|B\|$
RM27	134.2M	1.1B	18GB	4GB	512MB	9
RND	268.4M	1.4B	24.7GB	5.2GB	512MB	11
TW	61.5M	1.5B	24.4GB	5.5GB	1GB	6
RM28	268.4M	2.1B	34.9GB	8GB	1GB	9
FR	65.6M	3.6B	58GB	13.5GB	1GB	14
UK	133.6M	5.5B	94.6GB	20.4GB	1GB	21
K30	1.1B	33.8B	628.3GB	120GB	8GB	16
CW	3.6B	126B	2.6TB	470GB	8GB	59

Table 2: Statistics of datasets.

Graph algorithms. We evaluate SOWalker with two second-order random walk-based applications discussed in Section 2, i.e., node2vec and the second-order PageRank. For node2vec, we set the parameter $p = 0.5$, $q = 2$. Each vertex samples 10 walks with a fixed walk length of 80. For the second-order PageRank, the maximum walk length is 20, and we simulate 2, 000 random walks starting at each query source vertex.

Systems for comparison. We perform a comprehensive analysis of SOWalker's performance and compare it with two state-of-the-art random walk systems.

- GraphWalker [27], an I/O-efficient system for first-order random walks. When executing second-order random walks, we adopt the state-aware I/O model to load a block with the maximum number of walks as the current block and iteratively load another block into memory as the ancillary block. Both GraphWalker and SOWalker use the same parameter configuration.
- GraSorw [28] is the first out-of-core graph processing system designed for second-order random walks. It iteratively selects a block as the current block and uses a learning-based block loading model. However, this model consists of three stages: getting the running logs under the full-load mode, training, and running with the trained thresholds. Both the first and third stages involve second-order random walks, rendering it deficient in real-world applications. Therefore, we only use the full-load mode to load the ancillary block. On the other hand, GraSorw fixes the number of blocks in memory to 2, so we set the block size to half the memory size.

4.2 Overall Performance

We first compare the execution time of the chosen algorithms on different graphs and systems. Figure 7 shows the execution time normalized w.r.t. GraphWalker. We can see that SOWalker is faster than both GraphWalker and GraSorw in all cases. Specifically, SOWalker achieves 1.4-8.3× and 2.4-10.2× speedups over GraphWalker on node2vec and the second-order PageRank, respectively. As for GraSorw, SoWalker achieves 1.2-5.7× and 1.4-5.4× speedups over it on node2vec and the second-order PageRank, respectively. The main reason for the speedup in SOWalker is twofold. First, SOWalker loads multiple blocks with the maximum accumulated updatable walks, which improves the I/O utilization and the walk updating rate, so it requires much fewer blocks I/Os to run second-order random walks. GraSorw, on the other hand, is unaware of the walk states, just iteratively selects a block as the current block and loads an ancillary block into memory. Although GraphWalker loads a block with the maximum number of walks as the current block, it is unaware of the number of walks that can be updated. Therefore, both of them suffer poor performance. Second, SOWalker adopts the block set-oriented walk updating scheme, which allows

Figure 10: I/O amount and reused block count.

the loaded walks can be updated as much as possible in the loaded block set, so as to further accelerate the random walk process and reduce the block I/O costs.

4.3 I/O-efficiency Evaluation

Block I/O comparison. To justify the above argument, we compare the block I/O time on SOWalker and the other systems. Block I/O time is the time cost of loading blocks. Figure 8 shows the block I/O time normalized w.r.t. GraphWalker. In all cases, SOWalker outperforms both GraphWalker and GraSorw. Specifically, the block I/O time in SOWalker is only 5.8-41.3% of that in GraphWalker, and 7.5-72.9% of that in GraSorw, respectively. This is mainly attributed to SOWalker's benefit-aware I/O model that loads multiple blocks with the maximum accumulated updatable walks, so as to accelerate the random walk process and significantly reduce the block I/O number. On the other hand, GraphWalker and GraSorw load blocks iteratively, which incur great I/O cost.

I/O utilization. To verify that SOWalker can improve the I/O utilization, Figure 9(a) shows the average I/O utilization for node2vec on Twitter, Friendster, and UK-Union, normalized w.r.t. GraphWalker. As we can see, for all the graphs, SOWalker shows the highest average I/O utilization. Compared to GraphWalker and GraSorw, the I/O utilization of SOWalker is improved by 13.2-34.2× and 2.3-26.4×, respectively. This is mainly attributed to the benefit-aware I/O model, which maximizes the number of walks that can be updated, thereby improving I/O utilization. Besides, according to our walk matrix, we only loads walks whose previous and current vertices are both in memory. This guarantees that all walks can be updated and provides 100% walk utilization. While GraphWalker and GraSorw are unaware of the number of walks that can be updated, resulting in low I/O utilization.

Walk updating rate. Figure 9(b) reports the average walk updating rate normalized w.r.t. GraphWalker. The average walk updating rate in SOWalker significantly outperforms GraphWalker by up to 62.7×. Benefiting from our block set-oriented walk updating scheme, which allows each walk to move as many steps as possible in the loaded block set, SOWalker achieves more walk steps. In contrast, in GraphWalker, once a walk reaches the boundary of the block, the updating of a walk will stop, so the walk steps are limited. Although GraSorw also allows walks to be updated across the two blocks in memory, SOWalker still achieves up to 1.6-15.6× average walk updating rate stemming from the fact that it maximizes the I/O utilization based on the benefit-aware I/O model.

I/O amount. As mentioned earlier, the I/O amount can be divided into two parts: edge data on blocks and walk data. Let N be the total number of block I/Os, M be the block size, and W be the total number of loaded walks, with each walk encoded with 128 bits. The total I/O amount $A = N * M + W * 128$. Since block size is pre-defined, the I/O amount is proportional to the number of block I/Os and loaded walks. Figure 10(a) shows the I/O amount that each system runs node2vec on Twitter, Friendster, and UK-Union. We can see that there is a significant reduction in I/O amount. Compared to GraphWalker, SOWalker achieves an I/O reduction of over 80% on these graphs. Furthermore, the I/O amount in SOWalker

is only 23.7-67.9% of that in GraSorw. This reduction can be attributed to the accelerated random walk process, which enables the walks to be completed faster and significantly reduces the number of block I/Os.

Reused block counts. Blocks in memory can be reused as they do not yield block I/O but walks in these blocks can be updated. Figure 10(b) shows the reused counts for each block on UK-Union. The reused block counts in SOWalker are usually much higher than those in GraphWalker. The reason is that we consider the contribution of loaded blocks in the benefit-aware I/O model. In contrast, in GraphWalker, only a few blocks are highly reused, because many walks stay in these blocks. This makes them more likely to be selected as the current block and cached in memory for a long time. On the other hand, other ancillary blocks are iteratively loaded, resulting in frequent swapping between memory and disk. Consequently, the reused counts of these blocks are low.

4.4 Design Choices

In this section, we conduct experiments to validate some of our critical design choices that are essential to achieve optimal performance for SOWalker.

4.4.1 Comparisons of Scheduling Models

We now evaluate the effectiveness of the block scheduling models by comparing the following models:

- Random: randomly chooses m blocks to load into memory, which is used as the baseline.
- Max-m: chooses top-m blocks based on the number of walks in a block.
- Exact: the exact benefit-aware I/O model according to the linear programming method.
- Benefit-aware I/O model (BA): the benefit-aware I/O model according to the simulated annealing algorithm.

We run node2vec on UK-Union. A similar trend can also be observed on the other graphs and algorithms; their results are omitted due to space limitations. Table 3 presents the execution time, block I/O time, and computation time for the above models. Note that the computation time of the Random model and Max-m model is very short by a negligible amount. There are two observations that can be found. First, both the Random and Max-m models yield relatively higher execution times than BA model. This is expected since the Random model is an arbitrary order without any optimization. The Max-m model also suffers poor performance as it only focuses on the maximum number of walks. Some loaded walks cannot be updated due to the lack of previous vertex information, which wastes precious disk bandwidth and slows down the processing of random walks. Second, BA model achieves both the best performance and the near-optimal block scheduling model. To verify the correctness of BA, we compare it with the Exact model. The results exhibit that BA gives rise to a similar but slightly higher block I/O cost over the Exact model. More importantly, BA provides a speedup of 6.7× of the Exact model, and the computation time of the simulated annealing algorithm is only 10 seconds. While the computation time of the Exact model is nearly 3.5 hours, which constitutes 85% of the total execution time, and we cannot afford such a level of slowdown. In summary, our BA model can achieve faster runtime and better I/O performance.

Model	Execution time (s)	Block I/O time (s)	Block I/O number	Computation time (s)
Random	4970	3234	9868	-
Max-m	3871	2162	6391	-
Exact	14311	548	1484	12097
BA	2133	575	1537	10

Table 3: The comparison with different block scheduling models. '-' means that the computation time is negligible.

4.4.2 Comparisons of Walk Updating Schemes

Next, we evaluate the effectiveness of SOWalker's block set-oriented walk updating through a comparison experiment with block-oriented walk updating.

Block-oriented walk updating cannot be directly used in SOWalker, since our benefit-aware I/O model requires the help of block set-oriented walk updating. Therefore, we design a baseline system, which loads a block with the maximum number of walks as the current block and iteratively loads another block into memory as the ancillary block. We incrementally add the block set-oriented or block-oriented scheme to the baseline system and evaluate the performance impact of our contribution.

Figure 11 exhibits the performance of node2vec running on Twitter, Friendster, and UK-Union. The block set-oriented scheme outperforms the block-oriented scheme for all graphs.

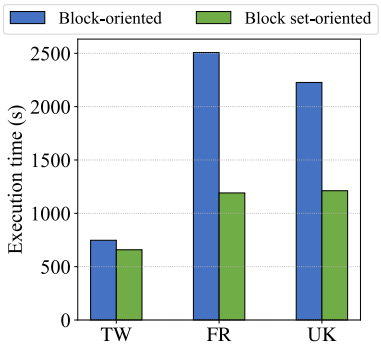

Figure 11: Block- vs. Block set-oriented walk updating.

The performance improvement is especially significant for Friendster, which yields up to 2.1× speedups. The reason behind this is that under the block set-oriented scheme, the walk can move across the entire loaded block set in memory. This leads to a longer walk steps in a block I/O. In contrast, the block-oriented scheme restricts walk updating to only one block, hindering the walk updating process and resulting in a large number of block I/Os.

4.4.3 Impact of Block Size

We also evaluate the impact on performance with different block sizes. Memory is limited to 4GB to illustrate the applicability. To demonstrate, we run node2vec on three representative graphs, Twitter, Friendster, and UK-Union. Figure 12 shows the execution time. The results on GraSorw are omitted since it fixes the number of blocks in memory to 2 and the block size is fixed to half the memory size. SOWalker presents superior performance over GraphWalker across all cases. This improvement is especially significant for small block sizes. This is because with the block-oriented walk updating scheme, GraphWalker restricts walk updating to a block, which severely wastes the vertex information in other blocks residing in memory. While our block set-oriented walk updating scheme allows walks to move across blocks in memory, so as to best utilize resources. Even when the block size is set to 2GB, i.e., 2 blocks in memory, the block-oriented walk updating scheme degrades into the block set-oriented walk updating scheme, the results are still encouraging. The reason is that our benefit-aware I/O model loads multiple blocks with the maximum accumulated updatable walks, so as to accelerate the random walk process. Besides, we observe that the block size should be neither too small nor too large to achieve a good performance in SOWalker. For the smaller block size, the walk updating rate is low. While for the larger block size, the I/O utilization is low. Therefore, according to our experiences, heuristically setting the block size to 1/4 of the memory size can produce the best performance.

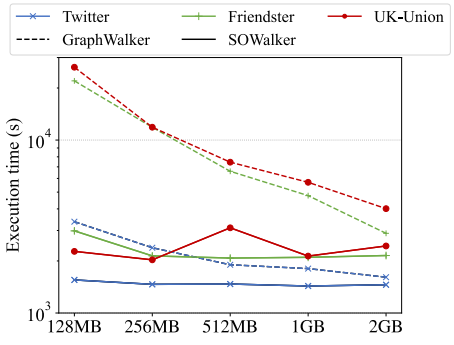

Figure 12: Impact of block size.

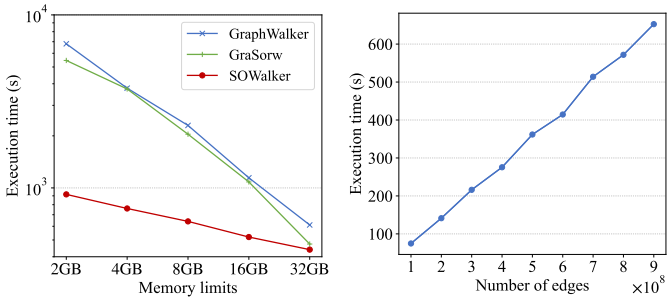

(a) Scalability with memory (b) Scalability with graph size

Figure 13: Scalability with memory and graph size.

4.5 Scalability

We evaluate the scalability of SOWalker by examining the performance improvements achieved with increased memory limits. Figure 13(a) illustrates the performance variance of node2vec on UK-Union as the memory increases. All three systems demonstrate good scalability when more powerful memory resources can be utilized. Although as memory increases, the performance disparities between systems tend to diminish, it is worth noting that SOWalker outperforms other systems utilizing 16GB memory, even when it is equipped with only 2GB memory. When the memory is increased to 32GB, the whole graph can fit into memory, and SOWalker still outperforms the other two systems, yielding 1.4× speedups.

We also evaluate the scalability of SOWalker with respect to graph size. We conduct experiments on random graphs and vary the number of edges from 1×10^8 to 9×10^8, with an average degree of 10. As shown in Figure 13(b), as the graph size increases, the implementation exhibits good scalability. However, due to the variability in the structures of different random graphs, some noise could be generated.

5 Related Work

Many graph systems have been proposed to process large graphs. In the past, numerous systems have emphasized the ability to run in a distributed environment, which use a cluster of machines to process large graphs [43–48]. However, distributed graph systems are still bugged by load imbalance problems and significant communication overheads.

Since out-of-core graph processing systems can represent large graphs in the external memory setting, they serve as a promising alternative to distributed solutions. GraphChi [22] is a pioneer in this category, which utilizes the Parallel Sliding Window (PSW) technique to reduce random I/O accesses from storage. X-Stream [49] provides a two-phase Scatter-Gather programming model that makes tradeoffs between random memory access and sequential access from streaming

data. GridGraph [23] presents a 2-level hierarchical partitioning scheme to improve the locality and reduce the number of I/Os. DynamicShards [24] uses dynamic shards to reduce disk I/Os. CLIP [25] and LUMOS [50] make full use of the loaded blocks to reduce disk I/O operations. However, these existing works were not originally designed for random walks and thus give sub-optimal performance.

With the increasing interest in the performance optimization of random walks, a large number of systems have been designed to handle random walks. DrunkardMob [26] is the first random walk system, which enables the simulation of billions of random walks on massive graphs, on just a single computer. However, it adopts the iteration-based model, which limits the efficiency and scalability of random walks. GraphWalker [27] develops a state-aware I/O model and an asynchronous random walk updating schedule to improve the I/O utilization. As it is designed for first-order random walks, it still incurs excessive disk I/Os when executing second-order random walks. GraSorw [28] is designed specifically for second-order random walks. It develops a bi-block execution engine and a learning-based block loading model to improve the I/O efficiency. However, its bi-block execution engine limits the number of blocks in memory to 2, which is less flexible for different-scale graphs and random walks. Moreover, the learning-based block loading model has to run the second-order random walk task twice to get the runtime statistics, rendering it deficient in real-world applications. SOWalker differs from all these systems in the walk representation, block scheduling model, and walk updating scheme. It designs a walk matrix to avoid loading non-updatable walks, proposes a benefit-aware I/O model to improve the I/O utilization, and adopts a block set-oriented walk updating scheme to boost the walk updating rate.

Meanwhile, memory optimizations and the increased number of cores make it possible to process large graphs more efficiently on a single machine. For example, ThunderRW [38] employs the step interleaving technique to hide memory access latency by switching the executions of different random walk queries. FlashMob [39] tries to harvest spatial and temporal locality underneath the apparently random nature of random walks. Besides, Shao et al. [40] proposed a memory-aware framework for second-order random walks, which automatically assigns a suitable sampling method for each node to minimize the time cost within a memory budget. While SOWalker focuses on I/O optimizations, some of these techniques can be implemented to further enhance the in-memory performance.

6 Conclusion

In this paper, we propose an I/O-optimized out-of-core graph processing system for second-order random walks, called SOWalker. To eliminate useless walk I/Os, we propose a walk matrix to prevent loading non-updatable walks. To improve the I/O utilization, we develop a benefit-aware I/O model to load multiple blocks with the maximum accumulated updatable walks. To boost the walk updating rate, we adopt a block set-oriented walk updating scheme to allow each walk to move as many steps as possible in the loaded block set. Our optimizations yield significant performance benefits compared to the state-of-the-art random walk systems and greatly reduce the I/O cost.

In the future, we would like to explore promising directions of second-order random walks. The current graph partitioning is quite simple, so we plan to design carefully graph partitions in order that random walkers should be trapped for long times in good partitions. Besides, we note that cache stall is also a performance bottleneck. The in-memory optimization of the second-order random walk is another attractive study to follow.

Abstract

Emerging NVM is promising to become the next-generation storage media. However, its high cost hinders its development. Recent deduplication researches in NVM file systems demonstrate that NVM's cost can be reduced by eliminating redundant data blocks, but their design lacks complete insights into NVM's I/O mechanisms.

We propose Light-Dedup, a light-weight inline deduplication framework for NVM file systems that performs fast block-level deduplication while taking NVM's I/O mechanisms into consideration. Specifically, Light-Dedup proposes Light-Redundant-Block-Identifier (LRBI), which combines non-cryptographic hash with a speculative-prefetch-based byte-by-byte content-comparison approach. LRBI leverages the memory interface of NVM to enable asynchronous reads by speculatively prefetching in-NVM data blocks into the CPU/NVM buffers. Thus, NVM's read latency seen by content-comparison is markedly reduced due to buffer hits. Moreover, Light-Dedup adopts an in-NVM Light-Meta-Table (LMT) to store deduplication metadata and collaborate with LRBI. LMT is organized in the *region* granularity, which significantly reduces metadata I/O amplification and improves deduplication performance.

Experimental results suggest Light-Dedup achieves 1.01–8.98× I/O throughput over the state-of-the-art NVM deduplication file systems. Here, the speculative prefetch technique used in LRBI improves Light-Dedup by 0.3–118%. In addition, the region-based layout of LMT reduces metadata read/write amplification from 19.35×/9.86× to 6.10×/3.43× in our hand-crafted aging workload.

1 Introduction

Recently, Non-Volatile Memory (NVM) has been becoming increasingly popular. Its byte-addressability, persistence, and low latency enable it to be attached to the memory bus, sitting alongside the DRAM [24, 44, 52, 67]. Optane DC Persistent Memory Module (DCPMM) is the latest commercially available NVM. However, it is much more expensive than Hard Disk Drive (HDD) and Solid State Drive (SSD). Therefore, reducing the price of NVM is paramount for its future usage.

Deduplication, a system-level data compression approach, can enlarge the logical space and reduce the amortized cost of storage devices [16, 56, 62, 68]. Deduplication is widely used in file systems [72], backup systems [18–20, 39, 63], cloud computing [37, 57], etc. It usually calculates the fingerprints of data blocks and then identifies duplicates according to their fingerprints. For the redundant block, deduplication increments the reference count in the corresponding metadata to maintain data integrity.

Traditional disk-based deduplication approaches, such as using the cryptographic hash (e.g., SHA-256 and MD-5) to identify redundant data blocks, do not fit well with NVM since fast NVM has shifted the performance bottleneck from I/O to CPU. Prior works on deduplication for NVM [7, 28, 58, 75] propose several ways to address the issues. First, some works use offline deduplication to reduce the overhead of deduplication on the critical path, such as DeNOVA [28]. However, such background deduplication can neither enhance the file systems' write performance nor improve NVM's endurance. Second, many works use the non-cryptographic hash (e.g., CRC32 and xxHash [11]) to accelerate the identification of duplicate blocks. For example, NV-Dedup [58] leverages non-cryptographic hash to avoid calculating cryptographic hashes for most unique blocks, while DeWrite [75] shows that combing the non-cryptographic hash with byte-by-byte comparison is efficient for deduplication at cache line granularity.

Despite these efforts, existing works still fail to fully exploit the performance of NVM during deduplication due to a lack of comprehensive insights into NVM's I/O mechanisms. First, NVM's read/write asymmetry encourages researchers to combine non-cryptographic hash with byte-by-byte content-comparison to quickly identify the duplicate data [67, 75]. Thus the overheads of cryptographic hash calculation can be eliminated. Second, we observe other two NVM I/O features that hinder NVM deduplication performance: (1) *Long media read latency*. Despite its read/write asymmetry, NVM's read latency is 2–3× higher than the write since the write buffer inside NVM hides the long media write latency [67]. Therefore, there is still a large room left for the acceleration of content-comparison by hiding the read latency. (2) *Coarse media access granularity*. The mismatch between the size of deduplication metadata (commonly 16–64 bytes for each data block) and the coarse media access granularity in NVM (e.g., 256 bytes XPLine of DCPMM) can lead to severe metadata I/O amplification if the access to the metadata lacks locality,

[*] Jiansheng Qiu and Yanqi Pan are co-first authors of the paper.
[§] Now working at Tsinghua University.

which degrades not only deduplication performance but also NVM's endurance, especially when the system is aged.

This paper presents Light-Dedup, a novel light-weight inline deduplication framework for NVM file systems. Light-Dedup is designed with two specific goals in mind: (1) Maximizing the deduplication performance by considering NVM's memory interface, read/write asymmetry, and access granularity, while adding negligible overhead to the critical path. (2) Retaining low deduplication metadata I/O amplification even if the file system is severely aged (i.e., many holes).

To achieve the first goal, Light-Dedup proposes Light-Redundant-Block-Identifier (LRBI) to quickly identify the duplicate blocks. Unlike the prior works that use both non-cryptographic and cryptographic hash [58] or that straightforwardly combine non-cryptographic hash with byte-by-byte content-comparison [75], LRBI considers both NVM's read/write asymmetry and long media read latency in redundant block identification. Specifically, LRBI uses xxHash, one of the fastest non-cryptographic hashes [11], to quickly identify most non-duplicate blocks. For those blocks with the same fingerprint, LRBI leverages NVM's memory interface to enable asynchronous NVM reads and proposes speculative prefetch to minimize the read latency seen by content-comparison. In particular, speculative prefetch uses *In-Block* and *Cross-Block Prefetch* to exploit the parallelism between NVM read and CPU computation.

To achieve the second goal, Light-Dedup organizes its in-NVM deduplication metadata table, Light-Meta-Table (LMT), as a *region*-based linked list. Each *region* contains multiple continuous metadata entries. Each entry stores the critical information for both basic deduplication and speculative prefetch used in LRBI. The allocation of metadata entries is done first by allocating a *region* and then by allocating entries in that region almost sequentially, which significantly reduces the deduplication metadata I/O amplification caused by NVM's coarse access granularity, especially in an aged file system. In addition, LMT trades 1× extra deduplication metadata space usage for zero garbage collection overheads, which retains the stabilization of deduplication performance.

In summary, this paper makes the following contributions:

- We perform an in-depth analysis of how deduplication can be affected by several NVM's I/O mechanisms and introduce how to maximize NVM deduplication performance with full consideration of them.
- We propose an inline deduplication framework for NVM file systems, Light-Dedup, with two key techniques: (1) LRBI combines non-cryptographic hash with speculative-prefetch-based content-comparison to fully leverage NVM's I/O asymmetry while hiding its media read latency by enabling asynchronous NVM reads. (2) The *region*-based layout is adopted in LMT to manage deduplication metadata with a good locality and retain low metadata I/O amplification.
- We implement Light-Dedup in Linux kernel 5.1.0 based on NOVA [66], one state-of-the-art NVM file system. The code is available at https://github.com/Light-Dedup/Light-Dedup. Furthermore, we make a comprehensive evaluation of various synthetic and real-world workloads. The results show that Light-Dedup adds negligible overhead while significantly improving the file system's write performance under a high duplication ratio.

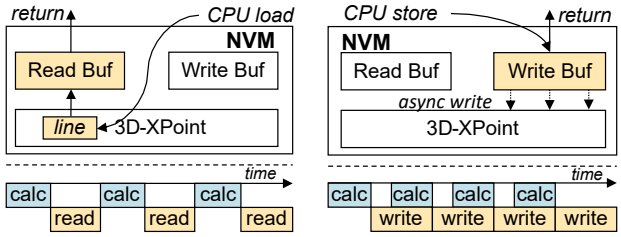
2 Background and Related Work

2.1 NVM and NVM File Systems

With its byte-addressability, low latency, persistence, and low power consumption [3, 21, 26, 35, 40, 41, 46], NVM becomes a promising candidate for next-generation storage media. In this work, we focus on high-density storage-type NVM with the memory-like interface [29] that serves as persistent storage media. For brevity, we denote such storage-type NVM as NVM. According to the latest research on the commercial DCPMM [64, 67] and our investigation on existing NVM devices [6, 34, 50, 51, 65, 71], this paper concludes the following **five common I/O features** of NVM that potentially have impacts on NVM deduplication performance:

- *Asymmetry in Read/Write Bandwith*. The read bandwidth of NVM is up to 3× than its write [67]. The feature is common for persistent storage media such as Phase Change Memory (PCM) [50, 71], STT-RAM [6, 34], memristor [65], 3D-XPoint [67], NAND flash [1], etc.
- *I/O with Buffers*. For writes, NVM leverages the buffer to write asynchronously to hide long media write latency. While for uncached reads, NVM fetches data synchronously from the media. The data will be cached in the internal read buffer for future reads [51, 64, 67]. Figure 1 shows the I/O mechanisms of NVM.
- *Coarse Access Granularity*. Coarse media access granularity is common for storage-type NVM. For example, the row buffer size of a PCM is preferred to be larger than 128 bytes [30]. Coarse access granularity (and the above I/O buffers) is beneficial for improving storage bandwidth and bridging the performance gap between storage and CPU. Since NVM is denser but slower compared to DRAM, it is reasonable that NVM has a larger access granularity than a cache line.
- *Long Media Read Latency*. The underlying non-volatile media generally introduces relatively longer media latency than DRAM [29, 30, 43, 54]. The synchronous data fetch mechanism fails to hide such latency [64].
- *Memory Interface*. With the memory interface, NVM can be accessed by CPU store/load. This feature makes asynchronous CPU prefetch possible, which can be leveraged to address NVM's long media read latency.

To well exploit the physical characteristics of NVM devices, several NVM file systems [8, 12, 17, 70] are proposed. Among these file systems, NOVA [66] is the state-of-the-art one, which aims to exploit the potential of DRAM and NVM



(a) Synchronous reads (b) Asynchronous writes

Figure 1: NVM I/O buffering mechanisms.

hybrid memory systems while providing strong consistency guarantees. Specifically, NOVA allocates a separate log for each inode (i.e., file), appends single inode operations as entries of the inode's log, and atomically updates the log's tail to commit the operations. For operations involving multiple inodes, NOVA records the log tail's pointers of the affected inodes in the journal to update them atomically. Further, NOVA accelerates search operations by maintaining radix trees of directories and files in DRAM.

2.2 Inline Deduplication Techniques for NVM

File system deduplication [62] is a block-level redundancy elimination technique and has been needed in many applications [18–20, 59, 63, 72]. This paper focuses on inline deduplication since the offline approach neither enhances file systems' write performance nor improves NVM's endurance. Typically, an inline deduplication framework consists of several techniques, including redundancy identification, deduplication metadata management, indexing, etc.

Redundant Block Identification Techniques. Traditional disk-based deduplication approaches, such as using the cryptographic hash to determine the duplicates [16, 56, 68], do not fit well with fast NVM devices due to their heavy software overhead. Recent works [7, 58, 75] leverage non-cryptographic hash functions to reduce the computation cost of fingerprints. However, non-cryptographic hash suffers from hash collision (different blocks have the same hash). To address the issue, existing approaches either apply cryptographic hash (e.g., NV-Dedup [58]) or straightforwardly perform byte-by-byte content-comparison (e.g., DeWrite [75]) to verify if the blocks are duplicate when their non-cryptographic hashes equal[1]. However, (1) cryptographic hash calculation is a bottleneck when there are many duplicates; (2) the long latency of uncached reads hinders the performance of content-comparison, especially when the concurrency level is low and read/write asymmetry is not obvious. In contrast, our approach (i.e., LRBI) combines non-cryptographic hash with a speculative-prefetch-based content-comparison technique to exploit I/O asymmetry and hide long media read latency.

In-Storage Deduplication Metadata Management. To manage redundant blocks, deduplication approaches must maintain in-storage structures to store the basic information about the deduplicated blocks (e.g., the mappings between fingerprints and physical blocks, reference count, etc.). Besides, some additional bits are required for the collaboration with redundancy identification. Existing NVM deduplication approaches (e.g., NV-Dedup [58], LO-Dedup [7], DeWrite [75]) often reserve a fixed in-NVM table to store the deduplication metadata and to allocate/free them by the free list. Additionally, NV-Dedup maintains both non-cryptographic and cryptographic hash in the table; LO-Dedup organizes the deduplication metadata as an ordered linked list structure to accelerate the continuous matching. However, such free-list-based management is not NVM-friendly since its allocation strategy can introduce significant fragmentation when the system is aged, causing a severe metadata I/O amplification. In contrast, our proposed LMT manages the deduplication metadata as a *region*-based linked list, provides course-grained metadata management, and significantly reduces metadata I/O amplification under aged file systems.

In-NVM Deduplication Metadata Index Techniques. Searching for in-NVM deduplication metadata based on the calculated fingerprint is a critical step in deduplication. To prevent frequent NVM accesses, existing works usually build an in-DRAM index, such as static hash tables or red-black tree, to accelerate the search [7, 58]. We use a dynamic hash table (i.e., *rhashtable* [13]) for its resizability and efficiency.

3 Observations and Motivations

3.1 Data Redundancy & NVM Deduplication

Data redundancy is a common phenomenon in storage systems with the exponential growth of data. Prior works [19, 20, 63, 72] have observed a large number of redundancies in modern primary storage systems. For example, there are 95% and 47% duplicates (in 4 KiB block granularity) in two real-world traces collected by FIU: *Mails* and *WebVMs* [27, 33]. Thus, the deduplication approach is a promising solution to enlarge logical storage space and reduce storage costs. As the next-generation storage media, deduplication for expensive NVM is profitable and urgent. Recently, many research efforts have designed deduplication schemes specifically for NVM file systems [7, 58]. However, they fail to fully exploit the characteristics of NVM's I/O mechanisms and leave substantial room for improvement from the performance point of view. This paper aims to develop a more efficient inline deduplication framework scheme for NVM file systems that can fully exploit the I/O characteristics of NVM devices.

3.2 I/O Asymmetry and Read Latency in NVM Redundant Block Identification

The efficiency of redundant block identification is essential to NVM deduplication performance. Traditional disk-based deduplication approaches use the cryptographic hash to identify the duplicate blocks [16, 32, 56, 68]. However, it does not suit NVM deduplication well due to its computation overhead, which wastes much CPU computation and thus starves

[1] LO-Dedup does not address the hash collision of the non-cryptographic hash used in their paper. Thus, we omit its redundancy identification technique.

Table 1: The breakdown deduplication time. Light denotes Light-Dedup, and *LD-w/o-P* denotes a simple deduplication file system that incorporates non-cryptographic hash with content-comparison into the write path and deduplicates 4 KiB blocks. With the introduced speculative prefetch technique (i.e., Light), content-comparison time is dropped by 62.2%.

System	Calc. Lat (ns)		I/O Lat (ns)		Bandwidth (MiB/s)
	fp	others	write	cmp	
NOVA	0.0	84.7	2275.6	0.0	1401
LD-w/o-P (1st)	309.9	1072.5	**585.3**	0.0	1612
LD-w/o-P (2nd)	308.0	571.6	0.0	**3263.0**	870
Light (1st)	310.0	1131.3	**559.8**	0.0	1592
Light (2nd)	0.0	343.3	0.0	**1234.8**	1914

NVM. We observe the problem in NV-Dedup [58]. In a simple sequential write 4 GiB workload, the write bandwidth of NV-Dedup drops by 52.5% with the duplication ratio increasing from 0% to 75%. The root cause is that cryptographic hash calculation (i.e., MD-5) dominates up to 64.9% of the whole write time since NV-Dedup relies on the cryptographic hash to handle its non-cryptographic hash collision.

To address the above heavy computation, DeWrite [75] uses non-cryptographic hash and byte-by-byte comparison in the combined manner [10]. The method is well aligned with the characteristic of NVM since it prevents heavy CPU computation and leverages the large read/write asymmetry to trade slow duplicate writes for faster reads (i.e., content-comparison). However, recent researches about NVM reads [64, 67] show that they can still be a bottleneck since uncached reads have to fetch data from media synchronously, which introduces long media read latency and thus negatively affects the content-comparison performance.

We examine how exactly NVM I/O affects the deduplication performance. Table 1 shows the breakdown latency of orderly writing two 4 GiB files with identical content (2 MiB per I/O) to NOVA and *LD-w/o-P*[2] under a single thread. Note that the first write conducts no duplicate blocks, but the second write causes 100% duplicates and results in reads (caused by content-comparison). We observe several interesting phenomena from Table 1. First, *LD-w/o-P* has a surprisingly low write time (585.3ms) compared to NOVA (2275.6ms) because asynchronous write enables the parallelism between CPU computation and write I/O. Thus, computation hides part of NVM writes latency (as shown in Figure 1b). Second, during the second writes, the write bandwidth of *LD-w/o-P* drops by 46% compared to the first. We find that the content-comparison time arises to 3263.0ns, which dominates 78.8% deduplication latency. The above observations suggest that non-cryptographic hash-based redundant block identification adds negligible overheads to the normal non-deduplication write path (i.e., the data blocks to be written are all unique). However, deduplication performance is significantly limited by the long read latency and is far from ideal. We believe there are two reasons: (1) NVM's read/write asymmetry under low thread count is not large enough [67]. (2) Current hardware prefetcher of intel 64 bits architecture fails to remedy the drawbacks of NVM's long media read latency since it is designed for DRAM and only attempts to prefetch two cache lines ahead of the prefetch stream [23].

[2]We build *LD-w/o-P* based on our proposed Light-Dedup by removing the speculative prefetch technique. This means that the deduplication metadata management and indexing are the same as in Light-Dedup, but they have negligible performance impacts on the experiments of this subsection.

Table 2: The average NVM extra reads/writes of deduplication metadata for writing each block.

Approaches	First Write		Second Write	
	Read (B)	Write (B)	Read (B)	Write (B)
ideal	≈40	40	40	≈40
All-in-NVM	726.12	293.17	528.65	259.05
Entry-based	126.94	79.56	774.13	394.54
Ours	116.28	75.75	244.19	137.17

In summary, NVM's long read latency hinders content-comparison performance during NVM deduplication. Considering NVM's asynchronous writes and the limitations of hardware prefetcher, we are motivated to think: Can we manually achieve asynchronous reads to hide media read latency? Memory characteristics of NVM inspire us to obtain our first motivation: We can leverage memory prefetch instructions to enable asynchronous NVM reads and thus accelerate content-comparsion. However, applying prefetch to NVM deduplication is not straightforward. There are two technical challenges: (1) The limited number of concurrent prefetch instructions that a CPU core can handle. (2) How to incorporate the prefetch mechanism into deduplication logic.

3.3 Metadata I/O Amplification in NVM Deduplication Metadata Management

During NVM deduplication, deduplication metadata can be frequently accessed and updated, causing a large amount of small NVM accesses. Metadata I/O amplification will get larger if these small NVM accesses exhibit a random pattern due to NVM's coarse access granularity. However, existing NVM deduplication file systems pay little attention to the issue. In this subsection, we investigate two widely used NVM deduplication metadata management approaches.

All-in-NVM Management. DeNOVA [28] takes an All-in-NVM design and constructs an in-NVM hash table to store and index the deduplication metadata to reduce DRAM consumption. However, hash tables typically exhibit random access patterns [36, 45, 64, 73, 74], which leads to severe read/write amplification. To verify this, we implement an inline deduplication system with an All-in-NVM design based on *Light-Dedup*: Its deduplication metadata are organized as a static hash table in NVM. We write the same 64 GiB file twice and measure the extra NVM reads/writes of deduplication metadata using *ipmctl* [22]. The experimental results are shown in Table 2. Ideally, each block write results in about 40 bytes NVM read/write (i.e., 32 bytes for deduplication

metadata entry, 8 bytes for the mapping from block number to metadata entry, see §4.2). In this case, read and write amplification are $528.65/40 \approx 13.2\times$ and $293.17/40 \approx 7.3\times$. Note that the reason why read amplification is nearly $2\times$ of theoretical upper bound ($8\times$) may be due to the prefetch mechanism and buffering strategy of internal Optane DCPMM hardware [64].

NVM-DRAM Hybrid Entry-Based Management. NV-Dedup [58] and LO-Dedup [7] store the deduplication metadata in NVM and maintain the in-DRAM index to locate them efficiently, which alleviates the problem of all-in-NVM design. Their deduplication metadata is managed at the granularity of cache lines, aligned in a manner favored by CPUs, and allocated/freed through a free list. We refer to this approach as *entry-based*. It is acceptable for a fresh new file system, but when the file system is aged, the physical location of allocated free entries can be random, which results in random access to NVM and causes severe read/write amplification. To show the problem, we make an extensive evaluation in §5.5 and present part of the results in the *Entry-based* row in Table 2, in which the first write is performed in the fresh new system and the second write is in the aged system. The results suggest that such entry-based metadata management can lead to significant read/write amplification in the aged system, about $774.13/40 \approx 19.35\times$ and $394.54/40 \approx 9.86\times$, respectively.

In summary, the severe metadata I/O amplification observed in Table 2 wears out NVMs and leads to performance degradation under aging file systems. To alleviate the problem, we focus on redesigning the hybrid deduplication metadata management strategy. Inspired by mimalloc [31], which shards its free list in page granularity, we obtain our second motivation: managing deduplication metadata in the *region* (i.e., 4 KiB block) granularity to maintain access locality, which elegantly reduces metadata I/O amplification. However, the issue of how to reclaim stale entries (i.e., garbage collection) with minimal overhead and design entry fields that collaborate with LRBI remains unresolved.

4 Design and Implementation

4.1 System Overview

Based on the observations of NVM's internal I/O mechanisms, we propose Light-Dedup, a light-weight inline deduplication framework for NVM file systems, as shown in Figure 2. It includes two key techniques:

- **Light-Redundant-Block-Identifier (LRBI)**. LRBI is proposed to quickly identify duplicate blocks by exploiting NVM's large read/write asymmetry and hiding long media read latency. It combines non-cryptographic hash with a speculative-prefetch-based byte-by-byte content-comparison technique. Specifically, speculative prefetch leverages NVM's memory interface and uses *In-Block* and *Cross-Block Prefetch* techniques to asynchronously load speculated data into CPU/NVM buffers, which exploits the parallelism of NVM I/O and CPU computation and thus markedly hides read latency.

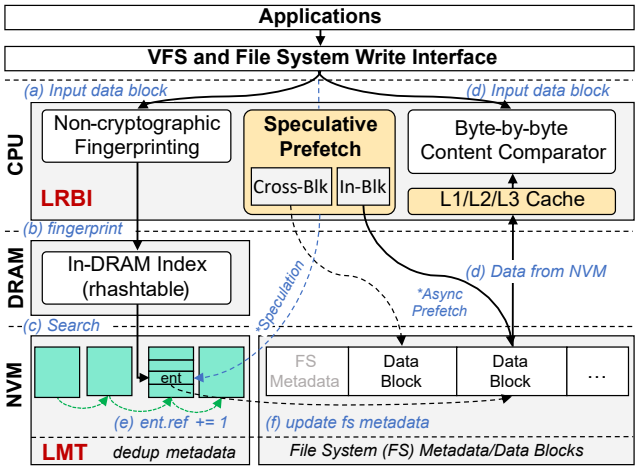


Figure 2: Light-Dedup overview.

- **Light-Meta-Table (LMT)**. LMT is an in-NVM table responsible for (1) storing basic deduplication metadata, such as the mapping from fingerprints to physical blocks; (2) maintaining speculation information, such as the hint of where and whether to prefetch the to-be-compared block. LMT adopts *region-based layout* to retain the locality of deduplication metadata. A *region* is a 4 KiB block, and *regions* are linked by 8 bytes pointers. Each dedup metadata is allocated in the *region* almost sequentially, hence reducing metadata I/O amplification. In addition, to prevent GC overheads brought by sequentiality, LMT trades $1\times$ more space for zero GC overheads.

In-DRAM Index. Light-Dedup adapts a *rhashtable* in DRAM to locate in-NVM deduplication metadata entry, whose key is the hash value (i.e., fingerprint) and value is the in-NVM position of the corresponding entry. We use *rhashtable* since it is a mature, well-tested, and efficient dynamic hash table implementation in the mainline Linux kernel [13], which suits for point-query (i.e., searching for a specific deduplication metadata entry by the given fingerprint). Meanwhile, *rhashtable* leverages efficient Read-Copy-Update (RCU) Lock [38] to handle the concurrent accesses to LMT. Note that this paper does not aim to redesign a specific index structure since in-DRAM hash table indexing is commonly efficient (e.g., usually achieves constant access time), and there have been many works dedicated on this [36, 45, 73, 74].

Put NVM I/O Features & Light-Dedup Together. We summarize Light-Dedup's insights into the presented NVM I/O features. First, read/write asymmetry can be leveraged to improve NVM deduplication performance by combing non-cryptographic hash with content-comparison, trading the slow duplicate writes for the faster reads (§4.2). Second, this paper observes that long media read latency hinders content-comparison performance dramatically. To address the problem, we propose LRBI, which follows the non-cryptographic hash-based infrastructure but leverages NVM's memory inter-

face and I/O buffering to enable asynchronous reads, and thus markedly accelerates content-comparison (§4.3). Third, Light-Dedup addresses the metadata I/O amplification brought by NVM's coarse access granularity by organizing LMT as a *region*-based linked list (§4.4).

4.2 Basic Deduplication Logic

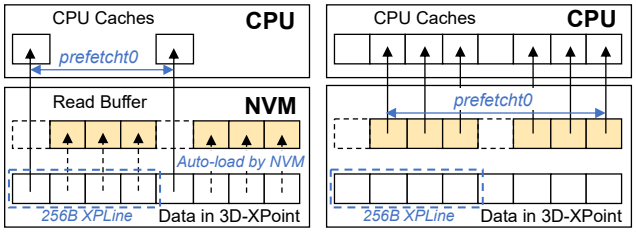
This subsection will introduce the basic deduplication flows of Light-Dedup (without speculative prefetch) to show how non-cryptographic hash and byte-by-byte comparison can be integrated into NVM file systems. Notably, we refer to this version as *LD-w/o-P*, as mentioned in §3.2.

Write Logic. Assume that the file system is writing a 4 KiB duplicate block. As shown in Figure 2, during the write, (1) Light-Dedup first calculates the non-cryptographic hash as the fingerprint of the input block (see steps (a), (b)), (2) and then efficiently locates the corresponding deduplication metadata entry (refer to as entry for brevity) in LMT by searching for the given fingerprint in *rhashtable* (see step (c)). (3) Once the entry is found (i.e., hash value matches), Light-Dedup compares the content of the input block and the block corresponding to the found entry byte-by-byte (see step (d)). (4) Finally, assuming comparison determines that the input block is duplicate, Light-Dedup increments the reference count of the duplicate block and records its duplicate block number in the file system metadata (see steps (e), (f)).

There are two exceptional cases to be handled. Given the fingerprint of the input block, (1) if no entry with the same fingerprint is found in LMT, suggesting that the input block is unique, then it will be written normally by the file system. After that, both its fingerprint and the block number are stored in a newly allocated entry with the reference count set to one. (2) If an entry is found, but the content of the stored block and the input one are different, then the input block becomes a non-dedup block, i.e., Light-Dedup does not allocate an entry for it, which will not affect the correctness of the deduplication system since only the file system has access to that block.

Deletion Logic. Light-Dedup maintains another in-NVM table that maps the block number to the offset of the corresponding deduplication metadata entry (i.e., similar to an inverse index). Note that the mapping maintenance introduces another 8 Byte metadata write in the write path (this is why the ideal NVM access is 40 bytes instead of 32 bytes). To delete a block, Light-Dedup first locates its deduplication metadata entry with the aforementioned table. If the entry is not found in the table, suggesting that the block number has not been inserted into the metadata table, then Light-Dedup frees the block directly. Otherwise, Light-Dedup decreases the reference count of the block (recorded in the entry) by one. If the reference count becomes zero, then the block can be safely freed. Deleting blocks in Light-Dedup does not cause the garbage collection of deduplication metadata due to the tradeoff in LMT (see §4.4).

Read Logic. The read path remains the same as the non-dedup file systems. Note that deduplication fragments files' data, which may lead to random reads. However, Light-Dedup deduplicates 4 KiB blocks and large random access to NVM does not cause significant performance degradation [64].



(a) 1st: Prefetching XPLines. (b) 2nd: Prefetching read buffer.

Figure 3: *In-Block Prefetch (IBP)* mechanisms. Each square in the figure indicates one 64 bytes cache line.

4.3 LRBI: Dedup with Speculative Prefetch

In this subsection, we present the step-by-step design of speculative prefetch used in LRBI, which aims to reduce the read latency seen by content-comparison (§3.2). Its key design principle is to enable asynchronous NVM reads and to markedly improve the parallelism between NVM I/O and CPU computation. It consists of two prefetch strategies: *In-Block Prefetch* and *Cross-Block Prefetch*.

4.3.1 In-Block Prefetch (IBP)

IBP speculates that the content-comparison always tends to compare all bytes and leverages memory prefetch instructions, e.g., `prefetcht0` assembly instruction in x86 [23], to enhance the parallelism of reading bytes in the same block.

Prefetch-Cmp-64 (P64). The most straightforward prefetch strategy is issuing 64 prefetch instructions to load 64 cache lines of the block into CPU caches (i.e., $64 \times 64 = 4096$ bytes) before comparing it with the input block (if they have the same fingerprint value). However, the maximum number of concurrent prefetch instructions a CPU core can handle is limited. In our machine, that number is in the open range $(8, 16)$. Therefore, many prefetch instructions in *P64* are executed in a serial manner, and thus the parallelism is limited.

In-Block Prefetch (IBP). We leverage the large access granularity of NVM (e.g., 256 bytes XPLine) to address the problem of *P64*. As Figure 3 shows, first, we issue 16 prefetch instructions with stride 256 bytes to touch the first cache line of XPLine, and the whole block is loaded automatically into CPU caches or NVM read buffer [64], where most of the NVM read is in parallel. Second, we issue prefetch instructions with stride 64 bytes to bring the in-read-buffer data into CPU caches. Note that *In-Block Prefetch* is a general optimization technique that can be applied to some other block-based NVM I/O scenarios, but it is beyond the scope of this paper.

4.3.2 Cross-Block Prefetch (CBP)

Unlike *IBP*, *Cross-Block Prefetch* exploits the parallelism among CPU tasks (i.e., fingerprint calculations and content-comparison, etc.) and NVM I/O tasks (i.e., reading a to-be-compared data block), and thus hides NVM's media read

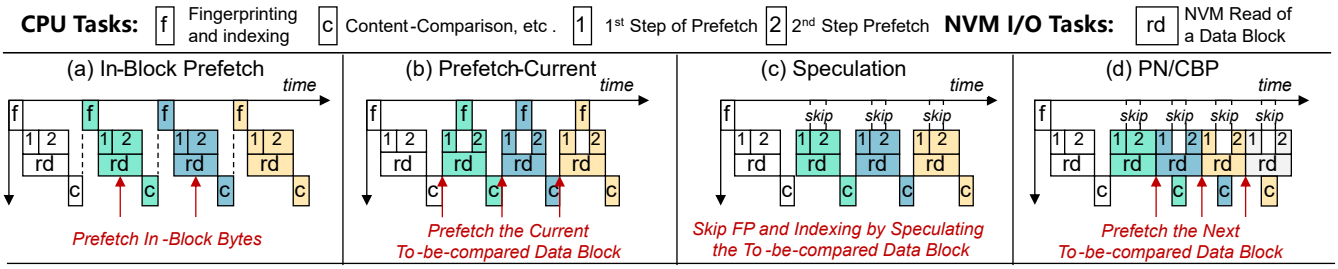


Figure 4: Simplified time sequence of Light-Dedup using different prefetch mechanisms: *IBP* improves parallelism of reading an NVM block while *PC*/*SP*/*PN*/*CBP* further improves the parallelism between CPU and NVM I/O tasks. Here, task c includes content-comparison, updating dedup/FS metadata, etc. Note that the time of running task 2 depends on the amount of data loaded into NVM's read buffer. Thus, task 2 can be faster (shorter) after running tasks f and c in *PC* and *PN*/*CBP*, respectively.

latency. This subsection introduces the technique with step-by-step explorations, as shown in Figures 4(b)–(d).

Determining Where and Whether to Prefetch the To-be-compared Data Block. This is critical for Light-Dedup to support *Cross-Block Prefetch*. First, we incorporate a "hint" field into the deduplication metadata entry. The hint maintains both the location of the subsequent speculated block's entry and the *trust degree* (range: $[0,7]$) that indicates if the speculation is correct. Second, to maintain the hint, we keep track of the entry of the last written block and check the corresponding hint after the deduplication of the current input block finishes: *trust degree* is decreased by 2 if the hint is proven to be wrong, and increased by 1 if correct. The hint is trusted and followed only if the trust degree reaches the trust threshold (i.e., 4 for now). Third, since prefetch consumes NVM read bandwidth, we are conservative about its usage. Thus, we further introduce *per-CPU stream trust degree* to indicate the locality of the workload, which is increased/decreased along with per-entry *trust degree*s. Prefetch is enabled only if the *stream trust degree* of the current CPU reaches its maximum value (i.e., 7). Removing *trust degree* reduces the hit rate of CBP from 98.6% to 60.0% during WebVMs batch replay (the details of the workload are presented in §5.3), which shows the effectiveness of *trust degrees*.

Prefetch-Current (PC). As Figure 4(b) shows, the simplest idea is to prefetch the stored block that is possible to be compared with the current input block (based on the stored hints) before any deduplication calculations, and then follow the basic deduplication logic to deduplicate the input block. In this way, fingerprint calculations and index looking up (f in Figure 4) are executed parallelly with NVM reads, and then part of the NVM read latency can be hidden.

Speculation (SP). Furthermore, as Figure 4(c) shows, we leverage hints to skip the fingerprint calculations and indexing by directly locating the deduplication metadata entry (see **Speculation* arrow in Figure 2). If the content-comparison demonstrates that the compared two blocks are the same, then the duplicate block is found; otherwise, we fall back to the basic deduplication logic. *SP* outperforms *PC* since *SP* can reduce (skip) many deduplication calculations.

Prefetch-Next (PN). More aggressively, as Figure 4(d) shows, to maximize parallelism, we utilize the stored speculation hints to suggest the block that is likely to be compared with the subsequent input block, and then we prefetch that block after loading the current to-be-compared block into CPU caches (2 in Figure 4). Therefore, the NVM read of the next to-be-compared can be parallel with the following CPU tasks (e.g., content-comparison). Now, NVM read is almost fully parallel with the CPU computations.

Cross-Block Prefetch (CBP). From the above explorations, we take *PN* as the fundamental of cross-block prefetch. However, we find that *PN* significantly degrades the deduplication performance at a high concurrency level (as shown in Figure 11 later in §5.4) since the large amount of extra prefetch I/O exacerbates the contention of NVM read buffer. Thus, we further introduce *Transition* technique to mitigate the issue by dynamically enabling/disabling prefetch according to concurrency level. Specifically, we maintain the number of threads that access NVM concurrently with an atomic variable and do not prefetch the next block if the number of threads reaches the specified threshold. Note that the threshold is a kernel module parameter. It is set to 6 by default (and we use this default value in our tests) because according to Figure 11, PN's throughput drops below SP's throughput when the number of threads ≥ 6 due to buffer contentions. Now, we obtain the final version of *CBP* (i.e., *PN*+*Transition*).

4.3.3 Speculative Prefetch: Put IBP and CBP Together

Generally, speculative prefetch enables the asynchronous NVM reads for content-comparison at both byte and block levels. Among them, CBP is frequently triggered when the workload exhibits good duplication continuousness (i.e., most hints are trusted according to trust degrees). Otherwise, Light-Dedup falls back to IBP when the duplication continuousness is poor (since most hints are not trusted). Therefore, the functionalities of CBP and IBP are complementary and are combined together to deliver fast content-comparison performance in both cases. The performance evaluation shows that speculative prefetch can achieve up to 118% performance improvement. More details can be obtained in §5.4.

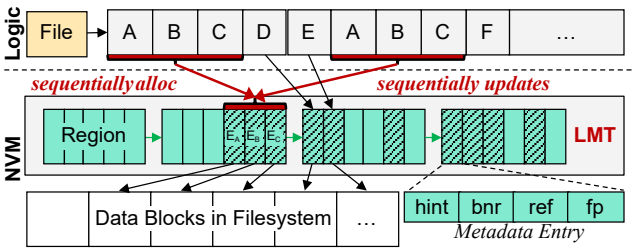

Figure 5: Illustration of Light-Meta-Table (LMT).

4.4 LMT: In-NVM Dedup Metadata Layout

In this subsection, we present the design of LMT, as illustrated in Figure 5. LMT is used for maintaining the mappings from fingerprints to physical blocks and providing hints for speculative prefetch. Furthermore, the deduplication metadata in LMT are laid out in the *region* granularity to reduce the read/write amplification of deduplication metadata access in NVM (i.e., allocating entries almost sequentially).

Deduplication Metadata Entry. In the LMT, each entry consists of 8 bytes *blocknr* (block number), 8 bytes *fp* (fingerprint), 8 bytes *refcnt* (reference count), and 8 bytes *hint* (used for speculative prefetch). The *blocknr* field refers to the corresponding block number in the file system, while the *refcnt* field refers to the number of references on a data block. The *fp* field stores the 8 bytes xxHash as the block's fingerprint. And the *hint* field contains 61 bits for the location of the subsequent speculated block's entry and 3 bits for *trust degree*.

Region-based Layout. To maintain the locality of deduplication metadata, we group metadata entries into *region*s and allocate entries in the currently used *region* almost sequentially. We use an in-DRAM variable ***Cur Region*** to represent this in-NVM region. For brevity, we do not distinguish *Cur Region* from the currently used in-NVM region. Each *region* is 4 KiB (aligned to the block size) so that the *region*s can be allocated by NVM file systems' block allocator directly [17, 66]. The *region*s are linked by 8 bytes pointers at the end of each *region*, and the first a few *region*s (*Region Header*) are reserved in a fixed place in NVM as the list head. In this way, the deduplication metadata table can grow dynamically. Therefore, Light-Dedup avoids unnecessary storage consumption and can scale flexibly when the storage size changes.

We regard a *region* as allocatable (i.e., we can use the *region* to allocate entries) if no more than half of the metadata entries (i.e., $4\,\text{KiB}/32\,\text{Byte}/2 = 64$ entries) are used in that region. Such design is a tradeoff between maintaining the locality of metadata entries' allocation and the space utilization of the region. To allocate regions in constant time, Light-Dedup maintains the positions of allocatable regions with the *Region Queue* in DRAM and keeps track of the number of valid entries in each region with an XArray [60]. Figure 6 illustrates the allocation and deletion of metadata entries:

- **Entry Allocation**. Light-Dedup checks the entries in the *Cur Region* one by one (①) until a free one is found (②), and then returns its position to the caller (③). If there is no free entry found (④), Light-Dedup evicts the *Cur Region* (⑤) and checks if the *Region Queue* is empty. If not, Light-Dedup takes out an allocatable region from the *Region Queue* as the new *Cur Region* (⑥(1)). Otherwise, Light-Dedup leverages the file systems' block allocator to allocate a new *region* as the *Cur Region*, and then links it into the tail of the in-NVM *region* list (⑥(2)). For the new *Cur Region*, Light-Dedup checks the entries in it one by one until a free entry is found (⑦) and returns its position to the caller (⑧).
- **Entry Deletion**. Light-Dedup first sets the *blocknr* of the target entry (⑨) to zero. If exactly half of the metadata entries in that *region* are free, then we insert this *region* back to the *Region Queue* to make it allocatable again (⑩). For the simplicity of concurrent control, the *region* will not be returned to the block allocator.

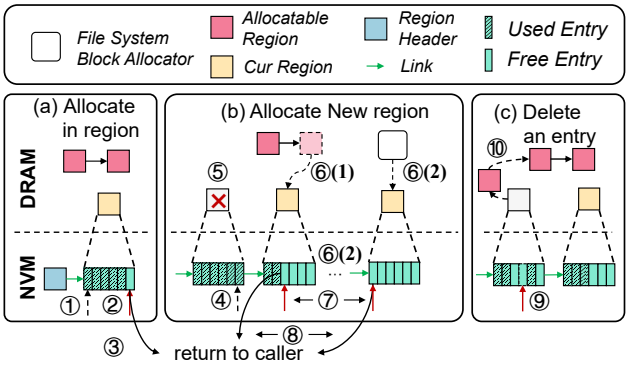

Figure 6: Illustration of region-based entry management. The cross-mark indicates that the *Cur Region* is evicted.

Reduction of Metadata I/O Amplification. To show this, we make the following analysis: (1) **For unique writes**, Light-Dedup allocates a metadata entry for each write almost sequentially in the *Cur Region*, so that the writes to these entries usually hit the NVM write buffer, and thus the metadata write amplification is reduced. (2) **For duplicate writes**, we assume the redundant data tend to be clustered, such as using *cp* or *rsync* to copy a file multiple times. In that case, since the file's deduplication metadata is allocated almost sequentially in a region, the subsequent accesses/modifications to them are also almost sequential, and thus the metadata read and write amplification are both reduced. The extensive study in §5.5 validates our analysis.

Avoidance of Garbage Collection (GC). Maintaining sequentiality (e.g., log-structured layout) often requires GC [66]. However, GC is complex and time-consuming. To address the issue, Light-Dedup does not reclaim allocated regions and allows to reuse them when half of the entries are free. In other words, Light-Dedup trades more NVM space for GC-free design. Such design does not bring significant storage consumption: assuming the capacity of NVM is x, then there are at most $\frac{x}{4\text{KiB}}$ unique blocks to be referenced by Light-Dedup.

Thus, at most $\frac{2x}{4\text{KiB}}$ entries are needed for GC-free design (i.e., all the allocated regions are half-full). Since each entry is 32 bytes, at most $\frac{2x}{4\text{KiB}} \times 32\,\text{Byte}/x \approx 1.56\%$ space of NVM is needed. Note that this is the worst case. The experiment shows that writing a 128 GiB non-duplicate file allocates 1.008 GiB of regions, which is only 0.79% of the data size.

4.5 Crash Consistency and Recovery

Light-Dedup maintains crash consistency lazily by collaborating with NVM file systems' recovery process. The lazy strategy guarantees crash consistency and avoids eager consistency overheads [9, 47, 68].

Normal Recovery: *Storing in-DRAM index, allocator, etc. to NVM and Reloading them back*. During the clean unmount, Light-Dedup stores in-DRAM *rhashtable* items and the valid entry counts in the reserved area in NVM. During the subsequent remount, Light-Dedup first initializes an empty index, and then inserts the saved items into it. Next, the valid entry counts are loaded into DRAM directly and the *Region Queue* is rebuilt accordingly. After this process, Light-Dedup is ready to accept new I/O requests.

Failure Recovery: *Fixing inconsistency of deduplication metadata in NVM and Reconstructing in-DRAM data structures*. To recover to the normal state, Light-Dedup scans the deduplication metadata during the file systems' recovery to fix two inconsistent cases: (1) A block is only referenced by the file system. It is a non-dedup block, so Light-Dedup does not reinsert it into the deduplication metadata table. (2) A block is only referenced by the deduplication metadata table. Since Light-Dedup treats the file system's metadata as the true source of information, it invalidates the corresponding deduplication metadata entry. After this, Light-Dedup rebuilds its in-DRAM structures similar to the normal recovery.

4.6 Portability

Port to Future NVM Devices. Although Optane DCPMM exited the market recently, we are still confident about NVM technology because it bridges the performance gap between DRAM and SSDs. Our work focuses on the common features of storage-type NVMs as discussed in §2.1, e.g., long media read latency, memory interface, and coarse media access granularity. Therefore, we believe our work can be applied to future commercial storage-type NVMs.

Port to Future CXL-based Devices. Compute Express Link (CXL) [15, 25, 53] is an emerging interconnect standard. We believe that Light-Dedup can also be applied to the storage systems using CXL (e.g., NVMs interconnected with CXL) if the systems exhibit the common features that Light-Dedup focuses on. We leave this as our future work.

Port to Other Instruction Sets. Although Light-Dedup is currently implemented on x86, the idea of hiding long NVM media read latency with speculative prefetch can be applied to other instruction sets with prefetch instructions, such as ARM with the PRFM instruction [2].

5 Performance Evaluation

This section seeks to answer the following questions: (*i*) How does Light-Dedup perform against state-of-the-art NVM (deduplication) file systems? (§5.2) (*ii*) How does Light-Dedup perform in real-world scenarios? (§5.3) (*iii*) How does speculative prefetch in LRBI contribute to final performance? (§5.4) (*iv*) How efficient is the design of LMT? (§5.5) (*v*) How expensive is the Light-Dedup recovery mechanism? (§5.6)

5.1 Experimental Setup

Testbed. We evaluate Light-Dedup on a server with an Intel Xeon Gold 5218 CPU clocked at 2.3 GHz, which has 16 cores (32 hyper-threads) and 22 MiB of L3 cache with *clwb* support. The machine is equipped with 512 GiB Optane DCPMM (2×256 GiB DIMMs) in non-interleaved AppDirect Mode, and 128 GiB DRAM (4 × 32 GiB DIMMs). The server runs CentOS with kernel 5.1.0 modified by NOVA [48].

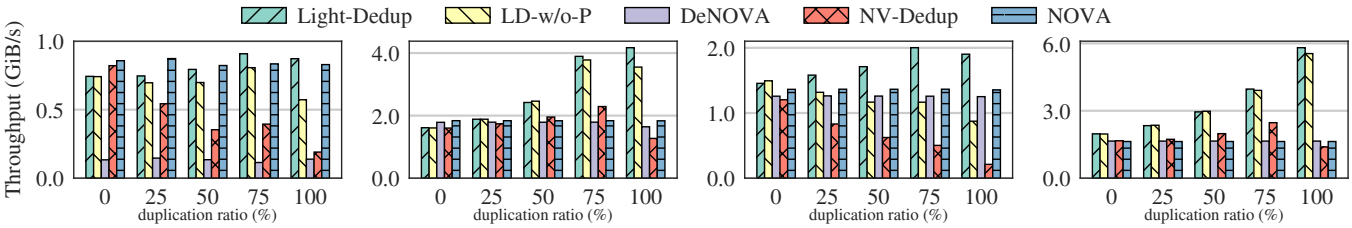
Compared Systems. We compare Light-Dedup with NOVA, NV-Dedup, DeNOVA, and LD-w/o-P. Among them, the source code of NV-Dedup is not publicly available, thus we re-implement it on top of NOVA[3], following the same configurations in their paper [58]. For DeNOVA, we implement the Deduplication Daemon (DD) based on the open-source version and deduplicate the data in the background aggressively (i.e., *DeNOVA-Immediate* [28]).

Methodology. FIO [4] is used to measure extensive I/O performance. We use *sync* as I/O engine to guarantee the persistence; 0–75% duplication ratio is emulated with parameter *dedupe_percentage*. For the 100% duplication ratio, we perform the same FIO twice and measure the performance of the second run. The reason is that 100% *dedupe_percentage* results in issuing a few unique blocks, which is quite different from the real scenarios. Moreover, we also measure four real-world workloads: copying compiled Linux kernel as code archiving scenario, replaying three realistic traces as frequent data operations scenarios. Among these traces, *WebVMs* and *Mails* are collected from FIU [27, 33]. *Homes* is generated from 50 students' home directories on our OS Lab server: we break the files into 4 KiB blocks, generate each of them md5 digest similar to FIU traces, and use the files' creation time as timestamps. Each measurement is repeated 5 times, and the average values are presented. All coefficients of variation are less than 5%, which suggests reproducibility and stability. The evaluation scripts are available at https://github.com/Light-Dedup/tests.

5.2 Microbenchmarks

We use FIO to evaluate the write performance of Light-Dedup under the different duplication ratios, write patterns, and concurrency levels, i.e., a single thread and 8 threads. Adding more threads does not contribute to the performance improvement due to the contention on the Optane DCPMM [67]. The workload data size is set to 128 GiB to observe a more stable result. Note that under the 100% duplication ratio, each

[3] https://github.com/Light-Dedup/nv-dedup



(a) Single thread (4KiB per I/O) (b) 8 threads (4KiB per I/O) (c) Single thread (2MiB per I/O) (d) 8 threads (2MiB per I/O)

Figure 7: Microbenchmark with FIO under different write patterns (4 KiB/2 MiB per I/O) and concurrency levels.

run performs 64 GiB writes. Further, to better support the large workload in FIO, we modify NOVA by removing the threshold of log extending and by making the extension always double the size of the inode log, which eliminates a substantial amount of many unnecessary *Fast GC*s [66]. The experimental results are shown in Figures 7.

Block-based I/O (4 KiB). Figures 7(a) and (b) represent the throughput of 4 KiB I/O writes. We find that: (1) Light-Dedup achieves 1.70–4.58× throughput over NV-Dedup when the duplication ratio is ≥75% since NV-Dedup suffers from cryptographic hash calculation overheads, while LRBI enables the efficient deduplication in either concurrency levels. (2) Light-Dedup is 3–15% slower than NOVA for the 0% duplication ratio, but the throughput can be 1.05–2.28× to the throughput of NOVA when the duplication ratio is ≥75%. (3) *IBP* contributes to 1–52% performance improvement under single thread compared to LD-w/o-P. However, its contribution is reduced with the increasing threads number due to dramatically enlarged read/write asymmetry; thus, the improvement of *IBP* is diluted. Notably, *CBP* cannot work ideally across syscalls. A possible reason is that the load queue [49] is flushed during the context switch.

Continuous Block I/O (2 MiB). Figures 7(c) and (d) represent the throughput of 2 MiB I/O writes, i.e., writing 512 4 KiB blocks in one syscall. We find that: (1) all the evaluated file systems gain higher write performance due to fewer syscalls. Among them, DeNOVA benefits the most since the contention of DD's dequeue and enqueue decreases significantly. (2) Under the single thread, Light-Dedup achieves 72–118% performance improvement when the duplication ratio is ≥75% compared to LD-w/o-P since *Cross-Block Prefetch* can leverage the locality of workloads to speculate the subsequent block efficiently in a single syscall.

Read-Write Interference. Although Light-Dedup trades slow duplicate writes for faster asynchronous reads, the mixed read/write I/O under multi-thread environments can potentially interfere with each other. This is because writing duplicate blocks require content comparisons and do not write redundant data, which can be seen as a reader-like operation. Conversely, threads that write unique blocks can be seen as writer-like because they aim to write new blocks. Such interference has been previously observed in NyxCache [61] and MT [69]. However, the goal of Light-Dedup is to improve overall performance by eliminating duplicate data blocks, and

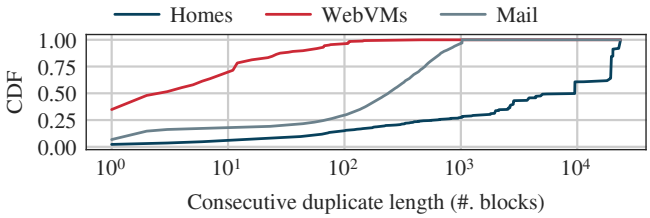


Figure 8: Cumulative distribution function of duplication continuousness of evaluated traces.

Table 3: Characteristics of evaluated real-world workloads.

Workload	Total I/O	Write Prop.	Dup Ratio	Granularity
Copy	13.85 GiB	100%	100%	2 MiB
Homes	63.52 GiB	100%	84%	4 KiB for Blk Max 2 MiB for Bat
WebVMs	54.53 GiB	78%	47%	4 KiB for Blk Max 2 MiB for Bat
Mails	173.27 GiB	91%	95%	4 KiB for Blk Max 2 MiB for Bat

we argue that even though individual tasks can be negatively affected, the overall performance can still be improved.

To show this, we run a set of experiments (not shown in the figure) on the case of 50% duplication ratio and 8 threads. To obtain the separate bandwidth of readers and writers, we make four threads write the duplicated data (as readers) while the remaining four write unique data (as writers). We observe that the bandwidth of Light-Dedup decreases to 1316 MiB/s for readers and 1052 MiB/s for writers when compared to the bandwidth of non-interfered systems with 4 readers (3380 MiB/s) and 4 writers (1608 MiB/s), respectively. However, when compared to the bandwidth of non-interfered systems with 8 writers (1624 MiB/s), the overall bandwidth of Light-Dedup with mixed 4 readers and 4 writers is improved to 2368 MiB/s. Experimental results show that Light-Dedup's non-cryptographic-hash-based deduplication approach can improve overall deduplication performance even in the presence of read-write interference.

5.3 Real-world Scenarios

In this subsection, we study the performance of Light-Dedup under real-world scenarios. The characteristics of the four workloads are summarized in Table 3. Specifically, **for *Copy***, we copy compiled Linux kernel twice from SSD to NVM, and the bandwidth of the second copying is measured. *Copy* can be considered as a real-world application that uses NVM as the storage of code repositories. **For the other three traces**,

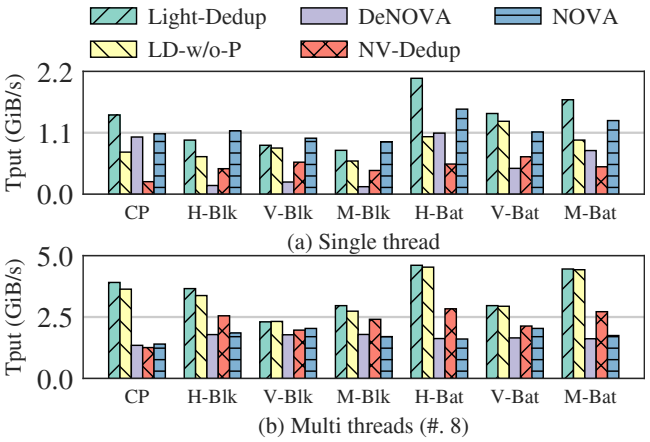

Figure 9: Performance comparison of real-world scenarios. Here, H, V, M indicate *Homes*, *WebVMs*, and *Mails*, respectively. Suffix "-Blk" (***block replay***) and "-Bat" (***batch replay***) indicate that each I/O processes one block and a batch of no more than 512 consecutive blocks, respectively.

we implement *trace-replayer*[4] to emulate the behaviors of a real-world application and replay traces. Unlike previous block-level trace replay tools [27, 33], *trace-replayer* can batch consecutive logical blocks in one syscall, which has the same rationale as many real-world applications (e.g., batching the reads/writes using a local buffer). The insights can be reflected in Figure 8. *Homes* and *Mails* traces show good spatial locality, which the speculative prefetch can well exploit. For *WebVMs*, there are only 30% duplicate blocks whose consecutive length is $>$10 blocks (point $(10, 0.70)$), which shows relatively poor continuousness.

Figure 9 compares the throughput of Light-Dedup and the other four approaches under different real-world workloads. For DeNOVA, we configure *trace-replayer* to replay the traces by appending data but ignoring the given data offset due to its bugs of handling overlapping writes. Light-Dedup shows the best deduplication performance under all workloads in most cases. In particular, (1) during *Copy*, Light-Dedup is much faster than other approaches since speculative prefetch markedly hides read latency under a single thread (due to the continuousness of the workload). (2) During *block reply*, *In-Block Prefetch* shows its effectiveness under a single thread. With the increasing number of threads and the enlarged read/write asymmetry, the throughput of LD-w/o-P catches up with that of Light-Dedup. (3) During *batch replay*, speculative prefetch contributes a lot to single-thread performance with a high duplication ratio. For example, for single-thread *Mails*, Light-Dedup achieves 1.28× write throughput compared to NOVA under a single thread. However, LD-w/o-P cannot even catch up with NOVA's throughput.

5.4 Speculative Prefetch Efficiency

In this subsection, we study the efficiency of prefetching and speculation by using FIO with block size set to 2 MiB, and *Copy* as our benchmarks.

Single-thread Comparison. Figure 10(a) writes the same 64 GiB data twice (using **FIO**) with a single thread, and the second writing bandwidth is measured. *PN* significantly exceeds other variants by 1.11–2.19×, mainly because prefetch enables the parallelism of CPU calculation and NVM I/O and significantly reduces content-comparison time. We further measure the deduplication performance of *Copy* under a single thread. Figure 10(b) presents the throughput of the second copy. The result is similar to FIO, except the overall throughput is lower. This is because there are 44% small files (less than 4 KiB) in the Linux kernel source code, and these small files degrade the deduplication performance.

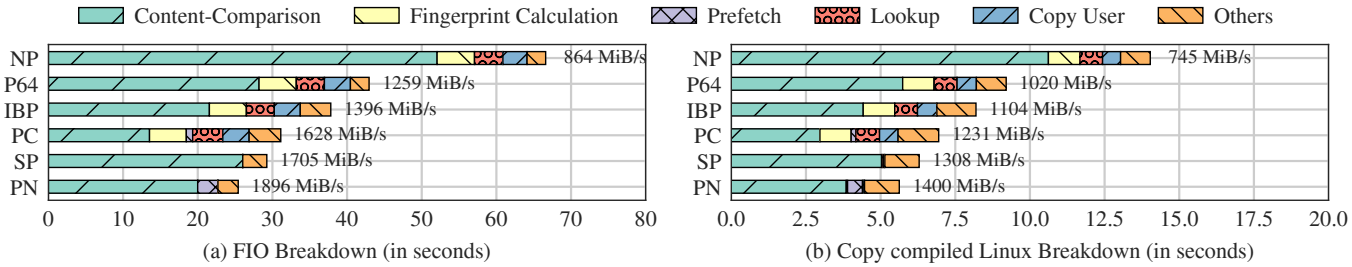
Multi-thread Comparison and Observations. To study how *PN* scales with the increasing concurrency level, we use the same FIO benchmark but with the number of threads set to 1–16. Figure 11 presents the second write performance. The figure shows that: (1) The throughput of *PN* is 1.03–1.29× and 1.51–2.19× that of *SP* and LD-w/o-P when the threads number ≤ 5 since *PN* prefetches NVM data into the CPU cache, which reduces content-comparison time. (2) When the threads number ≥ 6, *SP* shows about 1.11–1.80× throughput compared to *PN*. According to the breakdown performance (not shown in the figure due to space limits), we find that the content-comparison time of *PN* rises up to 1.65× to that of *SP* under 16 threads, which suggests the large amount of extra prefetch I/O exacerbates the contention of in-NVM buffers and thus leads to longer I/O latency. (3) The evaluation shows that *CBP* (i.e., *PN+Transition*, see §4.3) combines the benefits of *SP* and *PN* and scales well with the increment of threads.

5.5 Metadata I/O Amplification in LMT

To study the efficiency of region-based layout in LMT, we have designed a workload to quickly age the file system. (1) We first write a 128 GiB file (2 MiB per I/O) to a newly mounted deduplication file system (Fresh System). (2) Next, we punch the file randomly by using `fallocate()` until the file size is reduced to half. This step creates random holes in the file system, which emulates the aging process (Aged System). (3) Finally, we write another 64 GiB file to fill the holes. In the aged system, the spatial distribution of free entries is random. Inappropriate metadata management (e.g., *entry-based* layout used in NV-Dedup [58]) can cause severe read/write amplification and consequently decline the system's I/O performance.

Table 4 shows the comparison between *region-based* and *entry-based* metadata layout in multiple dimensions under the aging workload. The evaluation shows that *region-based* consistently outperforms *entry-based* in all the dimensions and can resist fragmentation problems. Maintaining the locality of entries significantly reduces the write amplification under the aged system (i.e., from *entry-based*'s 9.86× to *region-based*'s 3.43×), and improves about 11.6% write throughput relative to *entry-based*. The results suggest that *region-based* meta-

[4]The tool is available at https://github.com/Light-Dedup/nvm_tools



(a) FIO Breakdown (in seconds)

(b) Copy compiled Linux Breakdown (in seconds)

Figure 10: Performance comparison and breakdowns of different variants. For simplicity, we denote LD-w/o-P as *NP* (i.e., no speculative prefetch), and recall that IBP is *In-Block Prefetch*. Note that *Cross-Block Prefetch (CBP)* is effectively equivalent to *PN* in single-thread experiments; thus, it is omitted in the above figures.

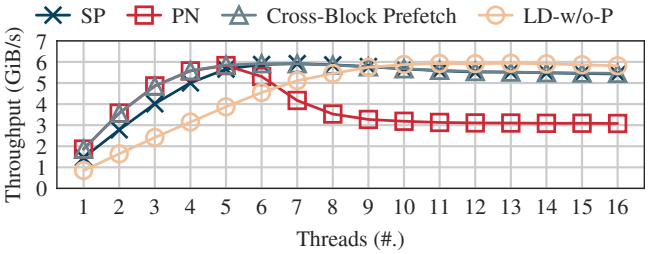


Figure 11: Performance comparison between different deduplication strategies under different threads.

Table 4: Comparison of region-based and entry-based metadata layout under the aging workload.

Dimension	Fresh System (128 GiB)		Aged System (64 GiB)	
	Region	Entry	**Region**	Entry
Reads Per Block (B)	116.28 (2.91×)	126.94 (3.17×)	**244.19 (6.1×)**	774.13 (19.35×)
Writes Per Block (B)	75.75 (1.89×)	79.56 (1.99×)	**137.17 (3.43×)**	394.54 (9.86×)
Throughput (MiB/s)	1747.5	1690.6	**1336.72**	1197.76

data layout is more friendly to NVM deduplication, especially in an aged file system (which is common in the production environments).

5.6 Recovery Overheads

Table 5 studies the unmount time, normal recovery time, and failure recovery time of NOVA and Light-Dedup with different sizes of files (the total number of files is fixed to 32). The results show that although Light-Dedup causes overheads during recovery, its unmount and failure recovery time remains the same trend as NOVA (linearly) as the file size grows. We argue that trading longer unmount/recovery time for more efficient runtime is reasonable for NVM deduplication.

6 Discussion

Memory Consumption of *rhashtable*. We observe that the memory consumption of writing 128 GiB data under 0%, 25%, 50%, and 75% duplication ratio is 1.26 GiB, 1.08 GiB, 658 MiB, and 331 MiB, respectively. The experimental results indicate that the memory consumption is less than 1% of the data size (e.g., $1.26GiB/128GiB \approx 0.98\%$).

Hardware-based Cryptographic Hash Calculation. There are several hardware accelerators developed for efficiently calculating cryptographic hash [5, 14, 42, 55]. However, they are not widely deployed and require special hardware. Therefore, they are not considered in this paper.

Table 5: Comparison of recovery overheads.

Dimension	File system	File system utilization (GiB)		
		32 × 1	32 × 2	32 × 4
Umount Time (s)	NOVA	0.385	0.775	1.502
	Light-Dedup	0.551	1.095	2.099
Normal Recovery Time (s)	NOVA	0.015	0.015	0.015
	Light-Dedup	0.617	1.223	2.398
Failure Recovery Time (s)	NOVA	0.315	0.488	0.829
	Light-Dedup	1.260	2.372	4.604

Scalability on Multiple Optane DCPMMs. We run a 32 GiB FIO workload with 75% duplication ratio on two interleaved 256 GiB DCPMMs. The experimental results show that the throughput of Light-Dedup increases from 952 MiB/s to 6238 MiB/s with 1–16 threads, suggesting Light-Dedup can scale with increasing threads on multiple Optane DCPMMs.

7 Conclusion and Future Work

In this paper, we propose Light-Dedup, a light-weight inline deduplication framework for NVM file systems. With the NVM-aware Light-Redundant-Block-Identifier (LRBI) and Light-Meta-Table (LMT), Light-Dedup is able to maximize NVM deduplication performance by fully considering NVM's I/O mechanisms (e.g., long media read latency). Evaluation results show that the deduplication cost is low, and the performance can be enhanced if the duplication ratio is high. Since memory usage is sensitive to server environment [28], we plan to incorporate other memory-efficient hash table design [36, 45, 73, 74] to optimize Light-Dedup's index further.

Abstract

This paper presents *TiDedup*, a new cluster-level deduplication architecture for Ceph, a widely deployed distributed storage system. Ceph introduced a cluster-level deduplication design before; unfortunately, a few shortcomings have made it hard to use in production: (1) Deduplication of unique data incurs excessive metadata consumption; (2) Its serialized tiering mechanism has detrimental effects on foreground I/Os, and by design, only provides fixed-sized chunking algorithms; and (3) The existing reference count mechanism resorts to inefficient full scan of entire objects, and does not work with Ceph's snapshot. *TiDedup* effectively overcomes these shortcomings by introducing three novel schemes: Selective cluster-level crawling, an event-driven tiering mechanism with content defined chunking, and a reference correction method using a shared reference back pointer. We have fully validated *TiDedup* and integrated it into the Ceph mainline, ready for evaluation and deployment in various experimental and production environments. Our evaluation results show that *TiDedup* achieves up to 34% data reduction on real-world workloads, and when compared with the existing deduplication design, improves foreground I/O throughput by 50% during deduplication, and significantly reduces the scan time for reference correction by more than 50%.

1 Introduction

Open source infrastructure management systems [18, 30] have helped cloud providers of different scales deliver services at low costs [4, 7, 14, 37]. Progresses in corporate digitalization and new classes of data-intensive applications are fueling fast growth of data in the cloud and call for scalable and efficient data storage [17, 34]. For such cloud serving storage, deduplication is expected to offer a means to mitigate the cost issue. However, most general-purpose distributed storage systems in use today do not provide cluster-level deduplication.

Several technical challenges partially explain why that is the case. First of all, all components in a successful deduplication architecture should be designed with scalability in mind. Moreover, the architecture should consider various data types, like file, block, and object, in search for data reduction opportunities. Last but not least, the architecture must have compatibility with existing services in the storage system, like snapshot operation. More comprehensive research is needed to make deduplication generally available in distributed storage systems (see Section 8 for further discussions).

The situation is no different in Ceph [42]. It has become a dominant open source distributed storage system in cloud environments thanks to its design that takes reliability and scalability as the first priority [7, 31]. However, capacity optimizations like deduplication were not seriously considered in early designs, and thus, Ceph has failed to meet growing data demands in various installed configurations.

Recently, a cluster-level deduplication design was proposed for Ceph [29]. While the work presents worthy efforts (and is a baseline in our evaluation in Section 5), it contains critical technical issues that we believe will hold back its use in production environments. We capture three of them here.

First, the prior design blindly performs deduplication regardless of the amount of unique contents in a target object. Deduplicating a unique object brings no benefit and only increases computation and storage overheads. Since the amount of unique contents in objects depends highly on the workload, this approach might undermine deduplication efficiency, even more so in Ceph because it is a general purpose storage system for diverse data sets.

Second, the prior design relies on a limited tiering architecture that depends on coarse-grained processing and fixed size chunking (FSC). A single background thread of Object Storage Daemon (OSD) is responsible for all tasks required for deduplication. This architecture suffers performance degradation due to time-consuming object enumeration with a lock and a limitation on on-demand deduplication by external agents. Moreover, FSC is not always the most effective way to find duplicate chunks in real-world workloads [28, 47].

Lastly, the prior design approach has drawbacks in its reference management method. Specifically, it does not work hand in hand with Ceph's snapshot feature because it lacks chunk reference management on an object snapshot. In addition, the reference counting method in the prior work takes a significant amount of time to identify reference mismatches on deduplicated chunks, because it requires full object search in the storage pool to count references.

In this work, we propose a new cluster-level deduplication

architecture, called *TiDedup*, which does not have the aforementioned issues while respecting the core design principles of Ceph. Thanks to its design choices and implementation strategies, *TiDedup* effectively targets a general purpose distributed storage system for both primary and backup storage [10, 11], by providing file, object, and block services. *TiDedup* incorporates three key design schemes:

1. Selective cluster-level crawling. *TiDedup* implements a crawler process that incrementally searches and identifies redundant chunks to selectively trigger deduplication. By doing so, *TiDedup* successfully removes only redundant chunks with minimum overheads.

2. Event-driven tiering mechanism with content defined chunking (CDC). *TiDedup* eliminates background work in OSD and is designed to execute reactions upon an event to handle multiple requests concurrently. On top of that, new tiering APIs (*set_chunk*, *tier_flush*, *tier_evict*, and *tier_promote*), as well as control and data path with CDC, are introduced.

3. Object ID (OID) shared reference scheme. We propose an efficient reference management method using OID. By sharing OID reference information between adjacent snapshots, *TiDedup* not only makes deduplicated objects compatible with snapshot, but also minimizes messages between OSDs at snapshot creation time. In addition, by using OID as a backpointer, *scrub*—a job to identify and fix inconsistencies (e.g., reference mismatch)—is able to check whether the reference is valid without performing a full object search.

Our evaluation results show that *TiDedup* effectively saves storage space by up to 34% on real-world workloads including industrial manufacture data and corporate cloud services. Moreover, *TiDedup* outperforms the prior approach by 50% in throughput during deduplication. Importantly, our implementation passes the *teuthology test* [38], Ceph's quality test suite, demonstrating the robustness and readiness of *TiDedup* for real-world evaluation and production uses. This paper makes the following contributions:

- We demonstrate the challenges in modern distributed storage system when applying deduplication and overcome the challenges by introducing *TiDedup* (Section 3 and 4). Compared to the previous approach [29], *TiDedup* is scalable and compatible with Ceph's existing design philosophy and features. *TiDedup* allows the use of various chunking algorithms with extensibility, different from other tiering-based architectures [9, 49]. Our cluster-level reference management design is more efficient than existing reference count techniques [6].
- We propose a pluggable design that is applicable to Ceph and show how the design works in detail (Section 4). Since our proposal is based on a hash algorithm to locate objects, it can be applied to other systems that build on a similar hash algorithm, like GlusterFS [15], Swift [36] and Cassandra [19].
- We perform comprehensive evaluation using a realistic experimental setup (Section 5). Our evaluation shows that *TiDedup* effectively performs deduplication while having little impact on foreground I/O, and achieves more than 50% scrub time reduction, compared to the existing approach. We discuss design trade-offs based on evaluation results (Section 6).
- *TiDedup* has been merged into the Ceph main branch and is the default deduplication engine for Ceph. *TiDedup* is available to anyone for evaluation and production.

2 Background

This section provides a brief overview of Ceph and explains several key terms that will be used throughout this paper.

2.1 Ceph

Ceph [42] is an industry-leading open-source distributed storage system. It provides file, object, and block services to clients on a unified distributed object store called a Reliable Autonomic Distributed Object Store (RADOS), comprised of multiple OSDs. Ceph exploits a decentralized hash algorithm, known as CRUSH [43], to determine the object location within RADOS. An OSD is responsible for serving, replication, and recovery of objects on top of a block device. In this paper, we mainly deal with RADOS because it is the primary component involved with all three services.

Ceph uses three terms—POOL (tier), Placement Group (PG), and object name—to represent the object location. The tier is a global namespace that consists of PGs, and PG indicates a logical group of objects. In addition, every PG links a replication group, which maps a set of OSDs. By using Ceph's OID format—this includes the tier and object name—as an input argument of CRUSH calculation, Ceph can find out PG ID. Therefore, if an OID is given, Ceph is able to look up the OSD where the object is located. Note that objects that belong to different PGs can co-exist in the same OSD.

2.2 Deduplication

Deduplication is a well-known data reduction technique to eliminate redundancy in data [24, 44]. Its typical process is composed of the following three steps: chunking (e.g., fixed size chunking [33] and content-defined chunking [26, 46]), fingerprinting (e.g., sha256), and comparison with existing fingerprints [29, 46]. However, performing deduplication does not always lead to space savings because datasets have different amount of redundancy; for example, datasets of web and mail servers [25] may have lower duplicate data than backup [39] and registry workloads [16, 49].

2.3 How deduplication works with Ceph

Previously, Ceph proposed selective post processing deduplication based on a tiering mechanism [29]. In this design, Ceph divides a logical storage space into two groups: a base tier and a chunk tier. They manage metadata objects and chunk objects, respectively.

Upon a write request, every object is written to the base tier first as a metadata object; at this time, it is considered

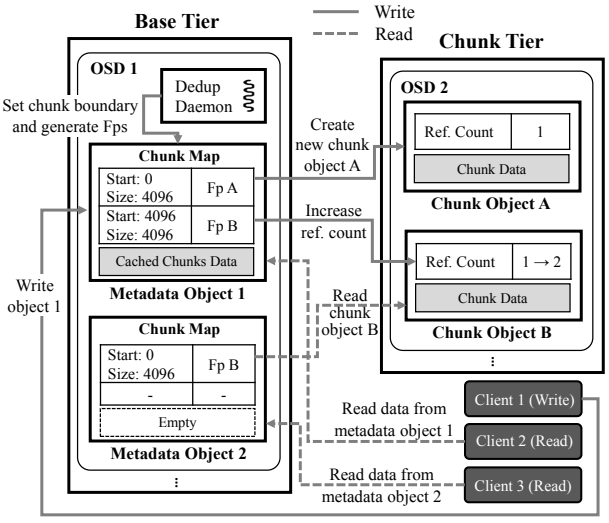

Figure 1: Ceph deduplication in prior work [29].

hot and is not eligible for deduplication. When the metadata object becomes cold (by LRU), OSD divides its content into several chunks using FSC, and generates a fingerprint from the corresponding chunk (e.g., Fp A and Fp B of Metadata Object 1 in Figure 1). Next, OSD stores the generated fingerprints in a chunk map of the metadata object. Then, using the fingerprint as OID, OSD stores the chunk as a chunk object in the chunk tier (Chunk Object A and B). If the chunk object already exists, OSD just increments the reference count by one. If not, OSD writes the chunk object, and sets the number of references to one.

To serve a read request, OSD searches metadata objects using the original OID. If the cached data resides in an object like Metadata Object 1 in Figure 1, the cached data is returned to Client 2. Otherwise, like Metadata Object 2, OSD retrieves the fingerprints from the chunk map, then it reads Chunk Object B by using the fingerprint (Fp B) as an OID. Finally, the OSD relays the data of Chunk Object B to Client 3.

Note that Ceph utilizes the CRUSH algorithm once again to calculate the chunk object location instead of maintaining a separate fingerprint index store. This technique is called double hashing [29].

2.4 Snapshot in Ceph

Ceph handles object snapshots via explicit APIs such as creation and deletion. OSD creates a new snapshot when a user makes a change on an object, at which point the version of the modified object is increased while keeping existing OID.

3 Motivation

3.1 Deduplication on unique chunks

In the prior approach, OSD decides whether an object needs to be deduplicated or not depending on which state the object is in between hot and cold instead of its redundancy; if the object is cold, OSD forces it to be deduplicated without checking its

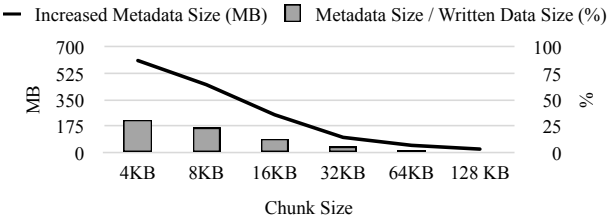

Figure 2: Metadata space overhead when deduplicating on unique objects. The total size of objects is 2 GB with 4 MB objects. Metadata size includes deduplication metadata (e.g., chunk information and fingerprint) and object (chunk and metadata) metadata.

redundancy. Therefore, the deduplication procedure inevitably generates unnecessary metadata even though the object has no redundant chunks. In the worst case, the amount of metadata could account for more than 30% of the total writes as shown in Figure 2. To eliminate the space overheads of the metadata, the best way is to remove only duplicate copies of chunks. To do so, however, we face the following two challenges:

Lack of knowledge of duplicate chunks. Ceph does not keep track of redundant objects. Moreover, to learn such information, each OSD would have to periodically check redundancy of all the objects in other OSDs, resulting in high overheads, interfering with foreground I/Os.

Object state and chunk-level management. The prior object management approach is unable to handle the cold object that has only unique chunks; when the object becomes cold, OSD deduplicates the cold object implicitly, degrading deduplication efficiency. To avoid this problem and maintain compatibility with the existing Ceph implementation, an additional state is needed to distinguish between unique and duplicate during the state transition from hot to cold. Moreover, there is a chance that an object has too few duplicate chunks to benefit from the reduced footprint of metadata. In this case, it's better not to deduplicate the object because the majority of the chunks are not redundant.

3.2 Structural limitations

Coarse-grained tiering mechanism. Ceph uses a coarse-grained tiering approach for deduplication; a background thread in each OSD updates the object state (hot or cold) and performs deduplication. However, it places a negative impact on the OSD foreground performance. In fact, to ensure consistency, Ceph holds a lock on PG even within an iterative loop for object enumeration to protect live objects in PG. Note that this PG lock is required when OSD handles a write operation to append a PG-level log for recovery. This is not a problem when the number of objects is small. However, if OSD contains a large number of objects, it is non-negligible because even simple object enumeration is very costly.

Moreover, the proposed tiering method does not expose the interfaces that allow other external modules to gather chunk information and trigger deduplication on demand. This strategy limits the effectiveness of deduplication.

No support for CDC. As an initial step, deduplication in Ceph was proposed based on FSC. FSC has the benefit of the low overhead calculation to determine chunk boundaries because it uses a predefined chunk size. However, it is well known that there is a boundary-shift problem [26] in some workloads. To avoid the problem, many studies have exploited CDC [10, 23, 24, 32]. We have tried complementing the fixed chunking's limitation using CDC. Unfortunately, applying CDC to the existing system leads to another challenge.

In the FSC approach, the user should configure the size of the chunk manually, then a background thread in OSD deduplicates the content of the chunk. This method is quite straightforward—there are only three operations: (1) set a chunk range (e.g., 8 KB chunk), (2) generate a fingerprint from the chunk, and 3) perform the content migration from the base tier to the chunk tier. In other words, once a range is set, the range remains valid until the range setting is changed. However, it does not seem well suited in terms of CDC because CDC generates different chunk sizes depending on the content; CDC may end up triggering multiple range changes even when a single chunk is mutated, so that the chunk ranges need to be recalculated.

Also, the prior approach uses three chunk states for deduplication: MISSING, DIRTY, and CLEAN. MISSING means that the content of the chunks does not exist in the base tier (not cached). DIRTY represents that the object was updated after the chunk was deduplicated, while CLEAN indicates that nothing has changed since the last deduplication operation. However, in CDC, there is no DIRTY state. If the chunk becomes dirty, its state becomes invalid as chunk range recalculation is required.

3.3 Inefficient reference management

The prior approach uses a false-positive based reference counting design [29]—while a chunk object is allowed to have a reference of deleted metadata object, the metadata object is guaranteed to always point to a valid chunk object—to prevent the failures. Nevertheless, it has other limitations, as follows:

Limitation of using the reference count. Reference mismatches may occur if OSD crashes and fails to successfully complete operations to update reference counts. To check reference mismatches in Ceph, the *scrub* process selects a chunk object, then scans all metadata objects to examine how many metadata objects have the reference of the chunk object; the expected reference count should be less than or equal to the reference count the chunk object holds. Note that the chunk object holds its own reference count, as explained in Section 2.3. Moreover, this behavior is repeated for all chunk objects, which in turn causes a scalability problem as the number of objects grows. The time complexity of the *scrub* process is $O(\#\text{chunk objects} \times \#\text{metadata objects})$.

Snapshot compatibility. In the previous approach, most of the features work with deduplicated metadata objects, but the snapshot feature does not, because reference management is missing for snapshot.

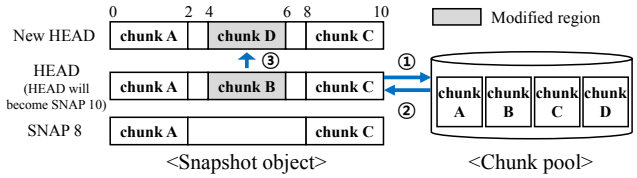

Figure 3: Ceph reference management (1. Send reference increment message, 2. ACK, 3. Update chunk information). SNAP represents a snapshot.

T	1	32	64	128	256	512
Latency (sec.)	0.13	0.32	0.72	1.8	3.96	9.37

Table 1: Snapshot creation time (T: the number of chunks on 4MB object, ten objects are used)

One straightforward yet naïve approach to supporting snapshot would be to increase (or decrease) the reference counts of all chunks of a deduplicated object whenever its snapshot is created (or deleted). However, this would generate an excessive number of messages among OSDs. Figure 3 describes the overhead. There is a HEAD that is the latest object version. For an incoming write to update the HEAD, OSD creates a snapshot (SNAP 10) in ascending order, excluding the new write. At this time, all chunk information within unmodified regions (chunks A and C) in the HEAD should be copied to the new HEAD's metadata ❸, after the reference increment (❶ and ❷) is done. Therefore, the snapshot creation will be delayed until OSD receives all ACKs for the reference increment. Note that an operation to increase reference count is synchronously done due to false-positive characteristics. Table 1 shows the snapshot creation time depending on the number of chunks. If there are 512 chunks on objects, the latency dramatically increases up to 9.37 seconds.

Aside from the delay, there is a redundant increase in the chunk's reference count if every snapshot has its own reference. For example, the reference count of chunks A and C will be three because new HEAD, SNAP 8 and SNAP 10 have the same chunks A and C in Figure 3. What is important is that even if the new HEAD, SNAP 8 and SNAP 10 are deleted, the reference count may not decrease due to the false-positive based reference counting strategy used. Although this reference leak can be fixed via the *scrub* process, it consumes additional space, until the *scrub* process is complete.

4 Design and Implementation of TiDedup

Figure 4 describes the overall structure of *TiDedup*. Basically, clients are not aware of the existence of the chunk tier and issue I/Os to the metadata objects in the same way as normal objects. For instance, the OSD stores content to the metadata object (W1) on a write request. In addition, upon a read request, OSD either returns the metadata object to the client immediately if it is cached (R1) or reads the content

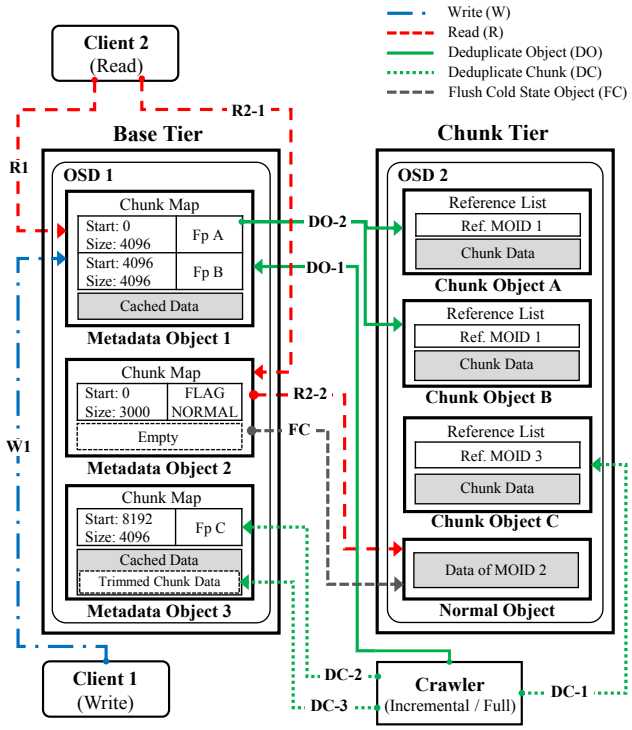

Figure 4: *TiDedup* architecture.

from the chunk object (R2-1 and R2-2). The crawler, which is responsible for triggering deduplication, scans objects—the scanning range is evenly divided and distributed to multiple threads in the crawler—on the base tier in either an incremental or full manner to look for redundant chunks. Then, the crawler checks the state of the metadata object using *stat*; *stat* retrieves the metadata object's information about hotness, deduplicated, and dirty. Depending on the state of the metadata object, the crawler works as follows.

- If the metadata object is hot, the crawler skips performing deduplication.
- If the metadata object is cold and contains more duplicate chunks than the threshold, the crawler performs deduplication if the object was not deduplicated before.
- If the metadata object is cold and has a few duplicate chunks, the crawler makes sure that the cached data is moved to the chunk tier (FC).

The crawler performs deduplication on the target object by using either *tier_flush* (DO1 and DO2 in Figure 4)—triggering CDC and moving chunks to chunk objects—or *set_chunk*—copying a target chunk to a chunk object in chunk tier (DC1) and setting a reference between metadata object and chunk object (DC2). Then, the crawler calls *tier_evict* to trim a range of the chunk in the metadata object, if necessary (DC3). These APIs will be described fully in Section 4.2.1.

4.1 Selective cluster-level crawling

To reduce the overhead as described in Section 3.1, we propose Selective cluster-level crawling, which crawls and carefully deduplicates objects on a base tier. The crawler is designed to run as a stand-alone application by decoupling a controller scheme—finding live objects and triggering deduplication—from OSD. Furthermore, we adopt incremental and full modes of crawling; both modes are introduced to figure out dedup-able objects on the base tier, but their crawling costs are different. In incremental mode, by choosing a small number of metadata objects gradually, the crawler reduces the chances of overutilizing system resources; during the daytime, it runs not to disturb user I/Os and unexpected high-priority I/Os, such as recovery and consistency checks. However, the incremental mode can not determine all dedup-able objects at once due to the limited range of search. To complement this weak point, full mode applies the full search without idle time. The drawback of the scheme is that it consumes more resources than the incremental mode does. Therefore, the crawler in full mode is scheduled to run once a week or at a longer interval, mostly during the nighttime when the system anticipates lower user I/O traffic.

In incremental mode, at first, the crawler gets a list of live objects sorted by OID on the base tier, then chooses a small group of objects from the list. Next, the crawler looks for redundant chunks among the selected objects—the crawler reads the objects, then runs CDC on the objects to calculate the fingerprint from the chunk, checking if the fingerprint is identical to other fingerprints collected before. The crawler considers the chunk a duplicate chunk if the chunk meets the condition; we define `chunk duplicate count`, which is the number of redundant chunks among the objects. If `chunk duplicate count` is higher than the threshold value K, the crawler regards the chunk as a good candidate for deduplication. Once duplicate chunks are found, the crawler has two tasks to do as follows. First, the crawler performs chunk-level deduplication (DC1, DC2, and DC3 in Figure 4). Second, the crawler checks information about how many duplicate chunks there are in an object. We call it `intra-object deduplication ratio`. The object, which has higher `intra-object deduplication ratio` than the threshold value L, is deduplicated via *tier_flush*, which is explained in the next section, by the crawler. The crawler pauses incremental mode when the tasks for the small group of objects are done, and resumes incremental mode, choosing the next small group of objects after the user-configured time T, 30 seconds by default. If there are no remaining objects in the list, the crawler refreshes a list of live objects. Then, it repeats the procedure in reversed direction while clearing the collected fingerprint list. In full mode, the differences from the incremental mode are the time interval and the search scope—it scans all objects in the base tier with a large time interval.

The crawler manages an in-memory fingerprint store to keep track of duplicate chunks; a key-value pair is used: ⟨fingerprint : redundant count⟩. The crawler updates the pair value when a fingerprint is calculated in either incremental

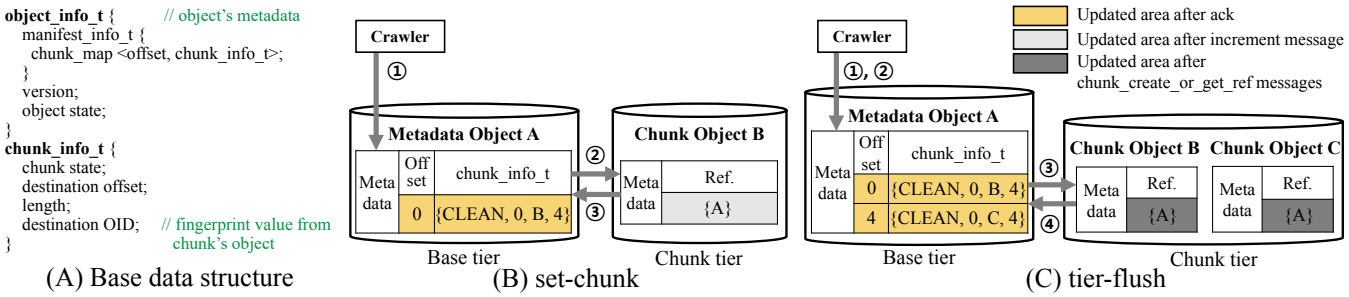

Figure 5: Base data structure and two API procedures (*set_chunk* and *tier_flush*).

or full mode. If memory usage exceeds a given threshold value configured at startup, the crawler deletes all entries in the fingerprint store, except for duplicate fingerprints—the number of redundancies is higher than the threshold—information. This strategy might lose deduplication opportunities; the crawler is likely to drop fingerprints that appear once in a while under memory pressure. However, the crawler can become stateless, which overcomes practical issues via simple re-execution.

Object Management. A metadata object in a base tier can be in one of the following states: hot, cold, or deduped. When an object is newly created, its initial state is set to hot by default; the hot object is not deduplicated because it is more likely to be mutated in the near future. The transition from hot to cold takes place over time when *TiDedup* determines that a certain hot object needs to be evicted based on LRU. Then, the cold object is deduplicated if the corresponding object contains more duplicate chunks than `intra-object deduplication ratio` by the crawler. Otherwise, the cold object is migrated to the chunk tier without deduplication process (no chunking and fingerprinting).

TiDedup promotes chunk objects to the base tier if they are either updated or frequently accessed by read operations to avoid decoding overhead of deduplication; the object state is changed to a hot state at this time. Since we decide not to use the background thread at all, as explained in the following section, OSD keeps the object state using existing in-memory object metadata (*object_info_t*) and updates its state when the object is accessed.

4.2 Event-driven tiering mechanism with CDC

We design event-driven tiering to process multiple requests concurrently and minimize interference to foreground I/Os. Event-driven tiering does not perform any background works that can affect incoming I/O requests. Instead, it exposes APIs to the crawler to perform deduplication on demand. In addition, we redesign the overall I/O path to support CDC.

Basic read and write. Upon a read request, OSD looks up the metadata of the corresponding metadata object (*object_info_t*) where *manifest_info_t*—metadata related to deduplication—is stored. As shown in Figure 5 (A), *manifest_info_t* has *chunk_map*, which is a map data structure including source offset and *chunk_info_t*, to maintain mapping information between the source and destination chunk. Plus, each *chunk_info_t* has a state variable that indicates either MISSING or CLEAN. If the chunk state is MISSING, OSD calls *tier_promote* to move the chunk object from the chunk tier to the base tier in advance of responding to the user. If the chunk state is CLEAN, OSD replies to the user with the existing content the metadata object has.

For a write request, before storing content to the metadata object, OSD clears the chunk information (*chunk_info_t* in *chunk_map*) within modified range, while sending delete messages; if the write request overwrites a whole range of the object, no *chunk_info_t* exists. This is because modifying content means that the corresponding chunks are no longer meaningful—all chunk boundaries should be recalculated by CDC.

4.2.1 APIs with CDC

Set_chunk. The purpose of *set_chunk* is to set a chunk boundary within a metadata object for deduplication to support a case that only a specific range of the metadata object is redundant. To do so, *set_chunk* stores the given input argument—<source OID, destination OID, source version, source offset, length, and destination offset>—to the corresponding *chunk_info_t* in *chunk_map*. *Set_chunk* has two main roles: (1) to increase the target chunk' reference count, and (2) to update the chunk information.

As soon as OSD receives a *set_chunk* message from the crawler (❶ in Figure 5 (B)), it sends a message to add the reference of the source object ❷. Since calling *set_chunk* implies that the source object takes a reference of the target chunk object, reference increment should be conducted before the chunk information is stored. We will describe reference management in more detail in the next section. After the reference increment is completed ❸, *TiDedup* updates *chunk_info_t*. For example, when a user calls *set_chunk* with <source OID, fingerprint OID, v2, 4096, 8192, and 4096>, the OSD adds *chunk_info_t* (CLEAN, 4096, fingerprint OID, 8192) to *chunk_map* at offset 4096 if the object's version is v2; note that OID includes tier information where the object is located and OSD increases the object's version number whenever the object is changed. The crawler is required to maintain the target version to deduplicate objects correctly.

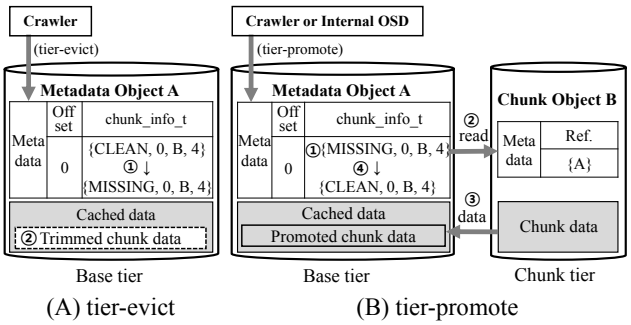

Figure 6: Procedure of *tier_evict* and *tier_promote*.

Set_chunk presumes that the target chunk is already copied to the destination OID before calling *set_chunk*, so the initial state of *chunk_info_t* is CLEAN.

Tier_flush. The crawler invokes *tier_flush* to remove redundancy on a metadata object, not a chunk; *tier_flush* deduplicates all contents on a metadata object explicitly if the object is not hot. Once *tier_flush* is called (❶ in Figure 5 (C)), OSD reads all contents from the metadata object, then executes CDC to generate chunks. After that, OSD generates a fingerprint value from each chunk ❷. Using given the fingerprint values as OID (B and C), OSD sends other OSDs in the chunk tier a compound operation, called *chunk_create_or_get_ref* ❸—this operation either increases the reference count if the target object is present or creates a new object with setting the reference count to one through transaction if the object does not exist. Once OSD receives all completion responses of the *chunk_create_or_get_ref*, it stores the metadata changes (e.g., *chunk_info_t*), and set the metadata object to deduped ❹. Although a failure can occur on rare occasions during *tier_flush*, *TiDedup* maintains consistency, because the metadata changes caused by *tier_flush* are not persistent until all the *chunk_create_or_get_ref* operations are completed. Note that *tier_flush* only updates metadata in terms of the metadata object. For example, if two out of ten *chunk_create_or_get_ref* are only successfully completed, *TiDedup* never updates the corresponding *chunk_info_t*. Instead, the crawler will retry to deduplicate the metadata object because it is not marked as deduped.

Tier_evict. *Tier_evict* removes the object's content using the punch-hole technique [20,22]. Figure 6 (A) demonstrates how *tier_evict* works. There is chunk B on the metadata object A. Once *tier_evict* is called, chunk B is marked as MISSING ❶, and then chunk B is trimmed from the metadata object A ❷, thereby resulting in a transition from a normal file to a sparse file. Note that the remaining parts of the metadata object A, which are not used as a chunk, remain on the metadata object A without removal. If a user tries to access the trimmed chunk, OSD in the base tier retrieves the original content from the chunk tier, before handling the user request.

Tier_promote. *Tier_promote* performs chunk migration from the chunk tier to the base tier even if a single chunk of metadata object is MISSING. Upon *tier_promote*, *TiDedup* finds chunks that have MISSING state in the metadata object ❶, as shown in Figure 6 (B), then sends read requests to corresponding chunk objects ❷. After the read requests are completed, *TiDedup* stores the given chunks in the base tier ❸. Unlike *tier_flush*, *tier_promote* updates chunk's content, and changes the chunk state from MISSING to CLEAN as soon as each read is succeeded ❹. For instance, although two out of ten reads are completed, *TiDedup* keeps the two completed chunks up-to-date.

4.3 OID shared reference management

To minimize *scrub* overhead and provide snapshot compatibility, we propose OID shared reference management design based on false-positive reference counting.

Data format for reference management. As described in the previous section, reference management using the number of references causes the *scrub* process to take a significant time to complete. To reduce the execution time for the *scrub* process, *TiDedup* makes use of Ceph's OID format to represent the reference instead of using a simple number. Since Ceph's OID contains location information, as described in Section 2.1, *TiDedup* can efficiently retrieve objects by their OID. In other words, if OID is used as a reference, *TiDedup* is able to recognize which metadata object refers to chunk objects like a back pointer and vice versa.

Scrub worker. *TiDedup* deploys a *scrub* worker as a separate thread in the crawler. *Scrub* worker wakes up periodically (the default value of wake-up period is equal to that in the full mode), then it begins to get a list of stored chunk objects on chunk tier and read their extended attributes one by one, each of which storing the reference information. Since the chunk object has its source OIDs, *scrub* worker does not need to read all metadata objects on the base tier to find reference mismatch. Instead, it just reads the metadata object whose OID is the source OID of the chunk object, then examines that the object has a reference to the chunk object. If the metadata object has a corresponding chunk object's OID, *scrub* worker repeats this until no more source OIDs that have not been checked present in the chunk object. If not, *scrub* process corrects the metadata object by removing the destination OID which is identical to the chunk object's OID.

Snapshot. To overcome snapshot-related limitations as described in Section 3.3, we introduce OID shared reference within an object. The key idea is that *TiDedup* does not generate an add/delete reference message if a chunk is identical—same offset, length, and destination OID—to a chunk in the adjacent snapshot. For instance, the reference count of BBB in Figure 7 is one; this means that only one add reference message is sent to chunk object BBB, because the chunk BBB in SNAP 7 is identical to chunk BBB in the new HEAD and SNAP 5, respectively. Note that we use the number of references here for the explanation.

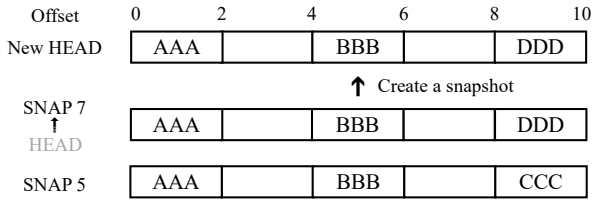

Figure 7: Snapshot reference management on snap creation.

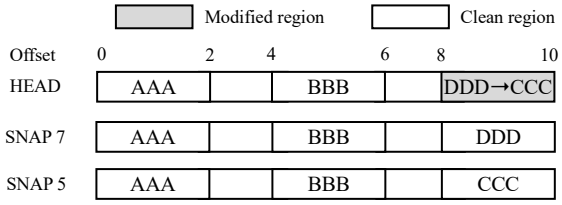

Figure 8: Snapshot reference management on overwrite (chunk DDD at offset 8 is changed to chunk CCC).

Figure 8 shows another example of a write operation. There is a modified region and clean regions in HEAD. *TiDedup* performs an add reference operation for chunk CCC—sending an add reference message then updating the corresponding *chunk_info_t* after the add reference message is done—, but does not generate a delete reference message for chunk DDD because SNAP 7 includes chunk DDD at offset 8. In addition, *TiDedup* does not do anything regarding all chunks in the clean region because each of the chunks is the same as the one in the previous snapshot.

However, a simple OID shared reference, as mentioned above, is insufficient to maintain consistency in reference management when the snapshot is removed. In Figure 8, SNAP 7 has a different chunk DDD compared to both SNAP 5 and HEAD at offset 8, so the reference count of chunk CCC is two, not one. At this point, if SNAP 7 is then removed, the reference count of chunk CCC will still remain two, even though it should be adjusted to one. To prevent this inconsistency, *TiDedup* checks both the prior snapshot and the next snapshot (SNAP 5 and HEAD in Figure 8) when the deletion occurs. If both chunks are identical, *TiDedup* sends a delete reference message.

As such, with OID shared reference, *TiDedup* generates only a limited number of add reference messages, regardless of many snapshot creations. Although *TiDedup* requires an additional search operation to identify the same chunks on the adjacent snapshots, this operation is relatively cheaper than handling the add reference operation.

OID shared reference can also work with proposed APIs, such as *set_chunk* (described in Section 4.2.1). In the *set_chunk* case; *TiDedup* exploits *set_chunk* to make a deduplicated chunk at any position in snapshots, as shown in Figure 9 (A), *TiDedup* performs an add operation for chunk AAA because there is no same chunk on the two snapshots (HEAD and SNAP 30), but nothing occurs in Figure 9 (B) because the HEAD includes chunk CCC. On the other hand, *TiDedup* generates a delete reference message for chunk CCC in Figure 9 (C) because both HEAD and SNAP 30 have the same chunk CCC.

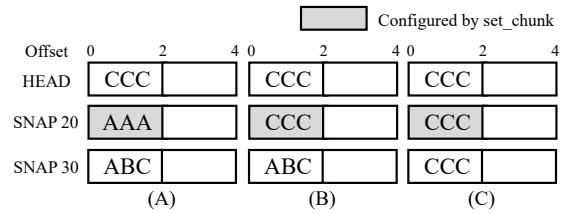

Figure 9: set_chunk (gray are new chunks by set_chunk).

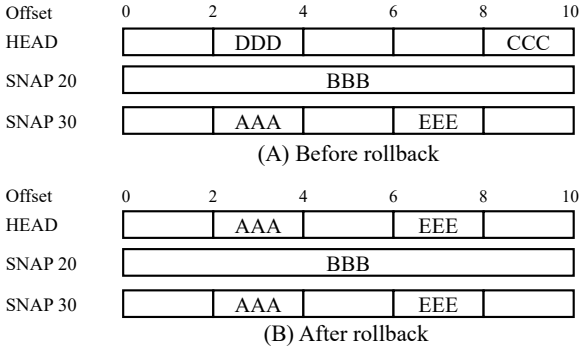

Figure 10: Rollback (HEAD is rollbacked to SNAP 30).

Rollback. *Rollback* replaces the HEAD with a given snapshot version. Upon *rollback*, *TiDedup* promotes all MISSING chunks both the HEAD and a given snapshot have from the chunk tier to the base tier. Then, the current HEAD is removed to make a correct clone into the HEAD. Figure 10 shows how shared reference count works with *rollback*. SNAP 30's chunks (chunks AAA and EEE) are copied to the HEAD (in Figure 10 (A)). Then, add operations for both AAA and EEE are needed because SNAP 20 has no identical chunks compared to the updated HEAD.

Crash consistency. OID shared reference management can maintain consistency after the crash because it is based on false-positive design. *TiDedup* guarantees the chunk object must exist if its metadata object has a reference. For this, the add operation for deduplicated chunks and update operation for relevant metadata are performed atomically. Moreover, *TiDedup* does not generate a delete reference message unless all shared chunk references in the object are unreferenced. Although *TiDedup* deletes *chunk_info_t* on sending a delete reference message without checking the completion of a delete operation—removing the metadata OID from the chunk object's extent attribute, this potential mismatch (a chunk object has a reference to a metadata object, but not vice versa) can be fixed by the *scrub* worker.

Reference set/get APIs. To set/get the reference, *TiDedup* adds four APIs that can be called by external clients and internal OSDs. *chunk_create_or_get_ref* creates a chunk object if the chunk object is not present, then adds a reference, which is the metadata OID. There are *reference_get* and *reference_put* to add/delete the reference of the chunk object. *read_reference* returns the list of references either the meta-

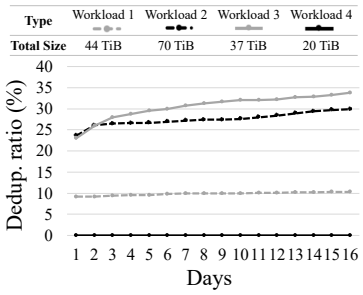

Figure 11: Space saving on factory data.

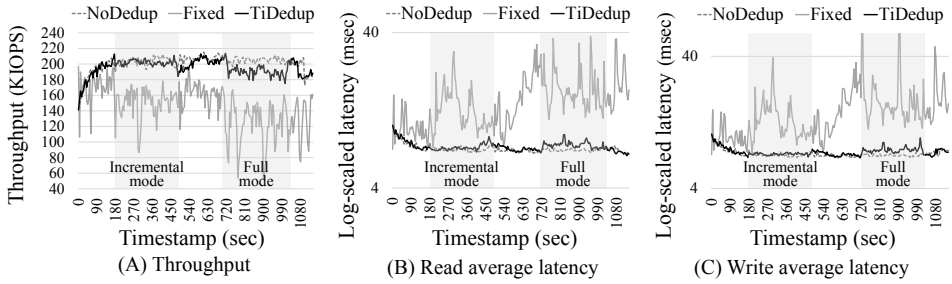

Figure 12: YCSB throughput (Workload a, record count is 500K, operation count is 20M).

data or the chunk object has. One important thing here is that the metadata object must return a reference list according to OID shared reference design; for example, in Figure 8, the reference list is {chunk AAA, BBB, CCC, CCC, and DDD}. On the other hand, the chunk object returns all references without considering OID shared reference.

5 Evaluation

5.1 Environmental setup

We use 10 machines in total, each of which is equipped with a 2-way AMD EPYC 7543 32-cores (80 threads) per NUMA node and 512 GB of DRAM. All nodes are connected with a 100 GbE network. Six nodes are used as storage nodes. Four nodes are clients to issue I/Os for evaluation. The latest version (Reef) of the Ceph storage cluster is configured by default parameters, except that the replication factor is two. Each machine has six BM1733 QLC SSDs (4 TB) and runs an OSD daemon on a single SSD. Note that we use high-performance equipments for evaluation to eliminate other performance factors. We use FastCDC [46] with the average chunk size set to 16KB. SHA1 is used to generate fingerprint value among the available fingerprint algorithm options (e.g., SHA1, SHA128, and SHA256). We set `Intra-object deduplication ratio` as 30% and `chunk duplication count` as four empirically. `NoDedup` represents default Ceph [42] without deduplication. `Fixed` means a prior deduplication approach for Ceph [29].

5.2 Deduplication ratio and throughput

5.2.1 Space saving

Internal cloud dataset. As shown in Table 2, `Fixed` shows limited data reduction compared to *TiDedup*. In `Logs` dataset, the data, which is partially mutated without data alignment, continues to be appended to Ceph cluster—the system monitor records similar logs from the cluster every 30 seconds, so that CDC is more effective than `Fixed`. In addition, CDC can save more space on `Virtual disks` dataset even if the dataset includes not only OS partitions but also user data. The reason is that the dataset is gathered from the internal developer cloud service, so user data includes duplicate data, such as mail, source code, and large images.

	Virtual disks			Logs		
Chunk size	8K	16K	32K	8K	16K	32K
Fixed	21%	12%	10%	5.7%	5.4%	5.3%
TiDedup	45%	36%	27%	18.5%	16%	12.6%

Table 2: Space saving on real-world datasets depends on the chunking algorithm and average chunk size. `Virtual disks` represents VMware vSphere images (10.1 TB) from a developer cloud service (67 users). `Logs` represents service logs (560 GB) for cloud infrastructure including monitoring and device state.

Factory dataset. We replay factory dataset generated during the semiconductor manufacturing on Ceph's object service (RGW). The factory dataset is normally used to detect or predict malfunctions of semiconductor products. We collect four types of data in total on a daily basis. As shown in Figure 11, *TiDedup* can achieve a high deduplication ratio (up to 30%) on Workload 2 (chip information during manufacturing). This is because Workload 2 has time-series monitoring logs having periodic values—the similar structured data is consistently appended. Unlike Workload 2, Workload 1 (equipment status) also includes time-series logs but has a smaller entry size—small tables with timestamps. This leads to less data reduction. Workload 3 (logs for photo lithography) has daily archive files stored in an incremental manner. It contains a large amount of redundant data and shows a high deduplication ratio. Workload 4 consists of metrology and inspection image files which are already compressed and contain little redundancy. Thus, it is not affected by deduplication at all.

5.2.2 Throughput

YCSB. We use YCSB workload a (read/write ratio is 50:50) to generate foreground I/Os. YCSB runs on four clients with sixteen threads using Ceph's block device service (RBD). As shown in Figure 12, the crawler is launched with incremental (at 180 seconds) and full mode (at 720 seconds), respectively—each of which runs for 300 seconds. Note that the elapsed time for incremental mode includes user idle time.

Figure 12 (A), (B), and (C) shows throughput and average latency. With *TiDedup*, throughput is not degraded significantly compared to `NoDedup` because *TiDedup* does not trigger the deduplication aggressively until the object is cold. *TiDedup* also achieves near-constant throughput unlike `Fixed`, which suffers a significant performance drop because a background thread blocks foreground OSD I/Os. Moreover, *TiD-*

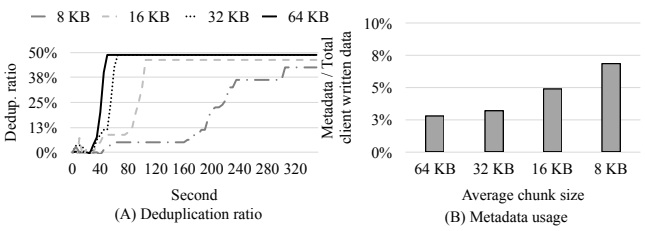

Figure 13: Space saving depending on the average chunk size.

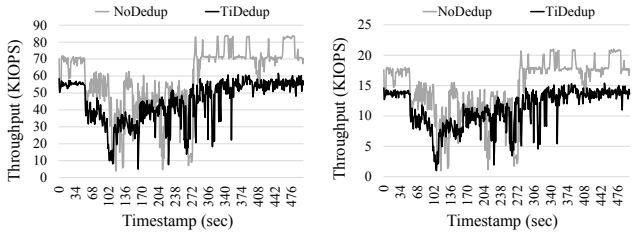

Figure 14: Recovery performance (Average IOPS of four clients).

edup with incremental mode has nearly no effect on both throughput and average latency due to a limited search scope. However, *TiDedup* with full mode badly affects performance, due to two reasons: (1) cold or deduped objects are accessed frequently in full mode, and, (2) YCSB's request can be blocked during *tier-flush*.

5.3 The impact of average chunk size

Figure 13 shows how much storage space can be saved depending on the average chunk size [46]. We generate 50% of redundant contents by `fio` with varying chunk sizes, then launch the crawler to perform deduplication. In the case of a large chunk (>16K), the amount of reduced data increases rapidly because the number of generated chunks is less than the small chunk's size, so the deduplication job can be done early. Also, we observe that the deduplication ratio does not reach 50% due to additional metadata for deduplication, as shown in Figure 13 (B). Interestingly, CDC generates non-aligned data, unlike FSC; for instance, a 8,200 byte chunk—not aligned by block size (4,096 byte)—can be generated by CDC, causing non-aligned data allocation. As a result, 12 KB is allocated even though the requested object size is 8,200 byte. This aggravates metadata consumption.

5.4 Worst-case recovery performance

We run fio with 8KB random read/write workload—the ratio between reads and writes is 8:2. During the mixed workload, the crawler issues bursty traffic—64 threads submit object reads and *tier_flush* concurrently—to the base tier, and triggers *scrub* using 16 threads. On top of that, 4 out of 36 OSDs are suddenly down during the test, resulting in generating recovery I/Os for data rebalance. Figure 14 (A) and (B) show *TiDedup*'s read and write IOPS over time. Overall, we observe performance fluctuation due to the bursty traffic from the crawler. At around 50 seconds, two OSDs are pulled out from the storage cluster and the performance decreases rapidly due to the recovery I/Os. After 50 seconds, two more OSDs are out and the fluctuation gets worse. However, at around 350 seconds, all four OSDs rejoin the cluster and the performance of foreground I/Os are recovered eventually. Compared to `NoDedup`, even in the worst case, *TiDedup* only reduces the performance by 25% on average. It is noteworthy that we can further mitigate foreground performance drop if the crawler employs a flow control technique in the event of congestion.

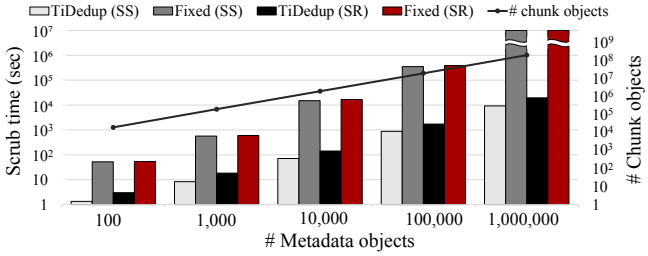

Figure 15: Scrub time comparison (SS: `Scrub-search`, SR: `Scrub-repair`). SR time includes SS time.

5.5 Scrub time

To compare *scrub* time between `Fixed` and *TiDedup*, we run a crawler, which spawns sixteen *scrub* threads (each thread issues six *scrub* requests asynchronously), with varying the number of metadata objects as shown in Figure 15. Each *Scrub* thread searches objects in the chunk tier and reads chunk information as described in Section 4. If the chunk object has a reference to the metadata object, the *scrub* thread reads either all metadata objects (`Fixed`) or a corresponding metadata object (*TiDedup*) in the base tier to check if the reference for chunk object is valid (`Scrub-search`). If the reference is invalid, *TiDedup* fixes the mismatch (`Scrub-repair`). In `Fixed`, *scrub* time increases considerably due to a full scan for metadata objects. *TiDedup* also takes considerable time for *scrub*, but the execution time is significantly reduced because *TiDedup* needs only a single read to check if the referenced metadata object is valid. In the case of one million metadata objects, *TiDedup* takes about four hours to complete, while we could not measure the `Fixed` *scrub* time because even after five days, the job had not been done.

5.6 Snapshot creation and deletion

Figure 16 (A) shows snapshot creation time (ten objects) as the number of deduplicated chunks grows. To measure snapshot creation time, we create deduplicated chunks on a metadata object and issue snapshot creation requests to the metadata object. In `Fixed`, the execution time to create a snapshot increases linearly because the more deduplicated chunks the snapshot has, the more operations (*chunk_create_or_get_ref*) OSD needs to handle. On the other hand, *TiDedup* takes a constant time even thanks to the OID shared reference count.

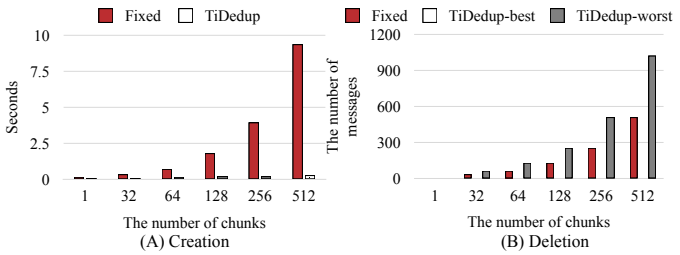

Figure 16: Snapshot creation/deletion comparison.

YAML	Description
dedup-io-mixed	read, write, set_chunk, tier_promote, tier_evict, tier_flush
dedup-io-snap	read, write, set_chunk, tier_promote, tier_evict, tier_flush, snap_create, snap_remove, rollback

Table 3: Integration test description.

Figure 16 (B) shows the number of generated messages from an OSD during snapshot deletion. *TiDedup*-best is the best-case scenario where no chunk differs from adjacent snapshots (e.g., chunk AAA at offset 0 in Figure 8). On the other hand, *TiDedup*-worst represents the extreme case where all chunks are different from adjacent snapshots and both the prior and next snapshots are identical (e.g., chunk DDD at offset 8 in Figure 8). In *TiDedup*-best, no messages are generated. However, compared to `Fixed`, *TiDedup*-worst generates a higher number of messages because *TiDedup* needs to reduce the references due to the same adjacent snapshots. But, these additional messages are proactively generated. Unlike *TiDedup*, `Fixed` would eventually generate the messages if further deletion occurs on either the prior or the next snapshot.

5.7 Integration test

We improve existing stress test coverage in Ceph to make *TiDedup* stable. With yaml as shown in Table 3 and the test code we added, Ceph's integration test framework, called *teuthology* [38], can perform the tests with/-without other tests (e.g., network disconnection and OSD fail) for reliability. Moreover, to ensure reference reliability, the workload generator also checks if the live chunk object's source reference is valid after all operations are done. *TiDedup* passes the combination tests conducted by *teuthology*.

6 Discussions

Small chunk vs. large chunk. Small chunk sizes (< 8KB) would result in numerous small chunk objects and potentially large space overheads. On the other hand, the use of a large chunk size may lead to a lower deduplication ratio. In order to hit a desirable trade-off point, *TiDedup* provides an *estimate* CLI, which shows how much storage space can be saved depending on options, to users. *TiDedup* allows the users to select suitable options (e.g., FSC, CDC, and chunk size) or even decide not to use deduplication at all.

How scalable is crawler? We did not fully address how our crawler design works at scale. In Section 5, we deploy a single application that has multiple threads for crawling. However, if the cluster has a large number of objects, this application may not be able to cover all objects properly. To solve this problem, the system administrator can deploy many crawlers on demand where each crawler is in charge of a sub-dataset of the storage cluster depending on the workload. This task is easily done by using container-based deployment because the crawler is stateless.

Additional space overhead for OID reference. Since the OID-shared reference scheme uses OID to represent a reference, chunk objects should maintain all metadata object's OIDs referring to the chunk objects, requiring more storage space than the reference count method. We limit the number of chunk object's references to a threshold value. *TiDedup* forces OSD to stop performing deduplication on the chunk objects in case their number of references is over the threshold value.

Applicability of *TiDedup*. *TiDedup* relies on two schemes that are prerequisites for integration with other distributed storage systems: (1) two separate address spaces (base and chunk tier), and (2) chunk object lookup by using a hash-based mapping between those two tiers. While the two address spaces scheme is easily applicable to other storage systems, the lookup method is tightly coupled with the hash-based object placement scheme [15, 19, 36, 43].

7 Lessons Learned

Rethinking a tiering mechanism in a distributed storage system with strong consistency. Ceph originally implemented the tiering structure where a background thread reads and migrates objects between tiers for cache tiering, so we anticipated that adding a deduplication feature on top of the existing architecture would be straightforward. However, we needed to consider recovery scenarios against a variety of failure types. Also, the deduplication jobs not only required holding a PG lock for an extended period, especially as the number of objects grew, but also introduced a new lock domain. Note that a strong consistency storage system, such as Ceph, handles I/O operations in strict order while holding locks. Unfortunately, this approach eventually led to an imbalance in I/O loads across different PGs, resulting in significant degradation of user-perceived performance and tail latency. Considering these challenges, we made the decision to deprecate the existing tiering mechanism. Instead, we opted to delegate the responsibility of the tiering mechanism within OSD to other components, such as the crawler.

Deduplication is promising only when data is dedup-able. In a distributed storage system, storing data entails duplicate copies to ensure availability through replication or erasure coding. However, this increases storage space overheads more than we expected due to the following two reasons: (1) additional metadata space for deduplication, and (2) unaligned existing metadata caused by the small size of the new meta-

Table 4: Comparison of previous deduplication architectures and this work.

	TiDedup	CephDedup [29]	Data Domain [9]	DupHunter [49]	Nitro [21]	idedup [35]

Implementation	Ceph mainline	research only	proprietary	research only	research only	proprietary

data added for deduplication. Moreover, a general purpose storage system cannot predict in advance whether incoming data is always dedup-able or not. As a result, based on the observation, we decided to perform deduplication only if the storage system is able to secure enough free space after deduplication is done.

Flexible namespace architecture for *TiDedup*. A single global namespace (tier) is not optimal for efficiently handling different types of data streams, as each stream may have its own unique access pattern. Considering that a general-purpose storage system must cater to diverse workloads, we have designed a flexible namespace architecture that allows users to create custom namespaces tailored to their specific workloads. With this architecture, users are able to create one or more custom namespaces, enabling them to handle multiple data streams while maintaining isolation between them. For example, users can align their custom namespaces (base tiers) with the corresponding services, such as object, file, and block, while utilizing a shared chunk tier.

8 Related Work

Although there is rich literature on deduplication [1,2,5,8,13,27,40,41,48,50,51], few studies evaluate their architecture in terms of scalability in real distributed storage systems and/or open their code for third party reproduction of results. In the next, we touch on the most relevant studies to our work. Table 4 gives a quick summary of their key properties.

Data Domain Cloud Tier [9] proposes a deduplication architecture based on two tiers, where it performs deduplication in the local tier first, and then backs up data in the remote tier. Unlike our work, Data Domain Cloud Tier targets a local storage and does not selectively performs deduplication according to redundancy. *TiDedup* is a cluster-level solution with scalability as key design consideration. To that end, *TiDedup* reduces the fingerprint index lookup overheads by using double hashing [29] and pursues selective deduplication.

DupHunter [49] builds on a multi-layer tier and employs a cache algorithm utilizing domain-specific knowledge (container image registry). Also, it takes a selective deduplication approach. We note that DupHunter targets a specific environment where container images are stored and distributed by docker registry. On the other hand, *TiDedup* is designed for more general environments where file, object, and block services are needed. It is unclear how DupHunter addresses the fingerprint index problem [12,45] and whether the design can coexist with other existing features in a real storage system.

Deduplication could hurt read performance when an object is scattered throughout the cluster. Several studies suggest techniques (e.g., prefetching and rewriting) [3, 11] to overcome degraded read performance. Among them, we believe that caching is the most efficient way to resolve the read performance problem. *TiDedup* exploits a caching technique and migrates chunk objects from chunk tier to base tier if the chunk object is frequently accessed. As a result, hot data will be served quickly with no overhead whereas serving cold data entails forwarding overheads between base and chunk tier.

Inline deduplication [13,21,35] eliminates data redundancy immediately. However, *TiDedup* adopts a post-processing technique along with caching. By doing so, *TiDedup* employs on-demand deduplication, allowing for minimizing performance degradation. We believe that it is more suitable for a general purpose distributed storage system.

9 Conclusion

This paper presents *TiDedup* towards efficient cluster-level deduplication for a general-purpose distributed storage system. *TiDedup* incorporates three new design schemes to overcome the scalability issues found in a prior proposal. We have a complete, fully validated implementation of the design and have integrated *TiDedup* into the Ceph main branch. Our comprehensive evaluation study reveals that *TiDedup* achieves storage space savings without hurting the scalability of Ceph. We hope that our work will become a foundation on which further research and development are undertaken.

A Artifact Appendix

Abstract

We provide the artifact that includes the source code and instructions to explain how to run *TiDedup* on Ceph. The artifact also includes a document to describe how *TiDedup* is applied to Ceph.

Scope

TiDedup is a cluster-level deduplication architecture for Ceph, so the goal of the artifact is to describe how to perform deduplication on Ceph cluster using either the artifact or mainline Ceph. As explained in README.md, we provide instructions to build, deploy, and run *TiDedup* on Ceph. In addition, the README.md also provides an explanation of how to run *TiDedup* using the latest Ceph without the artifact.

Contents

The artifact contains *TiDedup*'s source code integrated into Ceph and a README.md file to build source code and run Ceph while enabling deduplication.

Hosting

TiDedup is available at https://github.com/ssdohammer-sl/ceph/tree/tidedup with detailed instructions. Since *TiDedup* has been merged to Ceph mainline, the source code is also available at https://github.com/ceph/ceph.

LoopDelta: Embedding Locality-aware Opportunistic Delta Compression in Inline Deduplication for Highly Efficient Data Reduction

Abstract

As a complement to data deduplication, delta compression further reduces the data volume by compressing non-duplicate data chunks relative to their similar chunks (base chunks). However, existing post-deduplication delta compression approaches for backup storage either suffer from the low similarity between many detected chunks or miss some potential similar chunks, or suffer from low (backup and restore) throughput due to extra I/Os for reading base chunks or add additional service-disruptive operations to backup systems.

In this paper, we propose LoopDelta to address the above-mentioned problems by an enhanced embedding delta compression scheme in deduplication in a non-intrusive way. The enhanced delta compression scheme combines four key techniques: (1) dual-locality-based similarity tracking to detect potential similar chunks by exploiting both logical and physical locality, (2) locality-aware prefetching to prefetch base chunks to avoid extra I/Os for reading base chunks on the write path, (3) cache-aware filter to avoid extra I/Os for base chunks on the read path, and (4) inversed delta compression to perform delta compression for data chunks that are otherwise forbidden to serve as base chunks by rewriting techniques designed to improve restore performance.

Experimental results indicate that LoopDelta increases the compression ratio by 1.24∼10.97 times on top of deduplication, without notably affecting the backup throughput, and it improves the restore performance by 1.2∼3.57 times.

1 Introduction

Data deduplication has been widely used in computer systems to improve storage space and network bandwidth efficiency [26, 29, 36, 53]. Typically, it removes duplicate data at the chunk granularity (e.g., 8KB size) but fails to eliminate redundancy among (highly) similar but non-duplicate data chunks. Delta compression has been employed to further remove redundant data from post-deduplication non-duplicate but similar chunks, by compressing non-duplicate data chunks relative to their similar chunks (base chunks) [18, 19, 21, 37, 47, 48, 55].

In this paper, we focus on adding delta compression to inline backup storage which usually adopts only deduplication for data reduction. Some efforts have been made to achieve this. Shilane et al. [38] suggested that delta compression achieves more than 2× additional compression on top of deduplication, but it incurs extra I/Os for reading base chunks from storage, which significantly reduce backup throughput. One solution to this problem is to replace the hard disk drive (HDD) with other media with higher random I/O performance, such as solid state drive (SSD). However, this method is not cost-effective because HDD remains significantly cheaper than SSD. So, this paper focuses on HDD-based backup systems.

Zou et al. [55] proposed MeGA to perform delta compression for data chunks whose base chunks can be detected in the last and the current backups on top of deduplication. MeGA is developed based on the assumption that, after each backup, the system will reorganize both the data chunks and the base chunks of the delta-compressed chunks of this backup into a delta-friendly data layout. However, this assumption has a nontrivial impact on both the users and the backup systems, i.e., the backup operations for users are suspended in the reorganization process, and the backup system must perform service-disruptive reorganizations frequently and completes them promptly after each user's backup. This paper focuses on adding delta compression seamlessly to deduplication systems in a non-intrusive and non-service-disruptive manner.

Existing schemes that add delta compression to deduplication systems face many challenges. The first challenge is a low compression ratio. The base chunks required for delta compression are detected by indexing the sketches of chunks, and the compression ratio mainly relies on the strategies adopted to index the sketches [6, 11, 24, 32, 37]. Usually, sketches are weak hashes of the chunk data and can be used to detect similar chunks [4, 6, 11, 21]. Full indexing (indexing the sketches of all data chunks in storage) is the simplest indexing strategy. Our study in Section 3.1 suggests that when similar chunks appear within the same backup, this technique may decrease the compression ratio due to the selection of suboptimal base chunks.

Besides full indexing, the existing sketch indexing techniques can be classified into two categories: the logical-locality-based indexing [42, 55] and the physical-locality-based indexing [37, 38], which have complementary capabilities of detecting similar chunks. The former can detect most of the highly similar chunks by leveraging the logical locality between two adjacent backups but may miss some potential similar chunks; the latter can detect most of the potentially similar chunks by exploiting the physical locality preserved in storage units called containers but suffers from the low similarity of detected chunks. Our analyses in Section 3.1 indicate that the desirable properties of the two techniques can be combined by exploiting both the logical and physical locality.

The second challenge of adding delta compression to deduplication systems is extra I/Os for reading base chunks during backup, which prevent delta compression from being used in high-performance inline backup systems [37, 38]. A typical deduplication-based backup system organizes data chunks into containers each of which consists of hundreds or thousands of data chunks as the storage units [17, 53]. For such a system, a routine operation during deduplication is to prefetch metadata from containers being deduplicated against to accelerate duplicate detection. Our study in Section 3.2 demonstrates that containers holding potential similar chunks detected by using both the logical and physical locality can be prefetched by piggybacking on the routine operations without extra I/Os.

The third challenge is extra I/Os for reading base chunks during restore, which reduce restore performance significantly. More specifically, when delta compression is applied, data chunks may refer to previously written deltas, and the base chunks of these deltas may require extra I/Os during restore. To address this issue, it is necessary to identify such previously written deltas and avoid referring to them. Our analyses in Section 3.2 suggest that existing approaches to identify such deltas either are vulnerable to garbage collection (GC) or require extra I/Os. Our analyses also suggest that the previously written deltas whose base chunks require extra I/Os during restore can be predicted during backup by using the metadata prefetched by the routine operations during deduplication.

The fourth challenge is the potential to miss base chunks when rewriting techniques are applied. Backup systems often adopt rewriting techniques to identify infrequently reused containers and give up deduplicating against them to alleviate chunk fragmentation [14, 16]. To cooperate with rewriting techniques, data chunks in infrequently reused containers cannot serve as base chunks for delta compression, resulting in a compression loss. Our analyses in Section 3.3 suggest that if the target of delta compression is changed to previously written chunks, rather than data chunks in the ongoing backup as in the traditional delta compression method, to generate additional encoded copies of the previously written chunks, the un-encoded copies of previously written chunks can be eliminated during GC to achieve data reduction, which is equivalent to the effect of delta compression.

With the above observations, we propose LoopDelta based on the deduplication strategy that groups data chunks into containers and prefetches metadata from them for duplicate detection during deduplication [17, 53]. By combining the following four key techniques, LoopDelta embeds delta compression in inline deduplication non-intrusively.

- **Dual-locality Similarity Tracking.** LoopDelta tracks data chunks and base chunks of delta-compressed chunks of the immediate predecessor backup to capture highly similar chunks by leveraging the logical locality and tracks the containers holding the aforementioned data chunks to capture similar chunks stored in these containers by exploiting the physical locality.
- **Locality-aware Prefetching.** LoopDelta prefetches base chunks by piggybacking on routine operations to prefetch metadata during deduplication, thereby avoiding extra I/Os for reading base chunks on the write path.
- **Cache-aware Filter.** LoopDelta identifies the previously written deltas whose base chunks require extra I/Os during restore with the assistance of the recently prefetched metadata during deduplication and avoids referring to such deltas, thereby eliminating extra I/Os for reading base chunks on the read path.
- **Inversed Delta Compression.** For data chunks whose detected similar chunks are forbidden to serve as base chunks by rewriting techniques, LoopDelta delta-encodes the detected similar chunks relative to these data chunks while deferring the removal of the data of these delta encoded chunks to the GC process.

Experimental results based on real-world datasets indicate that LoopDelta significantly increases both the compression ratio and restore performance on top of deduplication, without notably affecting backup throughput.

2 Background

2.1 Data Deduplication

Deduplication and Restore Processes. Typically, a backup stream is divided into data chunks, which are fingerprinted with a secure hash (e.g., SHA1) [12, 31, 33, 35, 46, 49]. Each fingerprint is queried in a fingerprint index to determine whether the system already stores a copy of the fingerprinted data chunk. If true, the system does not store the data chunk but refers it to the previously written copy. Meanwhile, consecutive unique data chunks are grouped into a large I/O unit, called a container, and written to HDDs.

When a backup completes, a *recipe* recording the fingerprint sequence of the backup stream is stored for the future restoration [16]. When a stored backup is requested, the restore process accesses data chunks one by one according to their order in the recipe to reconstruct the original data. In this

process, a *restore cache* is maintained in memory [7]. The read unit in this process is a container.

Redundancy Locality in Backup Workloads. Backup workloads typically consist of a series of copies of primary data [3,28,41,43]. *Redundancy locality* in the backup workloads refers to the repeating patterns of the redundant data among consecutive backups [16]. The repeating pattern before deduplication is called *logical locality*, which is preserved in the recipe and sequence of consecutive data chunks before deduplication. That repeating pattern after deduplication is called *physical locality* (also called *spatial locality* [53]), which is preserved in containers.

Both categories of the locality have been widely exploited to improve deduplication performance [9, 17, 23, 27, 44, 53]. For example, a fingerprint index mapping fingerprints to the physical locations of the chunks is required for detecting duplicates. However, storing the index in HDDs would result in low backup throughput, while putting it in memory would limit system scalability. Zhu et al. [53] put the index in HDDs and alleviate the indexing bottleneck by using physical-locality-based caching. Lillibridge et al. [23] and Guo et al. [17] put the index in memory and reduced its memory footprint by using logical-locality-based sampling and physical-locality-based sampling.

Chunk Fragmentation and Rewriting. Deduplication renders data chunks of a backup stream to be physically scattered, and this is known as *chunk fragmentation* [14, 22, 30, 56]. Chunk fragmentation decreases the locality and efficiency of the techniques exploiting this locality. For example, it decreases restore performance and backup throughput of container-based backup systems [2, 22]. Backup systems often adopt rewriting approaches to identify *infrequently reused containers* and give up deduplicating against them to alleviate fragmentation [7, 8, 15, 20, 22, 39]. Here, the infrequently reused containers are previously written containers that contain only a few data chunks referenced by the current backup. The data chunks that refer to previously written data chunks stored in infrequently reused containers are called *fragmented chunks*, which will be stored (rewritten) along with unique data chunks to improve the locality of the current backup.

Among rewriting approaches, Capping [22] processes the backup stream in non-overlapping segments, each of which contains a sequence of consecutive data chunks. Within a segment, data chunks can refer to at most T old (previously written) containers. If the number of old containers exceeds T, only the most referenced T containers can be referenced, and data chunks referring to other old containers are rewritten to reduce fragmentation. The value T, also called *capping level*, is a configurable parameter that trades deduplication for restore performance.

2.2 Post-deduplication Delta Compression

Post-deduplication delta compression consists of three stages: (1) resemblance detection (finding similar candidates), (2) reading the base chunks, and (3) delta encoding.

Resemblance Detection. For data chunks not removed by deduplication, a sketch calculation approach calculates sketches for data chunks [32, 51, 54]. Sketches are usually weak hashes of the chunk data [4, 6, 11, 21]. Two chunks are considered similar if they have the same sketches. The sketch indexing strategy has a critical impact on resemblance detection efficiency, which will be discussed in Section 3.1.

Reading the Base Chunks. Reading the base chunks for an HDD-based system is the performance bottleneck. Shilane et al. [37, 38] indicated that I/O overheads required to read back the base chunks decrease the backup throughput to an unacceptable level. MeGA [55] monitors the containers holding the base chunks and does not perform delta compression for the data chunks whose base chunks are stored in rarely referenced containers to reduce I/Os for reading base chunks. Besides, PFC-delta [52] prefetches base chunks by piggybacking on the routine I/Os during deduplication.

Delta Encoding. Xdelta [25] is a popular delta encoding technique that employs hashing and indexing to identify and eliminate repeated strings between the target and base chunks. Edelta [45] simplifies this process by replacing some of the hashing and indexing operations with fast byte-wise comparisons through exploiting fine-grained locality between similar chunks.

2.3 Garbage Collection

Garbage collection (GC) removes invalid chunks (chunks not referenced by any unexpired backups) from the system to consolidate free space [5, 14, 17, 40, 56]. Duplicate chunks will be removed in the GC process [2, 10]. To improve write performance, a deduplication-based backup system might choose to write (rewrite) occasional duplicate chunks while deferring deduplication to a GC process [2].

GC first traverses live backups and marks the live chunks. For a data chunk with multiple physical instances, GC marks one (often the most recently written one) of them as the live chunk [10]. Then, it copies live chunks from partially-invalid containers to form new containers. Then, previous containers whose live chunks are copied out of are reclaimed.

3 Observations and Motivations

3.1 Analysis of Sketch Indexing Efficiency

Besides the full indexing technique, existing sketch indexing techniques can be divided into two categories: logical-locality-based indexing techniques and physical-locality-based indexing techniques. This section analyzes the efficiency of these two categories of indexing techniques as well as the full indexing technique.

3.1.1 Logical-locality-based Sketch Indexing

Substantial similar chunks for delta-compressing a backup can be detected from data chunks of its immediate predecessor backup and similar chunks of this backup. This is because

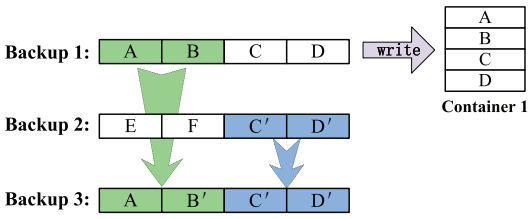

Figure 1: Chunks B', C', and D' are respectively similar to chunks B, C, and D. For backup 3, A and B' inherit from backup 1, while C' and D' inherit from backup 2. When detecting similar chunks for data chunks of backup 3, the logical-locality-based indexing techniques will miss B in backup 1, which is actually similar to B'.

each backup is often a modified copy of the last backup. Based on similar observations, MeGA [55] and HARD [42] index sketches of the data chunks and base chunks of the delta-compressed chunks of the last backup for resemblance detection. These sketch indexing techniques essentially exploit the logical locality between two adjacent backups.

An advantage of these indexing techniques is the high similarity of base chunks. In most cases, the best base chunk for the delta compression of a data chunk is its previous copy in the last backup because similar chunks are usually stemming from small edits to the last backup. A disadvantage of these indexing techniques is that they may miss some potential similar chunks. We observe that data chunks of a backup can inherit from multiple previous backup versions, for example, when data rollback occurs. This means that similar chunks may exist across backup versions. These similar chunks do not have a direct relationship to the immediate predecessor backup and thus cannot be detected by logical-locality-based indexing techniques. Figure 1 gives an example to illustrate how this problem may arise.

3.1.2 Physical-locality-based Sketch Indexing

Stream-Informed delta compression (SIDC) [38] is a physical-locality-based sketch technique that detects similar chunks by exploiting the physical locality among backups. Since physical locality is preserved in containers, SIDC is built on container-based deduplication systems. When a duplicate chunk is detected, the container holding the most recently written instance of this duplicate is selected for deduplicating against, and sketches of all data chunks in this container are indexed for matching similar chunks.

An advantage of this indexing technique is that it can detect most similar chunks including the ones missed by logical-locality-based indexing techniques. For data chunks that are inherited from versions older than the immediate predecessor backup, their sketches would be indexed if they are stored in the containers that would be deduplicated against, even if they do not have a direct relationship to the last backup. As shown in Figure 1, when the system deduplicates chunks in backup 3, container 1 is selected for deduplicating against because it holds the previously written copy of chunk A. Therefore, the

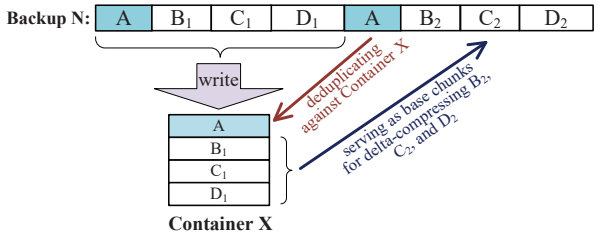

Figure 2: A in backup N is a self-referenced duplicate chunk, and the rest are self-referenced similar chunks. B_1, C_1, and D_1 are similar to B_2, C_2, and D_2, respectively. The first four data chunks are stored in container X. When deduplicating the second A, the system will select container X for deduplicating against because this container holds the previous-written copy of A. Then, sketches of data chunks in container X are indexed and B_1, C_1, and D_1 are detected as the base chunks for delta-compressing B_2, C_2, and D_2.

sketches of B in this container will be indexed and detected as a similar chunk of B'.

A backup may contain duplicates and similar chunks in itself, where the former are referred to as *self-referenced duplicate chunks* and the latter as *self-referenced similar chunks*. Compared with self-referenced similar chunks, similar chunks detected from the previous backups tend to share more redundancy with unique chunks of the on-going backup. This is because the latter are much more likely to result from the former after they are slightly modified. Consequently, the physical-locality-based sketch indexing technique can be suboptimal for datasets containing self-referenced duplicate and self-referenced similar chunks. This is because self-referenced duplicate chunks may cause the newly-written containers holding data chunks of the on-going backup to be selected for deduplicating against, which further causes the self-referenced similar chunks to be matched as the base chunks for delta compression. Figure 2 presents a simplified example to illustrate how the problem may arise.

3.1.3 Full Sketch Index

The full sketch indexing technique indexes sketches of all data chunks in the backup system and it is often serves as an upper bound for compression ratio evaluations when delta compression is involved [42, 52, 55]. Since the size of sketch indexes grows with the number of backup versions, it is challenging to organize the sketch indexes. Maintaining them in memory would limit system scalability, while putting them in HDDs would greatly reduce query throughput.

Another problem facing this technique is that it can be suboptimal for datasets containing self-referenced similar chunks. This technique indexes sketches of all data chunks in the system, including self-referenced similar chunks. Thus, when self-referenced similar chunks are ingested, the sketches of the best base chunk candidates for delta compression in previous backups may be replaced by those of self-referenced similar chunks, causing self-referenced similar chunks to be

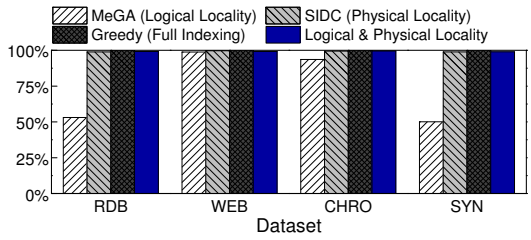

Figure 3: Percentage of potential similar chunks detected by MeGA, SIDC, Greedy, and the approach exploiting both logical and physical locality on four datasets.

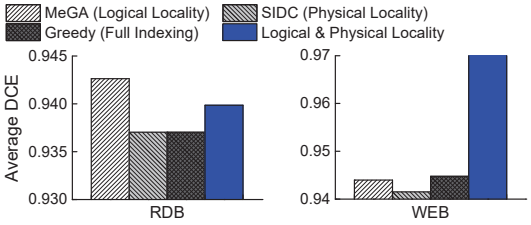

Figure 4: Average DCE of MeGA, SIDC, Greedy, and the approach exploiting both logical and physical locality on the RDB and WEB datasets.

matched as base chunks for delta compression.

3.1.4 Combining the Best of Both Worlds

Figures 3 and 4 respectively show the percentage and the average delta compression efficiency (*DCE*) [51,54] of detected similar chunks of existing sketch indexing techniques including MeGA, SIDC, and the full indexing (Greedy) for datasets whose characteristics are detailed in Table 1 in Section 5.1. Multi-version inheritance is common in RDB and SYN datasets, and the WEB dataset contains substantial self-referenced duplicates and similar chunks. *DCE*, which is calculated as $1 - \frac{chunk\ size\ after\ delta\ compression}{chunk\ size\ before\ delta\ compression}$, measures the similarity of the detected similar chunks. A larger value of *DCE* indicates higher similarity.

The results in the two figures agree with the earlier analysis in this section, i.e., the logical-locality-based technique can detect most highly similar chunks but may miss potential similar chunks, while the physical-locality-based technique can detect most potential similar chunks but suffers from low similarity. We found that the two categories of techniques have complementary capabilities for detecting similar chunks. This motivates us to propose a dual-locality-based sketch indexing approach to combine the advantages of both logical and physical locality. The dual-locality-based approach can not only detect most potentially similar chunks but also ensure high similarity between detected chunks, as shown in Figures 3 and 4. Since the full indexing technique can be suboptimal for datasets containing self-referenced similar chunks, the dual-locality-based approach can achieve higher *DCE* than the full indexing on such datasets.

3.2 Avoiding I/Os for Reading Base Chunks

Extra I/O overheads for reading base chunks on both the write and read paths prevent delta compression from being used in high-performance backup systems. In this subsection, we discuss and analyze the possible approaches to reducing or eliminating I/O overheads for reading base chunks to make delta compression feasible and practical for backup systems.

3.2.1 On the Write Path

For container-based deduplication systems, such as Data Domain backup systems [53], a routine operation during deduplication is to access containers for prefetching metadata to accelerate duplicate detection, which provides an opportunity to eliminate I/Os for reading base chunks. If the containers holding similar chunks will be accessed for prefetching metadata during deduplication, base chunks can be prefetched by piggybacking on the routine operations during deduplication without requiring extra I/Os.

Fortunately, if similar data chunks are detected by exploiting both logical and physical locality, as suggested in Section 3.1.4, due to redundancy locality, most of the containers holding potential similar data chunks would be prefetched during the metadata prefetching process in data deduplication. As a result, potential similar chunks can be prefetched, i.e., piggybacked on the retrieval of the metadata to serve as potential base chunks, thereby avoiding extra I/Os for reading base chunks on the write path. Zhang et al. [50] employed a similar base-chunk prefetching technique based on different observations, but their approach can only be applied to specific backup datasets (i.e., packed datasets containing substantial small files) and detects similar chunks only when rewriting is applied. In contrast, our approach can be applied to all backup datasets and can work without rewriting.

3.2.2 On the Read Path

During restore, base chunks of deltas also need to be read from storage for delta decoding. If base chunks are prefetched along with metadata during deduplication, they would be prefetched along with other chunks (or deltas) during restore, without requiring extra I/Os. However, when a data chunk refers to an old (previously written) delta, the base chunk of this delta may require extra I/Os during restore and decrease restore performance. Data chunks that refer to old deltas whose base chunks trigger read operations during restore are referred to as *base-fragmented chunks*, which should be rewritten for improved restore performance.

Existing approaches either are vulnerable to GC or require extra I/Os. SDC [52] can identify base-fragmented chunks by simulating the data restore process using container IDs during backup. However, it requires knowledge of the container IDs of the base chunks of referenced old deltas, which is difficult to obtain. Storing container IDs of base chunks along with deltas in containers is vulnerable to GC because base chunks can move around due to GC. Storing fingerprints of base chunks and obtaining their container IDs through the fingerprint index and cache may incur a large number of extra I/Os. Rewriting techniques, which are employed to identify fragmented chunks for deduplication systems, face the same

problem in identifying base-fragmented chunks because they also need the container IDs of base chunks for calculating the containers' reuse ratios.

When excluding base chunks, the order in which data chunks are processed during backup is the same as that during restore. Thus, if the base chunk of a referenced old delta can be directly found in the restore cache during restore and thus does not require extra I/O, its fingerprint would also be directly found in the prefetched metadata during deduplication. That is, base-fragmented chunks can be identified with the assistance of the prefetched metadata during deduplication.

3.3 Fine-grained Redundancy Prohibited by Rewriting

The rewriting technique declares infrequently reused containers, which should not "share" redundant data with the current backup to alleviate chunk fragmentation. To this end, fragmented chunks need to be rewritten. To cooperate with rewriting, data chunks in the infrequently reused containers also cannot serve as base chunks for delta compression. However, existing rewriting techniques only consider duplicate chunks when identifying infrequently reused containers, without the consideration of similar chunks. In practice, infrequently reused containers may contain many similar chunks. This will lead to a significant compression loss if these similar chunks cannot serve as base chunks for delta compression.

Actually, delta compression can be considered a process involving two steps. Specifically, the first step is to generate a delta for the target chunk, which leads to two versions of the target chunk: an encoded delta and an un-encoded one. The second step is to remove the un-encoded target chunk. If the target of delta compression is changed to previously written chunks, rather than data chunks in the ongoing backup as in the traditional delta compression method, there will be two versions of a previously written chunk. If the un-encoded one can be removed during GC, delta compression benefits will be obtained from the data chunks in infrequently reused containers without affecting the efficiency of rewriting.

4 Design and Implementation

4.1 LoopDelta Overview

LoopDelta is built on a typical deduplication strategy that groups data chunks into containers and accesses containers to prefetch metadata during deduplication to accelerate duplicate detection. It aims to embed delta compression in inline deduplication for highly efficient data reduction. The key idea behind LoopDelta is the combined use of the following four key techniques:

- **Dual-locality-based Similarity Tracking.** By exploiting both the logical and physical locality based on the observations in Section 3.1, dual-locality-based similarity tracking identifies the containers that hold potential similar chunks, as detailed in Section 4.2.

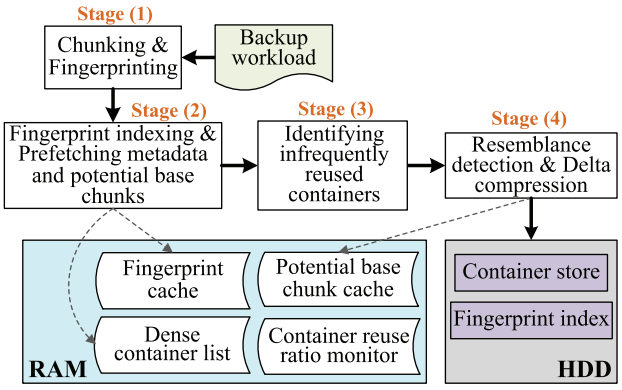

Figure 5: An overview of LoopDelta. The dashed arrows point to key data structures residing in DRAM required for the corresponding LoopDelta stages.

- **Locality-aware Prefetching.** For containers holding potential similar chunks declared by the dual-locality-based similarity tracking, when they are accessed during deduplication to prefetch metadata, data chunks are also prefetched, i.e., piggybacked on the retrieval of the metadata to serve as potential base chunks, thereby avoiding extra I/Os for reading base chunks during backup, as detailed in Section 4.3.
- **Cache-aware Filter.** LoopDelta identifies base-fragmented chunks with the assistance of recently prefetched metadata during deduplication and rewrites them to prevent extra I/Os for base chunks during restore, as detailed in Section 4.4.
- **Inversed Delta Compression.** For data chunks whose similar chunks are prefetched from infrequently reused containers, LoopDelta delta-encodes the prefetched similar chunks relative to these data chunks while deferring the removal of the data of these delta encoded chunks to GC, as detailed in Section 4.5.

The overall workflow of the LoopDelta is illustrated in Figure 5, which includes four key stages. In stage (1), the backup stream is chunked and fingerprinted. Then, duplicate chunks are identified by indexing fingerprints in stage (2). In stage (2), potential base chunks and their sketches are loaded into the potential base chunk cache.

In stage (3), a rewriting approach is adopted to identify infrequently reused containers and fragmented chunks. This stage can be skipped to disable rewriting. Note that base-fragmented chunks are also identified in stages (2) and (3), as detailed in Section 4.4. In stage (4), for all unique, fragmented, and base-fragmented chunks, LoopDelta detects their similar chunks from the potential base chunk cache and performs delta compression for them if their base chunks exist. Finally, unremoved unique chunks and deltas are appended to a container.

In LoopDelta, a container consists of a metadata section and a data section, the same as that in [17, 53]. Data chunks and deltas are stored in the data section, while their metadata such

as fingerprints, chunk length, and positions in the container are stored in the metadata section. We use a bitmap to specify which ones in the container are stored as deltas. For deltas, the metadata of their base chunks is also stored in the metadata section. For data chunks, their sketches are stored along with data chunks in the data section.

4.2 Dual-locality-based Similarity Tracking

The dual-locality-based similarity tracking is designed to identify similar chunks for delta-compressing the next backup. To capture similar chunks with logical locality, it tracks data chunks and base chunks of delta-compressed chunks of the ongoing backup. Meanwhile, to capture similar chunks with physical locality, it tracks data chunks stored in the same containers as the aforementioned data chunks.

Specifically, we define the *reuse ratio* of a container for a backup as the fraction of data chunks in this container referenced by this backup, $\frac{\textit{the recorded chunk size}}{\textit{the container size}}$, and use a *container reuse ratio monitor* to keep track of the reuse ratio of containers referenced by data chunks and base chunks of delta-compressed chunks of the on-going backup. When the backup completes, all containers holding potential similar chunks are recorded in the container reuse ratio monitor and are stored in a *dense container list*. Containers in this list will be prefetched to provide potential similar chunks for resemblance detection in the next backup.

Our approach for prefetching base chunks requires extra transfer time, thereby decreasing backup throughput, as detailed in the next subsection. To reduce this transfer time, only containers holding a large number of potential similar chunks can be recorded in the dense container list. Since containers with a larger reuse ratio are likely to contain more potential similar chunks for the next backup, we define a *dense container threshold* and only *dense containers* whose reuse ratios are greater than this threshold are included in the dense container list.

4.3 Locality-aware Prefetching

Locality-aware prefetching is designed to prefetch potential base chunks by piggybacking on routine operations for prefetching metadata during deduplication. LoopDelta adopts the duplicate detection strategy proposed by Zhu et al. [53], which employs an on-disk fingerprint index combined with an in-memory fingerprint cache and a Bloom filter for duplicate detection. Specifically, for each data chunk presented for storage, its fingerprint is compared against a fingerprint cache, and on a miss, a Bloom filter is checked to determine whether the data chunk is likely to exist in the system. If true, the on-disk fingerprint index is checked, and the metadata in the corresponding container is prefetched into the fingerprint cache. The fingerprints of the subsequent data chunks are likely to be matched in the fingerprint cache due to redundancy locality.

To prefetch potential base chunks by piggybacking on read operations for prefetching metadata, the dense container list of the last backup is loaded into memory to build a lookup table at the beginning of a backup. For each container to be accessed during deduplication, we check whether it exists in the dense container list generated by the last backup. If true, the whole container, including metadata and data chunks, is prefetched for both deduplication and delta compression; otherwise, only metadata are prefetched for deduplication. If the whole container is prefetched, all data chunks in the container as well as their sketches are inserted into the potential base chunk cache for resemblance detection. In LoopDelta, only non-delta-compressed chunks can serve as base chunks, as suggested by [37]. Thus, deltas are not loaded into the potential base chunk cache. When eviction occurs, based on the Least Recently Used (LRU) policy, data chunks and sketches from a container are evicted from the potential base chunk cache as a group.

Though locality-aware prefetching eliminates the seek and rotational delays of I/Os for reading base chunks, it increases the transfer time for prefetching data chunks in dense containers. The proposed dual-locality-based similarity tracking reduces this overhead by defining a dense container threshold, as detailed in the last subsection. Prefetching potential similar chunks according to a dense container list may be inefficient as containers in the list might have been reclaimed by GC, for which how to update the dense container list judiciously to minimize the problem will be discussed in Section 4.6. The previous technique for caching metadata on an SSD [1] is orthogonal to LoopDelta and could be used in LoopDelta to increase backup throughput.

4.4 Cache-aware Filter

Cache-aware filter is designed to identify base-fragmented chunks, which will be rewritten to achieve better restore performance. As introduced in Section 3.2.2, base-fragmented chunks can be identified with the assistance of the prefetched metadata during deduplication. Since the metadata prefetched by the routine operations during deduplication are loaded into the fingerprint cache, if the base chunk of a referenced previously written delta can be directly found in the restore cache during restore and thus does not require extra I/O, its fingerprint would also be directly found in the fingerprint cache in the fingerprint indexing stage.

When rewriting is applied, even if a base chunk's fingerprint can be directly found in the fingerprint cache, this base chunk can still trigger I/Os during restore. This is because a container whose metadata are prefetched into the fingerprint cache might be identified as an infrequently reused container by the rewriting approach in the next stage, i.e., stage (3) in Figure 5, so the data chunks it containers cannot serve as base chunks. Accordingly, the cache-aware filter adopts a two-step approach to identify base-fragmented chunks. First, it identifies the base-fragmented chunks referring to deltas whose base chunks do not exist in the fingerprint cache during

fingerprint indexing. Then, it identifies the base-fragmented chunks referencing to deltas whose base chunks exist in the infrequently reused containers.

Specifically, in the fingerprint indexing stage, if a data chunk (say, *CK*) refers to a previously-written delta (say, *Delta_old*), the fingerprint of the delta's base chunk is fetched from the fingerprint cache and compared against the fingerprint cache. If the fingerprint does not exist in the fingerprint cache, *CK* is identified as a base-fragmented chunk; otherwise, the detected container ID (say, *CID_base*) of the base chunk is associated with *CK*. In the stage of identifying infrequently reused containers, if *CK* is identified as a fragmented chunk by the rewriting approach, there is no need to identify whether it is a base-fragmented chunk because it will be rewritten; otherwise, if *CK* is not a fragmented chunk, we further check whether the container whose ID is *CID_base* is selected to avoid being deduplicated against by the rewriting approach. If true, *CK* is identified as a base-fragmented chunk; otherwise, *CK* is identified as a duplicate chunk.

4.5 Post-deduplication Delta Compression

Inversed Delta Compression. The data chunks in the infrequently reused containers cannot serve as base chunks for delta compression; otherwise, the efficiency of the rewriting technique would be reduced. Inversed delta compression is designed to exploit the benefits of delta compression prohibited by rewriting. For a new chunk (say, *N*) that has a similar chunk (say, *S*) detected from the potential base chunk cache, the traditional direct delta compression approach delta-encodes *N* relative to *S* and generates a delta (say, $Delta_{n,s}$). Then, $Delta_{n,s}$ is stored instead of *N* to achieve data reduction.

On the contrary, inversed delta compression delta-encodes *S* relative to *N* and generates a delta (say, $Delta_{s,n}$), and then *stores* $Delta_{s,n}$ *along with N*. Since inversed delta compression generates an additional encoded *S*, the un-encoded *S* in the infrequently reused container will be removed during the next GC. It should be noted that delta-decoding a delta generated by inversed delta compression usually does not require extra I/Os for reading the base chunk because the delta (e.g., $Delta_{s,n}$) is stored together with the base chunk (e.g., *N*) in the same container, except that GC may occasionally disperse them to different containers.

Inversed delta compression increases the size of the data to be stored because it needs to store additional deltas, thereby increasing the I/O overheads for writing data relative to direct delta compression. Since LoopDelta is I/O-intensive, it only performs inversed delta compression for data chunks whose base chunks are prefetched from infrequently reused containers. Besides, inversed delta compression also causes more duplicate chunks to be removed during GC, which will be discussed in Section 4.6.

Delta Compression Workflow. For each unique, fragmented, and base-fragmented chunk, LoopDelta detects its base chunk from the potential base chunk cache and performs either direct or inversed delta compression according to whether rewriting is disabled or not. If it is disabled, LoopDelta only performs direct delta compression; otherwise, data chunks in the potential base chunk cache are divided into two categories: the ones prefetched from frequently reused containers and those prefetched from infrequently reused containers. When detecting base chunks, LoopDelta prefers the data chunks prefetched from frequently reused containers. Only if no such data chunk is detected, can data chunks prefetched from infrequently reused containers, if any, be selected as base chunks.

Table 1: Workload characteristics of the tested datasets.

Name	Size	Workload descriptions	Key property
RDB	1080GB	200 backups of the redis key-value store database.	Multi-version inheritance
WEB	330GB	120 days' snapshots of the website: news.sina.com. Snapshots of each day are combined into a tar file.	Self-reference duplicate and similar chunks
CHM	284GB	100 versions of source codes of Chromium project from v84.0.4110 to v86.0.4215. Each version is combined into a tar file.	
SYN	335GB	180 versions of synthetic datasets generated by simulating file create /delete/modify operations.	Multi-version inheritance

4.6 Garbage Collection

In the GC process, for a data chunk with multiple physical instances, the system marks the most recently written one as the live chunk. The delta-encoded chunks for inversed delta compression are removed in this process. GC may reduce the efficiency of locality-aware prefetching because containers in the dense container list generated by the proposed dual-locality-based similarity tracking in the last backup might have been reclaimed. To solve the problem, we update the dense container list to track potential base chunks after GC. Note that each backup stream has only one list to be updated. Thus, compared with GC, overheads for updating the dense container lists are negligible.

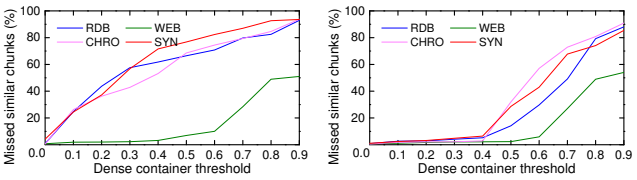
Moreover, inversed delta compression causes more duplicate chunks to be removed during GC, and the extra overhead introduced by inversed delta compression are negligible. This is because GC is time-consuming as it involves a large number of I/Os and the deduplication phase is not the bottleneck [10, 14, 17, 40].

5 Performance Evaluation

5.1 Evaluation Setup

Experimental Platform. We perform our evaluation experiments on a workstation running Ubuntu 18.04 with an Intel Xeon(R) Silver 4215R CPU @ 3.20GHz, 32GB memory, Samsung 860 PRO SSDs, and Seagate 7200RPM SATA III HDDs.

System Configurations. For all approaches under evaluation, deduplication is configured to use the Rabin-based chunking algorithm [33, 34] with the minimum, average, and maximum



(a) LoopDelta without Capping (b) LoopDelta with Capping

Figure 6: Percentage of missed similar chunks as the dense container threshold varies from 0 through 0.9 on the four datasets. The Capping's capping level in this test is 15, namely, a 20MB segment (a sequence of consecutive data chunks) refers to at most 15 containers [22].

chunk sizes of 2KB, 8KB, and 64KB respectively for chunking and the SHA1 hash function for fingerprinting. The fingerprint cache has 256 slots to hold prefetched metadata. During restore, the restore cache is configured as a 512-container-sized (2GB) LRU cache.

For delta compression, we use Odess [54] for finding similar chunks and Xdelta [25] for delta encoding. For data chunks neither deduplicated nor delta-compressed, we compress them with a local compressor called ZSTD [13] before writing them into a container, the same as in [32]. The the container size is set to 4MB. To simulate backup and restore scenarios, an HDD is used as the backup space to store ingested data, and an SSD is used as the user space to store the original datasets.

Performance Metrics. We use three metrics to evaluate the performance of LoopDelta. *The compression ratio* is used to measure the total data reduction achieved by any compression technologies, including deduplication, delta compression, and local compression. It is calculated as $\frac{original\_bytes}{post\_compression\_bytes}$, so a compression ratio of greater than 1 means data reduction.

The speed factor (MB/container-read) is defined as the mean data size restored per container read [7, 8, 22], which is used to measure the restore performance. A larger speed factors indicates better restore performance. *The backup throughput* is measured by the throughput at which the input data are deduplicated, delta compressed, and written to the disk. We run each experiment five times to obtain a stable and average value of the backup throughput. Additionally, the shown speed factor is the average of the last 20 backups and the shown backup throughput is the average of the last 10 backups.

Evaluated Datasets. Four datasets, shown in Table 1 with their key characteristics, are used for performance evaluation. These datasets represent various typical workloads, including database snapshots, website snapshots, an open-source code project, and a synthetic dataset.

5.2 A Performance Study of LoopDelta

5.2.1 Dense Container Threshold

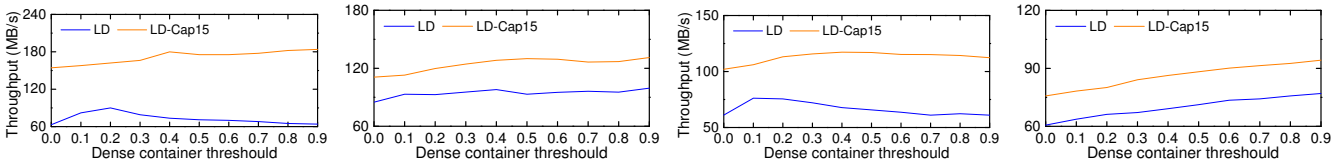
The dense container threshold can affect the number of detected similar chunks because it prevents containers whose reused ratios are smaller than it from being prefetched to supply potential similar chunks. Figure 6(a) suggests that, without rewriting, the percentage of similar chunks missed by LoopDelta increases quickly with the dense container threshold. One exception is the WEB dataset, where the percentage of missed similar chunks is low when the dense container threshold is small than 0.6. This is because this dataset contains substantial self-referenced duplicate chunks and most of the containers' reuse ratios are greater than 0.5.

Figure 6(b) suggests that Capping [22], a state-of-the-art rewriting approach introduced in Section 2.1, significantly decreases the percentage of missed similar chunks, especially when the dense container threshold is smaller than 0.4. By increasing the sequential layout of the current backup, rewriting improves both the logical and physical locality for the current and subsequent backups. This is why the percentage is low when the dense container threshold is small than 0.4. As the threshold increases beyond this, some containers holding data chunks that are inherited from the last backup are prevented from being prefetched for resemblance detection and thus the percentage of missed similar chunks grows quickly. When the dense container threshold is 0.3, LoopDelta only misses 1%-5% of similar chunks on the four datasets.

The dense container threshold can also affect backup throughput because it is related to two categories of I/O overheads: (1) transfer time for prefetching dense containers, which decreases as the threshold increases because fewer containers will be prefetched, and (2) container-writeback time saved by delta compression, which decreases as the threshold increases because fewer chunks will be delta compressed.

Figure 7 suggests that, except for the SYN dataset, the backup throughput hits a maximum and then either decreases or flattens out. This is because when the dense container threshold is very low, almost all containers holding potential similar chunks will be prefetched, leading to significant extra transfer time that exceeds the amount of container-writeback time saved by delta compression and resulting in very low throughput. This trend continues with the increase in dense container threshold until the decrease in extra transfer time for prefetching is offset by the decrease in the container-writeback time saved by delta compression. Beyond this point, the extra transfer time for prefetching becomes either greater than or equal to the decrease in container-writeback time saved by delta compression, causing the throughput to decrease or remain unchanged.

The SYN dataset contains only a few similar chunks that can be delta-compressed, and thus the container-writeback time saved by delta compression has a limited impact on backup throughput. Consequently, the backup throughput increases with the dense container threshold. Considering the two metrics (backup throughput and compression ratio) as a whole, in what follows, when rewriting (Capping) is applied, the dense container threshold is set to 0.3 as suggested by Figure 6(b) and discussed earlier.



(a) RDB (b) WEB (c) CHRO (d) SYN

Figure 7: Backup throughput as the dense container threshold varies from 0 through 0.9 on the four datasets. LD refers to LoopDelta without rewriting and LD-Cap15 refers to LoopDelta with Capping of a capping level of 15.

Table 2: Compression ratio and speed factor for LoopDelta (LD), with and without the cache-aware filter (CAF), and with and without rewriting (Capping), for the four datasets.

Dataset	Approach	Compression ratio w/o GC	Speed factor
RDB	LD w/o CAF	142.6	2.73
	LD	139.2 (-2.4%)	2.81 (+2.9%)
	LD-Cap15 w/o CAF	68.4	3.1
	LD-Cap15	60.9 (-11%)	4.67 (+50.6%)
WEB	LD w/o CAF	112.2	2.81
	LD	105.7 (-5.8%)	2.96 (+5.3%)
	LD-Cap15 w/o CAF	51.2	6.84
	LD-Cap15	46.9 (-8.4%)	7.64 (+11.7%)
CHRO	LD w/o CAF	70.7	2.66
	LD	70.3 (-0.6%)	2.73 (2.6%)
	LD-Cap15 w/o CAF	20.8	6.09
	LD-Cap15	20.4 (-1.9%)	8.12 (+33.3%)
SYN	LD w/o CAF	33.9	0.84
	LD	33.8 (-0.3%)	0.85 (+1.2%)
	LD-Cap15 w/o CAF	17.1	1.38
	LD-Cap15	15.4 (-9.9%)	2.04 (+47.8%)

5.2.2 Cache-aware Filter (CAF)

This subsection investigates the efficiency of the cache-aware filter (CAF). Since base-fragmented chunks identified by CAF will be rewritten, and rewritten data will be removed during GC. We do not run GC to show the trade-off between the decrease of compression ratio and the increase of speed factor caused by CAF.

Table 2 suggests that CAF slightly increases the speed factor (1.2%-5.3%, average of 3%) when rewriting is not applied, and it significantly increases the speed factor when rewriting is applied (by up to 50.6%, average of 35.9%), at the expense of a modest decrease (0.3%-11%, average of 4.8%) in compression ratio. CAF reduces the compression ratio because base-fragmented chunks are rewritten and not removed from storage as GC is not run. The decrease in compression ratio caused by CAF on the WEB and CHRO datasets is relatively small compared to the other two datasets. This is because these two datasets are tar-type files containing substantial small files, so most of their rewritten chunks can be delta-compressed.

A larger fingerprint cache can help to identify more base-fragmented chunks at the cost of increased computational overheads. Since the bottleneck of LoopDelta lies in I/O overheads, the computational overhead of CAF has almost no impact on backup throughput. We found that, most base-fragmented chunks can be identified by the first few slots at the front of the fingerprint cache due to locality, especially when rewriting is applied. To reduce the computational overhead, we suggest using the first 20 slots of the fingerprint cache to identify base-fragmented chunks when rewriting is applied and using the first 64 slots when rewriting is not applied. This strategy does not compromise restore performance because base-fragmented chunks that are not identified will still be recognized due to their container IDs not being found in the fingerprint cache.

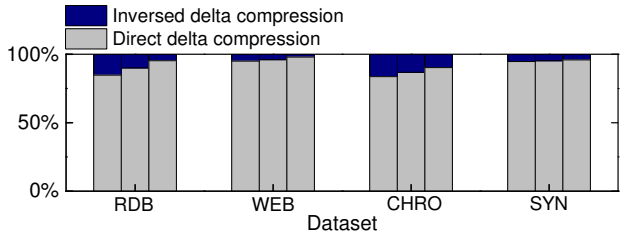


Figure 8: Proportion of compression ratio achieved by direct and inversed delta compression with different capping level on the four datasets. The three bars on each dataset from left to right represent the three capping levels of 10, 15, and 20, respectively.

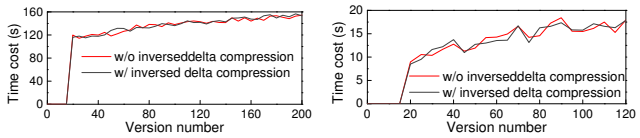


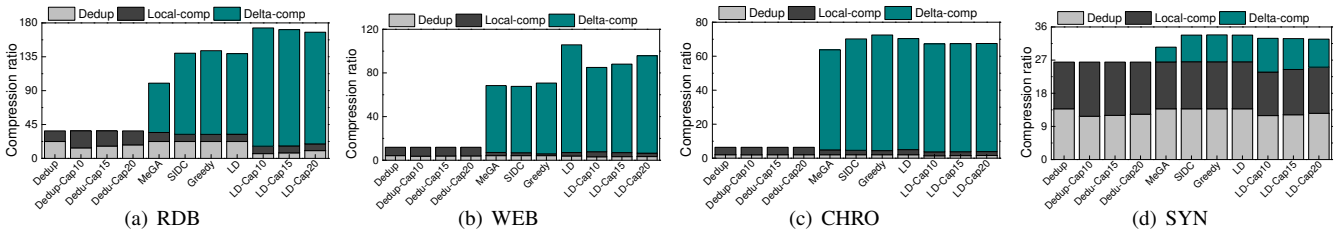
(a) RDB (b) WEB

Figure 9: Time cost of GC for LD-Cap10 with and without inversed delta compression on the RDB and WEB datasets.

5.2.3 Inversed Delta Compression

This subsection investigates the efficiency of inversed delta compression. Figure 8 suggests that the compression gains achieved by inversed delta compression account for 2.2%-16.4% of the combined compression gains by direct and inversed delta compression. For example, for LD-Cap10, the compression ratio achieved by inversed delta compression accounts for 15.3%, 5%, 16.4%, and 5.3% respectively of that achieved jointly by direct and inversed delta compression on the four datasets.

Inversed delta compression causes more data to be stored because it needs to store the deltas of data chunks being delta-encoded. For LD-Cap10, extra stored data caused by inversed delta compression account for 2.1%, 0.8%, 2.7%, and 0.1% of



(a) RDB (b) WEB (c) CHRO (d) SYN

Figure 10: Comparison of compression ratio achieved by the eleven approaches on the four datasets.

the total stored data on the four datasets respectively, which are marginal. This is because the size of a delta is often much smaller than that of a data chunk compressed with the local compressor, e.g., the former is 1/26-1/10 of the latter in size in our test.

Inversed delta compression also causes more data chunks to be removed during GC. Figure 9 compares the time cost of LD-Cap10 with and without inversed delta compression on the RDB and WEB datasets. To accumulate more deltas generated by inversed delta compression, we run GC after every 5 backups from the 20_{th} backup. The results in Figure 9 suggest that inversed delta compression has a negligible impact on the time cost of GC because the bottleneck of GC lies in marking and moving forward the live chunks, which requires a large number of I/Os.

5.3 Comprehensive Evaluation of LoopDelta

In this section, we comprehensively evaluate the performance of LoopDelta in terms of three key metrics: compression ratio, speed factor, and backup throughput. Five data reduction approaches are also tested: Dedup, Dedup-Cap, MeGA, SIDC, and Greedy. Specifically, Dedup is a deduplication approach proposed by Zhu et al. [53] without rewriting, and Dedup-Cap refers to Dedup with Capping. MeGA, SIDC, and Greedy have been discussed in Section 3.1. Dedup-Cap# and LD-Cap# represent Dedup-Cap and LD-Cap with a different capping level of #.

MeGA's restore performance and backup throughput are not evaluated because it requires additional offline and service-disruptive operations. In contrast, LoopDelta focuses on adding delta compression to inline deduplication systems in a non-service-disruptive manner. In evaluations of this section, we use a 20-container-sized base-chunk cache for LD-Cap#, and a 150-container-sized base-chunk cache for MeGA, SIDC, Greedy, and LD. With rewriting (Capping), a 20-container-sized cache can capture almost all similar chunks (not shown due to space limit).

Compression Ratio. In this test, we run GC after each backup from the 20_{th} backup. Figure 10 suggests that LD achieves a compression ratio comparable to SIDC and Greedy and higher than MeGA on the RDB, CHRO, and SYN datasets. This means that LD can detect most potential similar chunks by exploiting both logical and physical locality. On the WEB dataset, LD achieves the highest compression ratio because it can detect more highly similar chunks than the other approaches on the datasets containing self-referenced similar chunks. Specifically, LD outperforms MeGA, SIDC, and Greedy by 1.55×, 1.56×, and 1.5×, respectively, on the WEB dataset. Furthermore, LD achieves significantly higher compression ratios than Dedup, with improvements of 3.81× (RDB), 8.9× (WEB), 10.97× (CHRO), and 1.27× (SYN).

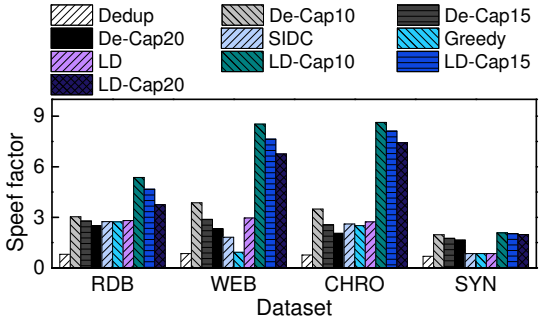


Figure 11: Comparison of speed factor achieved by the ten approaches on the four datasets.

Additionally, LD-Cap15 achieves 4.68× (RDB), 7.42× (WEB), 10.51× (CHRO), and 1.24×(SYN) higher compression ratio than Dedup-Cap15, respectively. Rewriting decreases the compression ratio of LD because a small number of similar chunks are missed, as analyzed in Section 5.2.1. One exception is the RDB dataset, where rewriting increases the compression ratio. This is because rewriting causes the rewritten chunks to be detected as base chunks. Compared to the data chunks written much earlier, rewritten chunks are more similar to the data chunks in the current backup. In our tests, the average DCE of LD and LD-Cap15 are 0.9398 and 0.9591, respectively. Note that while the total amount of redundancy eliminated by LD-Cap15 may not be significantly more than that eliminated by LD, compressing even a small amount of additional data can lead to a significant increase in compression ratio when the compression ratio is very high.

Note that LD-Cap# may achieve smaller deduplication gains and more delta compression gains than the other approaches. This is because LD-Cap# rewrite fragmented chunks and perform delta compression for them, which reduces deduplication gains but increases delta compression gains.

Speed Factor. Figure 11 suggests that LD achieves the highest speed factor among all approaches without rewriting and LD-Cap# also achieve a higher speed factor than Dedup-Cap#. Specifically, LD achieves 3.48× (RDB), 3.47× (WEB), 3.57× (CHRO), and 1.24× (SYN) higher speed factor than

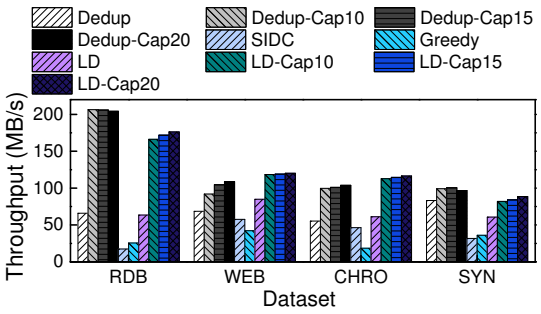

Figure 12: Comparison of backup throughput achieved by the ten approaches on the four datasets.

Dedup respectively, and LD-Cap15 achieves 1.68× (RDB), 2.65× (WEB), 3.17× (CHRO), and 1.2× (SYN) higher speed factor than Dedup-Cap15 respectively.

Generally, approaches combining deduplication and delta compression, i.e., SIDC, Greedy, and LD, achieve a higher speed factor than Dedup, which only performs deduplication. This is because delta compression has the potential to increase restore performance, which mainly depends on the number of read-in containers during restore. Delta compression decreases the number of written containers during backup and the number of read-in containers during restore. However, if base chunks require extra I/Os during restore, the improvement in speed factor resulting from delta compression will decrease. In LD, base chunks do not require extra I/Os during restore, and this is ensured by CAF.

Greedy detects similar chunks without considering the positions of base chunks. Thus, base chunks in it may require substantial I/Os during restore and this will lead to a lower speed factor, e.g., on the WEB dataset. SIDC detects similar chunks stored along with duplicate chunks, and thus, the base chunks of the delta-compressed chunks in it do not require extra I/Os during restore. However, SIDC fails to identify base-fragmented chunks. This is why LD achieves a slightly higher speed factor than SIDC on the RDB, CHRO, and SYN datasets. LD also achieves a higher speed factor than SIDC on the WEB dataset because it achieves higher compression ratio than SIDC, which means fewer read-in containers during restore.

Backup Throughput. Figure 12 suggests that LD and LD-Cap# achieve lower backup throughput than Dedup and Dedup-Cap# respectively on the RDB and SYN datasets and higher backup throughput than them on the WEB and CHRO datasets. Specifically, LD achieves 3.6% and 27.1% lower backup throughput than Dedup on the RDB and SYN datasets, and 24% and 10.5% higher backup throughput than Dedup on the WEB and CHRO datasets. Meanwhile, LD-Cap15 achieves 16.5% and 16.3% lower backup throughput than Dedup-Cap15 on the RDB and SYN datasets, and 13.9% and 13.5% higher backup throughput than Dedup-Cap15 on the WEB and CHRO datasets. Additionally, LD (LD-Cap15) achieves 1.3×∼3.7× (2.3×∼9.9×) higher backup throughput than SIDC and Greedy on the four datasets. This is because LoopDelta eliminates the seek and rotational delays of I/Os for reading base chunks.

Compared with deduplication-based backup systems, post-deduplication delta compression adds additional computational overheads, but the backup throughput is mainly decided by I/O overheads. In LoopDelta, multiple tasks in its workflow involve I/Os, including (1) looking up the fingerprint index, (2) prefetching metadata, (3) prefetching potential base chunks, (4) updating the fingerprint index, and (5) writing back containers. For datasets with low redundancy, such as the WEB and CHRO datasets, there are more unique chunks that lead to more I/Os in tasks (4) and (5), making them the performance bottleneck. Delta compression increases the backup throughput on such datasets because it alleviates the performance bottleneck by reducing I/Os in tasks (5). For datasets with high redundancy, such as the RDB and SYN datasets, there are more duplicate chunks that result in more I/Os in tasks (1), (2), and (3), making them the performance bottleneck. Delta compression decreases backup throughput because it aggravates the performance bottleneck by increasing I/Os in task (3).

To sum up, LoopDelta achieves a comparable or higher compression ratio, higher restore performance, and higher backup throughput than the other post-deduplication delta compression approaches. It also increases the compression ratio by 1.24∼10.97 times on top of deduplication, without notably affecting backup throughput, and improves the restore performance by 1.2∼3.57 times.

6 Conclusion

In this paper, we present LoopDelta to embed delta compression in inline deduplication. The key idea of LoopDelta is the combined use of four key techniques, i.e., dual-locality-based similarity tracking to detect similar chunks, locality-aware base prefetching to avoid extra I/Os for reading base chunks on the write path, cache-aware filter to avoid extra I/Os for reading base chunks on the read path, and inversed delta compression to perform delta compression for similar chunks prefetched from infrequently reused containers. The experimental results indicate that LoopDelta significantly increases compression ratio and improves restore speed over deduplication, without notably affecting backup throughput.

TC-GNN: Bridging Sparse GNN Computation and Dense Tensor Cores on GPUs

Yuke Wang, Boyuan Feng, Zheng Wang, Guyue Huang, and Yufei Ding
University of California, Santa Barbara

Abstract

Recently, graph neural networks (GNNs), as the backbone of graph-based machine learning, demonstrate great success in various domains (*e.g.*, e-commerce). However, the performance of GNNs is usually unsatisfactory due to the highly sparse and irregular graph-based operations. To this end, we propose **TC-GNN**, the first GNN acceleration framework based on GPU Tensor Core Units (TCUs). The core idea is to reconcile the "Sparse" GNN computation with the high-performance "Dense" TCUs. Specifically, we conduct an in-depth analysis of the sparse operations in mainstream GNN computing frameworks. We introduce a novel sparse graph translation technique to facilitate TCU processing of the sparse GNN workload. We implement an effective CUDA core and TCU collaboration design to fully utilize GPU resources. We integrate TC-GNN with the PyTorch framework for high programmability. Rigorous experiments show an average of 1.70× speedup over the state-of-the-art DGL framework across various models and datasets.

1 Introduction

Over the recent years, with the increasing popularity of graph-based learning, graph neural networks (GNNs) [27, 51, 59] become dominant in the computing of essential tasks across a wide range of domains, like e-commerce, financial services, and etc. Compared with standard methods for graph analytics, such as random walk [18, 22, 50] and graph laplacians [8, 32, 33], GNNs highlight themselves with significantly higher accuracy [27, 54, 59] and better generality [19]. From the computation perspective, GNNs feature an interleaved execution phase of both graph operations (scatter-and-gather [17]) at the ***Aggregation*** phase and Neural Network (NN) operations (matrix multiplication) at the ***Update*** phase. Our experimental studies further show that the aggregation phase which involves highly sparse computation on irregular input graphs generally takes more than 80% of the running time for both GNN training and inference. Existing GNN frameworks, *e.g.*, Deep Graph Library [55] and PyTorch Geometric [13], are mostly built upon the popular NN frameworks that are originally optimized for dense operations, such as general matrix-matrix multiplication (GEMM). To support sparse computations in GNNs, their common strategy is to incorporate sparse primitives (such as cuSPARSE [38]) for their backend implementations. However, cuSPARSE leverages the sparse linear algebra (LA) algorithm which involves lots of high-cost indirect memory accesses on non-zero elements of a sparse matrix. Therefore, cuSPARSE cannot enjoy the same level of optimizations (e.g., data reuse) as its dense counterpart, such as cuBLAS [40]. Moreover, cuSPARSE is designed to only utilize CUDA cores. Therefore, It cannot benefit from advancements in GPU hardware features, like Tensor Core Units (TCUs) on the recent NVIDIA Ampere and Hopper GPUs. Such a design is also the trend of many other AI-tailored accelerators/units (e.g., Google TPU [24] and Matrix Core [2] on AMD GPUs) and can significantly boost the performance of dense LA algorithms (e.g., GEMM and Convolution) in most conventional deep-learning applications (e.g., CV [20] and NLP [10]).

This work focuses on exploring the potential of TCUs for accelerating such GNN-based graph learning and our design/optimization principles will also benefit other similar AI hardware [2, 24] for sparse deep-learning workloads. We remark that making TCUs effective for general GNN computing is a non-trivial task. Our initial study shows that naively applying the TCU to sparse GNN computation would even result in inferior performance compared with the existing sparse implementations on CUDA cores. There are several challenges. ***First***, directly resolving the sparse GNN computing problem with the pure dense GEMM solution is impractical due to the extremely large memory cost ($O(N^2)$, where N is the number of nodes). Besides, traversing the matrix tiles already known to be filled with all-zero elements would cause excessive unnecessary computations and memory access. ***Second***, simply employing TCUs to process non-zero matrix tiles of the sparse graph adjacency matrix would still waste most of the TCU computation and memory access efforts. This is because TCU

input matrix tiles are defined with fixed dimension settings (*e.g.*, $height(16) \times width(8)$), whereas the non-zero elements of a sparse graph adjacency matrix are distributed irregularly. Thus, it requires intensive zero-value padding to satisfy such a rigid input constraint. ***Third***, although the recent CUDA release update enables TCUs to exploit the benefit of certain types of sparsity [37], it only supports blocked SpMM, where non-zero elements must first fit into well-shaped blocks and the number of blocks must be the same across different rows. Such an input restriction makes it hard to handle highly irregular sparse graphs in real-world GNN applications.

To this end, we introduce, **TC-GNN**[1], the first TCU-based GNN acceleration design on GPUs. Our key insight is to *let the sparse input graph fit the dense computation of TCUs*. ***At the input level***, instead of exhaustively traversing all sparse matrix tiles and determining whether to process each tile, we develop a new *sparse graph translation* (SGT) technique that can effectively identify those non-zero tiles and condense non-zero elements from these tiles into fewer number of "dense" tiles. Our major observation is that neighbor sharing is very common among nodes in real-world graphs. Therefore, applying SGT can effectively merge the unnecessary data loading of the shared neighbors among different nodes to avoid high-cost memory access. SGT is generic to any kind of sparse pattern of input graphs and can always yield the correct results as the original sparse algorithm. ***At the GPU kernel level***, for efficiently processing GNN sparse workloads, TC-GNN exploits the benefits of CUDA core and TCU collaboration. The major design idea is that the CUDA core, which is more powerful at fine-grained thread-level execution, would be a good candidate for managing memory-intensive data access. While TCU, which is more powerful in handling simple arithmetic operations (*e.g.*, multiplication and addition), would be well-suited for compute-intensive GEMM on dense tiles generated from SGT. ***At the framework level***, we integrate TC-GNN with the popular PyTorch [49] framework. Thereby, users only need to interact with their familiar PyTorch programming environment by using TC-GNN APIs. This can significantly reduce extra learning efforts, and improve user productivity and code portability.

To sum up, we summarize our contributions as follows:

- We conduct a detailed analysis (§3) of existing solutions (*e.g.*, SpMM on CUDA cores) and identify the potentials of TCUs for accelerating sparse GNN workloads.
- We introduce a sparse graph translation technique (§4.1). It can make the sparse and irregular GNN input graphs easily fit the dense computing of TCUs for acceleration.
- We build a TCU-tailored algorithm (§4.2) and GPU kernel design (§4.3) for CUDA core and TCU collaboration on GPUs to handle different sparse GNN computation.

[1] https://github.com/YukeWang96/TC-GNN_ATC23.git

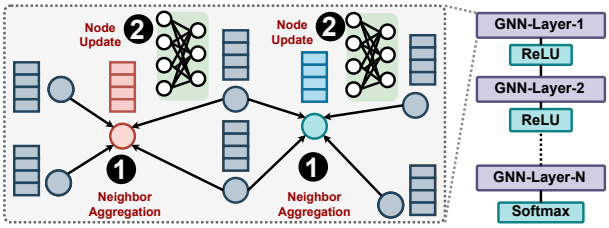

Figure 1: GNN General Computation Flow.

- Extensive experiments show TC-GNN achieves 1.70× speedup on average over the state-of-the-art GNN computing framework, Deep Graph Library, across various mainstream GNN models and dataset settings.

2 Background

2.1 Graph Neural Networks

Graph neural networks (GNNs) are an effective tool for graph-based machine learning. The detailed computing flow of GNNs is illustrated in Figure 1. GNNs basically compute the node feature vector (embedding) for node v at layer $k+1$ based on the embedding information at layer k ($k \geq 0$), as shown in Equation 1,

$$\begin{aligned} a_v^{(k+1)} &= Aggregate^{(k+1)}(h_u^{(k)} | u \in \mathbf{N}(v) \cup h_v^{(k)}) \\ h_v^{(k+1)} &= Update^{(k+1)}(a_v^{(k+1)}) \end{aligned} \tag{1}$$

where $h_v^{(k)}$ is the embedding vector for node v at layer k; $a_v^{(k+1)}$ is the aggregation results through collecting neighbors' information (*e.g.*, node embeddings); $\mathbf{N}(v)$ is the neighbor set of node v. The aggregation method and the order of aggregation and update could vary across different GNNs. Some methods [19, 27] just rely on the neighboring nodes while others [54] also leverage the edge properties that are computed by applying vector dot-product between source and destination node embeddings. The update function is generally composed of standard NN operations, such as a fully connected layer or a multi-layer perceptron (MLP) in the form of $w \cdot a_v^{(k+1)} + b$, where w and b are the weight and bias parameters, respectively. The common choices for node embedding dimensions are 16, 64, and 128, and the embedding dimension may change across different layers. After several iterations of aggregation and update (*i.e.*, several GNN layers), we will get the output feature embedding of each node, which can be used for various downstream graph learning tasks, such as node classification [11, 16, 25] and link prediction [6, 28, 53].

The sparse computing in the aggregation phase is generally formalized as the sparse-matrix dense-matrix multiplication (SpMM), as illustrated in Figure 2a, and is handled by many sparse libraries (*e.g.*, cuSPARSE [38]) in many state-of-the-art GNN frameworks [55, 57]. These designs only count on GPU CUDA cores for computing, which waste the modern GPUs

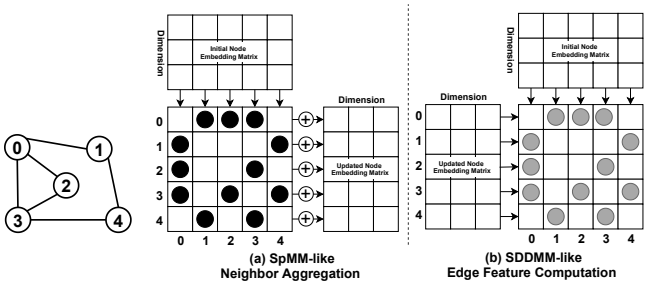

Figure 2: (a) SpMM-like and (b) SDDMM-like Operation in GNNs. Note that "→" indicates loading data; "⊕" indicates neighbor embedding accumulation.

with diverse computing units, such as the Tensor Core Unit (TCU). Specifically, we formalized the neighbor aggregation as SpMM-like operations (Equation 2)

$$\hat{\mathbf{X}} = (\mathbf{F}_{N\times N} \odot \mathbf{A}_{N\times N}) \cdot X_{N\times D}) \tag{2}$$

where $\mathbf{A}$ is the graph adjacency matrix stored in CSR format. $\mathbf{X}$ is a node feature embedding matrix stored in dense format. N is the number of nodes in the graph, and D is the size of node feature embedding dimension; $\odot$ is the elementwise multiplication and $\cdot$ is the standard matrix-matrix multiplication; $\mathbf{F}$ is the edge feature matrix in CSR format and can be computed by Sampled Dense-Dense Matrix Multiplication (SDDMM)-like operations (Equation 3 and Figure 2b).

$$\mathbf{F} = (\mathbf{X}_{N\times D} \cdot \mathbf{X}^T_{N\times D}) \odot \mathbf{A}_{N\times N} \tag{3}$$

Note that the computation of F is optional in GNNs, which is generally adopted by the Attention-based Graph Neural Network in PyTorch [51] for identifying more complicated graph structural information. Other GNNs, such as the Graph Convolutional Network [27] and Graph Isomorphism Network [59], only use the adjacency matrix for neighbor aggregation.

2.2 GPU Tensor Core

In the most recent GPU architectures (since Volta [43]), NVIDIA announced a new type of computing unit, Tensor Core Unit (TCU), for accelerating dense deep-learning operations (*e.g.*, Dense GEMM). A GPU Streaming-Multiprocessor (w/ TCU) is illustrated in Figure 3. Note that FP64, FP32, INT, and SFU are for double-precision, single-precision, integer, and special function units, respectively. Different from scalar computation on CUDA cores, TCU provides tile-based matrix-matrix computation primitives on register fragments, which can deliver more than 10× throughput improvement. In particular, TCU supports the compute primitive of $\mathbf{D} = \mathbf{A} \cdot \mathbf{B} + \mathbf{C}$, where $\mathbf{A}$ and $\mathbf{B}$ are required to be a certain type of precision (*e.g.*, half, TF-32), while $\mathbf{C}$ and $\mathbf{D}$ are stored in FP32. Depending on the data precision and GPU architecture version, the matrix size (MMA shape) of $\mathbf{A}(M \times K)$, $\mathbf{B}(K \times N)$, and $\mathbf{C}(M \times N)$ should follow some principles [41]. For example, TF-32 TCU computing requires $M = N = 16$ and $K = 8$.

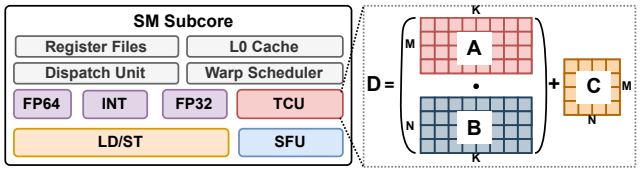

Figure 3: A Subcore of GPU SM with TCUs.

Listing 1: WMMA APIs for TCUs in CUDA C.

```
wmma::fragment<matrix_a, M, N, K, tf32, row_major> a_frag;
// Load tiles (global/shared mem. -> register fragments).
wmma::load_matrix_sync(a_frag, A, M);
// Execute GEMM on loaded tiles on register fragments.
wmma::mma_sync(c_frag, a_frag, b_frag, c_frag);
// Move results (register fragments -> global/shared mem).
wmma::store_matrix_sync(C, c_frag, N, mem_row_major);
```

In the recent CUDA release (>=11.0) on Ampere (*sm*>=80), TF-32 serves as a good alternative to float/double on TCU-based GPU computing for modern deep-learning applications, according to NVIDIA's in-depth studies [45].

Different from the CUDA cores that operate at the thread level (*e.g.*, allowing the "if" branch among threads), TCU supports only the operation at the warp level (*e.g.*, forbidding the "if" branch among threads within a warp). Before calling TCUs, all registers in a warp need to collaboratively store matrix tiles into a new memory hierarchy *Fragment* [48], which allows data sharing across registers. This intra-warp sharing provides opportunities for fragment-based memory optimizations. TCU can be utilized in several ways. The simplest way is to call cuBLAS [40] by using the `cublasSgemmEX` API. The second way is to call the Warp Matrix Multiply-Accumulate (WMMA) (`nvcuda::wmma`) API [47] in CUDA C to operate TCUs directly with four major operations (Listing 1).

Since the appearance of the TCU, research efforts have been devoted to accelerating deep-learning (DL) workloads with TCUs. Ang and Simon [31] leverage 1-bit GEMM capability on Turing TCUs for accelerating binary Neural Network inference. Boyuan et al. [12] introduce GEMM-based scientific computing on TCUs with extended precision and high performance. Yuke et al. [56] treat batched quantized GNNs (partitioning large graphs into small graphs as batches) as batched dense GEMM computation and accelerate it on TCUs for inference. These prior efforts use TCUs in the dense DL applications that TCU is initially designed for, while TC-GNN jumps out of the scope defined by TCU designers and accelerates the sparse full-graph GNNs using TCUs.

3 Motivation

In this section, we will discuss the major technical thrust for us to leverage TCUs for accelerating sparse GNN computation. We use the optimization of SpMM as the major example in this discussion, and the acceleration of SDDMM would also benefit from similar optimization principles.

Table 1: Profiling of GCN Sparse Operations.

Dataset	Aggr. (%)	Update (%)	Cache(%)	Occ.(%)
Cora	88.56	11.44	37.22	15.06
Citeseer	86.52	13.47	38.18	15.19
Pubmed	94.39	5.55	37.22	16.24

Table 2: Medium-size Graphs in GNNs.

Dataset	# Nodes	# Edges	Memory	Eff.Comp
OVCR-8H	1,890,931	3,946,402	14302.48 GB	0.36%
Yeast	1,714,644	3,636,546	11760.02 GB	0.32%
DD	334,925	1,686,092	448.70 GB	0.03%

3.1 SpMM on CUDA cores

As the major component of sparse linear algebra operation, SpMM has been incorporated in many off-the-shelf libraries [1, 3, 5, 21, 38]. The close-sourced cuSPARSE [38] library developed by NVIDIA is the most popular solution and it can deliver state-of-the-art performance for most GPU-based SpMM computation. cuSPARSE has also been widely adopted by many GNN frameworks, such as Deep Graph Library (DGL) [55], as the backend for sparse operations. To understand its characters, we profile DGL on one layer of a GCN [27] model (*neighbor aggregation + node update*) on NVIDIA RTX3090. We report two key kernel matrices for only neighbor aggregation kernel, including L1/texture cache hit rate (*Cache*) and the achieved Streaming-Multiprocessor (SM) occupancy (*Occ.*). We select three representative GNN datasets: Cora with 3,327 nodes, 9,464 edges, and 3,703 node embedding dimensions; Citeseer with 2,708 nodes, 10,858 edges, and 1,433 dimensions; Pubmed with 19,717 nodes, 88,676 edges, and 500 dimensions.

From Table 1, we have several observations: ***First***, the aggregation phase usually dominates the overall execution of the GNN execution. From these three commonly used GNN datasets, we can see that the aggregation phase usually takes more than 80% of the overall execution time, which demonstrates the key performance bottleneck of the GNNs is to improve the performance of the sparse neighbor aggregation. ***Second***, sparse operations in GNNs show very low memory performance. The column *Cache* of Table 1 shows GNN sparse operations could not well benefit from the GPU cache system, thus, showing a low cache-hit ratio (around 37%) and frequent global memory access. ***Third***, sparse operations of GNNs show very inefficient computation. As described in the column *Occupancy* of Table 1, the sparse operation of GNNs could hardly keep the GPU busy because 1) its low computation intensity (the number of non-zero elements in the sparse matrix is generally small); 2) its highly irregular memory access for fetching rows of the dense matrix during the computation, resulting in memory-bound computation; 3) it currently can only leverage CUDA cores for computation, which naturally has limited throughput performance. On the other side, this study also points out several potential directions for improving the SpMM performance on GPUs, such as improving the computation intensity (*e.g.*, assigning more workload to each thread/warp/block), boosting memory access efficiency (*e.g.*, crafting specialized memory layout for coalesced memory access), and breaking the computation performance ceiling (*e.g.*, using TCUs).

3.2 Dense GEMM on CUDA Cores/TCUs

While the dense GEMM is mainly utilized for dense NN computation (*e.g.*, linear transformation and convolution), it can also be leveraged for GNN aggregation under some circumstances. For example, when an input graph has a very limited number of nodes, we can directly use the dense adjacency matrix of the graph and accelerate the intrinsically sparse neighbor aggregation computation on CUDA cores/TCUs by calling cuBLAS [40]. However, such an assumption may not hold even for medium-size graphs in real-world GNNs.

As shown in Table 2, for these selected datasets, the memory consumption of their dense graph adjacent matrix (as a 2D `float` array) would easily exceed the device memory constraint of today's GPU (less than 100GB). Even if we assume the dense adjacent matrix can fit into the GPU memory, the extremely low effective computation (the last column of Table 2) would also be a major obstacle for us to achieve high performance. We measure the effective computation as $\frac{nnz}{N \times N}$, where nnz is the number of the non-zero elements (indicating edges) in the graph adjacent matrix and N is the number of nodes in the graph. The number of nnz is tiny in comparison with the $N \times N$. Therefore, computation and memory access on zero elements are wasted.

3.3 Hybrid Sparse-Dense Solution

Another type of work [29, 37] takes the path of mixing the *sparse control* (tile-based iteration) with *Dense GEMM computation*. They first apply a convolution-like (2D sliding window) operation on the adjacent matrix and traverse all possible dense tiles that contain non-zero elements. Then, for all identified non-zero tiles, they invoke GEMM on CUDA cores/TCUs for computation. However, this strategy has two shortcomings. ***First***, the sparse control itself would cause a high overhead. Based on our empirical study, the non-zero elements are highly scattered on the adjacent matrix of a sparse graph. Therefore, traversing all blocks in a super large adjacent matrix would be time-consuming. ***Second***, the identified sparse tiles would still waste lots of computation. The irregular edge connections of the real-world graphs could hardly fit into these fixed-shape tile frames. Therefore, most of the dense tiles would still have very few non-zero elements.

Inspired by the above studies, we make several design choices in order to achieve high-performance sparse GNN operations. ***First***, we choose the hybrid sparse-dense solution as the starting point. This can give us more flexibility for optimizations at the sparse control (*e.g.*, traversing fewer tiles)

Table 3: Comparison among Sparse GEMM, Dense GEMM, Hybrid Sparse-Dense, and TC-GNN. Note that **MC**: Memory Consumption, **EM**: Effective Memory Access, **CI**: Computation Intensity, **EC**: Effective Computation.

Solution	MC	EM	CI	EC
Sparse GEMM (§3.1)	Low	Low	Low	High
Dense GEMM (§3.2)	High	High	High	Low
Hybrid Sparse-Dense (§3.3)	High	Low	Low	High
TC-GNN (This work)	**Low**	**High**	**High**	**High**

and dense computation (*e.g.*, increasing the effective computation/memory access when processing each tile). ***Second***, we employ shared memory as the key space for GPU kernel-level data management. It can help us to re-organize the irregular GNN input data in a more "regularized" way such that both the memory access efficiency and computing performance can be well improved. ***Third***, we choose TCUs as our major computing unit since they can bring significantly higher computing throughput performance in comparison with CUDA cores. This also indicates the great potential of using TCUs for harvesting more performance gains.

Finally, we crystallize all of our ideas and insights into TC-GNN that effectively coordinates the execution of GNN sparse operations on dense TCU. We show a brief qualitative comparison among TC-GNN and the above three solutions in Table 3. Note that *Memory Consumption* is the size of memory used by the sparse/dense graph adjacency matrix; The *Effective Memory Access* is the ratio between the size of the accessed data that is actually involved in the later computation and the total data being accessed; The *Computation Intensity* is the ratio of computing operations versus the data being accessed; The *Effective Computation* is the operations for generating the final result versus the total operations.

4 TC-GNN Design

In this section, we will first give an overview of TC-GNN through its high-level programming interface and then detail the TCU-aware GNN algorithm design. As detailed in Listing 2, TC-GNN consists of several key components to facilitate the programming of GNN models on GPU TCUs. TC-GNN introduces a set of pre-built popular GNN layers (e.g., `TCGNN.GCNConv`) that can be easily connected with some other existing neural network layers (e.g., `ReLU` and `softmax`), to help users define their own GNN model quickly. For those non-conventional GNN layers, users can directly use our low-level APIs (e.g., `TCGNN.spmm` and `TCGNN.sddmm`) to express the GNN computation easily. TC-GNN introduces an input **`Loader`** to load the GNN input graph as a *rawGraph* and capture the key input information for system-level optimizations. TC-GNN incorporates a **`Preprocessor`** to build tiles from *rawGraph* and generate TCU-aware *tiledGraph* (§4.1), and optimize runtime configuration (e.g., warps per block) for our TCU-tailored GPU kernel (§4.2 and §4.3) based on input. Finally, we train the initialized GNN model defined in TC-GNN as the regular GNN models defined in other frameworks through forward and backward computation.

Listing 2: Example of a 2-layer GCN in TC-GNN.

```
import TCGNN, torch
# include other packages ...
class GCN(torch.nn.Module):
    def __init__(self, inDim, hiDim, outDim):
        self.layer1 = TCGNN.GCNConv(inDim, hiDim)
        self.layer2 = TCGNN.GCNConv(hiDim, outDim)
        self.softmax = torch.nn.Softmax()

    def forward(self, tiledGraph, param):
        tiled_adj, X = tiledGraph.adj, tiledGraph.X
        X = self.layer1(X, tiledAdj, param)
        X = self.ReLU(X)
        X = self.layer2(X, tiledAdj, param)
        X = self.softmax(X)
        return X
# Define a two-layer GCN model in TC-GNN.
model = GCN(inDim=100, hiDim=16, outDim=10)
# Load graph and extract input information.
rawGraph, info = TCGNN.Loader(graphFilePath)
# Generate TCU tile and runtime configuration.
tiledGraph, config = TCGNN.Preprocessor(rawGraph, info)
# Run model through forward computation.
predict_y = model(tiledGraph, config)
# Compute loss and accuracy.
# Gradient backpropagation for training.
```

4.1 TCU-aware Sparse Graph Translation

As the major component of TC-GNN, we introduce a novel *Sparse Graph Translation* (SGT) technique to facilitate the TCU acceleration of GNNs. Our core idea is that *the pattern of the graph sparsity can be well-tuned for TCU computation through effective graph structural manipulation meanwhile guaranteeing output correctness*. Our key observation is that neighbor sharing is common in real-world graphs and has been exploited for various tasks like link prediction [63]. Our evaluated datasets (Section 5) have 18% to 47% (averaged 29%) neighbor similarity. Specifically, we condense (remap) the highly-scattered neighbor ids into highly-condensed new neighbor ids that can facilitate the dense TCU computation paradigm. Also, such condensing should not compromise any original information (*e.g.*, edge connections) and can generate the exact output as the conventional design.

As exemplified in Figure 4a and Figure 4b, we take the regular graph in CSR format as the input and condense the columns of each row window (in the red-colored rectangular box) to build TCU blocks (*TC_block*) (*a.k.a.*, the input operand shape of a single MMA instruction), in the orange-colored rectangular box. *nodePointer* is the row pointer array *edgeList* is the edges of each node stored continuously. In this paper, we demonstrate the use of standard MMA shape for TF-32 of TCU on Ampere GPU architecture, and other MMA shapes [41] can also be used under different precision (*e.g.*, `half` and `int8`) and GPU architecture (*e.g.*, Turing).

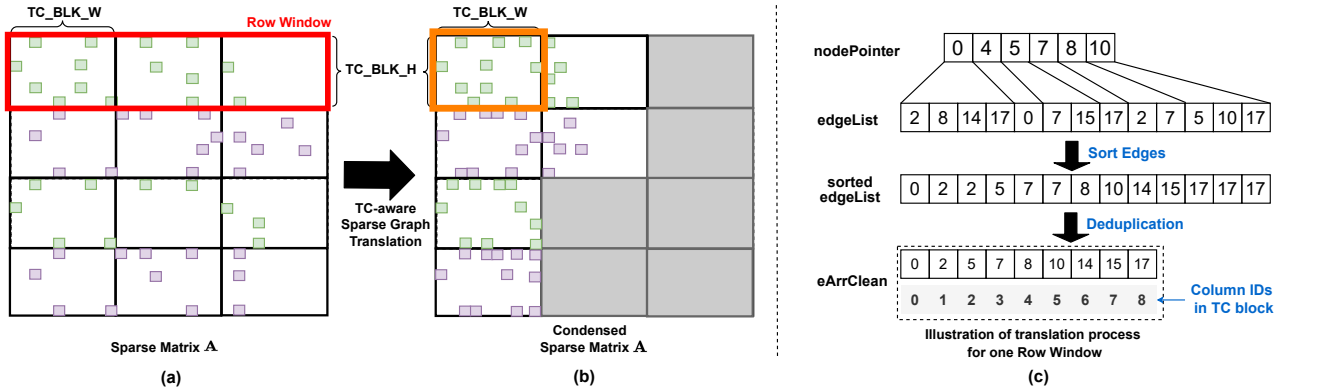

Figure 4: Illustration of Sparse Graph Translation. Note that the grey area indicates the TCU blocks that will be directly skipped.

Algorithm 1: TCU-aware Sparse Graph Translation.

input : Graph adjacent matrix **A** (*nodePointer*, *edgeList*).
output : Result of *winPartition* and *edgeToCol*.

```
/* Compute the total number of row windows.                    */
numRowWin = ceil(numNodes/winSize);
for winId in numRowWin do
    /* EdgeIndex range of the current rowWindow.               */
    winStart = nodePointer[winId * winSize];
    winEnd = nodePointer[(winId + 1) * winSize];
    /* Sort the edges of the current rowWindow.                */
    eArray = Sort(winStart, winEnd, edgeList);
    /* Deduplicate edges of the current rowWindow.             */
    eArrClean = Deduplication(eArray);
    /* #TC blocks in the current rowWindow.                    */
    winPartition[winId] =
      ceil(eArrClean.size/TC_BLK_w);
    /* Edges-to-columnID mapping in TC Blocks.                 */
    for eIndex in [winStart, winEnd] do
        eid = edgeList[eIndex];
        edgeToCol[eIndex] = eArrClean[eid];
    end
end
```

Algorithm 2: TC-GNN Neighbor Aggregation.

input : Condensed graph structure (*nodePointer*, *edgeList*, *edgeToCol*, *winPartition*) and node embedding matrix (**X**).
output : Updated node embedding matrix ($\hat{\mathbf{X}}$).

```
/* Traverse through all row windows.                           */
for winId in numRowWindows do
    /* #TC blocks of the row window.                           */
    numTCblocks = winPartition[winId] ;
    /* Edge range of TC blocks of the row window.              */
    edgeRan = GetEdgeRange(nodePointer, winId);
    for TCblkId in numTCblocks do
        /* The edgeList chunk in current TC block.             */
        edgeChunk = GetChunk(edgeList, edgeRan, TCblkId);
        /* Neighbor node Ids in current TC block.              */
        colToNId = GetNeighbors(edgeChunk, edgeToCol);
        /* Initiate a dense tile (ATile).                      */
        ATile = InitSparse(edgeChunk, winId);
        /* Initiate a dense tile (XTile).                      */
        XTile, colId = FetchDense(colToNId, X);
        /* Compute XnewTile via TCU GEMM.                      */
        XnewTile = TCcompute(ATile, XTile);
        /* Store XnewTile of X̂.                                */
        X̂ = StoreDense(XNewTile, winId, colId);
    end
end
```

SGT takes several steps for processing each row window, as detailed in Algorithm 1 and visualized in Figure 4c. *winPartition* is an array for maintaining the number of TC blocks in each row window. *edgeToCol* is an array for maintaining the mapping between the edges and their corresponding position in the graph after SGT. Note that *edgeToCol* has the same length as *edgeList* but with *column-id* from *eArrClean*. *colToRow* maps *column-id* of adjacency matrices to the *row-id* of embedding matrices. We choose the size of the row window (*winSize=TC_BLK_H*) and column width (*TC_BLK_W*) according to TCU MMA specification (*e.g.*, *TC_BLK_H*=16, *TC_BLK_W*=8 in TF-32). After condensing the graph within each row window, the time complexity of sliding the *TC_block* can be reduced from $O(\frac{N}{TC\_BLK\_W})$ to only $O(\frac{nnz_{unique}}{TC\_BLK\_W})$, where N is the total number of nodes in the graph and nnz_{unique} is the size of the unique neighbor within the current row window, which equals *eArrClean.size* in Algorithm 1. The density (computation intensity) of each identified TCU block can be largely improved. Considering the case in Figure 4, after the sparse graph translation, we can achieve 2× higher density on individual TCU blocks (Figure 4b) compared with the original one (Figure 4a).

Compared to existing sparse matrix formats (e.g., Blocked-Ellpack [37]) which use the regular matrix tiles to cover the irregularly scattered non-zero elements, SGT reduces the irregularity of non-zero-elements layout to fit them into fewer number TCU blocks, thus, reducing the unnecessary computation and memory overhead. SGT is applicable for both the SpMM and SDDMM in GNN sparse operations and can be easily parallelized because the processing of individual row windows is independent. In most cases, SGT only needs to execute once and its result can be reused across many epochs/rounds of GNN training/inference.

Additionally, SGT can be generally used with other ac-

celerators (e.g., AMD-GPUs with matrixCore and TPUs) that offer similar dense MM primitives. CPUs have no direct alternative to TensorCore-like MM primitives. However, with AVX-vectorized instructions, CPUs can benefit from SGT by setting *BLK_H*=1 and *BLK_W*=(#elements-per-AVX-instruction). TC-GNN currently targets GNN training. SGT is conducted once before training. SGT cost can be offset by training iterations (averaged 2% for 200 iterations as DGL).

4.2 TCU-tailored GNN Computation

Besides the effective way to condense the sparse tiles, the next major challenge is *how to tailor the computation schedule of GNN algorithms* so that we can capitalize on the performance of condensed sparse graphs and the powerful TCUs. We focus on two major types of computation in GNNs.

Neighbor Aggregation The major part of GNN sparse computing is neighbor aggregation, which can generally be formalized as SpMM operations by many state-of-the-art frameworks [55]. And they employ the cuSPARSE [38] on CUDA cores as a black-box technique for supporting sparse GNN computation. In contrast, our TC-GNN design targets at TCU for the major neighbor aggregation computation which demands a specialized algorithmic design. TC-GNN focuses on maximizing the net performance gains by gracefully batching the originally highly irregular SpMM as dense GEMM computation and solving it on TCU effectively. As illustrated in Algorithm 2, the node aggregation processes all TC blocks from each row window. *nodePointer* and *edgeList* are directly from graph CSR, while *edgeToCol* and *winPartition* are generated from SGT discussed in the previous section. Note that **InitSparse** is to initialize a sparse tile in dense format according to the translated graph structure of the current TC block. Meanwhile, **FetchDense** returns a dense node embedding matrix tile $XTile$ for TCU computation, and the corresponding column range *colId* (embedding dimension range) of matrix $\mathbf{X}$. This is to handle the case that the width of one $XTile$ could not cover the full-width (all dimensions) of $\mathbf{X}$. Therefore, the *colId* will be used to put the current TCU computation output to the correct location in the updated embedding matrix $\hat{\mathbf{X}}$.

Edge Feature Computing Previous research [51, 54] has demonstrated the great importance of incorporating the edge feature for a better GNN model algorithmic performance (*e.g.*, accuracy, and F1-score). The underlying building block to generate edge features is the Sampled Dense-Dense Matrix Multiplication (SDDMM)-like operation. In TC-GNN, we support SDDMM with the collaboration of the above sparse graph translation and TCU-tailored algorithm design, as described in Algorithm 3. The overall algorithm structure and inputs are similar to the above neighbor aggregation. The major difference is the output. In the case of neighbor aggregation, our output is the updated dense node embedding matrix ($\hat{\mathbf{X}}$), where edge feature computing will generate a sparse output with the same shape as the graph edge lists.

Algorithm 3: TC-GNN Edge Feature Computation.

```
input : Condensed graph data (nodePointer, edgeList, edgeToCol,
        winPartition) and node embedding matrix (X).
output: Edge Feature List (edgeValList).
/* Traverse through all row windows.                          */
for winId in numRowWin do
    /* #TC blocks in the row window.                          */
    numTCblocks = winPartition[winId] ;
    /* Edge range of TC blocks of the row window.             */
    edgeRan = GetEdgeRange(nodePointer, winId);
    for TCblkId in numTCblocks do
        /* EdgeList chunk in current TC block.               */
        edgeChunk = GetChunk(edgeList, edgeRan, TCblkId);
        /* Neighbor node Ids in current TC block.            */
        colToNId = GetNeighbors(edgeChunk, edgeToCol);
        /* Fetch a dense tile (XTile_A).                     */
        XTile_A = FetchDenseRow(winId, TCblkId, X);
        /* Fetch a dense tile (XTile_B).                     */
        XTile_B = FetchDenseCol(colToNId, edgeToCol, X);
        /* Compute edgeValTile via TCU GEMM.                 */
        edgeValTile = TCcompute(XTile_A, XTile_B);
        /* Store edgeValTile to edgeValList.                 */
        StoreSparse(edgeValList, edgeValTile,
                    edgeList, edgeToCol);
    end
end
```

Note that fetching the $XTile_A$ only needs to consecutively access the node embedding matrix $\mathbf{A}$ by rows while fetching the $XTile_B$ requires first computing the TCU block column-id to node-id (*colToNId*) to fetch the corresponding neighbor node embeddings from the same node embedding matrix $\mathbf{X}$.

Despite the dataflow similarity with dense-GEMM computation (e.g., CUTLASS [39]), TC-GNN has to overcome the limited parallelism (imbalance workload) and sparse/irregular access with novel algorithmic and kernel designs. While these challenges are absent in dense-GEMM computation with naturally high parallelism and data-access locality.

4.3 TCU-centric Workload Mapping

In collaborating with our TCU-tailored algorithm design, an effective mapping of our algorithmic design to low-level GPU primitives is indispensable for high-performance delivery. We discuss two key techniques: *GPU-aware Workload Decomposition* and *TCU-optimized dataflow design*.

4.3.1 GPU-aware Workload Decomposition

Different from previous work [13, 55] focusing on CUDA cores only, TC-GNN highlights itself with CUDA core and TCU collaboration through effective two-level workload mapping. The idea is based on the fact that CUDA cores work in SIMT fashion and are operated by individual threads, while TCU designated for GEMM computation requires collaboration from a warp of threads (32 threads). Our key design principle is to *mix these two types of computing units as a single GPU kernel*, which can efficiently coordinate the kernel

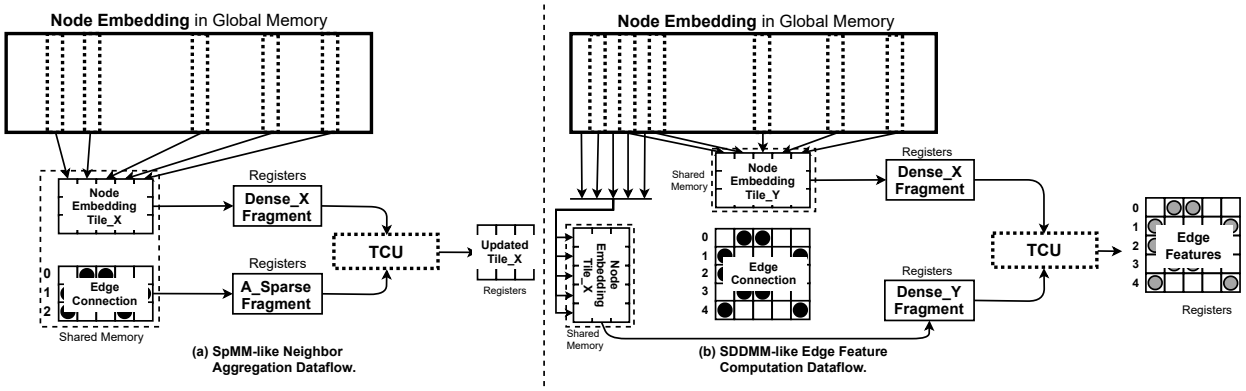

Figure 5: TCU-optimized Dataflow Design for (a) Neighbor Aggregation and (b) Edge Feature Computing in GNNs.

execution at different levels of execution granularity.

In TC-GNN, we operate CUDA cores by thread blocks and manage TCU by thread warps. Specifically, threads running CUDA cores from the same thread block will load data (*e.g.*, edges) from the global memory to shared memory. Note that in our design we assign each row window (discussed in §4.1) to one thread block. The number of threads in each block should be divisible by the number of threads in each warp (32) for better performance. Once threads running on CUDA cores (CUDA-core threads) finish the data loading, threads from each warp (TCU threads) will operate TCU for GEMM computation (including loading the data from the shared memory to thread-local registers (fragments), applying GEMM computation on data in registers, accumulating results on registers, and storing the final results back to global memory). Note that there would be a large overlap of the CUDA-core threads and TCU threads, both of which are threads from the same blocks but running at a different time frames. In general, we use more CUDA-core threads than TCU threads considering that global memory access demands more parallelization.

There are two major benefits of such two-level workload decomposition. First, threads from the same block can work together to improve the memory access parallelization to better utilize memory bandwidth. Second, warps from the same block can reuse the loaded data, including the information (*e.g.*, column index mapping) of the translated graph and the tiles from the dense node embedding matrix. Therefore, we can avoid redundant high-cost global memory operations.

4.3.2 TCU-optimized Dataflow Design

As the major technique to improve the GPU performance, shared memory is customized for our TCU-based sparse kernel design for re-organizing data layout for dense TCU computation and reducing the redundant global memory traffic. Our design takes the TCU specialty into careful consideration from two aspects, 1) the input matrix tile size of the TCU, which is M(16)×N(16)×K(8) in the case of TF-32, and 2) the tile fragment layout for fast computation. The common practice of the loaded tile A and B are stored in row-major and column-major for better performance. Next, we will detail our TCU-optimized dataflow design for both neighbor aggregation and edge feature computation.

Neighbor Aggregation In Figure 5a, shared memory is mainly used for caching several most frequently used information, including the tile of sparse matrix A (`sparse_A`), the column-id of the sparse matrix **A** to row-id of node embedding matrix **X** (`sparse_AToX_index`), and the dense tile of **X** (`dense_X`). When handling each TCU block, we assign all threads from the same block of threads for loading the sparse tile while allowing several warps to concurrently load the dense row tile from the matrix X. The reasons for enforcing such caching are two-fold. First, it can bridge the gap between the sparse graph data and the dense GEMM computing that requires continuous data layout. For example, the adjacent matrix **A** is input as CSR format that **cannot** be directed feed to TCU GEMM computation, therefore, we use a shared memory `sparse_A` to initialize its equivalent dense tile. Similarly, we cache rows of **X** according to the columns of **A** to the row of **X** mapping after our sparse graph translation, where originally scattered columns of **A** (the rows of **X**) are condensed. Second, it can enable data reuse on `sparse_AToX_index` and `sparse_A`. This is because in general, the `BLK_H` (16) cannot cover all dimensions of a node embedding (*e.g.*, 64), multiple warps will be initiated of the same block to operate TCU in parallel to work on non-overlapped dense tiles while sharing the same sparse adjacency matrix tile.

Edge Feature Computation Similar to the shared memory design in neighbor aggregation, for edge feature computing, as visualized in Figure 5b, the shared memory is utilized for `sparse_A`, `sparse_AToX_index`, and `dense_X`. We assign all threads from the same block of threads for loading the sparse tile while allowing several warps to concurrently load the dense row tile from the matrix **X**. Compared with dataflow design in neighbor aggregation, edge feature computing demonstrates several differences.

First, the sizes of `sparse_A` are different. In the neighbor aggregation computation, the sparse matrix **A** is used as

Table 4: Datasets for evaluation.

one operand in the SpMM-like computation, therefore, the minimal processing granularity is 16×8, while in edge feature computing by following SDDMM-like operation, the sparse matrix $\mathbf{A}$ serves as the output matrix, thus, maintaining the minimum processing granularity is 16×16. To reuse the same translated sparse graph as SpMM, we need to recalculate the total number of TC blocks. ***Second***, iterations along the embedding dimension would be different. Compared with neighbor aggregation, edge feature computing requires the result accumulation along the embedding dimension. The result will only be output until all iterations have finished. In neighbor aggregation, the node embedding vector is divided among several warps, each of which will output their aggregation result to non-overlapped embedding dimension ranges in parallel. ***Third***, the output format has changed. Compared with SpMM-like neighbor aggregation which directly output computing results as an updated dense matrix $\hat{\mathbf{X}}$, SDDMM-like edge feature computing requires a sparse format (the same shape as `edgeList`) output for compatibility with neighbor aggregation and memory space. Therefore, one more step of dense-to-sparse translation is employed.

5 Evaluation

Benchmarks: We choose two representative GNN models widely used by previous work [13, 34, 55] on *node classification* tasks. Specifically, 1) Graph Convolutional Network (**GCN**) [27] is one of the most popular GNN model architectures. It is also the key backbone for many other GNNs (e.g., GraphSAGE [19] and differentiable pooling (Diffpool) [61]). Therefore, improving the performance of GCN will also benefit a broad range of GNNs. For GCN evaluation, we use the setting: *2 layers with 16 hidden dimensions per layer*, which is also the setting from the original paper [27]. 2) Attention-based Graph Neural Network (**AGNN**) [51]. AGNN differs from GCN in its aggregation function, which computes edge features (via embedding vector dot-product between source and destination vertices) before the node aggregation. AGNN is also the reference architecture for many other recent GNNs for better model algorithmic performance. For AGNN, we use: *4 layers with 32 hidden dimensions per layer*.

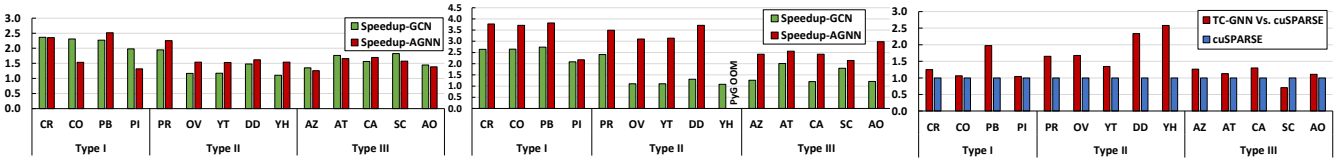
Baselines: 1) Deep Graph Library (**DGL**) [55] is the state-of-the-art GNN framework on GPUs, which is built with the high-performance CUDA-core-based cuSPARSE [38] library as the backend and uses PyTorch [49] as its front-end programming interface. DGL significantly outperforms other existing GNN frameworks [13] over various datasets on many mainstream GNN model architectures. Therefore, we make an in-depth comparison with DGL. 2) PyTorch Geometric (**PyG**) [13] is another GNN framework. PyG leverages torch-scatter [14] library (highly-engineered CUDA-core kernel) as the backend support, which highlights its performance on batched small graph settings; 3) Blocked-SpMM [37] (**bSpMM**) accelerates SpMM on TCU. It is included in the recent update on the cuSPARSE library. bSpMM requires the sparse matrix with Blocked-Ellpack format for computation. Its computation on non-zero blocks can be seen as the hybrid sparse-dense solution (§3.3). Note that the bSpMM has not been incorporated into any existing GNN frameworks. We also compare TC-GNN with **tSparse** [62] and **Triton** [52] for non-vendor-developed highly optimized kernels on TCUs.

Datasets, Platforms, and Metrics: We cover three types of datasets (Table 4), which have been used in previous GNN-related work [13, 34, 55]. Specifically, **Type I** graphs are the typical datasets used by previous GNN algorithm papers [19, 27, 59]. They are usually small in the number of nodes and edges, but rich in node embedding information with high dimensionality. **Type II** graphs [26] are the popular benchmark datasets for graph kernels and are selected as the built-in datasets for PyG [13]. Each dataset consists of a set of small graphs, which only have intra-graph edge connections without inter-graph edge connections. **Type III** graphs [27, 30] are large in terms of the number of nodes and edges. These graphs demonstrate high irregularity in its structures, which are challenging for most of the existing GNN frameworks. The core design of TC-GNN consists of around 2.5K lines of code. TC-GNN backend is implemented with C++ and CUDA C, and its front end is implemented in Python. Our major evaluation platform is a server with an 8-core 16-thread Intel Xeon Silver 4110 CPU and an NVIDIA RTX3090 GPU. To measure the performance speedup, we calculate the average latency of 200 end-to-end runs.

5.1 Compared with DGL

Figure 6a shows that TC-GNN achieves 1.70× speedup on average compared to DGL over three types of datasets across GCN and AGNN models on end-to-end training. Our kernel profiling via Nsight Compute shows that TC-GNN achieves high SM occupancy (averaged 85.28%), which is on average 21.05% higher compared to DGL across all datasets.

Type I Graphs: The performance improvements against DGL are significantly higher for GCN (on average 2.23×) compared to AGNN (on average 1.93×). The major reason



(a) (b) (c)

Figure 6: Speedup over (a) DGL and (b) PyG on GCN and AGNN; (c) Speedup over cuSPARSE bSpMM on TCUs.

is their different GNN computation patterns. GCN only consists of a neighbor aggregation phase (SpMM-like operation) and a node update phase (GEMM operation). Whereas in the AGNN, the aggregation phase would also require an additional edge attention value (feature) computation based on SDDMM-like operations. Compared with SpMM-like operations, edge attention computation in SDDMM is more sensitive to the irregular sparse graph structure because of much more intensive computations and memory access. Thus, the performance improvement is relatively lower.

Type II Graphs: TC-GNN achieves averaged 1.38× speedup on GCN and 1.70× speedup on AGNN for the Type II graphs. Speedup on Type II graphs is relatively lower compared with Type I, since Type II datasets consist of a set of small graphs with very dense intra-graph connections but no inter-graph edges. This leads to a lower benefit from the sparse graph translation that would show more effectiveness on highly irregular and sparse graphs. Such a clustered graph structure would also benefit cuSPARSE due to more efficient memory access, *i.e.*, less irregular data fetching from the sparse matrix. In addition, for AGNN, TC-GNN can still demonstrate evident performance benefits over the DGL (CUDA core only) that can mainly contribute to TCU-based SDDMM-like designs that can fully exploit the power of GPU through an effective TCU and CUDA core collaboration.

Type III Graphs: The speedup is also evident (on average 1.59× for GCN and average 1.51× for AGNN) on graphs with a large number of nodes and edges and irregular graph structures. The reason is the high overhead global memory access can be well reduced through our spare graph translation. Besides, our dimension-split strategy further facilitates efficient workload sharing among warps by improving the data spatial/temporal locality. On the dataset AT and SC, which have a higher average degree within Type III datasets, we notice a better speedup performance for both GCN and AGNN. This is because 1) more neighbors per node can lead to a higher density of non-zero elements within each tile/fragment. Thus, it can fully exploit the computation benefits of each TCU GEMM operation; 2) it can also facilitate more efficient memory access. For example, in AGNN, fetching one dense embedding x from the dense matrix X can be reused more times by applying a dot-product between x and many columns of the dense matrix X^T (neighbors embeddings).

Table 5: Compare TC-GNN with tSparse and Triton.

Dataset	tSparse (ms)	Triton (ms)	TC-GNN (ms)
AZ	18.60	31.64	4.09
AT	9.15	12.86	3.06
CA	13.84	15.50	3.26
SC	9.74	14.38	3.59
AO	11.93	21.78	3.41

Additionally, our performance breakdown analysis shows that for graphs with highly scattered and irregular edge distribution, such as Type I and III graphs, SGT would contribute more (averaged 64%) to the overall performance improvements since it helps significantly reduce the unnecessary workload. For graphs with highly dense and more regular edge connections, such as Type II datasets, SGT contributes relatively minor (averaged 23%) to the overall performance since it could not squeeze out more redundant computations from already condensed edge tiles.

5.2 Compared with other baselines

Compared with PyG Figure 6b shows TC-GNN can outperform PyG with an average of 1.76× speedup on GCN and an average of 2.82× speedup on AGNN. For GCN, TC-GNN achieves significant speedup on datasets with high-dimensional node embedding, such as *Yeast (YT)*, through effective TCU acceleration through a TCU-aware sparse graph translation while reducing the synchronization overhead by employing our highly parallelized TCU-tailored algorithm design. PyG, however, achieves inferior performance because its underlying GPU kernel can only leverage CUDA cores, thus, intrinsically bounded by CUDA core performance.

Compared with cuSPARSE bSpMM Figure 6c shows that TC-GNN outperforms bSpMM with on average 1.76× speedup on neighbor aggregation and improves effective computation by 75.8% on average. Our SGT technique can maximize the non-zero density of each non-zero tile and significantly reduce the number of non-zero tiles to be processed. However, bSpMM in cuSPARSE has to comply with the strict input sparse pattern (indicated in official API documentation [42]). For example, all rows in the arrays must have the same number of non-zero blocks. Thus, more redundant computations (on padding non-structural non-zero blocks) in bSpMM lead to inferior performance. We also notice that for

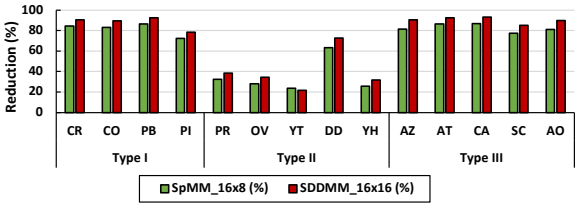


Figure 7: SGT Effectiveness on SpMM and SDDMM.

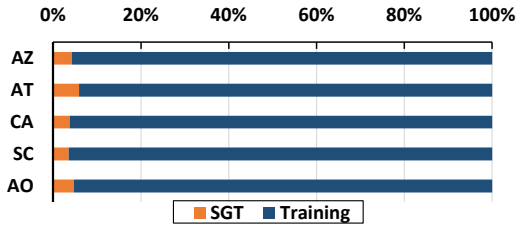

Figure 8: The overhead analysis of SGT.

SC datasets with a high average node degree and clustered node distribution, bSpMM would benefit more due to its usage of a larger block size of 32×32 (fewer TCU invocations) compared to 16×8 in TC-GNN (more TCU invocations).

Compared with tSparse and Triton From Table 5, TC-GNN can outperform tSparse with on average 3.60× speedup on SpMM. The major reason behind this is that TC-GNN can well reduce the graph structural-level irregularity through our novel SGT strategy to benefit the dense TCU-based computation. In contrast, tSparse only considers partitioning the input sparse matrix into dense/sparse tiles based on their non-zero elements but ignores the potential of compressing non-zero elements into fewer tiles to reduce the workload. TC-GNN also outperforms Triton with on average 5.42× speedup on SpMM. Triton's block-sparse GEMM for TCU acceleration is designed for dense neural networks (focusing on feature maps' sparsity), which is quite different from GNNs (focusing on the graph adjacency matrix's sparsity) with significantly larger sparse matrix size and more irregular pattern.

5.3 Additional Studies

SGT Effectiveness & Overhead We conduct a quantitive analysis of SGT in terms of the total number of TCU blocks between graphs w/o SGT and the graphs w/ SGT applied. Note that in the SpMM-based aggregation, the size of TCU blocks is 16×8 since it serves as one of the operands in TCU GEMM. While in SDDMM-based edge feature computation, the size of TCU blocks is 16×16 since it serves as the resulting matrix of TCU GEMM. Figure 7 shows that across all types of datasets, our SGT technique can significantly reduce the number of traversed TCU blocks (on average 67.47%). The major reason is that SGT can largely improve the density of non-zero elements within each TCU block. In contrast, the graphs w/o SGT would demonstrate a large number of highly sparse TCU blocks. What is also worth noticing is that on Type II graphs, such a reduction benefit is lower. The reason is that Type II graphs consist of a set of small subgraphs that only maintain the intra-subgraph connections, which already maintain dense columns. We evaluate the overhead of SGT (Figure 8), we find that its overhead is consistently low (on average 4.43%) compared with the overall training time (200 epoches as DGL [55]).

Sparsity Analysis We compare with bSpMM on synthetic matrix data with different sparsity (zero-element ratio). Note that we change the sparsity by varying the number of dense non-zero blocks (16×16) within each row window, the input adjacent matrix size is fixed to 4096×4096 while the dense embedding matrix dimension is fixed to 16. Table 6 shows that when sparsity increases from 93.75% to 99.61%, TC-GNN design demonstrates more throughput performance strength (averaged 6.9×) and this is also the common sparsity range (more than 95%) for most input graphs of GNNs. When the sparsity drops to around 87.50% the sparse would demonstrate more advantage due to more dense blocks for computation.

Table 6: Sparsity Analysis. Numbers for bSpMM/TC-GNN are in GFLOPs. "DB/W": dense blocks per row window.

DB/W	Sparsity (%)	bSpMM	TC-GNN
1	99.61	773.86	12,686.02
2	99.22	1,597.83	11,010.75
4	98.44	3,348.75	18,164.08
8	96.88	6,528.10	25,883.10
16	93.75	12,955.40	23,865.99
32	87.50	26,061.70	16,629.28

Warps per Block: Figure 9 shows that with the increase of the number of warps, the overall performance for training per epoch would first decrease due to the better parallelism for loading the graph data. However, the number of warps per block would decrease the overall performance under certain circumstances (e.g., 32). All three settings suffer from evident performance degradation. Because the global memory access contention will become severe, leading to lower execution performance. Different datasets would have different "optimal" choices of the warp-per-block parameter. For example, on the CA dataset, 2 warps per block can deliver the best performance, while AZ requires 8 warps per block. Based on our profiling and empirical study, the selection of this parameter should consider the average *#edges* per row window (*avg.edges*), which can be easily get during the preprocessing. Our `preprocessor` will generate $warpPerBlock = \lfloor \frac{avg.edge}{32} \rfloor$ to approach the "optimal" performance. For instance, the average edges per row window are 88 for CA, it reaches the best performance at 2 warps per block.

Throughput Analysis: For sparse matrix computations in GNNs, we measure the throughput performance of SpMM in TC-GNN when the dimension of node embedding increases for a roofline analysis. Because sparse matrix computation is largely limited by its memory access performance, which

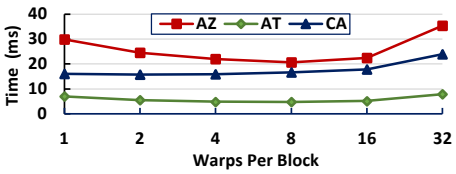

Figure 9: Performance Impact of Warps per Block.

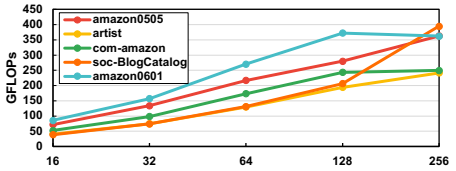

Figure 10: Analysis of TC-GNN kernel throughput when increasing the node embedding dimension from 16 to 256.

is quite different from the dense GEMM computation that is largely bounded by the computing performance. Figure 10 shows that the throughput of TC-GNN can scale proportionally with the growing number of node embedding dimensions. This also indicates that TC-GNN can effectively handle the graphs with high-dimensional node embeddings and well utilize GPU resources.

6 Related Work and Discussion

Other GPUs TC-GNN can easily generalize to other GPUs (e.g., A6000, H100, and RTX4090) with TCUs via recompilation (`python setup.py install`). TC-GNN also supports different TCU configurations (e.g., precision) by modifying (*BLK_H*, *BLK_W* in `TCGNN_conv/config.h`) and four parameters (`M, N, K, dataType`) in `wmma::fragment`, then recompile. For future GPUs with more TCUs, our TC-GNN can also be adapted to accommodate such changes and maintain its performance advantage. There are two future GPU designs that we anticipate. The first direction is to place more TCUs per SM while keeping the total number of SMs unchanged. There will be more active warps per thread block (This is mainly because TCUs are operated by warps) and each warp will process fewer neighbors. The cost of decomposition and mapping can be offset by parallelism among more warps. The second direction is to place more SMs on GPUs while keeping TCUs per GPU unchanged. In this scenario, there will be more thread blocks and each thread block will process neighbors from fewer nodes. The cost can be offset by parallelism among more thread blocks.

Other GNN Frameworks Besides DGL and PyG, other single-GPU GNN frameworks like GNNAdvisor [57], GE-SpMM [21], and fuseGNN [7], tailor their own GNN layers manually with low-level GPU kernel optimizations. Unfortunately, these designs limit their kernel optimizations to CUDA cores, thus, missing the golden opportunities to exploit the full potential of widely deployed AI-tailored GPUs with TCUs.

Graph Partitioning/Reordering ROC [23] introduces a learning-based graph partitioning to reduce the data movement between CPU and GPU when processing large graphs. Rabbit Order [4] and Reverse Cuthill Mckee Algorithm [9] are focusing on *row reordering/clustering* to improve node/row-wise computation locality. Our sparse-graph translation (SGT) technique is orthogonal and complementary to these graph partitioning and reordering techniques since our SGT focuses on *column (neighbor) re-indexing* to improve neighbor-wise locality for TCU computation.

Distributed GNN Computation There are two major ways of scaling-up GNN computing: 1) *Distributed sampled graphs* [13, 35, 55, 60] (where graph nodes and their embeddings are on the same GPU): TC-GNN can be incorporated directly since all sampled graphs along with their node embeddings are presented at the same GPU. 2) *Distributed full-graph* [15, 23, 34, 58] (where graph nodes and their embeddings may be on different GPUs): TC-GNN needs to be modified slightly by incorporating inter-GPU communication techniques (e.g., Unified Virtual Memory [46] and NVSHMEM [44]) to support the remote neighbor embedding access. We leave such exploration for our future work.

7 Conclusion

In this paper, we introduce TC-GNN, the first GNN acceleration framework on TCU of GPUs. We design a novel sparse graph translation technique to gracefully fit the sparse GNN workload on dense TCUs. Our TCU-tailored GPU kernel design maximizes the TCU performance gains for GNN computing through effective CUDA core and TCU collaboration and a set of memory/data flow optimizations. Our seamless integration with the PyTorch framework further facilitates end-to-end GNN computing with high programmability. Extensive experiments demonstrate the performance advantage of TC-GNN over the state-of-the-art frameworks. across diverse GNN models and datasets.

Furthermore, our TC-GNN design could also inspire potential TCU-like hardware features that can support (i) the dynamic shape of TCU input tiles and (ii) the dynamic structural sparsity of input tiles to yield higher performance benefits at the runtime. These proposed hardware features will help reduce more unnecessary computation in a more fine-grained and precise manner.

A Artifact Appendix

TC-GNN is the first TCU-based GNN acceleration design on GPUs. ***At the input level***, TC-GNN is equipped with a new *sparse graph translation* (SGT) technique that can effectively identify those non-zero tiles and condense non-zero elements from these tiles into fewer number of "dense" tiles. ***At the GPU kernel level***, TC-GNN exploits the benefits of CUDA core and TCU collaboration. The major design idea is that the CUDA core, which is more powerful at fine-grained thread-level execution, would be a good candidate for managing memory-intensive data access. While TCU, which is more powerful in handling simple arithmetic operations (*e.g.*, multiplication and addition), would be well-suited for compute-intensive GEMM on dense tiles generated from SGT. ***At the framework level***, TC-GNN is integrated with the popular PyTorch framework to reduce extra learning efforts and improve user productivity and code portability.

- Code repository: **Github**[2] and **Zenodo**[3].
- **Hardware, OS & Compiler**:
  - Intel Xeon Sliver 4110 CPU (8-core 16-threads) with 64GB host memory, NVIDIA RTX3090 GPU with 24 GB device memory.
  - Operating systems and versions: Ubuntu 16.04+.
  - Compilers and versions: NVCC-11.1+, GCC-7.5.0+ Libraries and versions: CUDA-11.1+, Pytorch-1.8.0, DGL-v0.6.0, PyG-1.6.3 Input datasets and versions: SNAP network datasets.

Step-1: Environment Setup

- 1.1a. [Method-1] Install via Docker (Recommended).

```
cd docker/
./launch.sh
```

- 1.1b. [Method-2] Install via Conda.

```
curl -O https://repo.anaconda.com/archive/Anaconda3
     -2021.05-Linux-x86_64.sh
bash Anaconda3-2019.03-Linux-x86_64.sh
source ~/.bashrc
conda create -n env_name python=3.6
conda install pytorch torchvision torchaudio cudatoolkit
     =11.1 -c pytorch -c conda-forge
conda install -c dglteam dgl-cuda11.0
pip install torch requests tqdm
pip install torch-scatter -f https://pytorch-geometric.
     com/whl/torch-1.8.0+cu111.html
pip install torch-sparse -f https://pytorch-geometric.

pip install torch-spline-conv -f https://pytorch-
     geometric.com/whl/torch-1.8.0+cu111.html
pip install torch-geometric
```

[2] https://github.com/YukeWang96/TC-GNN_ATC23.git
[3] https://doi.org/10.5281/zenodo.7893174

- 1.2. Install TC-GNN.

```
cd TCGNN_conv/
./0_build_tcgnn.sh
```

- 1.3. Download Datasets.

```
wget https://storage.googleapis.com/graph_dataset/tcgnn-
     ae-graphs.tar.gz
tar -zxvf tcgnn-ae-graphs.tar.gz
rm -rf tcgnn-ae-graphs.tar.gz
```

Step-2. Run Major Experiments.

- 2.1. TC-GNN model End-to-End.

```
./0_run_tcgnn_model.sh
```

Results: `1_bench_gcn.csv` and `1_bench_agnn.csv`.

- 2.2. DGL baseline (Fig-6a).

```
cd dgl_baseline/
./0_run_dgl.sh
```

Results: `Fig_6a_dgl_gcn.csv` and `Fig_6a_dgl_agnn.csv`.

- 2.3. TC-GNN single kernel.

```
./0_run_tcgnn_single_kernel.sh
```

Results: `1_bench_gcn.csv` and `1_bench_agnn.csv`.

- 2.4. cuSPARSE-bSpMM Baseline (Fig-6c).

```
cd TCGNN-bSpmm/cusparse
./0_run_bSpMM.sh
```

Results: `Fig_6c_cuSPARSE_bSpMM.csv`.

- 2.5. Dense Tile Reduction (Fig-7).

```
python 3_cnt_TC_blk_SDDMM.py
python 3_cnt_TC_blk_SpMM.py
```

Results: `3_cnt_TC_blk_SDDMM.csv` and `3_cnt_TC_blk_SDDMM.csv`.

- 2.6. tSparse Baseline (Table-5, column-2).

```
cd TCGNN-tsparse/
./0_run_tSparse.sh
```

Result: `Table_5_tSparse.csv`.

- 2.7. Triton Baseline (Table-5, column-3).

```
cd TCGNN-trition/python/bench
./0_run_triton.sh
```

Result: `1_run_triton.csv`.

Legion: Automatically Pushing the Envelope of Multi-GPU System for Billion-Scale GNN Training

Abstract

Graph neural network(GNN) has been widely applied in real-world applications, such as product recommendation in e-commerce platforms and risk control in financial management systems. Several cache-based GNN systems have been built to accelerate GNN training in a single machine with multiple GPUs. However, these systems fail to train billion-scale graphs efficiently, which is a common challenge in the industry. In this work, we propose Legion, a system that automatically pushes the envelope of multi-GPU systems for accelerating billion-scale GNN training. First, we design a hierarchical graph partitioning mechanism that significantly improves the multi-GPU cache performance. Second, we build a unified multi-GPU cache that helps to minimize the PCIe traffic incurred by caching both graph topology and features with the highest hotness. Third, we develop an automatic cache management mechanism that adapts the multi-GPU cache plan according to the hardware specifications and various graphs to maximize the overall training throughput. Evaluations on various GNN models and multiple datasets show that Legion supports training billion-scale GNNs in a single machine and significantly outperforms the state-of-the-art cache-based systems on small graphs.

1 Introduction

Graph neural networks (GNNs), such as [8, 10, 16, 22, 40, 50], are a class of deep learning algorithms that learn the low-dimensional embedding using the structure and attribute information of graphs. The learned embedding can be further used in machine-learning tasks including node classification and link prediction. GNNs have been successfully applied in many real-world applications, such as recommendation systems in e-commerce platforms, fraud detection and risk control in financial management, and molecular property prediction in drug development [13, 25, 37, 48, 49]. Systems such as DGL [42], PyG [31], and Graph-Learn [55] are proposed to ease the development and training of GNN models.

It is common to apply GNNs over large-scale graphs in industrial scenarios. For example, in Alibaba's Taobao recommendation system, the user behavior graph contains more than one billion vertices and tens of billions of edges [55]. In addition, as graphs are often skewed, it is infeasible to aggregate all neighboring vertices when training a specific vertex. Sampling-based mini-batch training, such as GraphSAGE [16], is proposed to extend GNN training to very large graphs. In the sampling-based GNN training, there are two key steps of data preparations before training a batch: (1) sampling the multi-hop sub-graph for each vertex in the batch, and (2) extracting the features of vertices in sampled sub-graphs. Systems such as DGL [42] and PyG [31] store the graph data in the CPU memory, prepare the training data of mini-batches using CPUs, and utilize GPUs for model training. As this approach requires transferring the sampled sub-graphs and high-dimension feature data to the GPU for every batch, the end-to-end training throughput is severely limited by the CPU-GPU data transferring bandwidth [23, 47]. In addition, the throughput of graph sampling using CPU is often insufficient to keep up with the throughput of GPU training, especially in multi-GPU machines.

Several cache-based approaches have been proposed to speed up GNN training [23, 29, 33, 47]. As it is the feature data that accounts for a majority of the CPU-GPU data transferring, caching the features of frequently accessed vertices in GPU can significantly reduce the amount of transferred data. To improve the throughput of graph sampling, GPU-based sampling has also been adopted in GNN systems [33, 42, 47].

We identify that existing approaches face severe limitations or performance issues in multi-GPU training, particularly when the graph is large. First, the multi-GPU cache scalability of existing cache-based systems is poor. Some cache-based GNN systems [33, 47] shuffle the training set across all GPUs and replicate an identical feature cache across all GPUs or NVLink cliques[1] to facilitate data parallel training. The cache capacity is constrained by the memory of a single GPU or

[1] NVLink clique denotes a group of GPUs where each pair of GPUs are connected with NVLink.

NVLink clique (an NVLink clique only consists of two GPUs in some multi-GPU architectures), resulting in poor cache performance when scaling up the number of GPUs (see the experiment in Figure 2). PaGraph [23] partitions the graph using a self-reliant algorithm and caches nodes with the highest in-degree for different partitions in different GPUs, trying to make use of data locality inside each partition. As partitions in PaGraph include the complete L-hop neighbors of their training vertices, there is a significant overlap between the caches of different partitions, resulting in the same duplication issue as the aforementioned cache-based GNN systems. Second, when adopting GPU-based graph sampling, existing systems manage the graph topology in a very coarse-grained manner: the topology has to be completely stored in a single GPU [33, 42, 47] or in the CPU memory [33, 42]. The former approach puts a hard limit on the graph scale, and further squeezes the cache capacity for features. The latter storing the topology in the CPU and accessing it from GPU would result in very low utilization of the PCIe bandwidth, as the data access of graph sampling is usually random and fine-grained.

This paper presents Legion, a GNN system that fully explores the hardware capabilities of modern multi-GPU servers for training large-scale graphs in a single machine. Legion proposes two key designs to fully exploit the memory space of multi-GPUs for feature and topology cache. First, to avoid cache replication, we propose **NVLink-aware hierarchical graph partitioning** technique that helps scale the cache on multi-GPU memory efficiently according to the specific hardware structure. Legion first partitions the graph with minimal edge-cut and assigns each partition exclusively to an NVLink clique, and then uses hash partition to further map the training vertices to GPUs inside each NVLink clique. Second, we propose a **hotness-aware unified cache** that manages both the feature and topology cache in a vertex-centric data structure. We enable an NVLink-enhanced cache space for the unified cache and prioritize the topology and features with the highest hotness to fill the cache, so as to improve the multi-GPU memory utilization.

The above designs pose a new challenge to Legion. Given a fixed size of GPU memory, it is hard to manually decide the optimal fractions of topology and feature cache such that the overall training throughput is maximized. To solve the challenge, we propose an **automatic cache management** mechanism. Specifically, we build a cost model in the mechanism to evaluate the key factor to the overall throughput, i.e., PCIe traffic, of both graph sampling and feature extraction in the training phase, which is used to guide the allocations of cache spaces for graph topology and feature. Overall, the three key designs in Legion enable automatic caching optimization and full utilization of hardware capability of various modern GPU servers. Experiments show that Legion can outperform state-of-the-art cache-based GNN systems up to 4.32×.

In summary, the contributions of this paper include:

1. We propose an NVLink-aware hierarchical graph partitioning technique that helps minimize cache replication between NVLink cliques and extends the threshold of cache capacity beyond the limit of an NVLink clique.
2. We propose a hotness-aware unified cache to store topology and features with the highest hotness in GPU memory, so as to improve the GPU memory utilization.
3. We present an automatic cache management mechanism that searches for the optimal cache plan without requiring extra knowledge of hardware specifications and GNN performance details from users.
4. We implement Legion that fully explores the hardware capabilities of multi-GPU systems targeting billion-scale GNN training, not supported by existing cache-based GNN systems, in a single server.

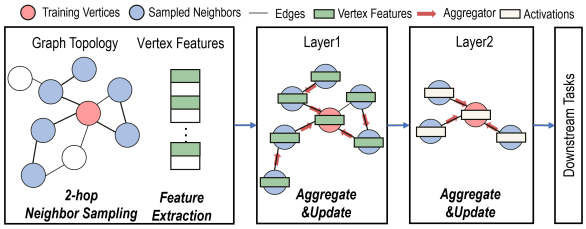

Figure 1: The workflow of 2-hop GraphSAGE training.

2 Preliminaries

In this section, we introduce the basic concept of GNN and the workflow of mini-batch GNN training.

2.1 Graph Neural Networks

Given a graph $G = (V, E)$, where each vertex is associated with a vector of data as its features $X_v, v \in V$, Graph Neural Networks(GNNs) learn a low-dimensional embedding for each target vertex by stacking multiple GNNs layers L. For each layer $l, l \in L$, vertex v updates its activation by aggregating features or hidden activations of its neighbors $N(v), v \in V$:

$$\begin{aligned} a_v^l &= AGGREGATE^l(h_u^{l-1} | u \in N(v)) \\ h_v^l &= UPDATE^l(a_v^l, h_v^{l-1}) \end{aligned} \tag{1}$$

2.2 Mini-batch GNNs Training

Mini-batch training is a practical solution for scaling GNN training on very large graphs. Neighbor sampling is used to generate mini-batches, allowing sampling-based GNN models to handle unseen vertices. For example, GraphSAGE [16] samples multiple hops of neighbors for training as shown in Figure 1. The workflow of GraphSAGE training follows a vertex-centric computation paradigm including the following steps: 1, selecting a mini-batch of training vertices from the training set. 2, uniformly sampling the multiple hops of fixed-size neighbors for each training vertex. 3, extracting the

features of the sub-graph consisting of the training vertices and their neighbors to generate the mini-batch training data. Finally, performing *AGGREGATE* and *UPDATE* according to Equations 1, as well as executing the forward and backward propagation to update the model parameters.

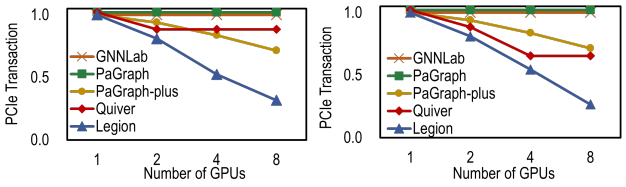
3 Observation and Motivation

When training large-scale graphs whose size exceeds the capacity of GPU memory on a multi-GPU server, the major performance bottleneck becomes the data movement from CPU to GPUs under the constraint of PCIe bandwidth. To this end, existing works [33, 42, 47] intend to relieve the PCIe bandwidth bottleneck by caching the hottest graph features on GPU memory. Though these cache-based approaches significantly reduce PCIe traffic, we still identify two issues of these existing cache-based GNN systems when training large-scale graphs: 1) poor multi-GPU cache scalability, and 2) coarse-grained GPU memory management for graph topology. In the following, we discuss each issue and the corresponding observation that motivates the design of Legion.

3.1 Multi-GPU Cache Scalability

As feature extraction occupies most of the data transferring from CPU to GPU, cache-based systems like GNNLab [47] maintain a global feature cache for vertices which are more frequently accessed via a pre-sampling phase. As training vertices are globally shuffled among all training GPUs, GNNLab replicates this cache across all GPUs involved in model training. Since a single GPU's memory space is quite limited, the fraction of cached features would inevitably become lower when the graph size grows, resulting in a lower cache hit ratio even on multi-GPU servers. To increase the cache capacity, the cache mechanism in Quiver [33] leverages high-speed NVLinks to support inter-GPU cache between NVLink-connected GPUs. Different from GNNLab, Quiver replicates feature cache between NVLink cliques and averagely hashes the features among GPUs in the same NVLink clique. However, this mechanism could still lead to poor cache scalability, especially when the NVLink clique is relatively small. E.g., the Siton server used in Table 1 has 4 NVLink cliques, each of which contains only 2 GPUs. Figure 2 illustrates that, in systems like Quiver, the PCIe transactions incurred by CPU-GPU data transferring stop decreasing when the number of GPUs is larger than the size of NVLink clique. This result shows that the cache performance in the above GNN systems cannot scale well with the increasing number of GPUs in modern servers.

To solve the scalability issue incurred by cache replication, PaGraph [23] partitions the graph in a self-reliance approach and maintains an independent cache for each partition using an in-degree-based metric on different GPUs. To train an L-layer GNN model, PaGraph extends every partition with redundant vertices and edges to include all the L-hop neighbor vertices for each train vertex in this partition. Each GPU only trains its own partition and synchronizes its local gradients periodically to update the model. However, the inclusion of the L-hop neighbor vertices leads to heavily duplicated cache contents on all GPUs. Figure 2 shows that the PaGraph exhibits a similar cache performance as GNNLab which adopts the cache replication mechanism. We further implement a PaGraph-plus design to alleviate the cache duplication issue in PaGraph. Specifically, we replace the graph partitioning algorithm in PaGraph with the XtraPulp [35] algorithm that minimizes edge-cuts between partitions and adopts a pre-sampling-based hotness metric to select the vertex features to be cached. Although PaGraph-plus achieves higher cache hit rates compared to PaGraph, the cache hit rates on different GPUs are very unbalanced as different partitions have various graph distributions. Figure 3 illustrates the load imbalance issue of PaGraph-plus by measuring the cache hit rates of eight GPUs. We observe that the hit rate varies by up to 17%.



(a) 2 GPUs per NVLink clique (b) 4 GPUs per NVLink clique

Figure 2: Comparing the cache scalability of cache-based GNN systems using the Products [17] dataset and 2-hop GraphSAGE [16] model in terms of normalized CPU-GPU PCIe transactions. The cache ratio is set to 5% $|V|$ on every GPU. The tested platforms are Siton (a) and DGX-V100 (b) servers, as shown in Table 1.

To sum up, for systems that globally shuffle the training vertices among GPUs in every iteration, such as GNNLab and Quiver, cache replication cannot be completely eliminated as each GPU may randomly access any vertex in the entire graph. Whereas the high-speed NVLinks between GPUs can be used to reduce the replication factor and expand the cache capacity. For systems that locally shuffle training vertices in each partition to produce mini-batches for different GPUs, such as PaGraph, the cache replication problem could be alleviated only when the model layer is small (e.g., less than 2). PaGraph-plus can further reduce cache duplication but faces another issue of unbalanced cache hit rates among GPUs.

Observation O1: Graph partitioning can be suitably guided by hardware structure. Different from Quiver, GNNLab, PaGraph, and PaGraph-plus do not take advantage of the NVLink between GPUs, which is a common capability in modern multi-GPU servers. As GPUs inside the same NVLink clique can access each other's memory via the low-latency high-throughput NVLink, an NVLink clique can hold the entire cache of a partition, which can be randomly sliced

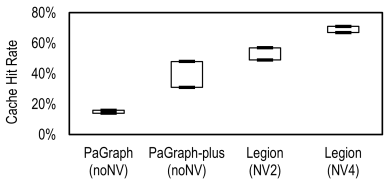


Figure 3: Cache hit rates of different systems in a server with 8 GPUs. The cache ratio is set to 5% $|V|$ on every GPU. The graph sampling follows the 2-hop GraphSAGE [16] model's setting using the Products [17] dataset. "NVx" means utilizing NVLink clique with x GPUs.

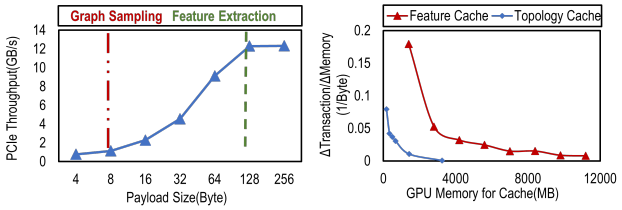

(a) PCIe throughput vs. payload size (b)

Figure 4: (a) The PCIe 3.0 throughput under different payload sizes of PCIe requests. (b) The PCIe traffic reduction rate for Paper100M with the growth of the cache capacity. The cache is on a single GPU and selected after pre-sampling.

and averagely allocated among GPUs inside a clique. This hardware-coherent design can balance the cache hit ratios between intra-clique GPUs. As the number of partitions is reduced to the number of NVLink cliques, it is more likely that the partitions follow a similar distribution (see the cache hit rate distribution of Legion in Figure 3). Inspired by **O1**, we propose an NVLink-aware hierarchical partitioning to preserve multi-GPU cache scalability in Legion (Section 4.1).

3.2 Coarse-grained GPU Memory Management for Graph Topology

In multi-GPU servers, the throughput of CPU-based graph sampling may not catch up with the throughput of GPU-based training. To improve the end-to-end training throughput, recent GNN systems [33,42,47] adopt GPUs to accelerate graph sampling. We observe that all these systems apply a very coarse-grained memory management mechanism for graph topology. In particular, they store the entire graph topology either in CPU memory or in a single GPU, depending on the size of graph topology: the graph topology is stored in CPU memory when it is too large or exceeds the capacity of a single GPU. The approach of storing the entire graph topology in a single GPU sets a hard limit on the scale of the graph. For example, a V100 GPU with 16GB memory can store at most 4 billion edges [16] without considering any other memory usage of feature cache and model training. When storing the graph topology in CPU memory, GPUs can directly access the graph topology via a unified virtual memory address (UVA [27]) technique. While the data access pattern of graph sampling is usually random and fine-grained. E.g., Figure 4a shows that the PCIe throughput of graph sampling is much lower than feature extraction. A large number of sampling PCIe transactions with small payload sizes will increase the CPU-GPU PCIe contention and lead to low bandwidth utilization.

Observation O2: The access of graph topology is skewed as graph features. Existing cache-based GNN systems [23, 33, 47] only maintain feature cache in GPU to reduce the CPU-GPU communication costs. However, we observe that the performance gain of the per-unit feature cache decreases once the cache capacity exceeds a threshold (see Figure 4b). We observe that the access of graph topology during graph sampling is also skewed as the access of features. Instead of allocating all the available GPU memory (except for the reservation for model training) for feature cache, it is reasonable to cache a subset of graph topology, i.e., edges of vertices that are frequently accessed during sampling, in the GPU memory to accelerate GPU sampling. Figure 4b shows that a relatively small topology cache can obviously reduce the number of PCIe transactions incurred by GPU sampling. Motivated by **O2**, we propose a hotness-aware unified cache in Legion. Specifically, Legion caches both graph topology and graph features with the goal of minimizing CPU-GPU communication overhead (see Section 4.2). Under the capacity limit of GPU memory, it is difficult to manually decide the optimal fractions of topology and feature cache. Legion solves this challenge with an automatic cache management mechanism, which can generate the optimal cache plan without requiring knowledge of hardware specifications from users.

4 Design of Legion

In order to address the aforementioned performance issues of existing cache-based GNN systems, we propose Legion, a cache-optimal GNN system that can push the envelope of the multi-GPU system automatically for billion-scale GNN training. The overall design of Legion is presented in Figure 5. We propose an NVLink-aware hierarchical partitioning technique (Section 4.1) in Legion that facilitates scaling up the cache capacity and reducing cache duplication in multi-GPU servers. To utilize GPU cache for both graph sampling and feature extraction, we present a hotness-aware unified cache (Section 4.2) that maintains both the topology and feature caches to optimize the overhead of PCIe traffic. We also develop an automatic cache management mechanism (Section 4.3) to automatically decide the memory allocations for both topology and feature caches.

4.1 NVLink-aware Hierarchical Partitioning

Motivated by **observation O1**, we propose a simple yet effective graph partitioning mechanism, referred to as **hierarchical**

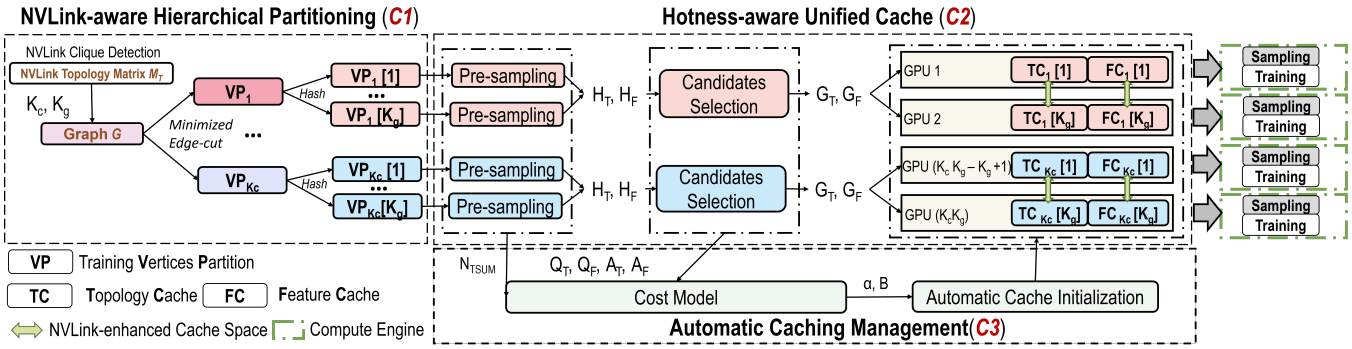

Figure 5: Design overview of Legion. Legion consists of three main contributions C1, C2, and C3.

partitioning, to facilitate cache scalability in Legion. Different from conventional graph partitioning algorithms which partition all edges/vertices of a graph into multiple tablets, hierarchical partitioning in Legion aims to divide the training vertices/edges into multiple disjoint tablets. The inputs of hierarchical partitioning are an NVLink topology matrix M_T of the underlying multi-GPU server and a graph G. The output is an assignment plan disseminating training vertices/edges among GPUs. Specifically, the process of hierarchical partitioning mainly consists of four steps:

S1: NVLink Clique Detection. With the topology matrix M_T of the server, Legion employs a MaxCliqueDyn algorithm [45] to identify the NVLink clique sets in M_T, and outputs the number of NVLink cliques K_c and the number of GPUs in each clique K_g.

S2: Inter-clique Graph Partitioning. To reduce the cache duplication between NVLink cliques, Legion uses an edge-cut minimizing partitioning algorithm, e.g., METIS [21] and XtraPulp [35], to split the input graph G into K_c partitions, i.e., P_1, P_2, ..., P_{Kc}, such that nodes are balanced among partitions and inter-partition edge-cuts are minimized. The training vertex set in P_i is denoted as VP_i. As the training vertices are randomly selected from G, the training vertex sets of different partitions are almost of the equal size. The number of partitions is equal to the number of detected NVLink cliques, and each NVLink clique hosts the cache for a dedicated partition. This way, Legion can reduce the cache duplication between NVLink cliques and take advantage of cache locality within an NVLink clique.

S3: Intra-clique Training Vertex Partitioning. As GPUs within an NVLink clique can access each other's memory via low-latency high-throughput NVLink interconnect, hierarchical partitioning further hashes the training vertex set of each partition into K_g tablets, where K_g is the GPU number in a clique. E.g., VP_i is split into $VP_i[1]$ and $VP_i[2]$ if K_g equals 2. Each tablet is exclusively mapped to a GPU in the corresponding NVLink clique. We explain how to generate the cache for each training vertex tablet in Section 4.2.

S4: Training Vertex Assignment. Finally, Legion assigns training vertices of each tablet to a corresponding GPU as the batch seeds, which will then be shuffled locally to generate mini-batches for graph sampling and training.

As such, Legion provides better cache scalability and load balancing compared to existing systems. Figure 2 shows the cache performance of Legion improves with the increase of GPUs almost linearly. Figure 3 illustrates that Legion has smaller fluctuations in the cache hit rates on multi-GPU servers with NVLink cliques of various sizes.

4.2 Hotness-aware Unified Cache

Motivated by the **observation O2**, we propose a hotness-aware unified cache to cache both graph topology and graph features. In this Section, we introduce the detailed mechanism of the unified cache.

4.2.1 Cache Structure

The unified cache consists of two parts: the topology cache and the feature cache. In particular, the topology cache maintains out-edge neighbor IDs for each selected hot vertex in the format of a compressed sparse row (CSR). As for the feature cache, Legion stores the feature vectors of selected hot vertices in the format of a 2D array, where each row is the feature vector of a selected hot vertex. Note that, the selected vertices in the topology and feature caches could be different.

4.2.2 Cache Construction

The construction of the unified cache is divided into three steps: (1) pre-sampling, (2) cache candidate selection, and (3) cache initialization. All the GPUs/NVLink cliques perform these steps concurrently to construct their own unified cache.

S1: Pre-sampling. Similar to GNNLab [47], Legion adopts a pre-sampling phase[2] to estimate the hotness metrics of graph topology and feature data during the training phase. Once the process of hierarchical partitioning is completed, the training vertex tablet assigned to each GPU is determined, which is used as the input for pre-sampling. The output of pre-sampling includes two hotness matrices: topology hotness matrix H_T and feature hotness matrix H_F. Each matrix's row represents the GPU IDs within an NVLink clique, the

[2]During pre-sampling, graph topology is stored in the CPU memory.

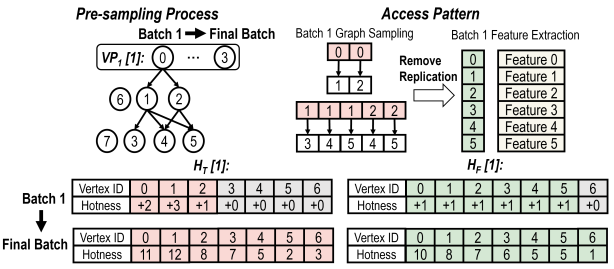

Figure 6: Update the hotness matrices of graph topology and features by pre-sampling. For simplicity, we only show the result for GPU 1.

column represents the vertex IDs, and the element H_{ij} of either matrix represents the hotness of the j-th vertex in the i-th GPU. During the pre-sampling, each GPU conducts a local shuffle on its own training vertex tablet to generate seeds for mini-batches, performs graph sampling for each mini-batch, and updates the corresponding row in H_T and H_F. Figure 6 shows a pre-sampling example. For H_T, whenever an edge is traversed during sampling, the hotness of its source vertex is incremented by 1. For H_F, the hotness for each vertex that appears in the sample results of the mini-batch is incremented by 1. Additionally, Legion uses Intel® Performance Counter Monitor (PCM) [18] to collect the summation of PCIe transactions number, N_{TSUM}, generated by all GPUs in an NVLink clique during pre-sampling.[3]

S2: Cache Candidate Selection. The objective of cache candidate selection is to select and disseminate the hot topology sub-structures and features among GPUs within the same NVLink clique based on pre-sampled hotness matrices. Thus this phase is conducted in the unit of NVLink clique, and each clique requires one GPU to perform the computation. The detailed process of cache candidate selection is presented in Algorithm 1. In brief, this algorithm computes the global topology/feature hotness of all vertices, i.e., A_T and A_F, in the NVLink clique by conducting a column-wise sum on H_T and H_F, respectively (Line 1). A_T and A_F are then sorted in descending order to generate Q_T and Q_F(Line 2). Next, We iterate Q_T and Q_F in order and assign every visited vertex to the GPU with the highest local hotness in H_T and H_F. For each GPU, we maintain two queues, i.e., G_T, G_F, whose order represents the priority of vertices to be included in this GPU cache. The outputs of Algorithm 1 are further used by the cost model (see Section 4.3) to generate the physical cache plan.

S3: Cache Initialization and Fill-up. Legion's cache management automatically decides the cache ratio for topology and feature so that the overall throughput is maximized (see Section 4.3). Guided by this mechanism, Legion allocates memory for both the topology and feature cache (TC and FC) of each GPU, and fetches the corresponding topology and feature data from CPU memory to fill up each GPU cache according to the corresponding cache orders in G_T and G_F.

[3] N_{TSUM} is further used by cost model's evaluation.

Algorithm 1 COMPLETE SHARING WITH LOCAL PREFERENCE (CSLP)

Input : K_g: number of GPUs per NVLink clique
H_F: feature hotness matrix
H_T: topology hotness matrix

Output : A_F: accumulated vertex-wise feature hotness vector
A_T: accumulated vertex-wise topology hotness vector
Q_T: vertex ID queue representing clique-level topology order,
Q_F: vertex ID queue representing clique-level feature order
G_T: vertex ID queue representing GPU-level topology order
G_F: vertex ID queue representing GPU-level feature order

/* Step 1: Accumulate each vertex's hotness from K_g GPUs. */
1 $A_F = H_F.columnWiseSum()$; $A_T = H_T.columnWiseSum()$;
/* Step 2: Sort vertices in A_F and A_T */
2 Q_F <- SortbyKeyDescend(A_F); Q_T <- SortbyKeyDescend(A_T);
/* Step 3: Assign each vertex to the GPU with the highest local hotness. */
3 **for** *v_id in* Q_T **do**
4 $gpu\_id = max(H_T[1:K_g][v\_id]).index$;
$G_T[gpu\_id].push(v\_id)$;
5 **end**
6 **for** *v_id in* Q_F **do**
7 $gpu\_id = max(H_F[1:K_g][v\_id]).index$;
$G_F[gpu\_id].push(v\_id)$;
8 **end**

4.3 Automatic Cache Management

The design of the unified cache poses a new challenge: how to properly specify the cache size for graph topology and features under the constraint of GPU memory such that the overall training throughput is maximized.

The general idea is to predict the overall throughput under different cache plans and search for the best cache plan that maximizes overall throughput. We define the cache plan as a cache memory management setting (B, α) at the NVLink clique granularity, where B is the multi-GPU cache memory size in an NVLink clique and α is the memory ratio for topology cache. B is identical among NVLink cliques and is by default set as the total multi-GPU memory minus the size of GPU memory reserved for GNN models and intermediate buffers in an NVLink clique. We need three steps to determine the optimal cache memory management setting (B, α), as discussed in Sections 4.3.1, 4.3.2, and 4.3.3.

4.3.1 Estimating Overall Throughput

The key goal of this Section is to build the relationship between the overall throughput and a cache plan. We build the relationship by estimating a key factor: the total PCIe traffic N_{total}, due to two reasons. First, the PCIe traffic is the major bottleneck of the overall system throughput, and lower PCIe traffic leads to higher overall system throughput. Second, varying cache plans major results in the variance of PCIe traffic.[4] Because each NVLink clique maintains caches for its own partition, we independently select the optimal cache plan for each NVLink clique so as to minimize the PCIe traffic of

[4] Though NVLink traffic is also influenced by the cache plan, we neglect it since NVLink has a much higher bandwidth than PCIe.

each NVLink clique. Thus, the overall system's PCIe traffic is minimized.

4.3.2 Cost Model to Estimate N_{total}

The key goal of this Section is to present a cost model to estimate N_{total} under a specific cache plan (B, α). First, given a specific cache plan (B, α), we can calculate the topology cache size m_T and the feature cache size m_F. Second, we find which vertices' topology/features should be stored in the topology/feature cache. Third, we estimate the PCIe traffic for graph sampling (N_T) and for feature extraction (N_F) with the current topology/feature cache utilization. At last, we estimate N_{total} by adding up N_T and N_F, as shown in Equation 2.

$$N_{total} = N_T + N_F \tag{2}$$

To estimate N_T and N_F, we need to collect other information apart from a given cache plan: the hotness vectors A_T and A_F, the summation of PCIe transaction number N_{TSUM} incurred by graph sampling, and the order queues of topology/feature cache candidates, Q_T and Q_F.

Estimating N_T. We estimate N_T when the memory size of a topology cache under one specific cache plan (B, α) is m_T, where $m_T = B \times \alpha$. The estimation consists of three steps.

First, with m_T, we decide which vertices' topology should be cached. We define V as the set of all vertices in the graph. And we define V_{Tcache} as the set of all vertices whose topology is cached under current topology cache size m_T. To get V_{Tcache}, we increase vertices and their topology into the cache with the growth of occupied topology cache memory by the order Q_T. Until the overall occupied topology cache memory size reaches m_T, we record V_{Tcache}. Equation 3 illustrates the relation between m_T and V_{Tcache}, where $nc(v)$ means the neighbor count of the vertex v. Here we assume the data types are Uint64 and Uint32 for the row and the column indices of the compressed sparse row format (CSR), respectively. We use s_{uint64} and s_{uint32} to denote the number of bytes to store a single Uint64 and Uint32 data accordingly.

$$\sum_{v \in V_{Tcache}} (nc(v) \times s_{uint32} + s_{uint64}) = m_T \tag{3}$$

Second, once we get V_{Tcache}, we can calculate the ratio of the PCIe transaction reduced by the topology cache by Equation 4. Let $a_T(v)$ mean the topology hotness of a specific vertex v ($a_T(v) \in A_T$).

$$R_T = \frac{\sum_{v \in V_{Tcache}} a_T(v)}{\sum_{v \in V} a_T(v)}) \tag{4}$$

Third, we get N_T by multiplying the entire PCIe transaction N_{TSUM} with the ratio of PCIe transactions that can **not** be reduced by the topology cache. We can get N_T by Equation 5.

$$N_T = N_{TSUM} \times (1 - R_T) \tag{5}$$

Estimating N_F. We explain how to calculate N_F when the feature cache memory size is m_F, where $m_F = B \times (1 - \alpha)$. There are also three steps in estimation.

First, given m_F, we decide which vertices' features should be cached. We define V_{Fcache} as the set of vertices whose feature data is cached. Then we increase the vertices with their feature into cache by the order Q_F until the occupied feature cache memory size reaches m_F, as defined in Equation 6. D represents the dimension of a feature vector and the feature data is the Float32 type each of which needs $s_{float32}$ bytes to store.

$$\sum_{v \in V_{Fcache}} D \times s_{float32} = m_F \tag{6}$$

Second, as shown in Equation 7, we calculate the total number of features U_F that still needs transferring through PCIe with a feature cache.

$$U_F = \sum_{v \in V} (a_F(v)) - \sum_{v \in V_{Fcache}} (a_F(v)) \tag{7}$$

Third, we get N_F by multiplying the transaction number needed by transferring one vertex's feature with the total number of features to be transferred, U_F, as shown in Equation 8. Here CLS means the transferred cache line size. CLS might be different for various CPUs and GPUs. We can get the CLS from PCM. E.g., CLS equals 64 in our machine settings. And $a_F(v)$ means the hotness of a specific vertex v ($a_F(v) \in A_F$).

$$N_F = (\lceil \frac{D \times s_{float32}}{CLS} \rceil) \times U_F \tag{8}$$

4.3.3 Searching for Optimal Cache Plan in Parallel

The key goal of this Section is to efficiently determine the optimal cache plan for each clique. As discussed in Section 4.3.1, we search for the optimal cache plan independently with one GPU for each NVLink clique. In each NVLink clique, we first need to traverse α from 0 to 1 by an interval $\Delta\alpha$ [5] to generate the candidate cache plans, and the calculate N_{total} accordingly. Then we need to search N_{total} sequences and find the smallest one with the dedicated α. To minimize overhead, the process is well parallelized, including four steps:

First, we generate all the candidate cache plans in parallel and get sequences of m_T and m_F in each setting.

Second, we get the boundaries of cached vertices set V_{Tcache} and V_{Fcache} using Equations 3 and 6, where the boundaries are the largest cached vertices' indexes in Q_T and Q_F. To do so, we get the topology and feature memory size of every single vertex in parallel and store them in two arrays, $S_{Tsingle}$ and $S_{Fsingle}$, following the vertices order, Q_T and Q_F. Next, we calculate the cumulative sum of $S_{Tsingle}$ and $S_{Fsingle}$ by a parallel inclusive scan and get S_{Tsum} and S_{Fsum}. Then for each cache plan with m_T and m_F, we use a parallel binary

[5] $\Delta\alpha$ is set to be 0.01 by default.

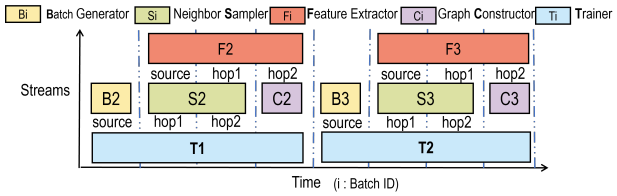

Figure 7: An example of fine-grained GNN training pipeline for 2-hop GraphSAGE model.

search towards S_{Tsum} and S_{Fsum} to get the boundary indexes of vertices, respectively.

Third, we get the R_T and U_F according to Equations 4 and 7. To do so, we calculate the cumulative sum of A_T and A_F by a parallel inclusive scan and get A_{Tsum} and A_{Fsum}. Then for each cache plan, we lookup A_{Tsum} and A_{Fsum} with the boundary indexes of vertices set V_{Tcache}, V_{Fcache}, and get $\sum_{v \in V_{Tcache}} a_T(v)$ and $\sum_{v \in V_{Fcache}} a_F(v)$, respectively. Similarly, after lookup the largest indexes in A_{Tsum} and A_{Fsum}, we get $\sum_{v \in V} a_F(v)$ and $\sum_{v \in V} a_F(v)$. As such, we can get the corresponding R_T and U_F.

At last, we calculate N_T and N_F for each cache plan according to Equation 5 and 8. Then we get N_{total} by Equation 2 and search in parallel for the smallest N_{total} with the corresponding α.

After getting the optimal cache plans (B, α), Legion can automatically allocate the cache space and fill up the cache.

5 Implementation of Legion

Legion mainly consists of two components, which are the sampling server and the training backend. The sampling server is implemented from scratch and the training backend is built on top of Pytorch [31]. The sampling server is responsible for generating sampled results, and the training backend takes the sampled results as input to train the GNN models.

In Legion, every GPU executes the graph sampling, feature extraction, and model training stages, and all these stages are scheduled in a fine-grained pipeline to fully utilize the GPU computation cycles. Figure 7 illustrates how the training process is pipelined for a 2-hop GraphSAGE [16] model. In order to improve the overall throughput, we design an inter-batch pipeline overlapping the tasks of the sampling server and the training backend for different batches. E.g., the training of batch B_i can be overlapped with the sampling and feature extraction of batch B_{i+1}. To further improve the throughput of sampling and feature extraction, we design an intra-batch pipeline inside the sampling server. Specifically, we break down the workloads of the sampling server into four types, each of which corresponds to a type of operator: (1) Batch generator shuffles the local training vertices to generate seeds for mini batches; (2) Neighbor sampler executes the L-hop neighbor sampling; (4) Feature extractor extracts the feature of the batch seeds and vertices in the sampled results; (4) Graph constructor is used to generating the subgraph based on the sampled results. For the same batch, graph sampling and graph construction can be overlapped with feature extraction.

Table 1: GPU Server Statistics.

Server	DGX-V100	Siton	DGX-A100
GPU Type	16GB-V100x8	40GB-A100x8	80GB-A100x8
NVLink Topo.	$K_c = 2, K_g = 4$	$K_c = 4, K_g = 2$	$K_c = 1, K_g = 8$
PCIe Gen.	3.0x16	4.0x16	4.0x16
PCIe Topo.	4 switches, 2 GPUs/switch	2 switches, 4 GPUs/switch	4 switches, 2 GPUs/switch
CPU Mem.	384GB	1TB	1TB
CPU Core Num.	96	104	128
Sockets, NUMA Num.	2, 1	2, 2	2, 1

Table 2: Dataset Statistics.

Dataset	PR	PA	CO	UKS	UKL	CL

6 Evaluation

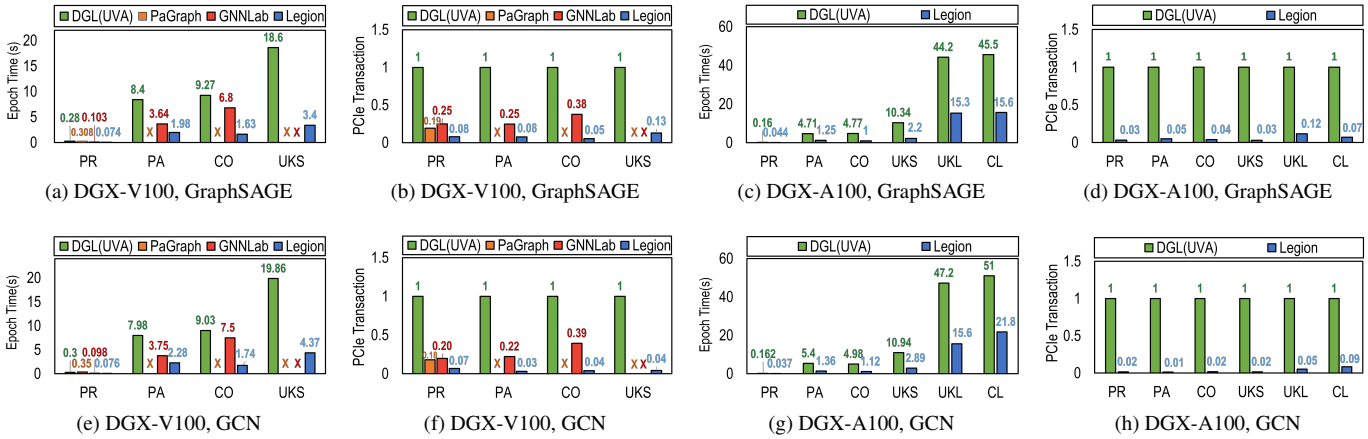
6.1 Experimental Setting

Experimental Platform. The experiments are conducted using three different GPU servers: DGX-V100, Siton, and DGX-A100, as shown in Table 1. For DGX-A100, we set the upper limit of GPU memory to 40 GB.

GNN Models. We use two sampling-based GNN models: GraphSAGE [16] and GCN [22], which both adopt a 2-hop random neighbor sampling. The sampling fan-outs are 25 and 10. The dimension of the hidden layers in both models is set to 256. Similar to existing work [47], the batch size is set to 8000. Unless explicitly explained, node classification is used as the GNN task.

Datasets. We conduct our experiments on multiple real-world graph datasets with various scales. Table 2 shows the dataset characteristics. The Products (PR) and Paper100M (PA) are available in Open Graph Benchmark [17]. The Com-Friendster (CO) graph is an online gaming network [46]. And the Uk-Union (UKS), UK-2014 (UKL), and Clue-web (CL) are from WebGraph [2–5]. As CO, UKS, UKL, and CL have no feature, we manually generate the features with the dimension specified as 128 or 256. Following PR's setting, we choose 10% of vertices from each graph as training vertices.

Baselines. We use DGL [42], PaGraph [23] and GNNLab [47] as the baseline systems. The DGL version is v0.9.1, which supports accessing graph topology and features via the UVA technique. We don't compare with Quiver [33] in the overall performance experiment as its open-sourced version cannot support training on servers with 8 GPUs. Instead,



(a) DGX-V100, GraphSAGE (b) DGX-V100, GraphSAGE (c) DGX-A100, GraphSAGE (d) DGX-A100, GraphSAGE

(e) DGX-V100, GCN (f) DGX-V100, GCN (g) DGX-A100, GCN (h) DGX-A100, GCN

Figure 8: Overall performance of Legion comparing with state-of-the-art systems. "×" denotes OOM (out of memory).

we implement a Quiver-like multi-GPU cache mechanism in Legion for comparison in Section 6.3.

6.2 End-to-end Performance

We compare the end-to-end performance of Legion with baseline systems on the DGX-V100 and DGX-A100 servers. On the DGX-V100 server, we evaluate PR, PA, CO, and UKS graphs whose graph topology and features can fit into 384 GB CPU memory. On the DGX-A100 server, we evaluate all six graphs. As PaGraph and GNNLab are implemented using CUDA 10 which cannot support A100 GPU, we exclude them from the experiments using DGX-A100.

Baseline Configuration. For all the baselines, we manually adjust their configurations to achieve optimal performance. DGL uses the UVA mode, where sampling is performed in GPU, and the topology and features are all stored in CPU memory. The number of worker threads in PaGraph is set to be 64 to maximize the CPU sampling throughput. For GNNLab, we adjust the numbers of sampling and training GPUs such that the overall throughput is maximized. In contrast, Legion relies on its automatic cache management mechanism to generate the unified cache plan.

Evaluation Metrics. We record the average epoch time for all systems. We also use PCM [18] to measure the maximum PCIe counter value across different sockets and report the normalized values based on the result of DGL for all systems.

Support training on large graphs. As shown in Figures 8a, 8e, 8c and 8g, Legion outperform all the baseline systems in every setting. Specifically, Legion achieves 3.78-5.69× speedup for GraphSAGE (3.5-5.19× for GCN) on DGX-V100 and 2.89-4.77× speedup for GraphSAGE (2.34-4.45× for GCN) on DGX-A100 over DGL(UVA). Figures 8b, 8f, 8d and 8h show that, compared with the baselines, Legion can sufficiently utilize the multi-GPU cache to minimize PCIe traffic incurred by CPU-GPU data transferring. GNNLab runs out of GPU memory for UKS on DGX-V100 as the size of graph topology exceeds the capacity of single GPU memory. PaGraph runs out of the CPU memory for most graphs except for PR on DGX-V100, as the memory management in PaGraph incurs extra memory overheads, including duplicated multi-hop neighbors in CPU memory and redundant intermediate buffers generated during computation.

Speedup over SOTA system on small graphs. Legion achieves 1.39-4.18× speedup for GraphSAGE (1.29-4.32× speedup for GCN) over GNNLab on the small graphs (PR, PA, CO). The performance gain mainly comes from two aspects. First, Figure 8b and 8f show that Legion significantly reduces the PCIe traffic for PA and CO, as it has a scalable multi-GPU cache design compared with GNNLab. The reduction of PCIe traffic relieves the CPU-GPU communication bottleneck such that the overall performance is improved. Second, Legion can use all GPUs for model training, while GNNLab needs to allocate several GPUs for sampling exclusively due to its factored design. In Legion, the graph sampling is overlapped by model training due to the fine-grained pipeline (see Section 5). E.g., when training GraphSAGE using the PR dataset, all the topology and feature data can be stored in GPU memory in both Legion and GNNLab. However, Legion can use 8 GPUs for training while GNNLab only uses 4 GPUs for training (see Figures 8a).

6.3 Effect of Hierarchical Partitioning

In this experiment, we examine the effect of hierarchical partitioning in Legion. We report the cache hit rates under different partition strategies in all three GPU servers: DGX-V100 (NV4: $K_c = 2$ and $K_g = 4$), Siton (NV2: $K_c = 4$ and $K_g = 2$) and DGX-A100 (NV8: $K_c = 1$ and $K_g = 8$).

6.3.1 Cache Performance

Baselines. For a fair comparison, we implement the cache designs of GNNLab, PaGraph-plus (described in Section 3.1), and Quiver-plus in Legion and compare their cache hit rates. Specifically, GNNLab maintains a globally replicated cache among all GPUs without using NVLinks (noPart+noNV).

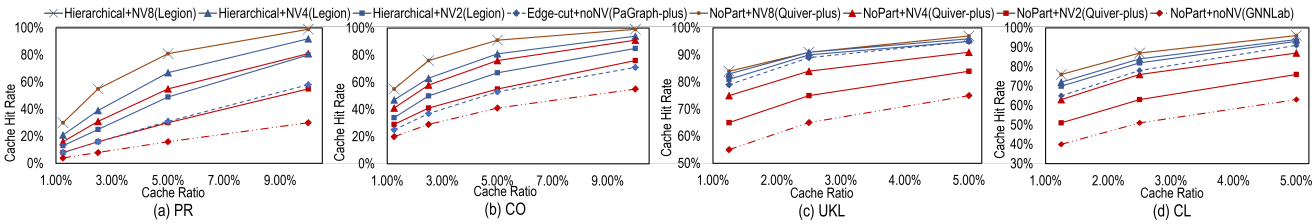


Figure 9: Effect of graph partition strategies (NoPart: no partitioning; Edge-cut: partitioning minimizing edge-cut; Hierarchical: hierarchical partitioning) to multi-GPU cache in terms of cache hit rate, with different NVLink infrastructures. (noNV: disable NVLinks; NV2: $K_c = 4$ and $K_g = 2$; NV4: $K_c = 2$ and $K_g = 4$; NV8: $K_c = 1$ and $K_g = 8$;).

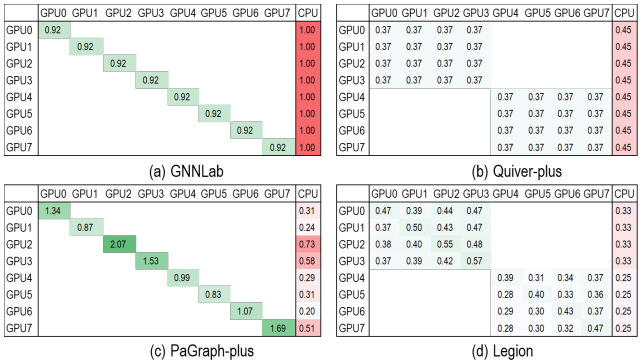

Figure 10: Data transferring in feature extraction of PA dataset on DGX-V100 (NV4). The rows and columns of each matrix denote the destination and source of data transferring. The right-most (red) column records the data transferring volume from CPU to GPU via PCIe. The middle (green) columns represent the GPU-GPU data transferring volume. We normalize the recorded values based on the CPU-GPU data transferring volumes in GNNLab.

Quiver-plus enables NVLink and maintains replicated cache among NVLink cliques (noPart+NV2 / noPart+NV4 / noPart+NV8). PaGraph-plus takes the XtraPulp [35] partitioning which minimizes across-partition edge-cuts and disables NVLinks (Edge-cut+noNV). Legion uses hierarchical partitioning (inter-NVLink-clique partitioning: XtraPulp) and enables NVLink (Hierarchical+NV2 / Hierarchical+NV4 / Hierarchical+NV8). We use the pre-sampling hotness metric for all these cache designs. The in-degree-based hotness metric in the original PaGraph and Quiver design are replaced with the pre-sampling hotness metric in Pagraph-plus and Quiver-plus, which has a better performance on cache hit rates [47].

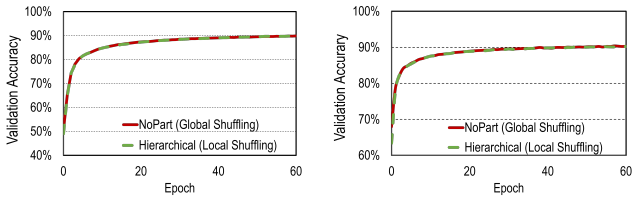
The datasets used in this experiment are PR, CO, UKL, and CL. We vary the cache ratio from 1.25% $|V|$ to 10% $|V|$ for PR and CO. For UKL and CL whose sizes are relatively large, the cache ratio varies from 1.25% $|V|$ to 5% $|V|$. Figure 9 shows that, for almost all the experiment settings, Legion has the highest cache hit rate. Specifically, Legion obviously outperforms Quiver-plus in the cases of NV2 and NV4, since Legion can reduce the inter-NVLink-clique cache duplication and achieves higher multi-GPU memory utilization compared with Quiver-plus. For the case of NV8, as all GPUs are in the same NVLink clique, the inter-clique graph partitioning in Legion can be skipped, and hierarchical partitioning turns into hash partitioning among all the GPUs, which is identical to Quiver-plus in the case of NV8. Legion outperforms PaGraph-plus because it has much less cache duplication. Specifically, PaGraph-plus's cache mechanism may replicate vertices with high global hotness on multiple GPUs. Compared with GNNLab, Legion has higher cache hit rates as it can scale up the cache capacity with the increase of GPUs, while GNNLab replicates the same feature cache across all GPUs. These results demonstrate that Legion can effectively adapt the cache plan to optimize the cache performance for multi-GPU servers with various NVLink topologies.

6.3.2 Data Transferring in Feature Extraction

In this experiment, we demonstrate the GPU-GPU and CPU-GPU data transferring volume during feature extraction using the PA dataset. Specifically, we perform the graph sampling and feature extraction stages using the PA graph on DGX-V100 (NV4) and record the data transferring volumes of feature extraction on each GPU in the format of a traffic matrix. We use GNNLab, PaGraph-plus, and Quiver-plus as the baselines, and set the feature cache ratio on each GPU to 2.5% $|V|$. The results are presented in Figure 10. We can see that Legion's data transferring volume from CPU to GPU is the smallest, indicating the best cache performance among the compared systems. As it is the GPU with the largest CPU-GPU data transferring volume that dominates the overall performance, although Legion's CPU-GPU volumes on some GPUs are higher than PaGraph-plus, Legion can still outperform PaGraph-plus because its largest CPU-GPU volume is lower than that of PaGraph-plus.

6.3.3 Model Convergence

Compared with global shuffling (randomly generating batch seeds from the vertex set of the entire graph), recent studies [23, 28] show that local shuffling (generating batch seeds within partitions) brings negligible impact on the rate of model convergence. Legion adopts local shuffling, and we conduct an experiment on the Siton server (NV2) to compare



(a) GraphSAGE (b) GCN

Figure 11: Comparing local shuffling and global shuffling on model convergence (NoPart: no partitioning; Hierarchical: hierarchical partitioning).

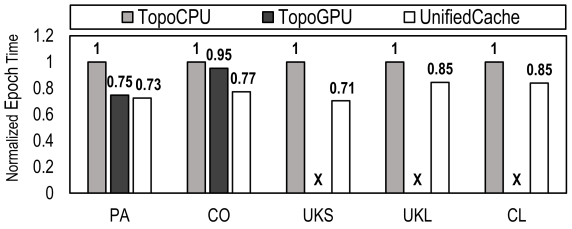


Figure 12: The impact of topology cache. "×" means OOM (out of memory).

its convergence speed with global shuffling on both GraphSAGE and GCN using the PR dataset. The results in Figure 11 show that the local shuffling of Legion could catch up with the convergence speed of global shuffling.

6.4 Effect of Unified Cache

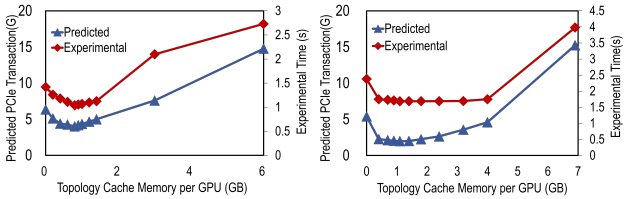
Different from existing cache-based systems, Legion's unified cache also takes graph topology into account. In this experiment, we demonstrate the benefits of topology cache.

We compare the training epoch time of unified cache in Legion with two baselines: (1) storing all topology in the CPU (denoted as TopoCPU) and (2) replicating the entire topology in every single GPU (denoted as TopoGPU). For a fair comparison, we implement both TopoCPU and TopoGPU in Legion and use the same GPU memory volume for the three settings. Among the three settings, TopoCPU has the most GPU memory available for the feature cache, and the TopoGPU has the least GPU memory for the feature cache or even runs out of GPU memory. We evaluate PA, CO, and UKS on DGX-V100 and evaluate UKL and CL on DGX-A100.

As shown in Figure 12, the unified cache outperforms the other two baselines for all graphs. This result demonstrates that, when the size of the feature cache exceeds a threshold, the increase of cache hit rate slows down. In this case, caching some hot topology data in GPU memory will save the system from severe PCIe contention incurred by graph sampling and benefit the overall GNN training throughput.

6.5 Evaluation of Cost Model

Legion proposes the cost model to guide allocating GPU memory for both graph topology and feature cache. In this experiment, we evaluate the effectiveness of this mechanism.



(a) PA, Single GPU (b) UKS, DGX-V100 (NV4)

Figure 13: Evaluation of cost model. The left y-axis means the PCIe transaction number predicted by the cost model. The right y-axis represents the experimental per-epoch graph sampling and feature extraction time.

Table 3: Evaluation of Partitioning Cost.

Dataset	PA (DGX-V100)	UKL (Siton)
Graph Partition(min)	7.2	75
Data Loading From Disk To Memory(min)	0.32	3.5
Node Classification Epoch(s)	1.98	15.6
Link Prediction Epoch(min)	49.8	402

Specifically, we compare the predicted PCIe traffic with the experimental per-epoch execution time of graph sampling and feature extraction. In the experiment using the PA dataset, the GPU memory allocated for the cache is 10 GB. And in the experiment using the UKS dataset, the GPU memory allocated for the cache is 8 GB. When varying the size of the topology cache, the size of the feature cache is adjusted accordingly. Figure 13 shows that our cost model can precisely predict the trend of per-epoch execution time without manual interference.

6.6 Partitioning Cost

In this experiment, we study the partitioning cost in Legion. We run our experiment on the UKL dataset that has the largest number of edges among all the datasets, resulting in the highest cost of edge-cut partitioning. We also present the results of the PA data (medium size) to show the partitioning costs of different graph scales. We partition PA on DGX-V100 and UKL on Siton using the XtraPulp algorithm. For node classification, we set the training set to be 10% of the total edges for both graphs. For link prediction, we set the training set to be 80% of total edges. When the graph is too large to be partitioned in memory, like UKL, we randomly sample a fraction of edges (25% for UKL) and keep all vertices in the graph such that the subgraph can be partitioned in memory. This technique can obviously speedup graph partitioning and preserves a low edge-cut ratio.

Table 3 shows the preprocessing cost of Legion's hierarchical partitioning. We observe that the partitioning cost is tolerable, because 1) we only partition the graph once but can use the partitioning results for multiple GNN training jobs, and 2) the GNN task like link prediction needs multiple epochs to converge while a single epoch often costs a long time to finish.

7 Related Work

To our knowledge, Legion is the first work that automatically pushes the envelope of multi-GPU systems for billion-scale GNN training. In the following, we contrast Legion and existing works in the following aspects.

GNN Frameworks. Several GNN systems [11, 12, 20, 23, 26, 33, 38, 42, 43, 47, 51, 53, 55] have emerged in recent years. Most of these GNN systems are built on top of deep learning frameworks like Pytorch [31], TensorFlow [1] and MXNet [9].

GPU Sampling. NextDoor [19] and C-SAW [30] focus on accelerating GPU sampling kernel. DGL [42] also supports GPU sampling in its recent release. Quiver [33] can support GPU sampling with the entire topology either stored in the single GPU or in the CPU memory. GNNLab [47] adopts a factored design where each GPU is dedicated to graph sampling or model training exclusively. In contrast, Legion uses all GPUs for end-to-end GNN acceleration.

Graph Partitioning. Graph partitioning such as [6, 14, 15, 21, 32, 35, 36, 39], has been widely adopted in GNN systems. DGL [42] adopts METIS [21] to partition the graph. PaGraph [23] adopts a self-reliant partitioning strategy with the goal of achieving balanced training vertex allocation across GPUs and improving data locality on every GPU. DGCL [7] adopts a partitioning algorithm to partition the graph's physical edges and features and store them among distributed machines. In contrast, Legion adopts hierarchical partitioning to automatically partition graphs to each GPU in a single multi-GPU server accordingly to GPU interconnections.

GPU Feature Cache. PaGraph [23], BGL [24], GNNLab [47], Quiver [33] and [29] explore feature caching on GPU to accelerate GNN training. PaGraph [23] and Quiver [33] use the in-degree of vertexes as the hotness metric. BGL [24] applies a FIFO dynamic cache policy and selects training vertices in a BFS order for a higher cache hit rate, but hinders model convergence and incurs cache replacement overheads. [29] uses a weighted reverse PageRank algorithm as a hotness metric. GNNLab [47] uses vertices' access frequencies in the pre-sampling epoch as a hotness metric. In contrast, Legion automatically caches both features and topology with the highest hotness. And Legion statically partitions the graph with minimal edge-cut to preserve intra-partition data locality. Figures 9 and 11 show that Legion can achieve a high cache hit rate even with small cache ratios without compromising the model convergence rate.

Large Graph Systems. SSD-based GNN systems [41] and distributed GNN systems [12, 24, 52, 54] also aim at large-graph training and propose distinct approaches to solve I/O problems at various levels. MariusGNN [41] minimizes I/O between SSD and CPU by including valid graph data in a single swap as much as possible. Systems like BGL [24], DistDGLv2 [54], and P3 [12] optimize network I/O between distributed machines, whose network performance can be improved when introducing GPU-centric SmartNIC [44]. In contrast, Legion focuses on utilizing GPU caches to minimize PCIe traffic from CPU memory to multiple GPUs, which is orthogonal to the above systems.

8 Conclusion

We present Legion, a system that automatically pushes the envelope of multi-GPU systems for billion-scale GNN training. Legion has three key innovations. First, we propose an NVLink-aware hierarchical partitioning technique that helps minimize cache replication and extends the threshold of cache capacity beyond the limit of a single GPU or NVLink clique. Second, we propose a novel hotness-aware unified cache mechanism that helps accelerate both graph sampling and feature extraction. Third, we present an automatic cache management mechanism enabling optimal cache planning without requiring extra knowledge of hardware specifications and GNN performance details from users. Experiments show Legion outperforms SOTA cache-based GNN systems up to 4.32× and supports training on billion-scale graphs. And Legion is open-sourced at https://github.com/RC4ML/Legion.

A Appendices

A.1 Generalization of Legion

Generalizing Legion to SSDs. Legion is primarily designed for in-memory graph training, but it can also be extended to SSD-based systems. First, Legion can still use GPU to execute end-to-end GNN training while storing graph topology and features in SSDs. The data path between GPU and SSDs could be enabled by BaM [34], which is a GPU-initiated on-demand high-throughput storage access technique. Second, the throughput of reading data from SSDs could be much lower than that in memory, leading to more severe I/O problems. Legion's hierarchical partitioning and unified cache design could still help reduce I/O and benefit overall throughput in this situation. Finally, due to the limited GPU memory, there still exists a trade-off between topology cache and feature cache in SSD-based systems. Thus automatic cache management could still be important and should be extended with more considerations of the specific hardware characteristics. We leave Legion's generalization to SSDs as our future work.
Generalizing Legion to none-NVLink systems. Legion can still bring performance benefits in multi-GPU systems without NVLink. To achieve this, Legion splits the graph into N partitions and each GPU maintains a cache for a partition. This approach can have a higher cache hit rate compared to replicating a global cache, as shown in Figure 9. We can also apply Legion on other GPU platforms, e.g., on AMD GPUs by leveraging the AMD Infinity inter-GPU bus.

Bridging the Gap between Relational OLTP and Graph-based OLAP

Abstract

Recently, many applications have required the ability to perform dynamic graph analytical processing (GAP) tasks on the datasets generated by relational OLTP in real time. To meet the two key requirements of performance and freshness, this paper presents GART, an in-memory system that extends hybrid transactional/analytical processing (HTAP) systems to support GAP, resulting in hybrid transactional and graph analytical processing (HTGAP). GART fulfills two unique goals that are not encountered by HTAP systems. First, to adapt to rich workloads flexibility, GART proposes transparent data model conversion by graph extraction interfaces, which define rules for relational-graph mapping. Second, to ensure GAP performance, GART proposes an efficient dynamic graph storage with good locality that stems from key insights into HTGAP workloads, including (1) an efficient and mutable compressed sparse row (CSR) representation to guarantee the locality of edge scan, (2) a coarse-grained multi-version concurrency control (MVCC) scheme to reduce the temporal and spatial overhead of versioning, and (3) a flexible property storage to efficiently run different GAP workloads. Evaluations show that GART performs several orders of magnitude better than existing solutions in terms of freshness or performance. Meanwhile, for GAP workloads on the LDBC SNB dataset, GART outperforms the state-of-the-art general-purpose dynamic graph storage (i.e., LiveGraph) by up to 4.4×.

1 Introduction

Graphs, due to their natural ability to model intricate relations among entities [12, 61], have been intensively adopted to model business data. Correspondingly, *graph analytical processing (GAP)* techniques are being developed to better understand graph data and are widely applied in many fields, such as recommendation systems [70, 74], supply-chain analysis [46], and fraud detection [29, 56]. As business data is constantly generated and updated, there calls for an urgent need for *dynamic* GAP workloads on *real-time* datasets. In many traditional business scenarios, data is usually updated by online transaction processing (OLTP) in relational databases [26, 47, 82].

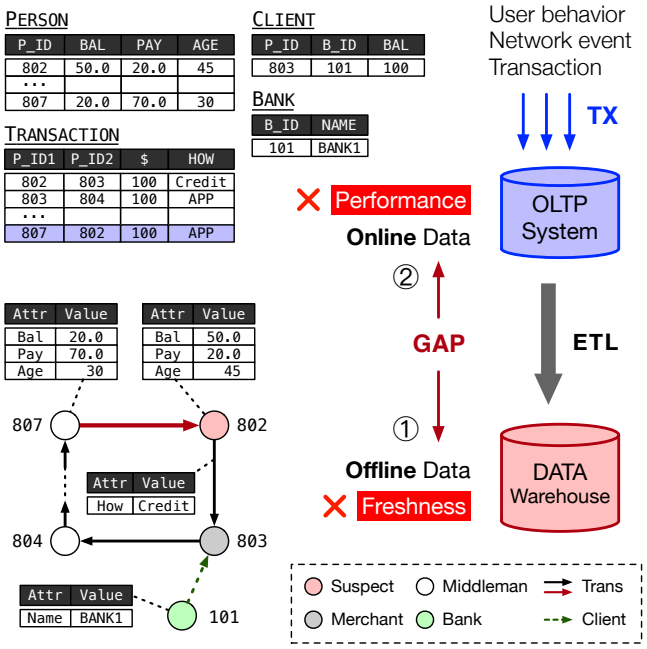

Fig. 1. *A comparison of solutions for dynamic graph analytical processing* (GAP) *on transactional datasets and their limitations.* **Solutions***: graph processing on offline data* (①) *or online data* (②).

Real-world Example. In Fig. 1, we demonstrate a simplified online credit card fraud detection task in e-commerce platforms [56], in which a suspect attempts to obtain short-term credit from a credit card via illegal transactions. To achieve this, the suspect (802) makes sham purchases paid by a credit card from a conspired merchant (803). The merchant, after receiving the money from the bank (101), transfers the money through a series of middlemen (804, . . . , 807) with other fraudulent transactions back to the suspect (802). In this scenario, the OLTP system maintains four tables (PERSON, TRANSACTION, CLIENT, and BANK), from which one can create a graph showing relationships of transactions among normal users, suspects, merchants, and middlemen. Whenever a new tuple occurs in the TRANSACTION table, the graph should be updated correspondingly. As soon as an upcoming transaction generates a cycle in the graph, an alarm should be triggered instantly to block the transaction for fur-

ther investigation. Therefore, an underlying detection system for such frauds should meet two key requirements simultaneously.

Performance. The *performance degradation* of both relational transaction and graph analytical workloads should be minimal compared to running them separately on specific systems. Thereby, both the transaction and detection should be completed before the user perceives any lag.

Freshness. The *time gap* between transactions committed on OLTP systems and their accessibility on detection systems should be minimal to prevent fraud on time. Recent studies [10, 56] show extreme requirements of 20-millisecond freshness for fraud detection or system monitoring.

In response, several solutions have been proposed to support such workloads. Unfortunately, none of them can simultaneously meet the requirements, as shown in Fig. 1.

Solution ①: graph processing on offline data. To achieve better GAP performance, this solution utilizes existing graph-specific systems (particularly for *static* graphs in many cases) [22, 31, 67, 76, 86], such as GraphScope [29], to handle GAP workloads efficiently. Since data is separately maintained in OLTP and graph-specific systems, an offline data migration with an ETL (Extract-Transform-Load) process is required. However, such a process is often expensive and slow, and results in a high lag between the transactional data in OLTP systems and the extracted graph data in graph-specific systems [82], which deteriorates the *freshness* guarantee.

Solution ②: graph processing on online data. Some OLTP systems [34, 37, 55, 84] attempt to translate graph-related operations into relational operations. However, prior work [21, 73] has found this solution causes *performance* degradation of GAP up to several orders of magnitude due to costly join operations and huge redundant intermediate data. On the other hand, graph databases [6, 7, 27] use a native graph representation to ensure the efficiency of GAP workloads and directly commit transactions on graphs. However, due to the more complicated management (e.g., maintaining adjacency lists instead of inserting a row) in graph databases to fulfill transactions [87], the *performance* of transactions in graph databases is significantly slower than the relational counterparts, which is also demonstrated in our experimental study (§6.2). Further, legacy business logic was usually designed and implemented on relational OLTP systems, and it is inevitable to process a costly migration to the graph databases.

The tradeoff between performance and freshness is still an open problem for dynamic GAP workloads. Fortunately, *hybrid transactional/analytical processing* (HTAP) is a new trend that processes OLTP and online analytical processing (OLAP) simultaneously in the same system. The state-of-the-art HTAP systems usually leverage a loosely-coupled design to guarantee both performance and freshness [19, 38, 45, 50, 65, 82], which gives an opportunity for dynamic GAP workloads. Analogously, we term dynamic GAP workloads on transactional datasets as *hybrid transactional/graph-analytical processing* (HTGAP).

Our approach. This paper presents GART, an in-memory HTGAP system extended from HTAP systems that can be deployed to bridge an existing relational OLTP system with a graph-specific system for requirements of *performance* and *freshness*. GART performs GAP workloads over the graph-specific system with little *performance* degradation. It reuses transaction logs to replay graph data *online* for *freshness* instead of offline data migration. Unlike the prior HTAP systems with only the relational model, GART also has to support the graph data model for GAP. Therefore, there are two unique goals not encountered by HTAP systems.

First, to adapt to rich workloads flexibly, GART needs to convert relational data to graph data transparently. Thus, some concise yet expressive interfaces should be proposed to the database administrator (DBA) for data conversion from the relational model to the graph model. To fulfill this goal, we propose a collection of *graph extraction interfaces* to define rules of relational-graph mapping in a newly designed component called *RGMapping*. We demonstrate that the interfaces are expressive enough to help GART automatically extract property graphs from relational data sources such as transactions.

Second, to guarantee performance, the dynamic graph storage should support both read and write operations efficiently. Existing *general-purpose* dynamic graph storages [26, 33, 87] support complex updates from transactions but provide sub-optimal GAP performance due to poor data locality and expensive concurrency control. Thus, based on observed characteristics of HTGAP workloads, we propose a new efficient dynamic graph storage for HTGAP with three key components: 1) an *efficient* and *mutable* CSR representation that guarantees the locality of edge scan when updating graph topology data; 2) a *coarse-grained* MVCC scheme that reduces the temporal and spatial overhead of versioning; 3) a *flexible* property storage that allows running different GAP workloads on snapshots generated based on their access patterns.

We implement GART by extending VEGITO [65], a state-of-the-art in-memory HTAP system. The extensions include graph extraction interfaces, the dynamic property graph storage, and integrating a unified graph computation system (GraphScope [29]). To demonstrate the efficacy of GART, we have conducted a set of experiments using two popular benchmarks (i.e., LDBC SNB [4] and TPC-C [71]), as well as diverse graph datasets. Our experimental results show that GART outperforms Solution ① and Solution ② by several orders of magnitude in freshness and performance, respectively. Meanwhile, GART outperforms the state-of-the-art general-purpose dynamic graph storage (i.e., LiveGraph [87]) by up to 4.4× for GAP workloads on the LDBC SNB dataset.

Contributions. We extend HTAP systems to support

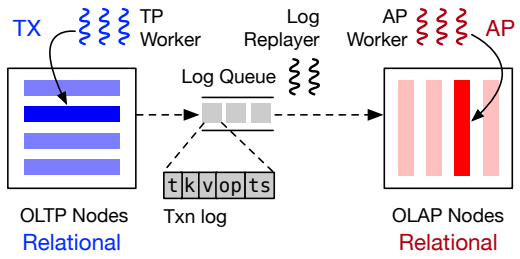

Fig. 2. *The overview of HTAP systems based on a loosely-coupled design.* ***Transaction (Txn) log****: table ID (t), primary key (k), value (v), operation type (op), and timestamp (ts).*

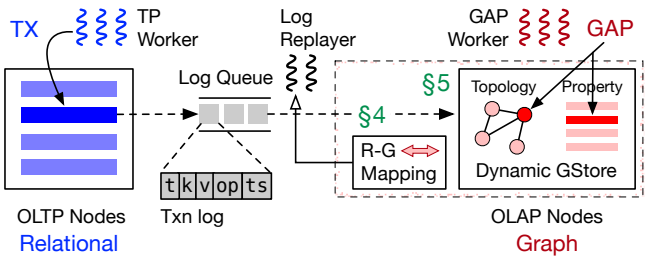

Fig. 3. *The architecture of* GART*. The components in the dashed box are newly designed for HTGAP.*

HTGAP by incorporating relational-graph mapping and a dynamic graph storage into existing computation engines. In summary, the contributions of this paper are:

- The first to extend HTAP architecture for HTGAP workloads with guarantees of performance and freshness (§3) that proposes expressive interfaces of relational-graph mapping for transparent data model conversion (§4).
- A new dynamic graph storage for efficient HTGAP workloads, which is optimized for data locality and concurrency control based on our key insights into HTGAP (§5).
- A prototype implementation (GART) that integrates existing HTAP and GAP systems, as well as a set of evaluations that confirm the efficacy of GART for HTGAP workloads with diverse applications and datasets (§6).

2 Opportunity: HTAP

Hybrid transactional/analytical processing (HTAP) is a new trend that bridges the gap between OLTP and OLAP for real-time analytics on datasets updated by transactions and is already being used in many scenarios [17, 53, 85].

The *loosely-coupled* design is a common choice of state-of-the-art HTAP systems, which dedicate OLTP and OLAP to different physical resources with specific storage types (see Fig. 2). Thereby, it is comparable in *performance* to specific execution engines and can synchronize data with transaction logs to guarantee *freshness* [38, 45, 50, 65, 82]. Specifically, logs of the OLTP node are used to update the extra *column* store on the backup (OLAP node), which is more appropriate for OLAP workloads; the log replayer applies logs in real time on the OLAP node. The log from the OLTP system (*Txn log* in Fig. 2) contains the necessary information for data replaying, such as the identifier of data updates (table ID and primary key), the after-image or delta of the tuple (value), and the temporal meta-data (version number or timestamp) [23, 52, 63, 66, 78]. Reusing logs for HTAP can avoid costly operations for change data capture (CDC).

HTAP systems usually utilize batch-based log replaying for freshness and consistency on the OLAP storage [45, 50, 65]. An efficient design [65] divides time into consecutive and non-overlapping *epochs*. The epoch is automatically increased in a fixed interval, such as several milliseconds, that can trade off between freshness and performance. During each epoch, logs can be replayed in parallel. When an epoch ends, it guarantees all the logs within the epoch have been replayed. Each epoch is specified by an epoch number, which is incremented when entering a new epoch. The system maintains a write epoch number (i.e., wepoch) to represent the epoch when the logs are being replayed. The latest stable epoch number that OLAP users can read is latest_repoch.

Opportunity. We observe that the guarantees of HTAP systems on both performance and freshness can benefit the dynamic GAP workloads. HTAP systems can be extended to process transactions and GAP workloads simultaneously on different storages. Specifically, for **performance**, HTAP systems provide specific storages and execution engines for hybrid workloads, which can fully reuse the effort on specific systems for OLTP and GAP. For **freshness**, logs in HTAP systems contain the updates of relational data, which can be synchronously applied to the graph data in real time without costly operations such as bulk loading, CDC and ETL.

However, to the best of our knowledge, none of the HTAP systems enable native GAP workloads on a dynamic graph storage. To achieve this, HTAP systems need to support conversion between the relational model and graph data model and an efficient dynamic graph storage for HTGAP.

3 Overview of GART

Inspired by the loosely-coupled design of HTAP systems [38, 65, 82], we propose GART, an in-memory HTGAP system that extends HTAP systems by retrofitting the log replayer and the storage for GAP workloads, as shown in Fig. 3. It should be noted that GART can reuse the execution engines of existing OLTP and graph-specific systems.

Architecture and workflow. In GART, transactions are committed in the OLTP nodes and generate logs, like prior HTAP systems [38, 65, 82]. To support rich workloads flexibly and efficiently, GART conducts data model conversion. Relational data in logs need to be converted to graph data and stored in a dynamic graph storage (GStore) of OLAP nodes. GART allows the DBA, who is responsible for defining the database schema, to define the relational-graph mapping through the *RGMapping* component. RGMapping guides the *log replayer* to convert the relational data in logs to the updates on graph data.

GART devises a new *dynamic graph storage* for real-time graph updates and different GAP workloads. Graph data consists of a topology and properties. The topology contains vertices and edges (i.e., an ordered pair of vertices), and the properties are a set of attributes for each vertex or edge. The storage always provides consistent snapshots of graph data (identified by an *epoch*) derived from relational data. Similar to HTAP systems (§2), the log replayer updates the storage with the epoch number wepoch. GAP workloads can read a fresh snapshot or earlier using an epoch number that does not exceed latest_repoch.

GART follows a loosely-coupled design, which can be deployed as a single-machine system or a distributed system that separates OLTP and GAP components (the dashed box in Fig. 3) on different machines for better performance isolation. For the distributed deployment, a crash of the GAP component will not stall the execution of the OLTP component. The graph data can be recovered from the relational data according to persistent RGMapping data. When the OLTP component fails, the existing fault-tolerance mechanism in HTAP systems still works [65], which is orthogonal to our work. In addition, we focus on in-memory processing that can buffer hot data in real-time GAP tasks and meet the freshness and performance requirements. GART is independent of whether the OLTP system is in-memory or not.

To support HTGAP workloads, GART should fulfill two unique design goals never encountered in prior work.

Goal 1: Transparent data model conversion (§4). In HTAP systems, the conversion does not change the data model and only depends on the schema of relational data (e.g., from row store to column store [38, 65]). However, the conversion between different data models for HTGAP workloads requires more semantic information. For example, it needs the mapping between relational tables and vertex/edge types, and the mapping between relational attributes and vertex/edge properties. Prior work [37, 55, 72] uses interface extension rather than data conversion, such as graph extensions on relational databases, which demands users to manually rewrite transactions or change log formats.

Goal 2: Efficient dynamic graph storage (§5). For the HTGAP system, write operations (from the log replayer) and read operations (from the GAP worker) are executed concurrently on the graph storage. The performance of both is important. Although many general-purpose dynamic graph storage systems [30, 32, 54, 87] have existed, their read performance for GAP workloads is sub-optimal due to neglect of HTGAP characteristics. The locality of read operations is sacrificed to guarantee the write performance and transaction semantics. First, adjacency-list-based topology storages ignore the locality of edge scan. Second, fine-grained versioning is expensive and breaks both the spatial and temporal locality. Third, property storages based on a column store cannot guarantee the locality of access patterns among different GAP workloads.

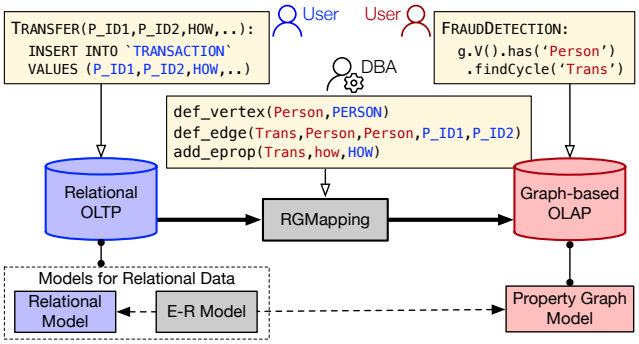

Fig. 4. *An example of data manipulation and graph extraction interfaces provided by* GART *using the dataset in Fig. 1.*

4 RELATIONAL-GRAPH MAPPING

To convert relational data to graph data automatically, it is necessary to provide a relational-graph mapping mechanism. GART uses the *property graph model* and provides the interfaces with the intuition from the *entity-relationship (E-R) model*. The property graph model [11] has been widely adopted to model graph-structured data. As shown in the lower left corner of Fig. 1, a property graph model defines a directed graph topology in which a vertex represents an entity and an edge from a source vertex to a target vertex represents a relationship. Each vertex (resp. edge) belongs to a vertex (resp. edge) type and has a property with attributes (Attr-Value pairs).

4.1 System Interfaces

The conversion from relational data to graph data needs additional semantic information. An intuitive solution is to directly add graph information to the transactions, such as graph extensions for relational databases [48, 55, 69], so that additional information can be added to the log. However, this solution has to extend the interface of the OLTP engine and change the log format; it implies that transactions must also be rewritten manually. Instead, GART decouples the interface into two groups, which are exposed to the user and the DBA, as shown in Fig. 4.

Data manipulation interfaces. GART integrates specific execution engines for OLTP and GAP workloads and retains their user interfaces. Therefore, existing transactions and graph queries can run directly on GART. As the example in Fig. 4 shows, users can execute a transaction called TRANSFER to transfer money. Meanwhile, users can run a query called FRAUDDETECTION to find all cycles on the graph consisting of Person vertices and Trans edges.

Graph extraction interfaces. The interfaces of the *RGMapping* component define the relational-graph mapping, which guides the log replayer to perform data conversion automatically. Fig. 5 lists two kinds of graph extraction interfaces.

Interfaces for adding vertices. In GART, each vertex type corresponds to one table in the relational model, and each

```
# Definition for vertices
def_vertex(vtype,table)
add_vprop(vtype,vprop,attr)
# Definition for edges
def_edge(etype,src_vtype,dst_vtype,pk) # 1-to-m
def_edge(etype,src_vtype,dst_vtype,src_pk,dst_pk) # m-to-m
add_eprop(etype,eprop,attr)
```

Fig. 5. *The graph extraction interfaces provided by* GART. *Arguments from the graph model and the relational model are shown in red and blue, respectively.*

property of vertices corresponds to one attribute in the table. The interfaces def_vertex and def_vprop are used to add new entities and construct the corresponding vertices. Specifically, def_vertex defines a type of vertices (vtype) according to the corresponding table (table). The attributes (attr) of the table can be further mapped to the properties (vprop) of vertices through the interface add_vprop.

Interfaces for adding edges. A relationship in the relational model can be added as a directed edge through the interface def_edge, where etype, src_vtype and dst_vtype correspond to the edge type, the type of source and destination vertices of this type of edges, respectively. To distinguish between different relationship types, RGMapping provides two def_edge for 1-to-m relationships (also 1-to-1 relationships) and m-to-m relationships, respectively. The difference between them lies in whether the interface requires the primary keys (pk) of one table or both tables as inputs. Furthermore, add_eprop is used to add the edge property (eprop).

The graph extraction interfaces make the OLTP engine and log formats unchanged. Moreover, unlike data manipulation interfaces, graph extraction interfaces are used only when defining the graph schema instead of used in each request. DBAs can define the RGMapping for a fixed data model just once according to workloads. For complex data models, DBAs can use automatic E-R model generation tools [1, 5] as a guide according to the relational schema, even if they have less knowledge about the workloads.

4.2 Expressiveness of RGMapping

We next show that graph extraction interfaces are expressive enough to map relational data to a property graph modeled by the same E-R model.

The E-R model has shown its powerful expressive capability in describing relationships and has been widely adopted in defining relational data [20, 28]. Generally speaking, the E-R model contains a set of *entities* with *attributes*, which usually represent objects in the physical world, and describes the *relationships* between entities. Intuitively, *for any E-R model, there exists a unique property graph schema that represents the E-R model* [59]. Entities and relationships can be mapped to vertex types and edge types of the property graph model, respectively, and use properties to store attributes. The interfaces also help DBAs extract a subgraph from the property graph. Note that edges in graphs are binary (2-ary) relations. An n-ary relationship of order greater than two can

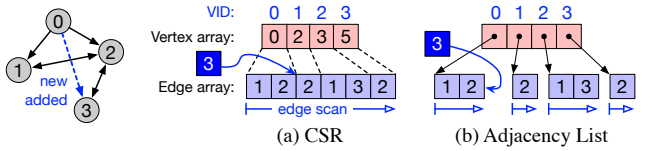

Fig. 6. *Two typical representations of an example dynamic graph topology, namely (a) CSR and (b) adjacency list.*

be mapped as a type of vertices with n associated edges.

Back to the example in Fig. 1 and Fig. 4, assume that a mapping scheme between the E-R model and the relational model has been defined (lower left dashed rectangles in Fig. 4). There is an entity called Person and a relationship called Trans that exists between instances of the Person entity in the E-R model. The DBA can utilize the interfaces (the middle part in Fig. 4) to define a property graph model that contains one type of vertices (Person) and one type of edges (Trans), which are derived by the entity Person and relationship Trans, respectively. Meanwhile, there is a property (How) on Trans derived from the HOW attribute.

RGMapping can map changes to relational data to property graphs *on-the-fly*. Depending on whether the data involves entity tables or relationship tables, the log replayer converts them to vertices or edges, respectively. Users can customize the extracted graphs partially so that the graphs extracted do not have to exactly match the E-R model.

5 DYNAMIC GRAPH STORAGE

The graph storage of GART stores the graph topology and properties and provides two kinds of operations: read for GAP workloads (e.g., edge scan) and write for the log replayer (e.g., insert and delete). For the graph topology, compressed sparse row (CSR), a compact graph representation, is widely adopted by (static) graph systems [29, 43, 73, 77], as shown in Fig. 6(a). However, CSR is also notoriously inefficient for dynamic workloads on the graph (e.g., edge insertion and deletions). Therefore, dynamic graph storage systems [30, 32, 33, 41, 54, 87] commonly use adjacency lists (based on linked lists or vectors) to store the graph topology (see Fig. 6(b)). For vertex (resp. edge) properties, a columnar storage is usually employed to efficiently read the same property for all vertices (resp. edges) with the same type [29, 55]. In addition, the dynamic graph storage also needs to record the version of vertex/edge/property updates for MVCC [30, 87].

The above traditional design has several performance issues for HTGAP workloads. First, using adjacency lists suffers from poor locality when sequentially scanning edges of all vertices, which is a common yet costly operation in GAP. A cache miss may occur when scanning the edges of an adjacent vertex. For example, transactions may insert edges randomly, resulting in unordered memory allocation for new edges of different vertices. Second, using fine-grained versioning for each vertex or edge update imposes a significant performance penalty for GAP workloads, since checking the

version for each read operation breaks both spatial and temporal locality and introduces additional overhead. Third, the existing property storages cannot guarantee locality flexibly for different access patterns among GAP workloads.

Key insights. Some unique characteristics of HTGAP workloads open opportunities to exploit the locality of a dynamic graph storage. Note that we term the time gap as the interval between a transaction committing an update and a graph query reading it. First, *the time gap in HTGAP (typically a dozen milliseconds, which is equal to the freshness of* GART *shown in Table 2) is sufficient to update a compact structure like CSR*. Thus, GART can still use a CSR-like storage for the graph topology instead of adjacency lists to improve the locality of edge scan. Second, *the GAP latency is almost always much longer than the time gap*. It implies that assigning versions to each update (fine-grained MVCC) is not necessary for GAP workloads. Thus, GART can use coarse-grained MVCC (i.e., at epoch granularity) to reduce memory and computation overhead, even though the committed updates cannot be read immediately. Third, *the access pattern of each GAP workload is usually fixed and easily detectable*. Given an HTGAP workload, fixed correlations between different attributes can be found by parsing the requests. For example, some attributes (e.g., balance and payment) may always be updated or read together. Therefore, GART can allow users to decide how to store different properties.

General idea. Based on the insights, we devise a new dynamic graph storage for HTGAP workloads. Fig. 7 illustrates the main structure of the dynamic graph storage for one type of vertex and edge. For the graph topology, a variant of CSR is proposed to exploit locality of edge scan, where the edge array is divided into multiple *edge segments* for dynamic updates. Using edge segments offers a tradeoff between read and write performance and allows the structure to be updated in batches. The vertex array is indexed by vertex ID (VID) and contains the links to the edges (neighbors) of each vertex. To reduce the overhead of edge insertion, the edges of each vertex are further divided into multiple *edge blocks*. Each vertex stores a pointer (tail) to the last edge block in the vertex array (not shown in Fig. 7 due to space constraints). To enable MVCC at epoch granularity, each vertex maintains an *epoch table*, which links to the edges inserted in the same epoch. It avoids attaching versions to each edge as in fine-grained MVCC. Similar to CSR, the epoch table stores the logical offset of the first edge for each (read) epoch number. In addition, vertex (resp. edge) properties are stored in *property blocks* within the vertex array (resp. edge segment). Each property block is a column store for one property or a group of correlative properties (column-family), which is indexed by the corresponding vertex (resp. edge) offset in the vertex array (resp. edge segment). Finally, a new interface is provided for combining correlative properties into a column family following access patterns of HTGAP workloads.

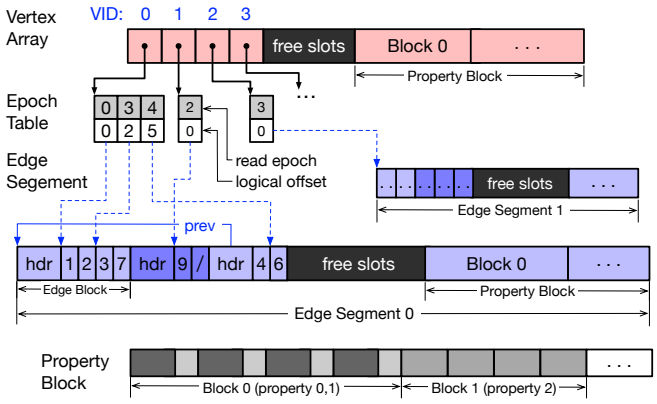

Fig. 7. *The key structure of the dynamic graph storage in* GART *for one type of vertex and edge.*

5.1 Efficient and Mutable CSR

GART devises an efficient and mutable CSR that guarantees high performance in both scans and updates on the graph topology, providing data locality similar to an immutable CSR. Each edge segment has a fixed initial size (e.g., 16KB) and stores edges (i.e., neighboring vertex IDs) of a fixed number of vertices (e.g., 4,096). The free slots are reserved for new edge blocks. Each vertex has a group of *edge blocks*, and new edges will be inserted into the tail edge block.

Fig. 7 shows an example where each segment stores the edges of two vertices (e.g., vertex 0 and 1). Initially, edges of the same vertex are stored consecutively in an edge block, so there is no overlap between edges of different vertices in an edge segment. As edges are continuously inserted, a vertex will allocate new edge blocks, which form a linked list (e.g., vertex 0). Each edge block has a header block (hdr) to store the meta-data of edges, such as the block size, the number of valid edges, and the pointer (prev) to the previous edge block of the same vertex.

Edge scan. Given a read epoch number, GART first uses the tail pointer and the epoch table of the vertex to find edges of that epoch within its edge blocks, and then scans edges forward based on the prev pointer stored in the header block (hdr). Note that each edge block only needs to be addressed once, which has little performance impact. In the beginning, GART can provide data locality comparable to vanilla CSR. However, after inserting numerous edges for different vertices, the edge blocks of a vertex will form a long linked list, leading to performance degradation in edge scan. To mitigate this issue, GART compacts an edge segment periodically or when the segment is close to full. After compaction, all edge blocks of the same vertex will be merged into one edge block (e.g., the first edge block of vertex 0).

Insertion. For a new vertex, GART atomically inserts it into a free slot of the vertex array and initializes an empty epoch table for it. When inserting an edge (e.g., from vertex 1 to vertex 4), the destination vertex ID will be directly inserted

into the tail edge block of the source vertex, if the edge block is not full (e.g., vertex 1 in Fig. 7). Otherwise, a new tail edge block of double the size is first allocated from the free slot of the edge segment, and then the edge is inserted into it. To reduce fragmentation, when the size of the tail edge block is smaller than a threshold, all edges will be moved to the newly allocated edge block to further improve data locality; the original edge block will be skipped. When an edge segment is full, a new segment of double the size is allocated, and all edges in the original segment are moved to the new one.

The write conflicts when concurrently inserting edges to the same vertex are resolved by per-vertex locks. Moreover, to resolve the conflicts when allocating edge blocks for different vertices on a full segment, the log replayer should lock the segment after checking for free space. Specifically, if the segment still has free space, the segment is locked in a shared manner; if the segment is full, the log replayer should exclusively lock the segment first and then allocates a new one.

Deletion. When deleting a vertex (resp. edge), a delete flag is appended to the vertex array (resp. edge block), which records the offset of the deleted vertex (resp. edge). When encountering the delete flag, the deleted vertex (resp. edge) will be skipped during scanning the graph topology. Furthermore, garbage collection (GC) will physically delete the vertices and edges and free up space in the background.

Discussion: structure parameters. We have tuned parameters including: (1) the number of vertices managed by each segment, (2) the initial size of edge blocks and segments, and (3) the resize factor of edge blocks (or segments) when they are full. Increasing (1) results in higher latencies for inserts, but it improves read performance. To balance read and write performance, we set (1) to 4096. The default values of (2) and (3) have minimal impact on read performance. We have adjusted these values to minimize the allocation of edge segments and optimize memory usage.

5.2 Coarse-grained MVCC

GART employs a *coarse-grained* MVCC scheme to reduce the temporal and spatial overhead of fine-grained MVCC. The scheme is based on the key observation that GAP workloads usually run longer at low concurrency than transactions. Thus, GART can enable MVCC at epoch granularity. In particular, the edge storage needs to adapt to the epoch instead of a fine-grained version for each edge. For each vertex, the epoch number of edges increases with the logical offsets. Since edges are append-only in edge blocks, edges with the same epoch number are consecutive. Therefore, GART can use an epoch number for a batch of edges.

Specifically, each vertex maintains an *epoch table* to store the offset in the edge segment for each epoch. As the example shown in Fig. 7, the 3rd to 5th edges of vertex 0 (offsets 2–4) are all inserted at epoch 3. At epoch 4, the GAP worker

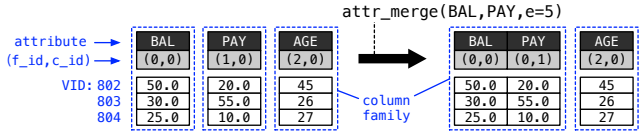

Fig. 8. *An example of the flexible property storage.*

will read all edges with the logical offset less than 5 at vertex 0. Since the logical offset of each epoch is immutable, GART can scan edges sequentially as if on a static graph. This design avoids checking versions for each edge and maintains the compact edge storage like in CSR.

When the log replayer inserts an edge with the epoch number, it will check whether the epoch number exists in the epoch table of the source vertex. The transaction protocol guarantees that the new epoch number must be greater than all existing epoch numbers [65]. If the epoch number does not exist, a new epoch number and the offset will be appended to the epoch table atomically.

The epoch table is stored as a ring buffer, since older snapshots are more likely to never be read again. For the corner cases where the oldest epoch number is still in use, GART uses a classical allocation amortization technique, similar to the C++ STL vector, to extend the ring buffer.

5.3 Flexible Property Storage

The storage model of properties influences the performance of read operations over properties. However, there exists no efficient property storage model for all GAP workloads. To support different GAP workloads in a more efficient way, GART presents a *flexible property storage* that allows system users to define the storage model according to application memory access patterns. Initially, GART utilizes a column store to store property data, which stores the same property (attribute) of the same type of vertices/edges continuously and is friendly to workloads that scan one or several attributes sequentially and independently.

To improve the property scan performance under different scenarios, users can combine several high-related attributes into a *column family* with the attr_merge interface *ahead of time*, as shown in Fig. 8. The Person vertex consists of three attributes: Bal, Pay, and Age. The meta-data of each attribute maintains the column family index (f_id) and the column index in the column family (c_id). The initial f_ids are different due to the pure column store.

As time goes on, the access patterns to some attributes may have certain correlations. Users can use the attr_merge interface to merge some attributes into the same column family *on-the-fly*, and generate a snapshot with a read epoch number. For example, if the attributes Bal and Pay are accessed together in a long-term GAP workload, users can merge them into a column family with read epoch 5. GART needs to generate a new version of the meta-data of these two attributes with epoch number 5, and copy them into a column family in the background. Then, the workload is processed on the new

Table 1: *Datasets used in evaluation, including TPC-C (warehouse=20) [71]* (CH)*, SNB-SF-10 [4]* (SB)*, Wiki [36]* (WK)*, R-MAT [18]* (RM)*, UK-2005 [16]* (UK)*, and Twitter-2010 [42]* (TT)*.*

Graphs	CH	SB	WK	RM	UK	TT

snapshot, which can also avoid some pre-processing tasks (e.g., the projection phase of GNN workloads to obtain required properties). We leave the automatic plan generation and attribute merging as future work.

6 Evaluation

We have implemented GART by extending VEGITO [65], a state-of-the-art in-memory HTAP system. VEGITO adopts DrTM+H [79] as the OLTP engine and supports tens-of-millisecond freshness with millions of transactions per second. This makes the HTGAP system design more challenging than in the case of low OLTP throughput. The extensions include the log replayer with relational-graph mapping and a new dynamic graph storage. We further integrated an open-sourced one-stop graph processing engine GraphScope [29] into GART, in order to support diverse GAP workloads.

6.1 Experimental Setup

Testbed. All evaluations are conducted on two dual-socket machines. Each machine has two 12-core Intel Xeon E5-2650 CPUs, 256 GB DRAM, and two 56 Gbps InfiniBand (IB) NICs via PCIe 3.0 connected to a Mellanox 40 Gbps IB Switch. Since the latency of GAP tasks is much higher than that of OLTP tasks, we end the execution of OLTP tasks after several rounds of GAP tasks to ensure the time of OLTP and GAP is similar in HTGAP workloads. Unless otherwise noted, we dedicate one machine for OLTP requests (OLTP server) and the other for GAP requests (GAP server). On the OLTP server, we pin 20 cores for OLTP worker threads and 1 core for the OLTP client thread. On the GAP server, we pin 12 cores for GAP worker threads, 10 cores for log replayer threads, and 1 core for the GAP client thread. The single core for clients is sufficient for request generation. We set the epoch interval to 15 milliseconds. For edge segment compaction (§5.1), we choose a strategy of compaction at edge insertion instead of periodic compaction, which can reduce repeated compaction when the OLTP throughput is high.

Benchmarks. Considering that there is no standard HTGAP benchmark, we first retrofit LDBC Social Network Benchmark (SNB) [4] and TPC-C [71] as two new HTGAP benchmarks and further select several typical graph datasets as our micro-benchmarks. The graphs are summarized in Table 1.

LDBC SNB is a GAP benchmark that contains a social network graph and different types of GAP workloads. We select to load 50% of edges and insert another 50% of edges for transactions. We set the scale factor (SF) of the dataset to 10 (about 8.4 GB) on each server.

TPC-C is a standard OLTP benchmark that contains relational datasets and five kinds of transactions. We extract two bipartite graphs (ORDER-ORDERLINE and CUSTOMER-ITEM graphs) from relational tables by mapping rows in entity tables as vertices and adding edges based on relationship tables. We deploy 20 warehouses on each server.

On the graphs of LDBC SNB and TPC-C, we choose three types of GAP workloads as prior work [29]:

- Graph analytics (GA): three representative graph algorithms from LDBC Graphalytics Benchmark [3], including PageRank (PR), Connected Components (CC), and Single Source Shortest Path (SSSP).
- Graph traversal (GT) [81]: three scan-dominated queries from LDBC SNB [4], including one interactive query (IS-3) and two business intelligence (BI) queries (BI-2 and BI-3). These queries access both the graph topology and properties.
- Graph neural network (GNN) [75, 83]: inference on three popular models, including Graph Convolution Network (GCN) [40], GraphSage (GSG) [35], and Simple Graph Convolution (SGC) [62].[1]

Comparing targets. To show the efficacy of the loosely-coupled design for HTGAP, we mainly focus on the performance of OLTP and GAP, and the freshness in GART against two different solutions (see §1). For Solution ①, we connect DrTM+H with GraphScope [29] (DH+GS), where transactions are served by DrTM+H (the same OLTP engine of GART), and transactional data are periodically loaded into GraphScope, a state-of-the-art GAP engine. For Solution ②, we evaluate Neo4j [6], a popular graph database that supports both transactions and GAP.[2]

To study the efficiency of our dynamic graph storage, we integrated LiveGraph [87], a state-of-the-art transactional graph storage, into GART (G/LG). LiveGraph uses a highly optimized adjacency list format (similar to Fig. 6(b)) to store the graph topology and a row store with fine-grained MVCC to store properties. GART's graph storage and LiveGraph provide the same interfaces. Therefore, GART outperforms G/LG solely due to three design choices of our graph storage. Note that all systems, except Neo4j, use the same OLTP and GAP engines, namely DrTM+H and GraphScope, with the same configurations (e.g., the number of worker threads) for fairness. Although we try our best to run HTGAP workloads on Neo4j and DH+GS, they still cannot support TPC-

[1] We run graph analytics and graph neural network workloads directly on the CUSTOMER-ITEM graph in the TPC-C dataset and PERSON-POST graph in the LDBC SNB dataset. Graph traversal queries from LDBC SNB are tightly coupled with its dataset. We rewrite queries on the TPC-C dataset and ensure that they have the same computation patterns as LDBC SNB.

[2] We also evaluated TigerGraph [24] as an alternative solution. However, TigerGraph's timestamp only provides second-level accuracy, which limits its ability to evaluate freshness with sub-second precision.

Table 2: *A comparison of OLTP throughput (in transactions per second), GAP latency (in milliseconds), and freshness (in milliseconds) using different workloads among* GART*, a combination of* DrTM+H *and* GraphScope *for offline data processing* (DH+GS)*,* Neo4j *(not support GNN workloads), and* GART *w/* LiveGraph (G/LG)*. Freshness ↓		18	15683	5	25	18	25

C due to costly code transcription and graph extraction from complex logs, respectively.

Coding effort. To extract graph data from relational data, we only write about 10 LoCs for each benchmark (LDBC SNB and TPC-C), thanks to graph extraction interfaces in GART (§4.1). This is far less code than OLTP and GAP programs, which can be inherited directly from existing specific systems. In contrast, we write 584 LoCs in DH+GS for loading graph data and 70 LoCs in Neo4j for rewriting transactions.

6.2 Overall Performance

We first show the overall performance of all baselines for HTGAP workloads in Table 2. We use transaction throughput as the evaluation metric for OLTP workloads, and computation latency (execution time) for GAP workloads. We also evaluate the freshness of each system, namely, the maximum time delay between an update was committed in OLTP and this update is visible in GAP workloads [65]. In a nutshell, among all baselines, only GART can simultaneously satisfy the requirements of *performance* and *freshness*.

OLTP performance. For systems based on the loosely-coupled design (GART, G/LG) and DH+GS, OLTP throughput is not impacted by GAP workloads. The peak throughput of GART can reach over 1,837,000 and 245,000 transactions per second on datasets LDBC SNB and TPC-C, respectively. GART performs 2-3 orders of magnitude better than Neo4j (Solution ②). Neo4j has the lowest OLTP performance as the graph data model is less efficient than the relation model for OLTP workloads. GART and G/LG show an OLTP throughput reduction of only 5% compared to DrTM+H with offline data processing (DH+GS). This result demonstrates that the loosely-coupled design can support HTGAP without necessarily sacrificing OLTP performance.

GAP performance. Among all baselines, DH+GS achieves the best GAP performance, as its graph data is stored as a *static* graph, which uses compact graph representation without concurrency control (e.g., MVCC). However, its freshness is extremely high. Neo4j performs much worse than GART and G/LG due to its adjacency-list-based storage [68, 87]. GART greatly outperforms G/LG except for the IS-3 query, thanks to our dynamic graph storage which takes the characteristic of HTGAP workloads into consideration (breakdown details in §6.3). The IS-3 query only involves a very limited graph data size, thus the overall execution time is dominated by cross-language invocation overheads. The backend and frontend engines of GraphScope are developed with Rust and C++, respectively.

Freshness. The freshness of GART is about 18 ms, which is much lower than most GAP latencies and is independent of datasets. It is three orders of magnitude better than DH+GS (Solution ①). Similar to VEGITO [65], the freshness of GART is only determined by the epoch interval (15 ms). DH+GS has the worst freshness (more than 15 seconds), which is unaffected by the ETL frequency and depends on the graph data size. This is because the immutable graph storage requires the entire graph to be reloaded whenever changes are made. The freshness of G/LG is 25 ms due to the lower write performance of the graph storage. The freshness of Neo4j is only about 5 ms, as data is committed in place.

6.3 Breakdown Analysis on GAP Performance

From Table 2, we observe that GART achieves a large performance improvement over other systems on graph analytics and traversal workloads and a relatively small improvement on GNN workloads. To gain a deeper understanding of the dynamic graph storage in GART, we perform a detailed comparison with G/LG.

We split a single execution of a GAP query into three parts: (P1) accessing the graph topology; (P2) getting properties from visited vertices or edges; and (P3) computation over the graph topology and properties obtained from (P1) and (P2) parts. Meanwhile, the performance gain of GART mainly comes from three aspects: (A1) the efficient and mutable CSR with good locality of edge scan; (A2) the coarse-grained MVCC that alleviates the costly versioning; and (A3) the flexible property storage that adapts to access patterns. Table 3 shows the results of a breakdown analysis of three GAP workloads for the LDBC SNB dataset. Since G/LG and GART have the same backend GAP engine, their performance in part (P3) is nearly identical. Meanwhile, the design differences between (A1) and (A2) affect the performance of the (P1) part, while the performance of the (P2) part is influenced by (A3).

Graph analytics. Table 2 shows the execution time of dif-

SGC	GART	36 (5%)	477 (61%)	266 (34%)	779
	G/LG	236 (19%)	732 (59%)	269 (22%)	1237

ferent algorithms and excludes the time of storing outputs. The latency of PageRank, CC, and SSSP on G/LG is 2.5×, 2.3×, and 2.0× higher than GART, respectively. The performance gain of GART on graph analytics workloads is mainly from the better performance of accessing the dynamic graph topology due to (A1) and (A2), and the higher efficiency of obtaining required properties thanks to (A3). For example, as shown in Table 3, the end-to-end execution time of PageRank is dominated by the graph traversal (edge scan) operations (P1) and getting required properties (P2). GART's graph storage outperforms G/LG by 6.2× in (P1), with 82% of the improvement attributed to (A1). GART also outperforms G/LG by 3.0× in (P2) due to (A3). Note that PageRank uses only one property, so GART does not group it with others.

Graph traversal. For graph traversal workloads, GART's latency is 3.5× and 4.4× lower than G/LG's for two BI queries (BI-2 and BI-3) on the LDBC SNB dataset, while GART performs almost as well as its competitor on the interactive query (IS-3). The reason is that compared with BI queries, the interactive query only involves a very limited graph data size (vertices and edges as well as their properties), and our optimized storage design cannot contribute much in such a circumstance. Instead, the computations of two BI queries rely on scanning one or several properties of a large number of vertices or edges, and (A1) to (A3) can benefit a lot. Observe that given a BI query (BI-3), compared with G/LG, GART performs 4.0× and 6.3× faster on accessing the graph topology (P1) and obtaining required properties (P2) parts, respectively (see Table 3).

Graph neural networks. On three GNN workloads, GART outperforms G/LG by 1.3× on average. GNN workloads need several/all properties of vertices/edges as raw features to conduct GNN computation, and (A3) allows users to store and get required properties in a more efficient way. As we can see from Table 3, on SGC, GART is 1.5× faster than G/LG in obtaining the required properties in (P2). Meanwhile, (A1) and (A2) make GART 6.6× faster than G/LG in (P1). The performance improvements over the TPC-C dataset are relatively small, because the CUSTOMER-ITEM graph in dataset TPC-C is very dense, and the end-to-end execution time of GNN workloads is dominated by the complex computations over properties of vertices or edges (P3).

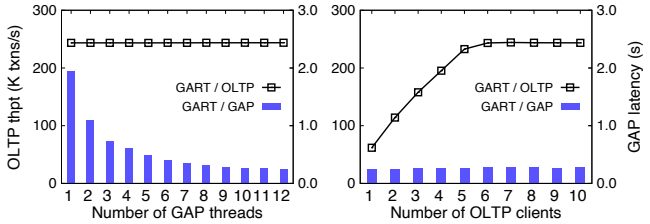

Fig. 9. *Performance isolation on GART with the increase of (a) GAP workloads and (b) OLTP clients, respectively.*

6.4 Performance Isolation

To demonstrate the performance isolation in the HTGAP workloads, we evaluate the OLTP and GAP performance with the increase of GAP and OLTP clients. We use the TPC-C benchmark as the OLTP workloads and execute PageRank on the CUSTOMER-ITEM graph derived from the TPC-C schema. We use the number of OLTP clients and the number of worker threads for a single GAP request to control the workloads.

In general, GART provides strong performance isolation between OLTP and GAP workloads. Fig. 9(a) shows the performance of OLTP and GAP workloads when we gradually increase the number of GAP worker threads. The OLTP performance degradation is trivial (1%), even if the GAP workloads are saturated. This is due to the physical isolation in GART, as GAP workloads do not interfere with transactions. On the other hand, when we increase the number of OLTP clients, as shown in Fig. 9(b), the performance degradation of GAP workloads is about 12%. This is because the number of edge versions also increases, causing additional overhead to check versions. At 5 clients, the OLTP server's maximum capacity is reached due to a fixed number of cores being allocated for its use.

6.5 Graph Topology Storage

Edge scan is a common and costly operation in GAP workloads, such as PageRank and LPA. To study how the performance of edge scan is affected by different graph topology storages, we compare the following typical graph storages.

- **CSR** is a compact structure without the support of updates, which is widely used by the *static* graph topology storages.
- **LiveGraph** [87] is a state-of-the-art dynamic graph storage that uses adjacency lists and fine-grained MVCC.
- **SegCSR** is a CSR-like topology storage proposed by GART, which uses segment-based design and coarse-grained MVCC. Note that each edge segment has a 1 MB initial size and manages 4,096 vertices.
- **SegCSR/TS** is similar to SegCSR, except that it uses fine-grained MVCC as LiveGraph.

To simulate diverse workloads, we load graphs in two patterns: (1) *bulk load*, i.e., edges are sorted by their source vertices and loaded sequentially, and (2) *random insertion*, i.e., edges are loaded randomly to simulate the behavior in trans-

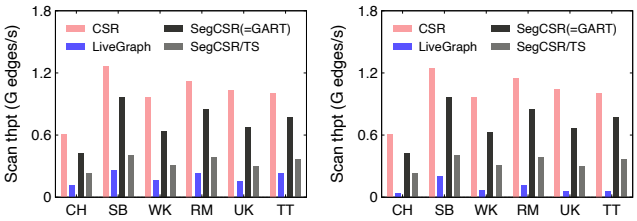

Fig. 10. *Comparison of single-version edge scan perf. for different topology storages using (a) bulk load and (b) random insertion.*

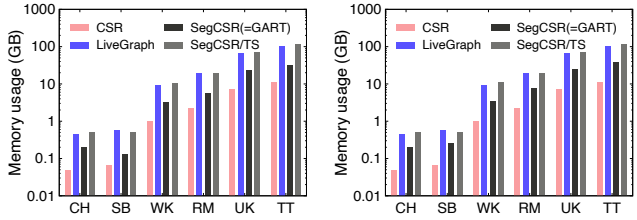

Fig. 11. *Comparison of memory usage (in log scale) for different topology storages using (a) bulk load and (b) random insertion.*

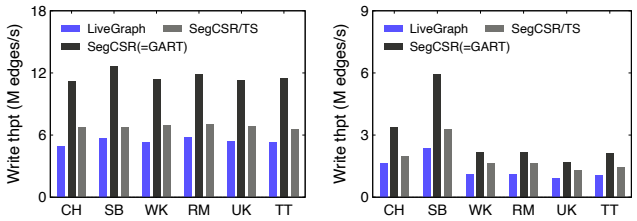

Fig. 12. *Comparison of write throughput for different topology storages using (a) bulk load and (b) random insertion.*

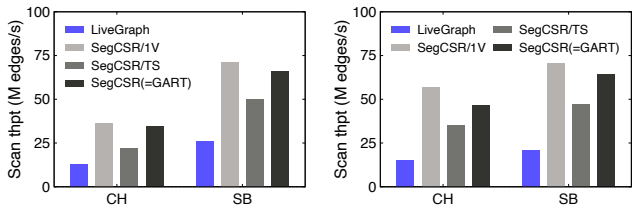

Fig. 13. *Comparison of multi-version edge scan perf. for different topology storages using (a) bulk load and (b) random insertion.*

actions. We scan edges of each vertex and evaluate edges read per second as scan throughput.

Read-only workloads. We first evaluate the performance of the single-version edge scan without version checking. As shown in Fig. 10(a), with the bulk load, SegCSR exhibits consistent performance behavior across various datasets. For example, SegCSR only incurs a 35% slowdown compared to CSR for WK, while LiveGraph incurs more than an 80% slowdown. Compared with adjacency lists for each vertex in LiveGraph, SegCSR has a better locality and fully exploits CPU prefetching as it associates the edges of many vertices in a segment. Moreover, the edge scan throughput of SegCSR is more than 2× that of SegCSR/TS since SegCSR adopts a simpler data structure for edges. With random insertion, the locality of LiveGraph suffers from memory allocation. As shown in Fig. 10(b), SegCSR outperforms LiveGraph by up to 12.5× (from 4.7×) and only incurs about a 30% slowdown compared to CSR.

The memory usage is shown in Fig. 11. Compared with CSR, SegCSR requires about 3× memory of CSR for updates, which is significantly less than that of LiveGraph (8.8× of CSR). The coarse-grained MVCC helps SegCSR reduce memory largely by using the epoch table for each vertex instead of timestamps for each edge. Compared to SegCSR/TS, SegCSR reduces memory usage by up to 3.8×. The memory usage of SegCSR/TS is higher than that of LiveGraph (typically less than 18%) due to the free slots in the edge segments.

Read-write workloads. We further evaluate the performance of the write and the multi-version edge scan. We scan the edges in latest stable version via latest_repoch (§2) when a dedicated number of edges have been inserted. For the bulk load setting, we use the ORDER-ORDERLINE graph in TPC-C and PERSON-POST graph in LDBC SNB. With the random insertion setting, we utilize a shuffled CUSTOMER-ORDER graph in TPC-C and PERSON-POST graph in LDBC SNB.

As shown in Fig. 12, the write throughput of SegCSR is about 2.2× and 2× of LiveGraph with the bulk load and random insertion, respectively. According to the performance of SegCSR/TS, about 70% of the performance improvement is due to the fact that the coarse-grained MVCC of GART writes the newly generated version (epoch) number to the epoch table only once, instead of writing the version number on every update. Moreover, writes of SegCSR do not perform costly GC-related operations, unlike with LiveGraph. SegCSR will copy edges from an old segment with insufficient space to a new segment with a larger space. It introduces high tail latency (more than 7,000× of ordinary edge insertion latency on average) in edge insertion, but the frequency of it being triggered is less than 0.01%.

As shown in Fig. 13(a), with the bulk load setting, read performance of SegCSR outperforms LiveGraph by 2.5× due to better locality and coarse-grained MVCC. It is very close to the upper bound (single-version read performance, SegCSR/1V), while LiveGraph is about 37% of SegCSR/1V. To show the efficiency of coarse-grained MVCC, SegCSR/TS outperforms LiveGraph only by 1.7×. With the random insertion setting shown in Fig. 13(b), SegCSR and SegCSR/TS outperform LiveGraph by 3.1× and 2.3×, respectively. It indicates that the coarse-grained MVCC in GART can largely increase read performance for dynamic workloads.

6.6 Flexible Property Storage

To study the performance of the flexible property storage, we compared it with two typical property storages: row store (row) and column store (col). For the read (resp. write) performance, we scan (resp.update) the properties of each vertex using CUSTOMER vertices derived from TPC-C. We control the number of columns scanned and updated, and evalu-

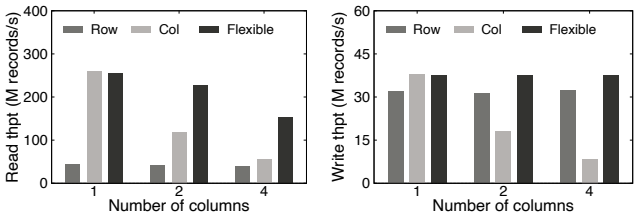

Fig. 14. *Comparison of (a) read throughput and (b) write throughput for different property storages with different numbers of columns read and written, respectively.*

ate the number of processed vertices per second as read and write throughput, respectively.

Fig. 14(a) reports the read throughput. The performance of the row-based property storage is fixed as the number of scanned columns increases since it needs to fetch at least one cache line. However, the performance of column-based property storage significantly drops due to cross-column access. Compared with the row-based storage, the flexible property storage achieves better performance, especially when scanning a few columns. For example, the flexible property storage achieves 5.9× read throughput when scanning only one column. The write operations of the flexible property storage also outperform existing storage models, as shown in Fig. 14(b). It achieves a speedup of 1.2× and 4.4× compared to row-based and column-based storages, respectively, when writing four columns of properties.

Row-based storages and column-based storages have different performance behaviors for reads and writes. We find that the read operation is light and dominated by the memory footprint, while the write operation is dominated by the number of writes due to the overhead of memory copy and atomic operations. The flexible property storage allows users to combine attributes into a column family *on-the-fly* with some overhead. In our experiments, it takes about 1.1 seconds to create a property snapshot with 4 columns as a column family for 229 MB properties.

7 Related Work

HTAP systems. HTAP systems have three main typical design choices. Dual systems [51, 57, 58, 82] combine two specialized systems for OLTP and OLAP scenarios, while single-layout systems [39, 60, 64] support HTAP workloads from either an OLTP or an OLAP system. Dual-layout systems [9, 14, 15, 19, 44, 50] aim to build a single system with different data layouts for the two scenarios. Vegito [65] is proposed to retrofit fault-tolerant backups to support hybrid workloads, which arrives at a sweet spot for the performance-freshness tradeoff. These works are developed for relational data, while GART extends Vegito to constantly maintain a graph layout for transactional data from an OLTP system to support dynamic graph analytical processing.

Graph databases. Graph databases [2, 6, 8, 27] support both OLTP and GAP in a single system. In order to conduct efficient graph updates, they typically adopt linked lists to store adjacency lists, which downgrades the performance of edge scan and the whole GAP workloads. LiveGraph [87] devises the Transactional Edge Logs (TELs) based on adjacency lists to support both efficient sequential scan and edge insertion. Adding a CSR-based in-memory property graph representation in a relational database has been investigated by Oracle, but without support for updates [13]. GART decouples OLTP and GAP execution to make both workloads more efficient.

Dynamic graph systems. Prior work presents many general-purpose dynamic graph systems [24, 30, 41]. Terrace [54] uses PMA [25, 80], a dynamic memory array based on tree-based index structures, to store edges of streaming graphs. CSR++ [32] combines segmented vertex arrays and vector-based adjacency lists for each vertex, which does not guarantee the locality of edge scan from adjacent vertices (see Fig. 6(b)). Moreover, CSR++ does not support multi-versioning. Sortledton [33] provides a general-purpose and transactional graph data structure based on adjacency lists. Teseo [26] and LLAMA [49] are also CSR-like and guarantee the locality of edge scan. While general-purpose dynamic graph storages can replace GART's storage in functions, they may face performance issues. For example, GART could use LLAMA [49] as the graph storage, but it would have to copy data pages for each snapshot, which would be inefficient for scenarios with high data generation rates or extreme freshness. Based on insights from HTGAP, the graph storage of GART does not need to support full transactional semantics, allowing for new designs and optimizations in the topology storage. In addition, GART also provides the flexible property storage for diverse GAP workloads.

8 Conclusion

This paper presents GART, the first hybrid transactional and graph analytical processing (HTGAP) system based on a loosely-coupled design. It proposes expressive interfaces for transparent data conversion and an efficient dynamic graph storage with good locality. Evaluations confirm its efficacy and efficiency. The source code of GART, including all benchmarks, is available at https://github.com/SJTU-IPADS/vegito/tree/gart.

Abstract

This work is an experience with a deployed networked system for digital agriculture (or DA). DA is the use of data-driven techniques toward a sustainable increase in farm productivity and efficiency. DA systems are expected to be overlaid on existing rural infrastructures, which are known to be less robust than urban infrastructures. While existing DA approaches partially address several infrastructure issues, challenges related to data aggregation, data analytics, and fault tolerance remain open. In this work, we present the design of Comosum, an extensible, reconfigurable, and fault-tolerant architecture of *hardware*, *software*, and *distributed cloud* abstractions to sense, analyze, and actuate on different farm types. We also present FarmBIOS, an implementation of the Comosum architecture. We analyze FarmBIOS by leveraging various applications, deployment experiences, and network differences between urban and rural farms. This includes, for instance, an edge analytics application achieving 86% accuracy in vineyard disease detection. An eighteen-month deployment of FarmBIOS highlights Comosum's tolerance to intermittent network outages that lasted for several days during many periods of the deployment. We offer practical insights on how FarmBIOS adapts to new DA vendors, reconfigurability challenges in the cloud, persistent failures that are unique to the DA context, and the system's current limitations.

1 Introduction

Digital agriculture (DA) is the use of data-driven techniques towards a "sustainable intensification" [65] in farm productivity and efficiency. DA is the next generation stemming from *precision* agriculture, which is local, offline, precise application of farm inputs (e.g., water, fertilizer, etc.) [44, 57, 58]. In contrast, DA systems involve more complex data processing and communication, both on and off rural farms [79]. DA systems are expected to be overlaid on existing rural infrastructures. However, rural infrastructures (e.g., Internet, power) are known to be less robust than urban infrastructure [17]. This is due, in part, to sparse populations [41], urban-centered technology design and standards [17], frequent outages [42], and limited maintenance [27]. These challenges make networked data aggregation and analytics on rural farms difficult [88].

While state-of-the-art approaches address several of these DA issues [26, 38, 85, 88], a lot of challenges related to data aggregation, data analytics, and fault tolerance remain open. First, although the diversity of sensor providers is growing [4, 5, 80, 83, 84, 87], data aggregation is difficult because of distributed data sources, incompatible sensors and data formats, and software dependencies. Second, the set of data analysis methods are increasingly leveraging advanced techniques such as machine-learning (ML) [45, 53, 68]; however, existing data analysis platforms rarely account for the variety of sensing mechanisms and crop types (e.g., row crop vs specialty farms). Third, state-of-the-art platforms [78, 88] partially address rural Internet and power challenges. However, fault tolerance is difficult to achieve across heterogeneous devices, networks, and cloud services. Overcoming these challenges requires extensibility, reconfigurability, and fault tolerance in the (1) underlying sensors and networking, (2) overlaying software, and (3) supporting cloud services.

In this paper, we present Comosum,[1] a cloud-based hardware/software architecture that takes a significant step toward this goal. Comosum is designed for researchers integrating heterogeneous DA platforms. To address the heterogeneity, Comosum relies on prior strong systems concepts such as separation of devices and device drivers [73], modularity [28, 43, 61], and reconfigurability of closed-source software/hardware [18]. Our general approach to DA-enabled farms is modular with abstractions for *hardware* (i.e., sensors and networking devices), *software*, and the *distributed cloud* (i.e., a cloud that combines the edge cloud at the farm, the public cloud, and sensor vendor clouds).

Specifically, the Comosum design presents three principles:

- **Extensible modules**: Comosum modules (§§ 3.2) pro-

[1] Named after Chlorophytum comosum, also known as spider plants, for their extensible leaves and adaptability to many conditions [67].

vide an abstraction on the acts of sensing, storing, computing, and actuating farm data. This abstraction is derived from the object-oriented programming idea of inheritable *instances*, which can be customized for different DA applications. Note that these modules are oblivious to the underlying hardware. This design consideration follows from the principle of dumb switches and smart control planes in Software-Defined Networking (SDN) [18]. In this manner, given a uniform API, the hardware (i.e., sensing and networking devices) and software modules can evolve independently.

- **Fault-tolerant distributed cloud**: The Comosum distributed cloud (§§ 3.3) addresses challenges in supporting elastic, vendor-neutral, and fault-tolerant data aggregation/analytics. Specifically, we highlight the complex data path where some data must be pulled directly from the sensor vendor, despite farm networking challenges. This need for networked data aggregation across the farm (or "edge") cloud, public (or "core") clouds, and private (or "vendor") clouds distinguishes the consequential fault tolerance trade-offs that are unique to DA environments (e.g., plants might die if not irrigated on time). Ultimately, by reimagining prior approaches such as CloneCloud [19], the Comosum design enables offline data collection and edge analytics during network outages.

- **Reconfigurable control plane**: Given software abstractions and distributed cloud deployment environments, the Comosum control plane (§§ 3.4) coordinates inter-module communication. To maintain reconfigurability and extensibility to heterogeneous devices, this component draws from the separation of devices and device drivers, inter-process communication (IPC), and SDN. Specifically, Comosum modules rely on a message-passing [89, 92] protocol to abstract away the distributed deployment environments.

We implemented a version of Comosum that we call FarmBIOS. We deployed multiple FarmBIOS instances in the Azure, AWS, and Google clouds. Further, we deployed these instances on one commercial farm and two research farms. Commercial farms are for-profit; in contrast, research farms are associated with land-grant universities [1, 9]. As a result, we operate multiple deployments (both in open fields and greenhouses) throughout the year with different Comosum module, cloud, and control plane configurations. The configurations differ such that they can meet the needs of animal (§§ 5.1), row crop (§§ 5.3), and specialty farms (§§ 5.2).

The results based on deployments and evaluation show that Comosum supports extensible, reconfigurable, and fault-tolerant DA systems. First, we applied FarmBIOS instances to a plant water stress application, as well as two ML-based applications that yielded 86% and 97% training accuracy in vineyard and dairy cow disease detection, respectively (§ 5). Second, we present an 18-month deployment with a million sensor readings from 80 sensors networked over cutting-edge hardware in two farm edge clouds (§§ 5.3). We further analyze Comosum's reconfigurability trade-offs based on our extensive deployment experience, application requirements, and comparative spectrum measurements of a 55-acre urban farm and a 615-acre rural farm (Appendix B). Third, we show Comosum's adaptability to faulty sensors in the field (§§ 6.2), its tolerance to a network outage over multiple days (§§ 6.1) at the edge, and the edge analytics' resilience to network outages (§§ 5.2). Deploying Comosum yielded several surprising architectural insights. First, failures at the edge (i.e., in the sensors and networking) vary differently from failure towards the core of the cloud (i.e., Internet and cloud module failures), and the differences in failure scope had to be identified, escalated, and optionally tolerated or repaired. Intermittent network failures were tolerated through offline data collection at the edge, or by directly performing analytics at the edge. Long-term sensor failures were escalated by digital twins. A digital twin is a digital representative of a physical object that behaves like its real-world counterpart. That is, we expanded the failure scope to cloud-based digital twins of sensors and notified human operators. We call this an *active* digital twin. A key takeaway was that the time to detect and tolerate a system component failure varied from seconds to weeks. Second, frequent unannounced API or data format changes by vendors led to many errors. Comosum evolved to shield DA application developers from this complexity by providing a uniform API; specifically, a unstructured platform layer and structured application layer. Third, Comosum was made cloud provider-agnostic by providing a cloud-independent layer (i.e., through cloud-agnostic abstractions such as tables/functions) and a separate cloud-dependent layer (through cloud-dependent services such as Azure Table and AWS Simple Notification Service).

We present an experience with a deployed networked system for DA, our contributions are as follows:

- Three case studies to demonstrate DA research challenges, and how they motivate our design goals
- An integrative approach that applies and advances the state-of-the-art to a portfolio of system challenges associated with building Comosum effectively across multiple subsystems and contexts (Table 3)
- The design and implementation of Comosum, a cloud-based architecture that unifies state-of-the-art DA approaches under a single interface by distilling largely complex black-box technologies down to classical ideas
- Evidence that Comosum supports various applications, tolerates intermittent network failures, and can be deployed across different farm types and cloud providers

Paper outline: § 2 describes three DA case studies to motivate design goals. § 3 delves into the Comosum system

software architecture. § 4 instantiates FarmBIOS, a Comosum implementation that unifies otherwise incompatible DA systems. § 5 describes three FarmBIOS applications and deployment contexts. § 6 describes system adaptations to ensure long-term maintenance. § 8 puts Comosum in the context of prior work before concluding in § 9. Appendix B demonstrates Comosum's reconfigurability trade-offs.

2 Challenges: Why DA is Hard

Comosum is borne out of four years of collaborative research building state-of-the-art systems to support DA. We describe the main challenges in building on existing technologies to motivate the architecture developed in § 3.

2.1 Challenge 1: Data Aggregation

Data aggregation involves pulling and processing data from a variety of sources. Consider, for example, DA researchers in animal science who need real-time monitoring of dairy cows to facilitate early disease detection [33, 34, 54, 72]. This requires integrating data from wearable and non-wearable cow sensors, herd management software, and manual data collection on site.

Existing wearable sensors capture behavioral, physiological, and performance parameters such as physical activity, rumination and eating time, estrous behavior, and internal temperature (e.g., [2, 3]). Non-wearable sensors include cameras, weather stations, milk meters and near-infrared spectrometers, and weight scales that deliver milk yield and body weight from a static location as cows pass through with every milking session (e.g., [4, 80, 84]). The data monitoring is possible via systems from various sensor providers running on the farm computer (e.g., [5, 83, 87]). The providers control and avail the data for download either as raw files (via FTP dumps) or JSON (through scripted API calls to the providers' servers).

However, data aggregation efforts face five major hurdles. First, the sensor data are siloed in monolithic platforms with *incompatible APIs*. Second, the datasets are delivered in various *incompatible formats* (e.g., Excel, JSON, or DIF). Third, the data is *distributed* between the farm computer and numerous sensor providers' servers. Fourth, the patchy data integration programs are *dependent* on the farm computer's operating system (e.g., to run PowerShell scripts) and disk storage layout (e.g., hardcoded, per-provider directories). Fifth, any ad hoc integration protocol is likely to introduce *data sparsity* as new sensors are incorporated and old sensors are retired. These hurdles highlight the need to aggregate sensor data from heterogeneous devices and platforms. *The system should enable data aggregation from arbitrary sensor vendor platforms, data formats, and data locations*.

2.2 Challenge 2: Data Analytics

Data analytics involves extracting actionable insights from big data. It is important in managing and predicting farm inputs and expected outputs, respectively. Consider, for example, DA researchers in plant pathology who need fast methods to detect vineyard diseases affecting grape and wine quality [7, 22, 68, 93]. This requires detecting symptoms typically visible on the leaves.

Existing grapevine disease detection methods include molecular tests, remote sensing, and digital models. Molecular tests involve plucking diseased leaves to be analyzed in laboratories. Remote sensing and digital models combine aerial imagery from Unmanned Aerial Vehicles (UAV), vegetation indices, and machine learning (ML) techniques [45, 52, 53, 68].

However, these existing data analytics approaches face three challenges. First, current remote sensor data cleaning and pooling processes, which are often *manual*, do not enable cross-farm analytics. Secondly, ML models have been shown to produce *contradictory analyses* depending on the choice of hyperparameters [15, 20, 81]. Lastly, molecular tests are *slow* (i.e., on the order of days) to yield actionable results in a setting where every second implies further disease spread. These challenges highlight the need for a reconfigurable approach for data storage and model training to enable fast iterations in any environment. *The system should enable fast plug-and-play of different analytics modules and sensing mechanisms*.

2.3 Challenge 3: Fault Detection/Tolerance

Fault tolerance involves detecting, recovering from, and optionally repairing system faults. It is important in providing timely manual or automated interventions when farm monitoring assets such as sensors have failed. Consider, for example, DA researchers in plant breeding who need to understand water status effects on plant growth by controlling for variables such as temperature, soil moisture, and CO2 levels [49, 71, 86]. This requires reliable sensor data collection with both short-term and long-term storage, processing, and actuation.

Existing systems (e.g., [78, 88]) generally comprise sensing hubs, an Internet gateway device, and optional cloud storage and processing. The sensor hubs communicate to the gateway over various protocols such as unlicensed TV White Spaces (TVWS) [88] or ZigBee [40]. The gateway relays the sensor data over various media (e.g., 4G/3G [40], WiFi [85]) to diverse cloud-based routing hubs (e.g., Azure IoT Hub [88], AWS IoT Core [46]) for long-term storage. With a few exceptions [26, 46], prototype deployments are often outdoors [85, 88].

However, fault detection and tolerance are difficult due, in part, to three challenges related to cascading failures. First, faulty sensors affect data collection. Second, network outages affect data storage and data processing both locally at the farm and in the cloud. Third, the complexity and heterogeneity of existing hardware/software systems pose significant troubleshooting issues in the field. Individually, these failures can present real consequences in farms (e.g., plants are not irrigated, animals are not fed, etc.). This highlights the importance of fault tolerance and detection in DA environments. *The system should detect, localize, tolerate and/or repair failures in sensor, network, and software components*.

2.4 Summary and Design Goals

These case studies highlight interoperability challenges within state-of-the-art systems. These challenges map to three core system design goals:

- **Extensibility**: In addressing data aggregation (§§ 2.1), we aim to provide an *extensible interface* that can generalize sensing, analytics, and actuation across APIs, clouds, hardware, and platforms.
- **Reconfigurability**: In addressing data analytics (§§ 2.2), we aim to *allow different points in the configuration space* towards data models that can be trained and used across different networking and cloud deployment scenarios.
- **Fault Tolerance**: In addressing fault detection/tolerance (§§ 2.3), we aim to *detect and/or tolerate intermittent failures* despite the heterogeneity of hardware, farm types, and cloud services.

3 Comosum Architecture

3.1 Overview

In this section, we describe Comosum's *hardware*, *software* and *distributed cloud* - the main components in the quest to sense, analyze, and actuate on rural farms (see Figure 1).

Hardware encompasses sensing, networking, and control devices. Sensing devices produce updates based on changes in real-world conditions such as temperature, soil moisture, vegetation density, etc. Networking devices provide infrastructure support via data routing and transfer between other devices, of which routers, switches, and antennas are typical representatives. Control devices offer digital interfaces with programmable logic control (PLC) functions. While programmable, control devices are limited to firmware running on a few kilobytes of memory.

Software encompasses possible manipulations of data generated by the hardware entities. The software modules, which we describe from left to right as shown in Figure 1, offer abstractions on the acts of sensing, storing, computing, and intervening based on real-world changes. The changes are communicated via interrupt and poll mechanisms (see Table 1). The telemetry module serves as an interface to capture and reflect physical and virtual state changes. Whereas physical updates read directly from sensing devices (e.g., GPIO pins), virtual updates are third-party reports (e.g., Excel files) from vendors on proprietary sensors (see §§ 3.3). The storage module is a logical abstraction over storage structures (databases, files, etc.) and formats (Excel, CSV, etc.). The compute module captures the various networked, temporal, and spatial arrangements of compute devices (see *Cloud* below) to produce actionable results. Together, the storage and compute modules form the analytics module. Henceforth, the analytics module is used interchangeably with the storage and compute modules. Lastly, the actuation module bridges the analytics module to control devices and farm operators.

Distributed cloud encompasses ubiquitous, convenient, on-demand network access [60] to storage media and compute devices at the farm edge, the public cloud, and the private cloud (i.e., sensor vendor servers, university servers, etc.). Storage media vary from low-end USB sticks to a pool of hard disk drives in the cloud. Compute devices span low-end Raspberry Pis at the edge to high-end virtual machines (VMs).

To achieve reconfigurability and extensibility, Comosum draws inspiration from Software Defined Networks (SDNs) [18]. Here, the data plane spans the hardware and software. The control plane then is the custom configuration process of hardware components and software modules to solve individually unique DA problems (e.g., Case 1-3 in § 2). Borrowing from the object-oriented design paradigm (OOP), the fundamental Comosum unit is the *instance*.

Comosum instance modules operate in an event-driven approach with per-module processes [89]. Independent, message-passing [92] modules have two advantages. First, this enables modules to be deployed anywhere in the distributed cloud. Secondly, it simplifies reasoning about application correctness for multi-threaded modules. For instance, irrigation should be triggered in the actuation module only after a dry forecast is observed in the compute module.

To summarize, each Comosum instance is a configuration of sensor, compute, storage, and actuation modules to map and solve different sets of real-world agricultural challenges. In the following subsections, we describe in depth the extensible Comosum modules, the Comosum distributed cloud architecture and its vendor neutrality goal (§§ 3.3), and the Comosum control plane's reconfiguration capabilities (§§ 3.4).

3.2 Comosum Modules

Telemetry Module. The telemetry module is the entry point into a Comosum instance's data plane. The telemetry module requires that any interested parties (observers) are notified of new sensor readings. To that end, we design the module as an abstract class following the observer design pattern [61]. The interface comprises *register*, *notify*, *read*, and *run* operations. In managing observers, the observer argument is an abstract data type (ADT). Upon being notified, observers receive a message indicating the state change. The message is similarly an ADT, and it is used to receive new updates through an invocation of the telemetry module's *read* method. By using an ADT, the module enables chained updates where downstream modules may serve as observables (other telemetry modules) and observers (any abstraction implementing the observer pattern). In practice, sensor updates are consumed by the analytics module.

Storage Module. The storage module is inspired by the classic UNIX [73] file system interface with simple *read* and *write* operations. To align with another prevalent storage model, the change feed, the module additionally supports

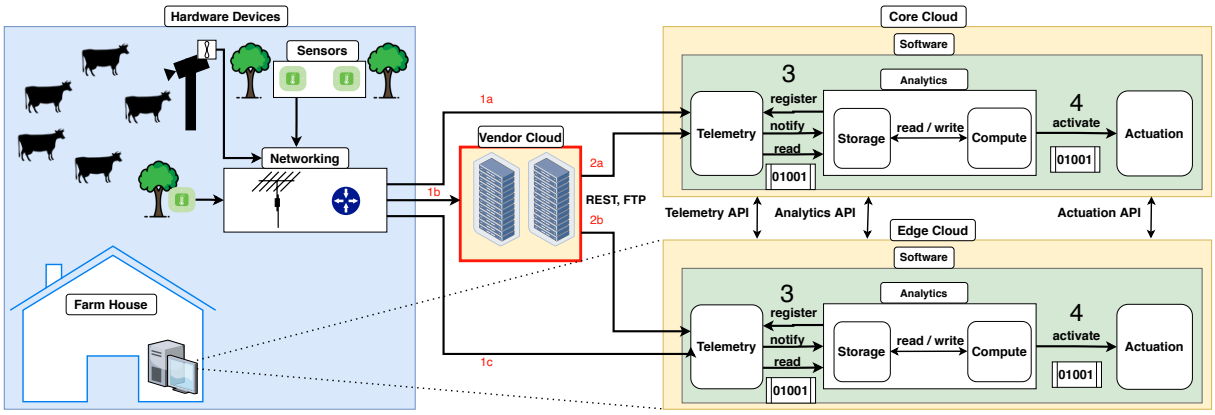

Figure 1: The Comosum distributed cloud partitions modules between the farm ("edge"), remote ("core"), and sensor vendor clouds.

change_feed and *next* methods that operate on iterators of new data (inserts, updates). Besides mimicking UNIX and database semantics, we strive for transparent access of stored objects [76]. In other words, similar to the observer argument in the telemetry module, the path argument in reads and writes is an ADT. This makes the storage module extensible to storage calls of various structures and data formats. Finally, to accommodate modules operating with topic-based storage services, the storage module supports the publish/subscribe paradigm. The pub-sub interface enables other modules to push data in addition to subscribing to updates based on topics of interest. Thus, the storage module exposes *subscribe*, *push*, *pull*, and *notify* operations.

Compute Module. The compute module operates on state changes from the telemetry and storage modules. Therefore, the module similarly follows the observer design paradigm. Acting as an observer, the compute interface supports four operations, namely *notification_sensor_rcv*, *notification_storage_rcv*, *analytics*, and *run*. The first two can be invoked to receive data based on previous compute module registrations and subscriptions to the telemetry and storage modules, respectively. The *analytics* method receives new procedure calls off the wire, and it uses the metadata and data to execute local/remote application logic. Optionally, the compute module invokes the storage module's *write* or *push* methods to store intermediary results.

Actuation Module. The actuation module is the final endpoint in the data plane. Like the sensor module, the actuation module provides an interface to physical operation of and virtual notification to real-world entities. That is, the actuation is either automated or mediated. For automated actuation, devices between the farmhouse and the field issue command messages. In this context, the module issues *activate* calls to the appropriate control devices. The command argument optionally identifies the device to execute the command. Upon an *activate* invocation in a mediated actuation scenario, the actuation module effectively is a wrapper for push notification services such as text messages and email.

3.3 The Comosum Distributed Cloud

The motivating case studies (§ 2) demonstrated that the sources of data consumed by DA applications greatly varies. While the sensor data is mostly generated locally, the initial storage and compute operations are executed on-demand by remote servers which are often owned by the sensor providers. Thus, another challenge for Comosum is achieving *vendor neutrality*. That is, hardware/software innovations must not be tied to a particular cloud-based service vendor.

To that end, we introduce the Comosum distributed cloud abstraction to support elastic, vendor-neutral sensing, storage, compute, and actuation capabilities. The Comosum distributed cloud (Figure 1) consists of the farm (or "edge"), public (or "core"), and private (or "vendor") clouds. The vendor cloud maps the more complex data path where some data must be pulled from sensor vendor servers instead of directly from the sensor abstracted away by Comosum. Unlike the "edge" and "core" clouds, Comosum modules cannot be deployed in the vendor clouds. Further, the Comosum distributed cloud design is similar in motivation to CloneCloud [19]. CloneCloud, which offloads computation from remote devices to the cloud, assumes an always-available, more powerful compute pool in the cloud. In contrast, Comosum enables computation and fault tolerance at the edge (remote device) when the (core) cloud is unavailable or too expensive to use.

While the *edge cloud*, *core cloud* and *vendor cloud* separation meets the resource elasticity and vendor neutrality goals, it also collides with limited bandwidth at farms.

On one hand, the edge cloud provides storage and computation closer to the data source. For applications with ephemeral storage and computation needs, this eliminates core cloud connectivity and latency challenges. Specifically, by leveraging networking advances such as LoRa [8] and TVWS [12], the edge cloud is capable of completely disconnected operation in deployments with large variations in area and granularity. Conversely, the edge cloud is generally unsuitable for storage- and compute-intensive Comosum applications (e.g. §§ 2.2).

On the other hand, the core and vendor clouds offer sig-

Module	Interface Method	In/Out?	Int/Poll?	Description
telemetry	register(observer)	Input	Int	Add sensor update observer
	notify(update)	Output	Int	Notify observers of a new update
	read(update)	Output	Poll	Read latest update
	run()	Input	Int	Run the sensor module
storage	write(path, data)	Input	Int	Write to storage medium
	read(path)	Output	Poll	Read from a storage medium
	change_feed()	Input	Poll	Offer an iterator to new data
	next(iterator)	Output	Poll	Get the next record from an iterator
	subscribe(subscriber, topics)	Input	Int	Register a new subscriber
	push(topic, data)	Input	Int	Publish new updates to storage
	notify(subscriber, data)	Output	Int	Push new updates to subscribers
	pull(topic)	Output	Poll	Pull recent updates, if any
	run()	Input	Int	Run the storage module
compute	notification_sensor_rcv(context)	Input	Int	Receive data from sensor update
	notification_storage_rcv(new_data)	Input	Int	Receive data from storage subscription
	analytics(arg)	Input	Int	Execute application business logic
	run()	Input	Int	Run the compute module
actuation	activate(cmd)	Output	Int	Execute a command on a control device
	run()	Input	Int	Run the actuation module

Table 1: The unified Comosum API is inspired by classic system design approaches (e.g., design patterns [61], UNIX file system [73]).

nificantly more storage and computation capacity, albeit at a higher network latency cost. Therefore, faced with 'reliably unreliable' [42] Internet at remote locales, an application whose progress relies on a consistent connection to the core and vendor clouds is bound to fail. Losing connection to cloud-based time critical decisions risks real consequences for farmers; plants may perish from water stress; cows may die from preventable diseases or difficult births; and vast vineyard swaths may succumb to virus infection.

In summary, the *edge cloud*, *core cloud*, and *vendor cloud* separation meets Comosum's resource elasticity and vendor neutrality goals. Note, however, that it also reveals difficult system trade-offs; for instance, latency in the context grapevine disease detection (§§ 5.3).

3.4 The Comosum Control Plane

An important Comosum goal is that initial design allows for the integration of devices and software modules. This is the guiding principle of the Comosum control plane. The control plane draws inspiration from device drivers, IPC, and SDNs. Comosum leverages a diverse array of networking and storage primitives. These primitives in turn define extensible libraries and configuration templates that accommodate communication between devices and software modules from current and future DA systems.

On the hardware front, sensing devices require wrappers for new serial device drivers or wrappers to existing standard interfaces (e.g., RS485 [69]). Networking devices necessitate new packet processing interfaces. Finally, control devices typically expose wrappers for their PLCs.

On the software and cloud components, the control plane specifies inter-module communication. Due to the distributed nature of Comosum modules, we use message passing [89,92] where modules communicate as follows.

Modules call a dispatcher with a message specifying the peer module to contact. The dispatcher in turn maps message queues to socket connections to the peer modules. In this scheme, the modules remain oblivious to the underlying networking. Further, this simplifies part of the control plane to IP address tuples which can be edited as the underlying network changes. While communication between Comosum modules is sockets-based, any module calls to other systems (e.g sensor vendor clouds) uses whatever higher-level abstraction that the external systems expose (e.g., REST APIs).

As discussed in the overview (§§ 3.1), a key Comosum goal is to easily reconfigure devices and software modules to fit different applications. Therefore, Comosum implementations must remain as close to a set of reusable configuration and compilation templates as possible. Configuration templates include cloud connection strings, sensor SKUs, IP addresses, etc. Compilation templates include Docker files [24], remote procedure call (RPC) definition files, package dependencies, etc. Thus, the hardware and software components are reconfigurable to solve various DA challenges.

4 FarmBIOS: A Comosum Implementation

The particular instantiation of the Comosum architecture presented here is the Farm Basic Input Output System (FarmBIOS), drawing inspiration from its unification of routinely incompatible hardware and software systems. Henceforth, we use FarmBIOS and Comosum interchangeably. FarmBIOS code and research datasets are open source (Appendix A).

We built FarmBIOS in Python, atop Google's protocol buffers (also known as protobufs) [35]. Protobufs provide a language-independent, efficient serialization protocol that allows not only the construction of Comosum modules in numerous languages, but also extensibility of RPC templates to enable integration with arbitrary DA systems. Figure 2 shows the FarmBIOS stack. Next, we briefly describe the most salient components of FarmBIOS instances.

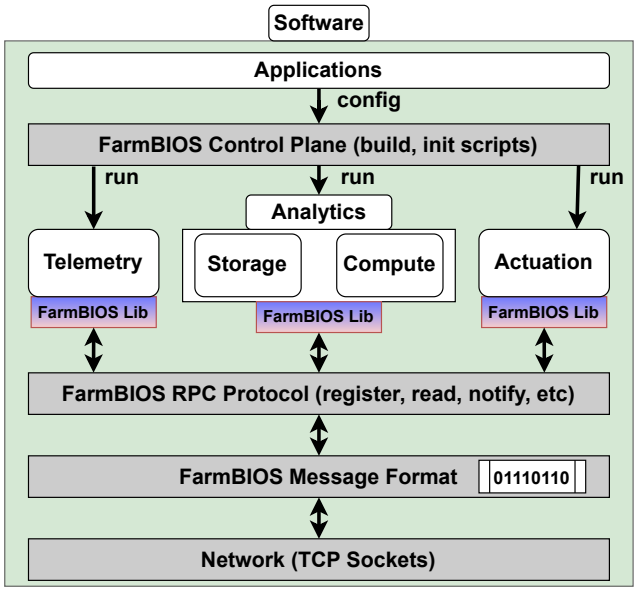

Figure 2: FarmBIOS - an implementation of Comosum

4.1 FarmBIOS Control Plane

At the top of the FarmBIOS stack, applications specify software configurations to the FarmBIOS control plane, which (1) provisions the appropriates edge and core cloud compute and storage resources (e.g., VMs, databases), (2) instantiates the required modules, and (3) builds any required Docker containers. Based on the application specific requirements, the modules are deployed and started in the edge or core cloud. Note, however, that not all modules in the middle layer are required by every application. These à la carte application configurations are at the heart of Comosum's vendor neutrality (e.g., pairing Azure compute and AWS storage).

4.2 FarmBIOS Library

The FarmBIOS library (FarmBIOS Lib) is the implementation of the Comosum module abstraction. That is, the library allows the customization of base telemetry, storage, compute, and actuation module classes to fit the purposes and configurations of different applications. Practically the library deals with challenges related to perpetual deprecation of hardware in the field and software libraries. The FarmBIOS Lib addresses this data processing challenge by providing wrappers to an array of services such as tables, databases, CSV readers, and email clients. In the current implementation, we provide wrappers around the Azure Table [62], Azure CosmosDB SQL [63], Azure Machine Learning Workspace (Azure ML) [64], Twilio [48], and OpenWeather [47] services in addition openpyxl [32] and CSV readers - with more templates to be added as our array of supported applications expands. Therefore, FarmBIOS Lib is a *structured, cloud-independent* application layer.

4.3 FarmBIOS RPC Protocol

FarmBIOS is built in a *network-agnostic* manner. This implementation choice is important for extensibility to arbitrary DA platforms. Specifically, the modules are unaware of differences between local and remote peer modules. By local we mean modules operating within the same host. Local and remote operations entail modules passing and receiving messages to/from their dispatcher. The dispatcher is tasked with routing the procedure call to the appropriate peer module based on the control plane configuration. The RPCs rely on a client-server architecture built on TCP sockets wrapped by a selector operating per-connection queues, and each connection tunnels to a peer module. In both scenarios, any data communication occurs over the common FarmBIOS RPC protocol. Note that the underlying (TCP) communication protocol is known only to the dispatcher, but not the modules. Further, the RPC protocol makes no assumptions on the data formats, thereby maintaining data introspection/formatting flexibility for applications through FarmBIOS Lib.

4.4 FarmBIOS Message Format

The Comosum modules exploit OOP, UNIX, IPC, and other intuitive semantics. In practice, however, the underlying implementations address two major obstacles. First, the number of data formats, which represent technical compatibility negotiations between research farms and sensor providers, are both unwieldy and subject to unexpected changes [23]. Therefore, similar to the Linux file abstraction, Comosum offers a uniform, byte-addressable format for inter-module data communication - the FarmBIOS Message Format. This format is an *unstructured* platform layer. Secondly, host operating systems eventually get upgraded or lose long term support. Comosum achieves independence from the host OS by leveraging application orchestration tools such as Docker [24] and Kubernetes [29].

5 Applications & Deployment Experiences

In this section, we describe the hardware contexts, FarmBIOS usage (§ 4), and deployment contexts of the motivating challenges (§ 2) to showcase Comosum's range of applications. Specifically, the applications are different Comosum configurations that meet the needs of animal farms (§§ 5.1), specialty farms (§§ 5.2), and row crop farms (§§ 5.3).

5.1 CowsOnFitbits

Building on Challenge 1 (§§ 2.1), CowsOnFitbits is a data aggregation component supporting early disease prediction models which achieve 97% training accuracy [59]. The edge

Training	Data Location	Data Size	Compute	Storage	Runtime	Accuracy
Edge	Local	4MB	8 CPUs	256GB	27.1s	84%
Edge	Cloud	-	8 CPUs	256GB	35.6s	86%
Azure ML	Cloud	-	2 vCPUs	100GB	86.5s	86%

Table 2: Grapevine disease detection: model training runtime and accuracy for various WineGuard configurations

cloud is a farm PC (16GB RAM, 500GB storage) running the Windows 10 Enterprise OS. The OS features a Docker engine deployed on its Windows Subsystem for Linux (WSL). The edge is connected to vendor clouds and a university cloud via a 1Gbps Ethernet connection.

CowsOnFitbits leverages FarmBIOS modules (packaged as Linux containers) as follows. Sensor reports are made available by the providers via FTP dumps to the edge cloud. The telemetry module continuously polls the local disk, awaiting the FTP dumps. New reports trigger the telemetry module's *notify* function call which, in turn, notifies its local compute module. The telemetry module's *read* method is called by the compute module. The compute module aggregates sensor data from multiple streams to be stored in the private university cloud, where a module exposes a REST API for data access and queries by ML applications. In the cloud, cows are identifiable across data streams through farm-unique cow ID's. The storage calls are made to an intermediate, non-FarmBIOS module operating a Cassandra database [70].

CowsOnFitbits has been actively tracking approximately 1,500 cows in a commercial farm for nearly three years; having collected 23GB of datasets at the time of writing. The testing/deployment experience with CowsOnFitbits offers two observations. First, the unstructured platform layer (§§ 4.4) is more stable than the structured application layer (§§ 4.2). Specifically, unannounced API/format changes on the vendor side, which routinely occur every few weeks, introduce breaking changes in FarmBIOS Lib. The API breaking changes affected the API to the *vendor-specific* application layer changes (i.e., breaks). FarmBIOS tolerates these API changes by insulating itself with *vendor-independent* layers that use unstructured files to store data from the vendor along with methods that can interpret the unstructured data according to the latest vendor interface definition. The CowsOnFitbits system adapted to a recent change in approximately one day. This required minor application changes and deploying a new Docker container. Subsequent versions may benefit from Kubernetes [29], especially its rollbacks and canary deployments. Second, we observed missing/duplicate data in the core cloud due to mismatched interpretation of floating points in protobufs vs Python, missing vendor reports, unexpected signal interference between RFID tags and electrical engines for manure systems, or farm workers tripping over wires. The floating point issue was resolved through meticulous end-to-end testing of FarmBIOS modules over the course of a year. The missing report and power outage issues remain as open issues, though we propose a potential fix (see § 6, § 7).

5.2 WineGuard

Building on Challenge 2 (§§ 2.2), WineGuard is a data analytics platform for grapevine disease detection; achieving up to 86% training accuracy. WineGuard's sensor data originates from plane flights over California vineyards in September 2020 using NASA's Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) [36]. The spectroscopic sensor data is publicly accessible from the NASA cloud [66]. The AVIRIS data is merged with disease ground truth data from molecular tests on select leaves from the same period. The merged data are uploaded to the Azure Cloud for experimental retrieval.

WineGuard employs FarmBIOS modules as follows. We built a wrapper for Azure ML [64] to kickstart a reconfigurable model training pipeline. Note that the application can similarly be built using equivalent tools from other cloud providers such as Amazon SageMaker [77]. The model training configuration includes Azure subscription ID strings, the name of a pre-provisioned workspace, the location of the training data, and a text file with required Python packages. Upon issuing the compute module's *analytics* command, the configuration is deployed for training.

We deployed the WineGuard training pipeline in an edge cloud and in the Azure Cloud (see Table 2) [2]. This deployment presents several insights. First, the model accuracy is relatively stable regardless of training location, and, as expected, training at the edge with local data incurs the least runtime. Second, there is a 31% runtime overhead when fixing the location at the edge. We observed that this is due to an initial "warm-up" of the training data download from the cloud. In the best case, cloud-based training and inference are instantaneous. Otherwise, during disconnected periods, inference can be done faster and locally at the edge. Third, the satellite coordinate data were occasionally off by a few meters compared to the ground truth disease data. Without requiring manual intervention, analytics on sparse data in near real-time was necessary to correct the errors. In particular, FarmBIOS enabled the rectification of the divergence by selecting only spectroscopic bands with reliable data while still enabling the training/inference to proceed.

5.3 WaterGuard

Building on Challenge 3 (§§ 2.3), WaterGuard is a plant water stress alert system for research farms. WaterGuard is prototyped with research software and hardware provided by

[2]We tried to use a Raspberry Pi 4B (4 CPUs, 32GB storage) as the edge cloud. However, the ARM processor could not execute Docker containers built on an x86-64 architecture (the alternative edge used here) [14]. Building on an armv7 base image also failed due to end of support for distro updates.

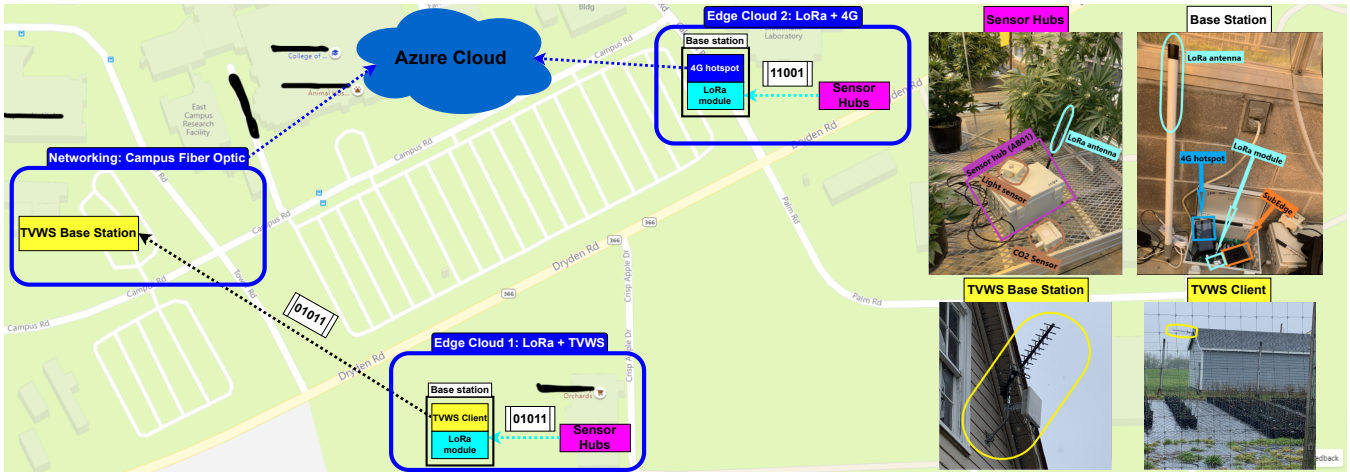

Figure 3: The Comosum hardware repertoire deployed for 18 months. Edge Cloud 1 (active since October 2020) serves an apple orchard water stress study. Edge Cloud 2 (active since March 2021) serves high-throughput corn, hemp, and strawberry breeding experiments.

Microsoft Research [88] (Figure 3). The hardware features sensor hubs from Seeed Studio operating on eight D-size batteries and supporting up to 13 analog and digital sensors. The sensor readings are networked over LoRa [8] to a base station comprised of an edge device, a LoRa module, and LoRa antenna (5dBi, 900MHz). The edge device is a general purpose UpBoard (4GB RAM, 32GB storage) running the Windows 10 IoT Core OS. In addition to the LoRa components, the device is connected to a TVWS Client (6Harmonics Inc), which provides physical and data link connectivity over a single TV channel (18, 497MHz) to a TVWS Base Station (TVBS) located at a research barn approximately a quarter of a mile away. Finally, the TVBS is wired to the university's 1Gbps fiber-optic Internet as a gateway for sensor data to Azure.

WaterGuard relies on FarmBIOS modules as follows. Sensor readings are relayed to Azure. Note that Azure table storage offers no *change feed* for observer notifications. Thus, the telemetry module relies on periodic *reads* (i.e., polling the storage module) to detect inserts that, in turn, should trigger its *notify* method. The analytics unit is notified via a *notification_sensor_rcv* call to the compute module. Next, based on the configuration received from the new update, the compute module *reads* from the shared storage module to get data on the appropriate sensor hub and start the *analytics*. Finally, upon reaching an irrigation decision, the compute module calls *activate* on the actuation module which notifies the researchers over text message using the Twilio API [48].

WaterGuard has been deployed for 18 months in two edge clouds with nine sensor hubs (Figure 3). Each sensor hub averages eight sensors and 223 days of data collection. Together, the hubs have collected over a million sensor readings. The biggest insight from this deployment was the unexpected mundane work required to adapt experimental DA systems ([88]) to new settings where failures can happen anywhere in the sensor-to-cloud continuum (see § 6).

6 Adapting to the Wild

The previous section described the hardware configurations, API usage, and deployment experiences/insights from three FarmBIOS instances. Here, we present the successes and system adaptations necessary for long-term Comosum maintenance. Though the adaptations are specific to WaterGuard, the key idea of *active digital twins* is broadly applicable.

6.1 Offline Data Collection Is Not Enough

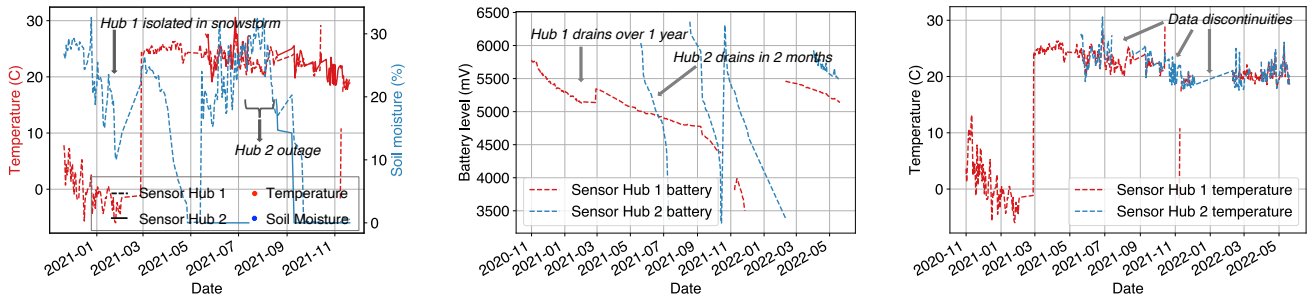
WaterGuard is capable of tolerating days-long network outages by relying on offline data collection and standard hardware redundancy. As shown in 4a, the pilot sensor hub (Sensor Hub 1) achieved disconnected operation during a snow storm and heat wave in February 2021 and May 2021, respectively. Until the 4G hotspot connectivity was restored, the sensor data was simply stored at the edge device.

However, data aggregation and analytics are still affected by faulty sensors and human error. Concretely, faulty CO2 sensors drained the batteries faster than expected (4b) and/or slight misconfigurations place data in incorrect columns. Both faults effectively result in data discontinuities (4c).

6.2 The Fix: Active Digital Twins

To streamline fault detection, Comosum evolved to include reactive monitoring [90]. That is, detecting, escalating, and optionally repairing system faults at different failure scopes. The Comosum design easily lends itself to this task by introducing ***active* digital twins.** A digital twin is a digital representation of a physical object, process, or environment that behaves like its real-world counterpart. In contrast, *active* digital twins combine the traditional digital twin concept with Comosum's actuation design.

The active digital twins were an emergent concept as we iterated over FarmBIOS to make it more fault-tolerant, especially in outdoor research farm deployments where a delayed



(a) Network outages (b) Faulty sensors (c) Data discontinuities

Figure 4: Adapting FarmBIOS to (a) network outages, (b) faulty sensors, and (c) data discontinuities

detection could imply troubleshooting sensor hubs in two feet of hardened snow (Figure 4a, [75]). When the digital twin diverges from its physical twin beyond a reconfigurable margin (e.g., five minutes), an action is taken by the system such as sending notifications to human operators. In Comosum, only the sensor hubs are twinned. We modeled timely data collection, and divergence from the physical system is characterized by missing telemetry over a 30 minute period.

Concretely, we implemented a web-based, reconfigurable notification system with three key functions. The Status page leverages the WaterGuard sensor hubs' digital twins to display their connection state and last activity. The Configuration page provides an interface for retrieving and editing each sensor hub's port configurations. Lastly, the Notifications page provides a reconfigurable set of functions including (1) whether the notification system is **enabled**, (2) an editable **threshold** (in minutes) for triggering outage notifications, (3) an editable **frequency** for outage checks, and (4) the set of **emails** to be notified during outages. Note that the notification system relies on data aggregation and analytics across multiple, separate cloud services (i.e., Azure IoT Hub, Azure Table, AWS Simple Notification Service), and the implementation simply plugs Comosum module implementations of these services with minimal or no change to other modules. Therefore, it is broadly applicable to detect failures at different stages from the sensors at the farm to the modules in the cloud.

7 Practical Insights and Limitations

The motivating challenges (§ 2) highlighted major interoperability issues within state-of-the-art DA platforms (see Table 3 for a summary). We mapped these challenges to three core system design goals: *extensibility*, *reconfigurability*, and *fault tolerance*. We summarize below both persistent and new lessons from our experiences, and, more importantly, how FarmBIOS practically addressed the challenges. We also state the system's current limitations.

- **Extensibility to new DA vendors comes with (minor) costs**: Table 3 details the challenges in DA data aggregation. Our design goal was to provide an *extensible interface* that can generalize across APIs, clouds, hardware, and platforms. FarmBIOS provides a unified interface to merge/analyze/actuate datasets spread across the distributed cloud. For instance, CowsOnFitbits (§§ 5.1) enables the merging of datasets from four different vendors. The tradeoff is that, for each new vendor, a new script (less than 50 lines of code) must be written to move vendor reports to the appropriate directories for FarmBIOS module triggers.

- **The cloud surprisingly complicates reconfigurability**: Table 3 details difficulties in system reconfigurations to support different farm networking and analytics pipelines. Our design goal was to *allow different points in the configuration space* towards data models that can be trained and used across different networking and cloud deployment scenarios. Indeed, we explored numerous hardware/software configuration possibilities (see Appendix B). However, as observed in WineGuard (§§ 5.2), the interface between the cloud and the long-lived deployed systems was not stable. In particular, the Azure ML APIs were subject to parameter deprecations which affect the WineGuard compute configurations. FarmBIOS evolved around these externalities by treating incoming parameters in telemetry and analytics modules as abstract data types. The result is a stable platform that shields users from these volatilities.

- **Failure in DA systems is the norm, not the exception**: Table 3 details the heterogeneity and failure cases that complicate DA system deployments and maintenance. Our design goal was to *detect and/or tolerate intermittent failures* despite the heterogeneity of hardware, farm types, and cloud services. In CowsOnFitbits (§§ 5.1) for instance, we observed missing data due to sensing/networking failures (frequency interference between sensors and manure systems), human factors (tripping over wires), etc. In another instance (WineGuard, (§§ 5.2)), analytics on sparse data is a necessity for deployed DA systems. We demonstrate how FarmBIOS copes with the unreliability of the underlying sys-

Why It Is Hard	System Challenge	Design/Implement Decisions	Supporting Results & Contributions
Data Aggregation	Incompatible platforms	Reuse classic ideas (§§ 3.1, §§ 3.2)	Unified platform API (§ 5)
	Incompatible formats	Byte-addressable payloads (§§ 4.4)	Extensible libraries (§§ 4.2)
	Distributed data	Mask data path/sources (§§ 3.3)	Merged across clouds (§§ 5.1)
	Host dependence	Containerization (§§ 4.4)	Cross-architecture transfer (§§ 5.1)
		RPC dispatcher (§§ 4.3)	Cross-platform transfer (§§ 5.1)
Data Analytics	Manual processing	Comosum design (§ 3)	Automated processing (§§ 5.2)
	Unreproducible models	Reconfig. models (§§ 3.3, §§ 3.4)	Distributed training (§§ 5.2)
	Data sparsity	Active digital twins (§§ 6.2)	Divergence detection (§§ 5.2)
	Slow actuation	Comosum design (§ 3)	Sub-minute inference (§§ 5.2)
Fault tolerance	Faulty sensors	Standard hardware redundancy (§§ 6.1)	18-month deployment (§§ 5.3)
		Active digital twins (§§ 6.2)	Reconfig. notification system (§§ 6.2)
	Network outages	Reconfig. control plane (§§ 3.4)	Reconfig. networks (§§ 5.2, Appendix B)
		Edge analytics design (§§ 3.3)	Edge inference (§§ 5.2)
		Offline data collection (§§ 3.3)	Tolerate 7-day outage (§§ 6.1)
	Complexity/heterogeneity	Modularity (§§ 3.2)	Comosum design (§ 3)

Table 3: A summary mapping of systems challenges to Comosum design decisions and their supporting results

tems through the broadly applicable idea of *active digital twins*. In the case of frequency interference, for example, the RFID sensors could be twinned. In the vineyard context, the error message indicating mismatch between ground truth and satellite data could be used as input for a digital twin model.

- **FarmBIOS evolution and limitations**: As emphasized above, failure is the rule and not the exception. FarmBIOS was designed to tolerate failure, and as stated in §§ 2.3, plant and livestock depend on a robust system. Therefore, the system was improved over time. For instance, the active digital twin implementation relied on the telemetry module abstraction to increase fault tolerance. One limitation is the *lack of support for automated movement of computations between the edge and core clouds during permanent power/network outages*. Recall, however, that the edge side of the architecture is, in fact, capable of operating autonomously, at a minimum to retrieve and store sensor data (§§ 5.3) and, if so configured, perform local computation (§§ 5.2). We leave this limitation for future endeavors.

8 Related work

8.1 Programming Frameworks

To streamline application development and partitioning for resource-constrained environments, recent community efforts leverage the cloud for mobile and IoT applications. By rewriting application executables, the CloneCloud [19] architecture intelligently partitions program portions for dynamic execution between mobile devices and their cloud twins. The partitioner identifies expensive application portions through static and dynamic code analysis that informs an optimizer to solve the execution partitioning challenge. Along with EdgeProg [55] and like CloneCloud, the TinyLink [26,39] systems form a set of cloud-native, generative systems of hardware configurations and software executables for IoT applications. TinyLink and EdgeProg expose high-level APIs and If-This-Then-That (IFTTT) languages to abstract away the low-level knowledge for developers, respectively.

In line with the prior work, Comosum exposes high-level APIs for interfacing with IoT platforms without deep knowledge of the underlying networking and hardware. Unlike CloneCloud, Comosum partitions applications at the module level, not the instruction level. Departing from EdgeProg's use of IFTTT and TinyLink's exclusive support of application development in C-like languages, Comosum supports module development with any language compatible with the (de)-serialization protocol shared by the modules.

8.2 Agricultural Sensor Networks

The rise of low-cost IoT sensor networks has led to an explosion of new communication standards and protocols being ported to industrial and consumer applications. For example, like WaterGuard, Gutiérrez *et al.* [40], Ahmad *et al.* [6], and Vasisht *et al.* [88] showcase the application of GPRS, XBEE, and TVWS technologies to agricultural monitoring systems, respectively. Further, Ayoub *et al.* [11] and Jawad *et al.* [50] present detailed overviews of both power-hungry (e.g., WiFi, Bluetooth, etc.) and low power wide area network (LPWAN) technologies (e.g., LoRa, NB-IoT, etc.) and their recent applications to, among others, dairy health care, automation, and greenhouse monitoring. Comosum demystifies these novel networking technologies' potential and limitations to interdisciplinary audiences interested in similar applications.

Besides IoT networking standards, the literature identifies open challenges in IoT networking, hardware, and software (co)design. The most salient include extensibility [82], durability [13], reliability [37,82], modularity [82], scalability [37], energy efficiency [39,82,88], and interoperability

among heterogeneous devices [82]. The Comosum design addresses extensibility, durability, reliability, modularity, configurability, and interoperability. Further, scalability is indirectly addressed through decoupling and thin APIs that allows independent evolution of the software modules and the underlying networking hardware, protocols, and devices.

Perhaps closest to our agricultural application of edge computing is Taneja *et al.*'s SmartHerd management system [85]. Like SmartHerd, Comosum co-opts a microservice approach, wherein the sensing, compute, storage, and actuation modules can seamlessly be placed in bandwidth rich as well as constrained environments. Further in line with SmartHerd, Comosum easily aggregates data from incompatible sensor vendors' private web servers to avoid vendor lock-in. Still, § 5 shows FarmBIOS's extensibility beyond dairy applications.

8.3 IoT Architecture Abstractions

Sisinni *et al.* [82] define a *reference IoT architecture* as a "higher level of abstraction description that helps identify issues and challenges for different application scenarios". This definition reflects the three years of exploration that resulted in the Comosum architecture. Previous architectural approaches identify sensing or perception [10, 25, 51, 91], physical [56], interface [91], networking [10, 25, 51, 91], transport [56], middleware [56], and service or application [10, 25, 51, 56, 91] layers as essential to an IoT application.

Although the architectures fundamentally serve applications with different business and technical needs, their essential layers are modules in the Comosum design. Thus, the benefit of Comosum is its partition of the physical *hardware* from the *software* that manipulates the networked data. That is, the *software*, by acting as a collection of byte-passing modules, is extensible because it is agnostic to the evolution, intricacies, protocols, or any other factors of the hardware.

9 Conclusion

In this paper, we present Comosum, a system software architecture to support digital agriculture (DA) applications in research and commercial farms. The architecture comprises *hardware*, *software*, and *distributed cloud* abstractions to build *extensible*, *reconfigurable*, and *fault-tolerant* sensor networks for farms. By supporting diverse DA applications in multiple clouds, we show that FarmBIOS, a Comosum implementation, meets these design goals. Eighteen months of Comosum instance deployments and adaptations reveal new insights on fault-tolerant sensor networks for DA. We introduce *active* digital twins to streamline fault detection, escalation, and optional repair from sensors to cloud-based modules. In ensuring that systems approaches employed in urban research farms readily map to rural farm realities, a thorough analysis highlights practical insights, limitations, and trade-offs (see Appendix) that are unique to DA applications as a starting point for community discussions of DA's potential contributions to networked system design and implementation beyond the current state-of-the-art.

A Artifact Appendix

Abstract

The artifact documents our deployment experience and open-source efforts to build a **Software-Defined Farm** (or **SDF**) [75], also known as the **Comosum** or **FarmBIOS** system in the present paper. Comosum is intended to provide an extensible, reconfigurable, and fault-tolerant platform for IoT data collection, processing, and actuation. On one hand, the paper covers the architecture (Comosum), the implementation (FarmBIOS), and our deployment experiences over 18 months. On the other hand, the artifact provides a standalone Docker image and a pointer to the open-source code that, together, can be used to demonstrate the instantiation of the telemetry, analytics, and actuation concepts. In particular, the artifact demonstrates the repeatability of these ideas through three applications: CowsOnFitbits, WineGuard, and WaterGuard.

Scope

In addition to inspecting the code and research datasets, the artifact can be used as a starting point for extending the FarmBIOS/Comosum platform with new cloud services and sensor vendors. The current release of the artifact is intended to validate the listed claims about the applications:

- The CowsOnFitbits application (§§ 5.1) can use the Comosum sensor module (aka telemetry module) and compute modules to aggregate data from **three** (anonymous) IoT vendors and **six** data sources.
- The WineGuard application (§§ 5.2) can use can use the Comosum compute module abstraction to train machine learning models and perform local inference with at least 75% accuracy in approximately 30 seconds.
- The WaterGuard application (§§ 5.3) demonstrates the potential of *active digital twins* in increasing the platform's fault-tolerance to failures in the path from the sensors to the cloud.

Contents

The artifact includes a Docker image named *comosum-atc-artifact-eval* and a zipped archive of the code base built from the usenix-atc23-artifact-eval branch and the b313d7e commit in the SDF GitHub repository.

Hosting

The artifact is hosted on the publicly-funded archival platform Zenodo under this unique DOI.

Requirements

- The Docker image was primarily built and tested on an X86-based system (Windows 10 Education OS, Version 22H2, OS Build 19045.2846 with WSL 2 installed to emulate a Linux-like environment, and Docker Desktop Version 20.10.10). Therefore, the image should be loadable on most Unix-like environments with Docker installed.
- In addition to the primary development environment listed above, we reproduced the results on a X86-based system (Ubuntu Linux OS 22.04.1, Docker Version 23.0.6) and an arm64-based Macbook Pro (macOS Ventura 13.3, Docker Version 23.0.5)
- Although we have successfully reproduced the results on a Mac with an Apple Silicon (M2) chip, we cannot guarantee reproducibility if the evaluation is conducted on macOS, especially the M chips which are known to have issues with Docker Desktop filesystem change notifications and port mapping/forward issues. The Comosum system extensively relies on change notifications and port forwarding.

B Understanding the Trade-offs

This section presents an exploration of network configurations for Comosum applications with two goals in mind. First, we showcase Comosum's potential reconfigurability from a 55-acre urban farm to a 615-acre rural farm. Secondly, we offer a way for interdisciplinary DA researchers to quickly establish their networking needs by assessing three factors: expected application payload frequencies (§§ B.1), network availability and throughput in urban versus rural locations (§§ B.2), and desired system latency (§§ B.3). The key observation is that the DA context has the potential for new lessons and challenges to well-established networking, storage, and application management assumptions. The Comosum experiences serve a crucial starting point for the community conversation.

Application	Payload	Frequency	LoRa (SF:12)	DSL	Satellite	4G LTE	TVWS (1x6)	TVWS (4x6)	Fiber-optic
WaterGuard	65B	6 min	0.44 sec	5.20e-4 sec	1.73e-4 sec	9.60e-5 sec	5.20e-5 sec	2.80e-6 sec	5.20e-7 sec
WineGuard	4MB	Daily	7.60 hr	32.00 sec	10.67 sec	5.93 sec	3.20 sec	0.17 sec	0.03 sec
CowsOnFitbits	17MB	Daily	1.39 days	2.30 min	45.87 sec	25.48 sec	13.76 sec	0.74 sec	0.14 sec

Table 4: Estimated cloud backup time for FarmBIOS applications under various network bottleneck scenarios.

B.1 Application Data Rates

Table 5 illustrates the significant range of data generation rates for the three Comosum applications; from a few bytes every six minutes to hundreds of MBs weekly. The WaterGuard total is based on a sensor hub deployment with seven sensors (see §§ 5.3). The WineGuard dataset is based on spectrometer values from a 500m*300m vineyard field. The CowsOnFitbits total is an estimation based on data from four sensor providers tracking approximately 1,500 cows on a commercial farm. The CowsOnFitbits sensor data generation varies from every 10 minutes to once daily.

Application	Payload	Frequency
WaterGuard	65B	6 minutes
WineGuard	4MB	Daily
CowsOnFitbits	17MB	Varies

Table 5: FarmBIOS application data rates and formats.

B.2 Achievable Network Throughputs

We consider five networking media for data transfers at a farm, namely LoRa, DSL, Satellite, 4G LTE, and TVWS. Table 6 shows the achievable data transfer rates for the different media. The LoRa settings reflect current settings from the WaterGuard sensor hubs.
The DSL throughput is included because DSL holds the largest footprint in rural housing units' Internet access [30]. The TVWS settings reflect observed throughputs in the literature [31], measured TV channel occupations (as of Sept. 2020) at a campus research farm and a more rural farm 25 miles away, and tower height-based channel availability estimations [21] for the two farms. Based on their GPS coordinates, the campus farm offers only separate, single channels while the more remote farm offers four contiguous channels.

Medium	Throughput	Internet?	Deployed?
LoRa (SF:12)	1.17 kbps	No	**Yes**
DSL	1 Mbps [30]	Yes	No
Satellite	3 Mbps [16]	Yes	No
4G LTE	5.4 Mbps [74]	Yes	**Yes**
TVWS (1x6MHz)	10 Mbps [31]	No	**Yes**
TVWS (4x6MHz)	186 Mbps [31]	No	No
Fiber-optic	1Gbps	Yes	**Yes**

Table 6: Rural uplink throughputs. SF = Spreading Factor.

B.3 Cloud Backup Bottleneck Analysis

The Comosum distributed cloud affords elastic compute and storage power. Practically, we transfer data not only to leverage more abundant compute resources for compute-intensive tasks in the cloud, but also to store the datasets for future retrospective analysis. Assuming each networking media (whether routing in the field or at the gateway) as an unreliable bottleneck in the data transfer, we compare the networking media/latency trade-offs in uploading each application's data.
Table 4 illustrates the expected latencies of different media for a given application. For instance, while a fiber-optic link in an urban farm would transmit CowsOnFitbits' 17MB of data in less than a second, the most popular Internet service in rural locations (DSL) would require three minutes. In another instance, while a research farm with one TVWS channel would route the data within 14 seconds at the edge, the four channels in the rural farm would transmit the same dataset in sub-second time.
In sum, by comparing urban and rural settings, this analysis shows the nuanced networking and storage strategies for DA applications in a distributed cloud setting. This motivates future research avenues in Comosum application migrations either as the network fails or edge resources deplete.

Oakestra: A Lightweight Hierarchical Orchestration Framework for Edge Computing

Abstract

Edge computing seeks to enable applications with strict latency requirements by utilizing resources deployed in diverse, dynamic, and possibly constrained environments closer to the users. Existing state-of-the-art orchestration frameworks (e.g. Kubernetes) perform poorly at the edge since they were designed for reliable, low latency, high bandwidth cloud environments. We present Oakestra, a hierarchical, lightweight, flexible, and scalable orchestration framework for edge computing. Through its novel federated three-tier resource management, delegated task scheduling, and semantic overlay networking, Oakestra can flexibly consolidate multiple infrastructure providers and support applications over dynamic variations at the edge. Our comprehensive evaluation against the state-of-the-art demonstrates the significant benefits of Oakestra as it achieves approximately tenfold reduction in resource usage through reduced management overhead and 10% application performance improvement due to lightweight operation over constrained hardware.

1 Introduction

Within almost a decade since its inception, edge computing has found a wide range of use cases in industry and research, especially for supporting latency-critical services like AR/VR [24], live video analytics [14], etc. [46]. However, despite significant interest, there have only been a handful of real-world demonstrations of edge so far [49]. Reasons for this are manifold and may include, on the technical side, the following. Firstly, resources at the edge are far less capable and more heterogeneous than datacenters [61] – usually of smaller form factor with specialized hardware, e.g., Intel NUCs [36], Coral AI board [20]), Jetson Xavier [50], Raspberry Pis, etc. Many such devices are designed to be deployed in proximity to the users utilizing unreliable (wireless) networks with limited bandwidth and high latency as primary communication mediums [64]. Moreover, the benefits of edge [47,68] are only apparent with the dense availability of computing resources – requiring significant investment and planning [21,46].

Secondly, the majority of popularly used orchestration frameworks, e.g., Kubernetes [34], K3s [29], KubeFed [35], etc., are off-shoot branches of solutions that were inherently designed to perform well in managed datacenter networks. Such frameworks make strong assumptions about the underlying infrastructure's (especially the network's) consistent reliability and reachability, which does not necessarily hold at the edge where resources are more dispersed. For example, recent investigations into Kubernetes' operations uncovered that its reliance on maintaining strong consistency in the datastore via etcd along with its limited scalability results in severe availability and efficiency issues in edge-like environments [37]. Moreover, the core components of such frameworks incorporate many heavyweight operations – limiting their use on constrained hardware. Furthermore, almost none of the existing solutions can currently support the edge's heterogeneity in hardware, networking, and resource availability.

In this work, we present Oakestra, a flexible, hierarchical orchestration framework that overcomes the many challenges just mentioned. Conceptually, Oakestra allows multiple operators over vast geographical regions to contribute their resources to a federated infrastructure – reducing the investment to achieve a dense computing fabric at the edge. Furthermore, Oakestra's implementation is lightweight and extensible, allowing it to manage effectively constrained and heterogeneous edge infrastructures. Specifically, our contributions are:

(1) We consolidate edge infrastructures in a logical three-tier *hierarchy*. With a root orchestrator managing many resource clusters, each controlled by a cluster orchestrator, we enable infrastructure federation. The cluster orchestrator exercises *local* fine-grained control but only sends aggregated cluster usage statistics to the root (§3). By design, Oakestra hides the internal infrastructure details within each cluster, allowing many providers to participate without exposing internal configurations. Application providers can deploy services at the edge by specifying high-level constraints (hardware, latency, geography) at the root. Oakestra uses a *delegated scheduling mechanism* that decouples the task placement by only making coarse-grained cluster choices at the root and

leaving fine-grained resource placement to the clusters.

(2) We design a novel semantic overlay network that transparently enables edge-oriented load balancing policies (e.g., connect to the closest instance), directly addressable using semantically-capable IPv4 addresses and hostnames (§3.4). This supports the portability of cloud-native applications, ensuring flexibility for application developers to optimize the service-to-service interactions at the edge. The overlay also allows `Oakestra` to dynamically adjust communication endpoints in response to infrastructure changes, e.g., migrations, failures, etc., ensuring uninterrupted service interactions.

(3) `Oakestra`'s lightweight and modular implementation is compatible with most popular cloud technologies and allows developers to extend internal components, e.g., schedulers, without much development overhead (§5). Our extensive evaluation in both high-performance computing and edge infrastructures demonstrates `Oakestra`'s capabilities as it consistently (and significantly) outperforms the popular production frameworks (e.g., Kubernetes and its derivatives). Our results show up to 10× lower CPU overhead, 60% reduction in service deployment time, and 10% application performance improvement. Under heavy loads, `Oakestra` reduces resource utilization by ≈ 20% compared to its closest competitor, K3s. `Oakestra` is an open-source project (`https://www.oakestra.io/`), and all its components are available at `https://github.com/oakestra`.

2 Background and Related Work

Kubernetes [34] has emerged as the most popular orchestration system in production, used by ≈ 59% of all respondents in a recent survey [23], and has been touted by many as the primary solution for edge computing. It decouples the execution runtime of the applications (*nodes*) from the global cluster decisions (control plane). Its smallest deployable units of computing are the Pods, which are a group of containerized services. The *nodes* embed the execution runtime of the pods, as well as the networking e monitoring components of the platform. The *control plane* exposes the APIs for developers and external tools, monitors and synchronizes the nodes, and reacts to cluster events, such as deployments, scaling, and failures. Kubernetes is designed for datacenter environments, and it assumes the nodes to be high-end managed resources interconnected by reliable low-latency networks. The platform guarantees strong consistency of the cluster status and resources in replicated control plane setup via the distributed key-value store called etcd. Recent studies have found that the strong consistency requirements of `etcd` are its primary limitation when ported to heterogeneous and diverse edge infrastructures. This has a noticeable impact on scalability when it comes to constrained resources that can slow down the entire infrastructure [37]. Network partitioning and multi-clustering still remain critical even in Kubernetes federation [35] as shown in [45]. In particular, distributed geographical areas lack cooperation and awareness of the remaining infrastructure. The inter-cluster communication then requires additional tools like Submariner [9] that requires global state transfer synchronization and prevents scalability. Lightweight distributions of Kubernetes such as KubeEdge [19], K3s [29], and Microk8s [43] either inherit the strong assumptions of kubernetes [15] or are meant to perform better on small scale clusters as later shown in our evaluation. In general, while extending Kubernetes or rearchitecting its components is a viable option, we argue that the effort for largely redesigning numerous of the core components would be substantial and instead re-formulate some of its base assumptions. Therefore, `Oakestra` pursues a different approach, built ground-up with the edge requirements in mind, it offers a familiar environment for current Kubernetes developers while providing flexibility to exploit the proximity to their clients and geo-distributed multi-owner infrastructure deployment. `Oakestra` does not aim at superseding the feature set of Kubernetes but rather fills the gap identified in those contexts where Kubernetes does not fit. Our ongoing work explores the integration of Kubernetes-based cloud clusters.

In the literature, we can also find other systems that have explored effective edge orchestration natively. CloudPath [48] envisions multi-tier on-path computing for deploying stateless functions closer to the clients. HeteroEdge [69] or SpanEdge [58] cater specifically towards streaming applications, FogLamp [65] focuses on data management and VirtualEdge [42] only considers edge servers within cellular networks. From the task scheduling perspective, we might relate to different hierarchical scheduler approaches that distribute tasks on a cloud-edge continuum [12, 18, 28, 38]. However, while these solutions focus on service scheduling, in our work, we must integrate the scheduling problem in a comprehensive orchestration framework offering both service and resource management. The work closest to ours is OneEdge [60], as it offers a hybrid two-tier control plane for managing geo-distributed edge infrastructures. However, we consider `Oakestra` to be a superset of OneEdge as the former is a general-purpose modular framework that allows developers to express geographic (and other) management constraints as scheduler *plugins*. We demonstrate such extensibility of `Oakestra` through an LDP scheduler plugin (§3.2) that optimizes on geographical and latency constraints – similar to OneEdge. Therefore, integration remains a possibility which we leave out for future work.

3 `Oakestra` Overview

Previous research has shown that both service deployment and resource management in distributed edge infrastructures are non-trivial problems, primarily due to the heterogeneity and dynamicity of the environment [16, 41, 66]. Simultaneously, the application providers are likely to deploy multiple

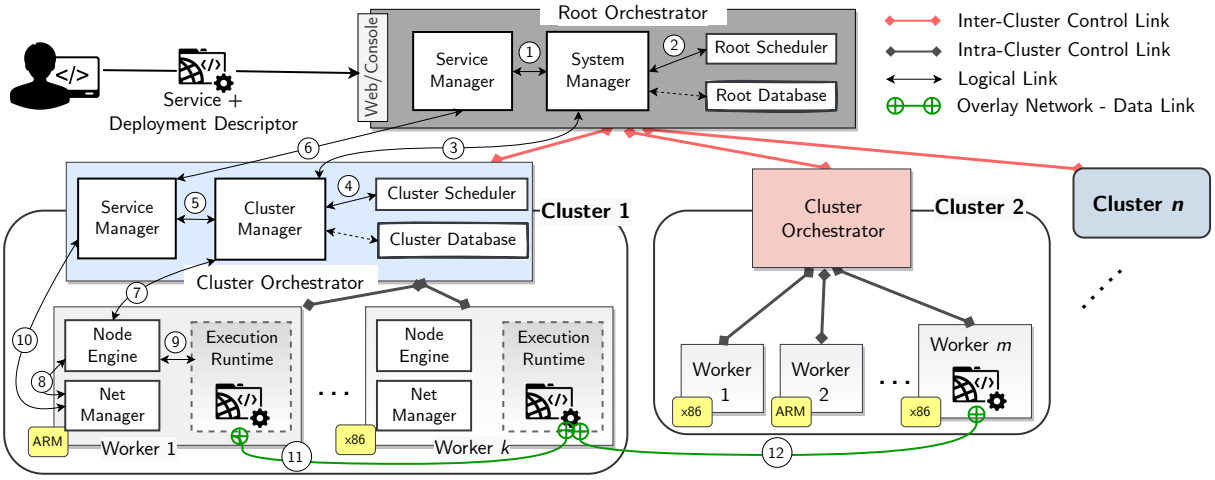

Figure 1: Oakestra Architecture and Workflow.

instances of their services across different edge clusters to have them close to their clients, both in terms of geographic distance and network latency [59]. Additionally, solutions at the edge must remain logically compatible with prevalent cloud techniques such that both existing and novel applications can coexist in edge and cloud realms, thereby providing scalability and flexibility. These and other unique operational viewpoints at the edge impose several design challenges for Oakestra, which we enlist below.

(1) Oakestra must support the infrastructure-at-scale – allowing scaling from thousands to millions of distributed nodes without management overheads. The framework should support a federated heterogeneous infrastructure deployed across geography and controlled by one or more administrative entities and topologies. Furthermore, the framework should allow (a) developers to utilize edge resources regardless of ownership and (b) infrastructure providers to retain management control over their resources.

(2) Extending the infrastructure to the edge of the network requires applications to be able to exploit the proximity with clients. The platform must envision a way for inter-connected microservices to seamlessly communicate and balance the traffic with nearby instances. Therefore, the framework must allow developers to describe the application's requirements with fine-grained SLA primitives (such as specialized hardware requirements, geographical placement, etc.), which must be respected throughout the application lifecycle.

(3) The orchestrator must consider the most up-to-date constraints of edge servers and must adapt to changes in conditions without impacting the applications. Each edge device can contribute with diversified hypervisors, drivers, hardware availability, network, and capacity. The system must abstract the management complexity and autonomously find a compatible node for the deployment issued by the developer.

3.1 System Architecture

Oakestra is a hierarchical orchestration framework for enabling running edge computing applications on heterogeneous resources (Figure 1). Instead of the flat management (inherent to most orchestration solutions [10, 19, 29, 31, 35]), Oakestra organizes the infrastructure into distinct *clusters* (see clusters 1 and 2). We leave the definition of "cluster" purposefully abstract and up to the liking of operators since Oakestra allows multiple edge operators (e.g., ISPs, cloud operators, etc.) to contribute their local deployments towards a shared infrastructure as separate clusters with independent administrative control. Each individual provider then deploys several clusters to segregate its resources, e.g., geographically. The fine-grained control of resources (*workers*) within a cluster is administered by the *cluster orchestrator* (operated by the provider), while *root orchestrator* coarsely controls the global infrastructure. Oakestra can also mimic the single master frameworks (like Kubernetes) with both root and cluster orchestrators deployed on the same machine, albeit with significant performance benefits to the state-of-the-art (§5). The resource and service management responsibilities are separated into independent components, `system manager` and `service manager` (§3.2). We carefully design and implement Oakestra as a modular and extensible framework – allowing the possibility to swap technologies and/or add new features as the requirements of edge computing evolve in the future (§5). Oakestra comprises of three main entities – *root orchestrator*, *cluster orchestrator*, and *worker*.

The **Root Orchestrator** is Oakestra's centralized control plane (analogous to Kubernetes's "control-plane" [10]) and is responsible for managing resource clusters. However, as we explain in §3.2, the root only provides (i) coarse high-level control and (ii) interactions across multiple clusters, as fine-grained control is retained within the cluster boundary. Regardless, we envision the root to be deployed on a machine

reachable from all clusters (in a widescale deployment, e.g., in the cloud). While the root orchestrator may appear to be a central point-of-failure initially, the context separation into fine- and coarse-grained management responsibilities across hierarchy allows Oakestra to continue its operations if the root fails and restarts (see *Fault Tolerance in §3.5)*.

To deploy applications, developers submit the code along with an SLA descriptor to the system manager. The SLA includes high-level operational requirements and constraints for service execution at the edge, e.g., virtualization, required hardware, geolocation, etc. (see §3.2). The system manager notifies the service manager of the new deployment request (step ①), and contacts the root scheduler (step ②) to calculate a priority list of clusters (based on aggregate information) to deploy the application. As such, Oakestra follows a multi-step *delegated service scheduling* approach as the root offloads the fine-grained scheduling operation to selected clusters schedulers (details in §3.2). The system manager is also responsible for registering new clusters and coordinating the control information.

The **Cluster Orchestrator** is a logical twin of the root but with management responsibility restricted to resources within the local cluster. An infrastructure provider registering its resources as a cluster with the root assigns the orchestrator role to a machine that is ideally reachable by all workers. The cluster manager periodically updates the root with *aggregated* statistics of overall cluster utilization and health/QoS of the deployed services (step ⑤, and ⑥) via HTTPS-based *inter-cluster control link* in a *push-based* manner (implementation details in §5). Note that the cluster orchestrator withholds minute information and retains majority administrative control of its member workers. For example, if the cluster orchestrator receives a delegated scheduling request from the root (step ③ and ④), it calculates the optimal resource selection considering the up-to-date availability, utilization, and capability reported by the attached workers. The Oakestra scheduler is designed to be modular and supports several different scheduling algorithms as language-agnostic *plugins*.

Worker Nodes are edge servers in clusters responsible for executing services. Each worker has a distinct capacity and capability, e.g., CPU, GPU, disk, RAM, etc., which it reports to the local cluster orchestrator at registration. If a worker's capacity and capability match the service's SLA constraints, the cluster orchestrator instructs the worker's NodeEngine to deploy the service ⑦, triggering a runtime (and network) instantiation ⑧ and service execution ⑨. Each worker periodically reports its utilization, health of operational services, and (potential) SLA default alarms to its cluster orchestrator via an MQTT-based *intra-cluster control link*. Note that for interconnecting microservices deployed across clusters, Oakestra does not require workers to have public IP addresses as the net manager natively supports both direct ⑪ and tunneled ⑫ communication (see §3.4 for details).

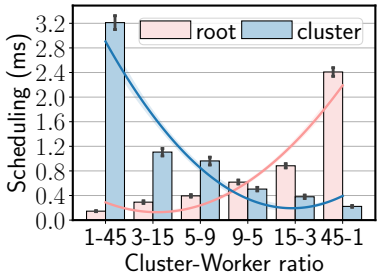

Figure 2: Scheduling time for different cluster sizes.

Why hierarchical orchestration? To understand if a hierarchical management design is inherently better for scalability at the edge, We created an experimental setup with 45 worker node VMs in a compute cluster and configured the orchestration with increasingly different cluster sizes. Starting from a single cluster with 45 nodes, we gradually increased the number of clusters up to 45 with only one worker. For each split, we performed 100 deployments and recorded the time the root and cluster scheduler took for the scheduling decision (see fig. 2). Note that the corner cases of the configuration, i.e., one cluster with 45 workers ($1-45$) and 45 clusters with one worker each ($45-1$), represent the flat orchestration design used in majority state-of-the-art, e.g., in Kubernetes-based solutions. The results indicate that decoupled orchestration reduces scheduling time, primarily since the infrastructure search space is a smaller subset. Optimal performance is achieved when the workers are somewhat balanced across multiple clusters in the hierarchy, and the minimum is around nine clusters with five workers. It is apparent (from the $3-15$ split) that using a two-layer hierarchy can be advantageous, especially for wide-scale infrastructure.

3.2 Resource and Service Management

Resource Management. As discussed in §3.1, edge resources in Oakestra are deployed in distinct clusters, with $R^i = \{R^i_1, R^i_2, \ldots, R^i_n, R^i_{CO}\}$ resources in the ith cluster. Here, R^i_{CO} is the cluster orchestrator of i-th cluster. Each resource R^i_n periodically *pushes* its current utilization (U^i_n) and other characteristics (e.g. location) to R^i_{CO} with update frequency $\lambda(R^i_n)$ over the intra-cluster communication channel. At each update, R^i_{CO} calculates the available capacity of R^i_n by correlating U^i_n to the maximum capacity C^i_n reported at registration. $\lambda(R^i_n)$ can be dynamically tuned for each R^i_n to balance between network overhead and the freshness of the information. We leave the exploration and impact of $\lambda(R^i_n)$ algorithms and the use of techniques such as AoI [62] to future work. Similar to intra-cluster, the update messages over inter-cluster links are also push-based. Each cluster orchestrator periodically sends the aggregate distribution of *available* current capacity, i.e. $\cup(A^i) = \langle \sum(A^i), \mu(A^i), \sigma(A^i) \rangle$ where $A^i = \{A^i_1, A^i_2, \ldots, A^i_n\}$ to the root. The aggregation allows different operators to (i)

Schema 1: Service Requirement Descriptor.

participate in the federated infrastructure while obscuring the minute details of their resources and (ii) freely scale up/down their cluster density without involving the root.

Service Deployment & Scheduling. Developers can deploy their (standalone or multi-microservice) applications by specifying high-level QoS requirements within the SLA description. The deployment descriptor used for submitting applications to `Oakestra` is composed of (i) a description of each microservice of the application (name, namespace, image, etc.) along with communication interlinks, and (ii) a service level agreement (SLA) describing the constraints that the platform must respect for each one of them. Schema 1 shows a fragment of the high-level SLA description supported by our framework. In addition to operational requirements already prevalent in cloud environments, such as processing performance, networking requirements, virtualization needs, etc., the schema allows developers to specify edge-specific restrictions, e.g., geographical location, specialized hardware, etc. Additionally, developers can fine-tune the precision of scheduling heuristics by enforcing *convergence time* and *decision rigidness* metrics. Convergence time specifies the maximum allowed time within which the scheduler should find the suitable edge server that supports the SLA requirements of the service, and rigidness defines the sensitivity for re-triggering service scheduling in case the selected resource violates the SLA (due to environment/infrastructure changes).

As described earlier, `Oakestra` follows a two-step *delegated scheduling* mechanism. Specifically, upon receiving a service deployment request from the developer, the `root scheduler` matches the SLA constraints to the current capacity of each cluster and calculates a priority list of best-fit clusters based on the latest aggregate cluster usage distribution. The root then offloads the deployment request (including SLA and the service) iteratively to cluster orchestrator(s) with decreasing priority. Upon receiving the request, the `cluster scheduler` calculates the optimal service placement within its cluster, leveraging the available schedulers (see §3.2.1). Note that we design `Oakestra`'s scheduling logic to be *language-agnostic* – allowing developers/researchers to implement custom algorithms as *plugins*.

Algorithm 1: Resource-Only Match

Input: A_n : Information about worker n.
$Q_{\tau_{p,i}}$: Requirements of i-th task of p-th service.
$f(A_n, Q_{\tau_{p,i}})$: Resource selection strategy.
Output: Best worker W to run $\tau_{p,i}$.

// Resource selection strategy examples:
// $f(A_n, Q_{\tau_{p,i}}) = *arg\,max_n \big[(A_n^{cpu} - Q_{\tau_{p,i}}^{cpu}) + (A_n^{mem} - Q_{\tau_{p,i}}^{mem})$
// $\wedge\, Q_{\tau_{p,i}}^{virt} \in A_n^{virt}\big]$
// $f(A_n, Q_{\tau_{p,i}}) = *first_n \big[Q_{\tau_{p,i}}^{cpu} \le A_n^{cpu} \wedge Q_{\tau_{p,i}}^{mem} \le A_n^{mem}$
// $\wedge\, Q_{\tau_{p,i}}^{virt} \in A_n^{virt}\big]$
1 $W \leftarrow f(A_n, Q_{\tau_{p,i}})$
2 **return** W

`Oakestra`'s delegated scheduling significantly reduces the search space of the multi-objective task placement problem by considering a subset of resources at each step. In case all microservices of an application cannot be placed within the same cluster, the root scheduler iteratively requests other clusters in the priority list for pending deployment(s). The worker `node engine` also keeps track of the deployed services through their lifecycle (see §3.3). In case of *failures* (resource – if the last update from a worker exceeds a threshold; service – if a worker raises an alarm), the cluster orchestrator marks all affected services as failed and attempts to re-deploy them on another suitable resource within the same cluster. If unsuccessful, the rescheduling request is propagated to the root for system-wide scheduling. Similarly, the cluster orchestrator can trigger *re-deployments* if it observes any SLA violations (exceeding specified rigidity).

3.2.1 Service Schedulers in `Oakestra`

Let $S = \{s_1, s_2, \ldots, s_{|S|}\}$ denote the set of services requested to be deployed by the developers at the root. Each service $s_p \in S$ can be composed of n individual microservices or *tasks*, i.e. $s_p = \{\tau_{p,1}, \tau_{p,2}, \ldots, \tau_{p,n}\}$ where $\tau_{p,i}$ denotes i-th task of p-th service. Each task $\tau_{p,i}$ requires a certain capacity (CPU, GPU, memory), denoted by $Q_{\tau_{p,i}}$. Other considerations like geographical location or virtualization technology, specified by the developer in the SLA, are also part of $Q_{\tau_{p,i}}$. The task of the scheduling components (in both root and cluster) is to find a suitable resource in the infrastructure that supports the requirements in $Q_{\tau_{p,i}}$. In this work, we propose and incorporate two different scheduling approaches.

(1) Resource-Only Match (ROM): As the name suggests, in ROM, the cluster scheduler finds a suitable resource that satisfies the service's capacity requirements (see Algorithm 1). The scheduling approach is analogous to greedy-fit and knapsack-based solutions popularly used for placing VMs on cloud servers in datacenters [63].

(2) Latency & Distance Aware Placement (LDP): LDP (shown in Algorithm 2) builds on the ROM scheduler but additionally considers latency and geographical distance con-

Algorithm 2: Latency & Distance Aware Placement

Input: A_n : Information about worker n.
$Q_{\tau_{p,i}}$: Requirements of i-th task of p-th service.
Output: Best workers W to run $\tau_{p,i}$.

$W \leftarrow \{n \in [1,|A|] \,|\, A_n^{cpu} \geq Q_{\tau_{p,i}}^{cpu} \wedge A_n^{mem} \geq Q_{\tau_{p,i}}^{mem} \wedge Q_{\tau_{p,i}}^{virt} \in A_n^{virt}\}$
if $|Q_{\tau_{p,i}}^{s2s}| \geq 1$ **then**
  for Q_j *in* $Q_{\tau_{p,i}}^{s2s}$ **do**
    $t \leftarrow Q_j^{trg}$
    $W \leftarrow \{n \in W \,|\, dist_{gc}(A_n^{geo}, A_t^{geo}) \leq Q_j^{geo\_thr} \wedge dist_{euc}(A_n^{viv}, A_t^{viv}) \leq Q_j^{viv\_thr}\}$
  end
end
if $|Q_{\tau_{p,i}}^{s2u}| \geq 1$ **then**
  for Q_k *in* $Q_{\tau_{p,i}}^{s2u}$ **do**
    $u \leftarrow Q_k^{lat\_trg}$
    $rtts \leftarrow \{rtt_{i,u} \,|\, i \in rnd(W), rtt_{i,u} = ping(i,u)\}$
    $vivaldiNet \leftarrow \{A_n^{viv} \,|\, n \in [1,|A|]\}$
    $U \leftarrow trilateration(rtts, vivaldiNet)$
    $W \leftarrow \{n \in W \,|\, dist_{gc}(A_n^{geo}, Q_k^{geo\_trg}) \leq Q_k^{geo\_thr} \wedge dist_{euc}(A_n^{viv}, U) \leq Q_k^{lat\_thr}\}$
  end
end
return W

straints for service placement. Since edge applications can be composed of multiple microservices that can either interact with each other (in a chain-like fashion) or directly with end users/devices, we allow the application provider to specify constraints for both service-to-service (S2S) and service-to-user (S2U) links. The root scheduler first filters unsuitable clusters by comparing their resource constraints along with approximate geographical operation zones to the SLA requirements. Within each cluster, the algorithm first creates a list of candidate workers that satisfy the resource constraints. Then, for all S2S constraints $Q_{\tau_{p,i}}^{s2s}$, the algorithm filters out workers that exceed the specified distance $Q_j^{geo\_thr}$ and latency thresholds $Q_j^{viv\_thr}$ to the target service $t = Q_j^{trg}$. LDP estimates geographic distance as the great circle distance ($dist_{gc}$) between the geographic location of worker n (A_n^{geo}) and the location of the target service A_t^{geo}. The approximated latency is the Euclidean distance ($dist_{euc}$) between the location of worker n (A_n^{viv}) and the location of the target service A_t^{viv} in the Vivaldi network [25]. Vivaldi is a network coordinate system embedding networked nodes into a d-dimensional coordinate system such that the Euclidean distance of two nodes approximates their round-trip time. If the developer has specified any S2U constraints $Q_{\tau_{p,i}}^{s2u}$, LDP measures the round-trip times ($rtts$) to the target as $Q_k^{lat\_trg}$ from a set of random workers in the cluster ($i \in rnd(W)$). The measurements approximate the user's position within the Vivaldi network via trilateration. Following that, LDP filters out workers that exceed the distance threshold $Q_k^{geo\_thr}$ to $Q_k^{geo\_trg}$ or the latency threshold $Q_k^{lat\_thr}$ to the approximated user position U.

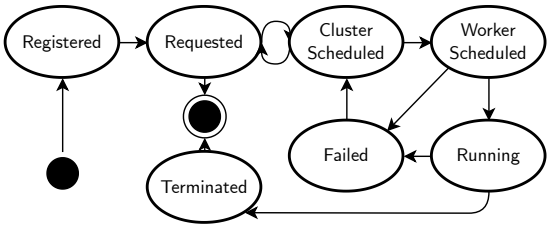

Figure 3: Lifecycle of a service's instance.

3.3 Application Lifecycle

In `Oakestra` an application is composed of multiple services. Each service, in turn, is composed of multiple instances. `Oakestra` keeps track of the instances deployed in the platform through a lifecycle state machine (fig. 3). At any point in time, an instance can have one of the following states.

`Registered`: The developer has submitted an application and its SLA (shown in fig. 1). The service manager in the root saved the service SLA and generated the instance metadata.

`Requested`: After receiving the deployment command, the instance is sent to the root scheduler, and the system manager awaits a suitable cluster. When there is no cluster able to guarantee the SLA, the deployment cannot be carried out.

`Cluster Scheduled`: The root scheduler designated a suitable cluster. The instance SLA is sent to the corresponding cluster orchestrator. The cluster orchestrator is now waiting for the cluster's scheduler decision. If no worker node is capable of hosting the instance, the request is sent back to the root in `Requested` status.

`Worker Scheduled`: The cluster scheduler finds a suitable worker node. The instance binaries (or image download details) are fetched from the root and transferred to the selected worker node while the ports for networking are allocated.

`Running`: The instance is operational as it satisfies the SLA constraints. The worker periodically tracks the current QoS and relays it to the cluster orchestrator along with current utilization in periodic *heartbeat* update messages.

`Terminated`: The service is no longer operational due to an explicit `terminate` command from the cluster orchestrator (issued by the developer at the root). Alternatively, the service gracefully finishes its execution and terminates.

`Failed`: The service execution has stopped with unexpected exit status. A service "fails" if the worker node explicitly reports this state to the cluster orchestrator as a failure alarm or if the node fails. A resource is considered "failed" if it has not sent a *heartbeat* for longer than a pre-defined threshold.

3.4 Service Communication

Supporting intra-service (and service-to-user) networking at the edge can be challenging since (i) infrastructures are susceptible to dynamic changes, (ii) application deployment is

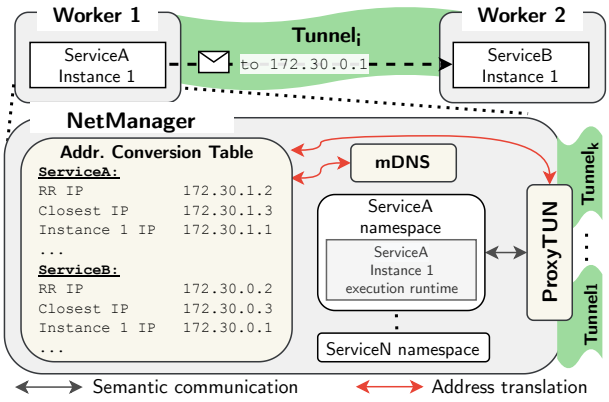

Figure 4: Service communication across edge servers.

fluid to remain close to clients [67], and (iii) several service instances can coexist simultaneously to achieve broader coverage, therefore addressing and balancing must dynamically adapt to the service placement. Moreover, it is impractical to presume that edge servers from multiple participating infrastructure operators can interact over a common/public network – an assumption implicit in the majority of existing solutions [29, 34, 43]. `Oakestra` includes a component called `NetManager` that enables: (a) dynamic routing policies transparently enforced via semantic service addressing to support load balancing catering to edge environments (§3.4.1) and (b) transport layer packet tunneling to interconnect services operating on resources with limited accessibility (§3.4.2).

`Oakestra` separates the bulk of data-plane complexity from the control-plane operations at the worker level. Particularly, the framework utilizes the branches in the multi-tier edge hierarchy only for core control-plane information propagation (e.g., routing updates, service/hardware utilization, and failures, etc.) and designates data-plane communication management to leaf workers using the `NetManager` component. Figure 4 shows the cross-section of `NetManager` with communication between services A and B deployed on workers 1 and 2, respectively. The `proxyTUN` actively maintains and dynamically adjusts endpoints of the tunneled connections to adapt to infrastructure changes, ensuring uninterrupted communication between services. Arguably, the proposed approach resembles some sidecar proxy solutions like Istio [3]. While the set of proposed functionalities might be similar, the `NetManager` does not need to deploy a sidecar along with each deployed application. While the design of solutions like Istio fits the abundance of resources in the cloud context, we propose a lightweight approach with a worker-level proxy used by all the applications, like the native Kubernetes network but featuring additional balancing flexibility and site-to-site tunneling out-of-the-box.

3.4.1 Service Naming and Addressing

Drawing inspiration from semantic routing [39], a `serviceIP` addresses all the instances of the service according to different balancing policies (e.g. *round-robin*, *closest*, etc.). For example, in fig. 4, worker 1 maintains the ServiceA's `closest` and `round-robin` `serviceIP`s – allowing services to select balanced instances through IP addresses. Note that the serviceIP is different from the host IP address as the former is ephemeral and addresses service instances (similar to ClusterIP in Kubernetes [34]). When receiving a packet to an address belonging to the load-balanced `serviceIP`, the `ProxyTUN` uses the conversion table to get the corresponding `Instance IP`. If no conversion entry is found, the `NetManager` registers an interest in that route and enquires the cluster component (see (10) in fig. 1). If the cluster orchestrator does not contain the information, the interest registration is propagated to the root. The root either knows the service route or the service does not exist at all, and no route can be propagated. The interest registration also allows the worker to receive future updates regarding the route. When a route is not used, the conversion entry is erased, and the interest is deregistered.

If properly configured, services can use DNS-based naming schemes which resolve to a *serviceIP* using a **mDNS** [57]. We envision a service naming schema that reflects the hierarchy `<instance_number>.<routing_policy>.<service_name>.<service_namespace>.<app_name>.<app_namespace>`. The `app name` and `namespace` portion of the domain is provided by the developer to uniquely address the application (e.g. videoAnalytics.org). The `service name` and `namespace` address different microservices in the application (e.g. ServiceA.default, ServiceB.default, etc.) while the `instance` number uniquely distinguishes individual service replicas. In case the developer does not care about connecting to a specific instance of the service, `<instance_number>` can be set to "any". The unique aspect of the proposed service naming is the `routing_policy`, as it allows developers to offload connection endpoint selection to `Oakestra` based on the current deployment state. For example, the "closest" policy resolves to serviceIP address representing the nearest service instance while "round-robin" balances connection load across multiple instances. Following the example of fig. 4, suppose *ServiceA* must send a request to the closest instance of *ServiceB*. The request can either be addressed using the semantic IPv4 address representing the *closest* routing policy, therefore `172.30.0.3`, or the name `any.closest.ServiceB.default.videoAnalytics.org`. The *ProxyTUN* component will convert the given semantic address to and *instance address* that represents the chosen instance accordingly to the balancing policy. It will then proceed tunneling the packet towards the destination.

The reachability of the services managed by `Oakestra` from external users can be achieved with standard DNS and API getaway solutions. For future extensions of this work, we are investigating techniques that can support client mobility and dynamicity of the endpoints for first-mile computation and fast handovers. In fact, traditional cloud solutions in edge contexts lead to frequent DNS resolutions and a lack of sup-

port for the discovery of services in close user proximity.

3.4.2 Connection proxying and tunneling

Oakestra enables inter-service communication across workers in different clusters with limited available ports (e.g. behind firewalls) through UDP tunneling. We can again refer to the example shown in fig. 4, where *ServiceA* on *worker 1* needs to communicate with *ServiceB* on *worker 2*. Every packet sent from *ServiceA* to *ServiceB* is handled by the **proxyTun** attached to a virtual bridge in worker 1. The *proxyTUN* component resolves the serviceIP of the destination *ServiceB*, selecting the *Instance IP* accordingly to the balancing policy enforced. If no resolution entry is found, the worker node subscribes to the updates regarding this route to the cluster orchestrator. The resolution entries for a service include a list of the available service instances, their respective IP addresses assigned from each local worker's subnetwork (Instance IPs), and each one of the destination worker's address and port that should be used for the tunneling. The tunneling is performed at L4 using UDP. The L4 implementation allows to transparently support all transport protocols (TCP/UDP/QUIC) out of the box. The only requirement in order to support nodes behind NATs and firewalls is to provide a port for the site-to-site tunneling. An open tunnel (i, j) connecting node i to node j for performance reasons is recycled for all the traffic of all the services communicating with instances belonging to those workers. Therefore, each node only has one ingress tunnel and k egress tunnels, one for each of the workers it's currently exchanging traffic with. To support router configurations without any open incoming ports we envision, in the future, allowing service's connections to transit via the cluster orchestrator. In this case, the *service manager* acts as a VPN server that tunnels the traffic between worker nodes.

If the *NetManager* cannot forward a message (e.g., due to out-of-date information), the route is immediately deleted, and a route refresh is performed. This mechanism avoids imposing a strong consistency requirement on the worker's caches. While this approach might miss the best balancing option when a route update is still propagating asynchronously, it reduces the synchronization effort and, thus, overhead.

We note that by assigning the majority of networking complexity to the worker node, Oakestra dramatically reduces the overhead of orchestration machines. The *service manager* sends only the most relevant routes for each service (according to an internal worker-wise priority list) to increase the scalability and avoid further congestion on the workers. The inherent decentralized networking design of Oakestra is also tolerant towards infrastructure failures. For instance, coupled microservices will continue to communicate with each other even if the cluster (and root) orchestrator becomes unavailable – as long as the host worker node is operational and the endpoints do not migrate (to a different cluster).

3.5 Fault Tolerance.

We now explore the different possible failure cases and how Oakestra manages them. While Oakestra decouples the two-tier *master-worker* orchestration design, prevalent in popular frameworks, in a hierarchical three-tier infrastructure, it is still dependent on the *root*, which may appear as a central point of failure. In case the *root orchestrator* fails, the platform is unable to register new applications as well as schedule new instances to new clusters. Applications that are already part of a cluster can locally replicate, scale, and migrate. The networking is partially affected by root failure since existing tunnels and communication will continue to work, but new inter-cluster links require the root network component for the setup process. Each cluster's aggregated information cannot be propagated, but it will be stored until the root is back online. Since the root is likely to be deployed in the cloud to maximize reachability, it is less frequently affected by failures due to hardware issues. Moreover, in such contexts, traditional redundancy and failover mechanisms can potentially be implemented with redundant replicas, synchronized key-value stores, and L7 load balancing to properly route the cluster's traffic to the active root instance.

A *cluster orchestrator* failure does not affect other clusters' activities. As soon as a cluster stops responding, the root marks the applications deployed within that cluster as failed and attempts to replicate the existing workload to new suitable clusters. The worker nodes will not be able to update their status on the failed cluster orchestrator, but the applications will remain operational. The root will then schedule new backup application replicas in the remaining clusters, and the network routes will reactively change toward the newly managed instances. *Worker node* failures may be frequent and expected at the edge; for this reason, the workloads deployed on a failed node are immediately rescheduled. The network automatically adjusts and balances the traffic to the active instances disregarding the unreachable ones. The cluster orchestrator discontinues aggregating failed node's resources from the cluster's pool in further updates.

In addition to the current fault tolerance strategies and assumptions, in future extensions, we envision having multiple replicas of the orchestrator components that coarsely stay in sync with the primary (similar to the multi-master setup in Kubernetes) and/or a leader election strategy to react to control plane failures. Moreover, we intend to explore the orchestration problem in contexts where byzantine behaviors can be expected at both worker and cluster levels.

4 Implementation

We implement Oakestra and its components (fig. 1) with constraints of heterogeneous edge infrastructures in mind. The implementation, spanning 18000 LOC, is modular, extensible, lightweight and open-source [52]. As we show later,

Oakestra can support production-ready applications at the edge much more effectively than the state-of-the-art.

Root and cluster orchestrators are implemented using Python in a similar structure owing to their architectural similarities. The schedulers, system/cluster manager and service manager are implemented as independent micro-services. The database is implemented as two separate instances of mongoDB [5], one for the service manager and one for the system/-cluster manager. The implementation does not force strong consistency in cluster's or root's data structures. They update asynchronously, improving the overall system's scalability – at the cost of occasionally dealing with application rescheduling. The scheduler microservice uses a celery task queue [1] to pull the incoming tasks and find the best placement asynchronously. Scheduling policies are described in Python but are designed to be language-agnostic. The system and cluster managers communicate with the database services and the service manager via REST APIs. The external root APIs for the infrastructure providers and application developers are implemented according to the Open API Specification [7] and authenticated using JWT tokens [4]. Inter-cluster links are RESTful APIs as well while the intra-cluster control links are implemented using MQTT. With a Mosquitto broker [6] hosted at each cluster orchestrator, a worker can subscribe to network routes updates, and publish internal resource consumption and task status. We also provide an Angular web-based frontend attached to the root that can be used by the developers to facilitate (i) creation of applications and describing the services graphically, (ii) monitor each service instance's status and position (fig. 13b), and (iii) scale the services up and down (see Appendix A).

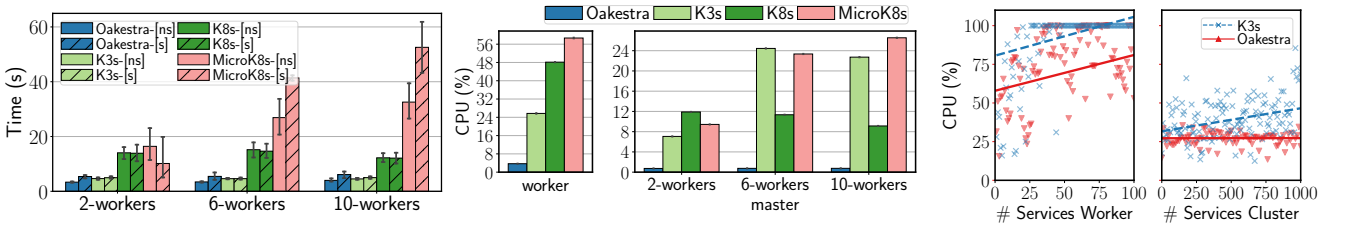
The NodeEngine component as well as the NetManager are implemented as independent services using GoLang to ensure low footprint and maximum support to many execution run-times SDKs. The container's execution runtime is supported with the integration of containerd [2]. Unikernel [40, 44] support is currently under development with QEMU [8] virtualization. The runtime selector is designed to be extended to support even more virtualization technologies in the future, e.g. microVM [11]. The NetManager component uses native Linux virtual network interfaces to create a bridge connected via veth pairs with the TUN interface (namely proxyTUN) and the service's network namespace. The *NetManager* minimizes system context changes and makes extensive use of Goroutines pools to resolve the incoming traffic with high parallelism. The semantic addresses are reserved from a pre-defined 10.30.0.0/16 sub-network. The traffic belonging to the semantic sub-network is forwarded to *proxyTUN*.

5 Evaluation

This section focuses on evaluating Oakestra as compared to the state-of-the-art on edge infrastructures and constrained devices. We use two different testbeds for our evaluation. The *High-Performance Computing (HPC)* testbed is a large, controlled, x86 processor-based cluster, in which we use *S*, *M*, *L*, *XL* VMs with <1,1>, <2,2>, <4,4> and <8,8> <CPU core,RAM (GB)> configurations, respectively. We use this cluster to flexibly spawn resources and emulate a heterogeneous infrastructure. Our *Heterogeneous (HET)* testbed is a local cluster composed of Raspberry Pis [33], Intel NUCs [36], mini-desktops, and Jetson Xavier [50] – representing different edge computing flavors [68]. The HPC cluster is interconnected by 1 Gbps Ethernet, while HET machines connect over Wi-Fi 802.11ac and 1 Gbps Ethernet links. We attempted to compare Oakestra against popular orchestration frameworks. However, despite careful management, KubeFed [35], KubeEdge [19], ioFog [31] and Fog05 [30] experience frequent failures, possibly because they are (i) in early development stages or (ii) not optimized for constrained hardware. Moreover, we could not locate OneEdge's source code [60], which is the only framework architecturally similar to Oakestra. As a result, we compare Oakestra against Kubernetes (K8s) [34] and its two lightweight derivatives, MicroK8s [43] and K3s [29]. All selected frameworks are widely used and have been considered for use with the edge [15, 37]. We use two application workloads, (i) an Nginx web server allowing us to control the operational load dynamically, and (ii) a video analytics application from [13]. The latter is composed of four microservices. The *source* sends a pre-recorded RTP stream [17], *aggregation* stitches and pre-processes each frame, *detection* uses YOLOv3 to detect objects, and *tracking* tracks objects across frames. To remain comparable with the "kube" frameworks, we operate Oakestra in standalone mode, i.e., all workers are deployed within the same cluster. We perform 10 runs for each experiment and clean intermediary files between runs.

5.1 Service Deployment

Figure 5a compares the time taken by each framework to deploy a containerized application on the infrastructure. For this experiment, we configure an *XL* VM as root, an *L* VM as cluster orchestrator in Oakestra (and master for others), and *S* VMs as workers. Oakestra uses the ROM scheduler, which is comparable to the default scheduling policy of the competitors [32]. We increase the cluster size from 2 to 10 workers and measure scheduling overheads by toggling its operation, shown with *s* (with scheduler) and *ns* (no scheduler). MicroK8s performs significantly worse ($\approx 10\times$ slower) than Oakestra, degrading further with increasing infrastructure size. As also noticed in [15], microK8s might easily lead to higher resource usage and generally slower performance. We attribute it to (i) *snap*, which brings extra virtualization overhead, and (ii) microk8s being optimized for single-node deployments. Kubernetes is 2–3$\times$ slower than Oakestra. Its scheduling operation adds almost negligible overhead – this



(a) Deployment time

(b) CPU utilization

Figure 5: Performance comparison for different infrastructure sizes.

Figure 6: CPU usage of worker & cluster orch. in stress (line=median).

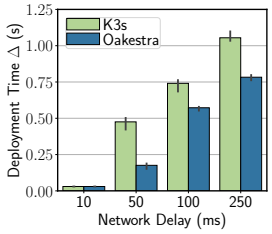


Figure 7: Deployment time with network delay.

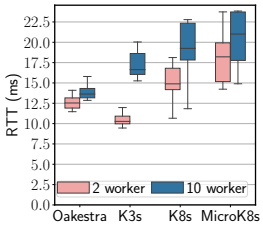

Figure 8: End-to-end latency

result is in line with other recent explorations [15]. One of the reasons why K3s has been generally considered lightweight is its single binary executable that also reduces the internal overhead and synchronization time. This approach, used by `Oakestra` as well, resulted in a comparable deployment time.

Repeating the experiment in our HET testbed, we introduced increasing networking delay using `tc` on the network interface to highlight the overhead due to master-worker synchronization. In fig. 7, we observe that `Oakestra`'s deployment times improve over K3s by a $\approx 20\%$ margin in high delay networks (common for wireless last-mile [22,26,46]). The behavior is similar for lossy networks as `Oakestra` achieved $\approx 50\%$ and 60% deployment time reduction with 20% and 50% losses, respectively (not shown for brevity). The eventual consistent store of `Oakestra` allows the platform to asynchronously manage the deployment with reduced network traffic. As shown later in §5.5, "kube" orchestrators send $\approx 2\times$ more control messages (from both worker and master) on average – hinting at the cause of their degradation to aggravating network conditions. Experiments on the HET cluster typically yielded better results than those on HPC. This is because a more powerful (yet still limited) Raspberry Pi 4 was used as the target device in HET, as opposed to the size *S* worker nodes utilized in HPC.

5.2 Scalability

First, we analyze the idle resource consumption of each framework to estimate the baseline overhead. Lower overhead at the worker indicates a platform's capability to operate on constrained devices. In comparison, lower overhead at the master (at different infrastructure sizes) highlights its ability to handle scale (fig. 5b). We observe that within the chosen competitors, K8s is the one that better handles cluster scalability at the masters, showing no noticeable increase in CPU usage. Meanwhile, K3s and MicroK8s masters show a lower average CPU usage than k8s in two-worker setup but much worse degradation in 6 and 10 workers clusters. At the worker level, k3s is almost 50% faster than K8s. MicroK8s exhibits, again, a higher footprint. We attribute this to the same motivations expressed in §5.1. Due to its asynchronous pub-sub communication and its cluster resource aggregation mechanism, `Oakestra` achieves $\approx 6\times$ and $11\times$ reduction in CPU on the workers and master, respectively. Particularly, an `Oakestra` worker only maintains an MQTT connection to the cluster's broker to periodically report the device resource usage. The orchestrator, subscribed to worker resource topics, only updates the internal database with the latest worker utilization information. Compared to k8s, `Oakestra` maintains a considerably reduced duty cycle while idling.

Since K3s comes closest to `Oakestra` at the worker's level, we perform a stress test comparing both for increasing service deployments. Figure 6 compares the CPU consumption as we increasingly schedule up to 100 Nginx containers on each worker in a 10 node cluster (totaling 1000 containers in the cluster). The left and the right half show the worker and cluster orchestrator (or K3s master) utilization, respectively. `Oakestra` sees negligible overhead performing $\approx$ 10–20% better than K3s – demonstrating its efficacy to support large service volumes. `Oakestra`'s average cluster CPU usage increases by less than 1% during the experiment since each node piggybacks the service status onto the internal resource consumption updates, lowering network usage and processing cycles at the orchestrator. Similarly, `Oakestra` shows significant operational advantages for constrained worker nodes. While K3s exhausted the worker's CPU at $\approx$ 40 services, `Oakestra` deployed the 100 services with a 30% average CPU surplus. Memory utilization showed a similar trend as `Oakestra` achieved $\approx$ 18% and $\approx$ 33% reduction to K3s in worker and master, respectively (not shown).

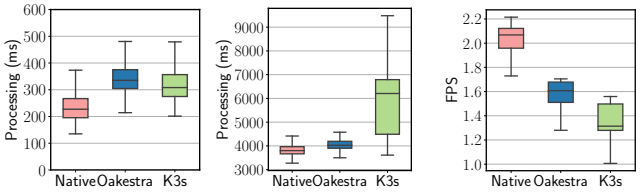
5.3 Networking

We evaluate the round-robin balancing policy of the networking scheme presented in §3.4 against the native balanced *cluster IP* of K3s, K8s, and MicroK8s. First, in a 2-worker setup, we deploy a Python client on the first worker and an Nginx server on the second worker. We then scale the number of workers to 10 and deploy one client and 9 Nginx servers, one on each worker node. The client performs continuous GET requests using a round robin *service IP* on `Oakestra` and a *cluster IP* on the *kube* family with a statically configured round robin policy. Figure 8 shows the average round-trip latency between the client and the closest server. On average, K3s performs better in a 1-to-1 (2 workers) setting (10–20% improvement), while Kubernetes and MicroK8s perform 17% and 30% slower. All competitors' load balancing is significantly worse than `Oakestra` in multiple replica settings, resulting in ≈ 15 up to 35% RTT inflation. The results show the benefits and overhead of the proposed addressing scheme. `Oakestra` performs proxying and site-to-site tunneling for every packet, even in a simple setup with just one client and one server, slightly increasing the overhead even in LAN setups, like the experiment above. On the other hand, this abstraction brings benefits when scaling up the system, introducing minimal additional overhead while balancing with more replicas and outperforming the other systems. In the future, we plan to optimize the 1-to-1 scenario by temporarily disabling the proxy and utilizing VXLAN-based solutions for nodes belonging to the same network.

We evaluated the impact of `Oakestra`'s tunneling on the bandwidth. While the proposed network component is mainly designed to implement semantic addressing, it can also tunnel the traffic between nodes on different networks. For this reason, we test the impact on the bandwidth by comparing it with `WireGuard` [27] – an open-source tunneling solution used by most frameworks. We emulate the network inconsistencies at the edge [46] by gradually increasing the delay between the client and the servers from 10 to 250 ms. Figure 12 compares the time to download a 100 MB file over HTTP using both approaches. We find that, even in high-delay networks, `Oakestra` is always within the competitive range (2-10%) of `WireGuard`. We consider this a promising result given that the proposed networking component performs proxying on top of the "simple" tunneling operations of WireGuard.

5.4 Scheduler Performance

This section shows a preliminary evaluation of ROM and LDP schedulers. Figure 10 depicts both schedulers' performance in a simulated infrastructure with up to 500 edge servers (virtually configured in HPC). We use network latencies between edge servers within 10–250 ms, a typical latency range between users and datacenters globally [21]. We instruct the schedulers (via the SLA) to find workers that satisfy 1 CPU, 100 MB memory, ≈ 20 ms latency (usual for immersive edge applications [46]), and 120 km operational distance. Since ROM only performs a best-fit match for computational requirements, its calculation time does not increase significantly while increasing the number of workers. LDP's calculation time grows increasingly with infrastructure size. However, LDP can effectively support latency-based constraints since it usually satisfies the RTT thresholds even in large edge infrastructures, which implies that the search space increases with the number of nodes. We leave a detailed comparison of different scheduling algorithms to future work as their performance is not the focal point of this paper.



(a) Tracking (b) Detection (c) FPS

Figure 9: Video analytics application performance.

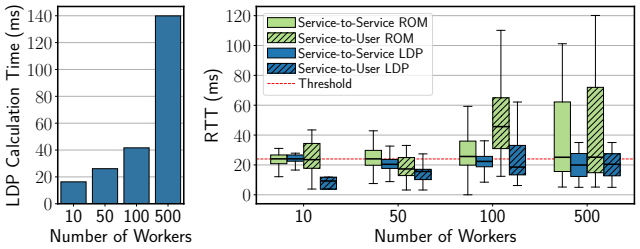


Figure 10: Performance of ROM and LDP schedulers.

5.5 Control Communication Overhead

Figure 11 shows a comparison between the number of exchanged control messages of `Oakestra` and K3s. First, we compare the K3s master and `Oakestra`'s cluster orchestrator for an apples-to-apples comparison. Then, we compare the control messages exchanged at the worker level. We record the network messages using the `strace`. Since K3s is a derivative of Kubernetes, they both use similar control communication. Both `Oakestra` and K3s workers send periodic updates to the master and receive control commands in return. However, the number of control messages ingress/egress on K3s far exceeds `Oakestra` (≈ 2×). These results help explain the observations presented in fig. 7. Moreover, a larger amount of control traffic also influences the time needed to synchronize the infrastructure and perform a deployment. Specifically, the master of "kube" based frameworks sends frequent messages to the workers, including specification of the pods to be attached to the workers, liveness checks, etc., requiring

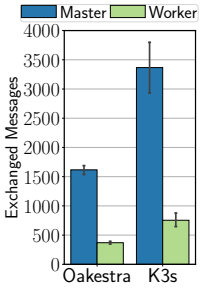

Figure 11: Control message overhead.

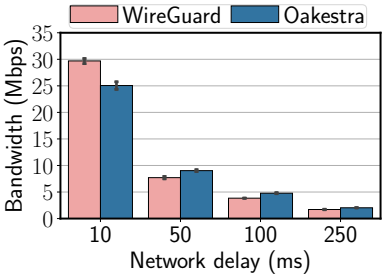

Figure 12: Oakestra vs. WireGuard tunneling overhead.

information/acknowledgment in return. The control communication of Oakestra, on the other hand, is simplified to send periodical aggregated service information from the worker over MQTT messages and keep a minimal footprint. It must be considered that Oakestra still does not provide the guarantees of a production-ready platform. Increasing the monitoring capacity and the update frequency will result in an increase of control traffic. We, therefore, plan on improving the control message communication channel in the future by dynamically tuning the update frequency depending on network conditions.

5.6 Video Analytics Application

We deploy the four microservices composing the video analytics pipeline described earlier on four *S* VMs in the HPC testbed. The provisioned resources do not support GPU acceleration and are single-core machines; therefore, the resulting FPS output is expected to be low. This setup is supposed to stress the platforms into executing this relatively heavy workload on extremely constrained resources. Both K8s and MicroK8s could not support the application since their orchestration components consumed most of the hardware capacity. As a result, we compare application performance over Oakestra, K3s, and without orchestration (native), with native acting as baseline (see fig. 9). Oakestra and K3s exhibit similar performance for object tracking, taking $\approx$ 300-400 ms. However, due to its minimal footprint Oakestra significantly outperforms K3s for supporting the more resource-demanding object detection service, achieving results closer to the baseline. Overall, application performance over Oakestra exceeded K3s by almost 10%. We omit our HET testbed results since they performed similarly to HPC.

6 Conclusion

We presented Oakestra, a flexible hierarchical orchestration framework designed for heterogeneous and constrained edge computing infrastructures. With its logical management hierarchy, Oakestra can sustain a high degree of context separation at scale. The delegated service scheduling of Oakestra reduces the task placement complexity and allows the framework to dynamically adjust to infrastructure changes irrespective of the scale. Furthermore, the proposed networking component enables developers to seamlessly and dynamically adjust the balancing policy with minimal overhead while natively being able to cross different networking boundaries. The lightweight implementation of Oakestra allows it to easily manage constrained resources likely to operate as "edge servers". In such contexts Oakestra superseded the performance of popular production frameworks (Kubernetes and its derivatives), achieving $\approx 10\times$ resource usage reduction and 10% application performance improvement.

We plan to add several feature extensions to Oakestra. For example, we aim to dynamically assign the cluster orchestrator role upon failovers via distributed leader election. We also intend to extend the scheduling and networking capabilities of Oakestra with recent research solutions for the edge, e.g. deadline-aware scheduling, multi-level tunneling, etc. To provide better QoS guarantees, we also aim to support and compare more recent application runtimes such as unikernels, demikernels, or Akka. Finally, we also seek to explore the possibility to incorporate Kubernetes deployments as Oakestra's clusters to achieve integration for existing cloud deployments.

Acknowledgments

We would like to thank the anonymous ATC reviewers and the shepherd for their helpful comments and insights during the review process of this paper. We would also like to thank the ATC Artifact Evaluation Committee for their meticulous examination and efforts to reproduce our results. We are also thankful to Hasso Plattner Institute (HPI) Germany for providing us access to their infrastructure which was instrumental for our experiments. This work was partly supported by the Federal Ministry of Education and Research of Germany (BMBF) project 6G-Life (16KISK002) and EU Health and Digital Executive Agency (HADEA) program under Grant Agreement No 101092950 (EDGELESS project).

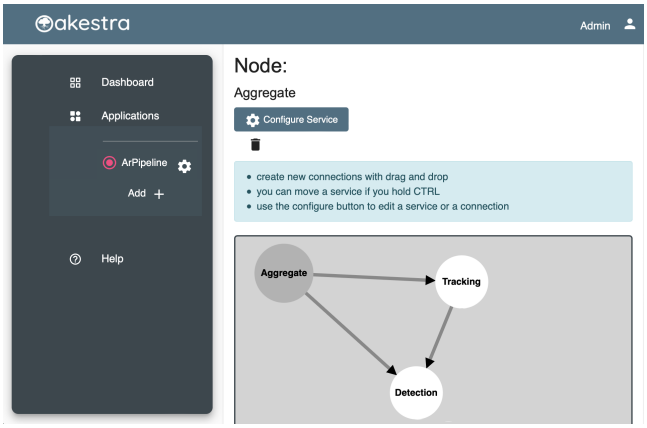
A `Oakestra` Frontend

Oakestra also provides a front-end application that can be used by the developers to create applications and describe the services composing them graphically. A developer can generate the SLA of each microservice through a form. Then, the services connections can be specified using the connection graph (fig. 13a). This graph allows developers to interconnect the services and specify their latency requirements. Once the connection graph is complete, the developer can ask the infrastructure to schedule the desired application. Via the interface, the developer can check each service instance's status and position (fig. 13b); they can also scale the services up, down, or terminate them.

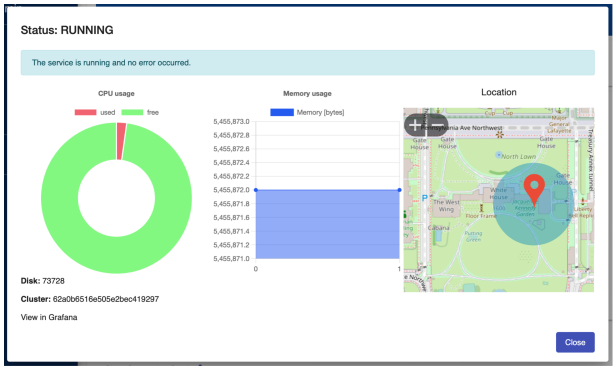
B Artifact Appendix

Abstract

`Oakestra` is an open-source project with all components publicly available on GitHub at https://github.com/oakestra. To ensure the reproducibility of the experiments



(a) Service connection graph



(b) Deployment monitoring interface

Figure 13: `Oakestra` web-based front-end application

conducted within this paper, we fork our project repositories at [54] and [55]. Additionally, we also provide a comprehensive `README`, which includes a `get-started` guide, that can be used for recreating our setup, experiments and familiarizing with the `Oakestra` platform [53].

Scope

The proposed artifacts represents a snapshot of the project that aligns with the paper. The proposed artifacts enable replicating the performance results of `Oakestra` as shown in section §5. However, if the reader is planning to use the latest version of the platform and utilize `Oakestra`'s latest functionalities, we recommend exploring the official website and repository instead.

Contents

Figure 14 shows how the components introduced in §3 can be related to the github repositories. Specifically, the source code, the release binaries and container images are split into the repositories as follows:

- `oakestra/oakestra` [54]: This repository contains the Root & Cluster orchestrators folders, as well as the Node Engine source code for the worker node. Inside the root orchestrator folder, the folders `system-manager-python/` and `cloud_scheduler/` contain the *System Manager* and the *Cloud Scheduler* source code, respectively. Similarly, the *Cluster Orchestrator* folder includes the source of the `cluster-manager/` and the `cluster-scheduler/`. Finally, `go-node-engine/` contains the implementation of the *Node Engine*.

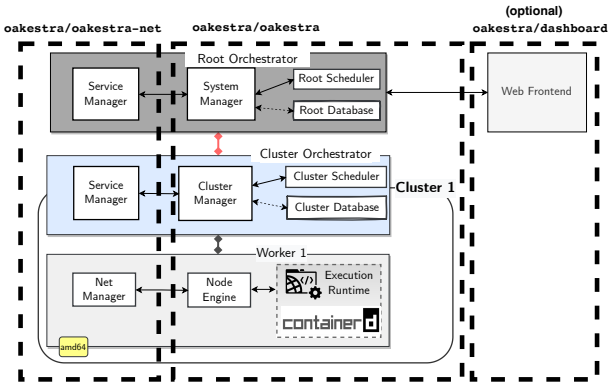


Figure 14: Summary of how the components are split across the repositories

- `oakestra/oakestra-net` [55]: This repository contains the Root, Cluster, and Worker *network* components. Note that the networking stack is not mandatory in `Oakestra`. Without `oakestra-net`, the developer can deploy applications on the infrastructure, but the applications will not be able able to carry out network-related tasks. Since our experiments utilize network-capable applications, our experiment's `README` provides detailed instructions regarding the installation of these components.

- `experiments` [53]: To replicate the experiments, we provide an `Experiments/` folder that includes the setup instructions to create your first `Oakestra` infrastructure and a set of scripts to automate the results collection procedure once the infrastructure is set up as shown in Table 1.

Requirements

We recommend the following minimum requirements for each `Oakestra` component.

1. *Root Orchestrator*: 2GB of RAM, 2 Core CPU, ARM64 or AMD64 architecture, 10GB disk, docker compose installed. Tested OS: Ubuntu 20.20, Windows 10, MacOS Monterey.

Folder	Description
`Test 1`	Deployment overhead calculation (figs. 5 and 7)
`Test 2`	Network overhead measurements (fig. 8)
`Test 3`	Bandwidth measurements (fig. 12)
`Test 4`	Control message measurements (fig. 11)
`Test 5`	Scalability stress test experiments (fig. 6)
`Test 6`	AR pipeline experiments (fig. 9)

Table 1: Experiments test folders

2. *Cluster Orchestrator*: 2GB of RAM, 2 Core CPU, ARM64 or AMD64 architecture, 5GB disk. Tested OS: Ubuntu 20.20, Windows 10, MacOS Monterey.

3. *Worker Node*: Linux Machine, 1 Core CPU, ARM64 or AMD64 architecture, 2GB disk, `iptables` utility.

Beyond the Paper

The AE repository only contains the performance evaluation of `Oakestra`. In addition to this appendix and the repo, the `Oakestra` project provides extensive documentation [56] on how to use `Oakestra` in a variety of infrastructure configurations and applications. In addition, interested researchers are welcome to join the community via GitHub [52] or Discord [51].

Explore Data Placement Algorithm for Balanced Recovery Load Distribution

Yingdi Shan[1,2], Kang Chen[2] and Yongwei Wu[2]

[1]Zhongguancun Laboratory
[2]Tsinghua University

Abstract

In distributed storage systems, the ability to recover from failures is critical for ensuring reliability. To improve recovery speed, these systems often distribute the recovery task across multiple disks and recover data units in parallel. However, the use of fine-grained data units for better load balancing can increase the risk of data loss.

This paper systematically analyzes the recovery load distribution problem and proposes a new data placement algorithm that can achieve load balancing without employing fine-grained data units. The problem of finding an optimal data placement for recovery load balancing is formally defined and shown to be NP-hard. A greedy data placement algorithm is presented, and experimental results demonstrate its superior performance compared to conventional techniques, with up to 2.4 times faster recovery. Furthermore, the algorithm supports low-overhead system expansion.

1 Introduction

In distributed storage systems, data is divided into smaller units called data units, which are grouped together in a placement group for reliability. For example, Google File System (GFS) [6] uses 64MB chunks as data units and replicates each chunk three times to form a placement group. The technique of erasure coding [7, 14, 18] can be utilized to calculate the parity of data units that have been grouped together to form a placement group, thereby providing another method for data reliability. If a single node fails in the storage system, the lost data units on that node must be repaired and distributed to other nodes, a process known as recovery. In this context, the term node is used to refer to an entity within the distributed system, which can be either a whole server or a single disk. Since there are many data units on a single node and different data units on the same node may belong to different placement groups, these storage systems can perform recovery in parallel, improving recovery speed [12, 13, 21]. Parallelized recovery has the potential to increase recovery speed so that it is limited by the cluster's bandwidth rather than the bandwidth of an individual node, improving the overall reliability of the storage system.

However, parallelized recovery does not necessarily imply faster recovery. An imbalance in the distribution of recovery load among various nodes can lead to congestion in certain nodes and prolonged recovery times. Imbalanced recovery loads can also negatively impact the performance of certain nodes, as they may have to devote a significant amount of their bandwidth to recovery.

To address these issues, distributed storage systems often employ fine-grained data units to balance the recovery load [6, 20]. By distributing a sufficient number of data units across various nodes, the recovery load can be evenly distributed through randomization [13]. However, this approach to fine-grained recovery, while effective in load balancing, also increases the risk that any placement group in the cluster fails [1–4, 9, 22]. Furthermore, the utilization of fine-grained data units can result in an uptick in overhead for the management of metadata.

This paper presents a novel data placement algorithm designed to achieve a more balanced recovery performance without the need for fine-grained data units. Data placement, which refers to the mapping of data units to disks, is challenging to design as it impacts data distribution and system scaling. Therefore, an effective data placement algorithm that can balance the recovery load should not have any negative impact on these perspectives.

To create a data placement algorithm for balancing the recovery load, this paper begins by formally defining the optimal recovery load distribution problem as selecting a set of nodes to minimize the weight of the edge with the highest weight in the recovery load graph. We then prove that this problem is NP-hard by showing that it can be transformed into a maximum independent set problem in polynomial time.

The paper then proposes a data placement algorithm based on a greedy strategy that is able to compute a more balanced data placement for recovery load distribution. The algorithm also supports low-overhead system expansion. Experiments demonstrate that the use of this data placement algorithm can improve the storage system's recovery performance by 1.7-2.4 times compared to the original data placement algorithm.

The contributions of this paper include:

- We formally define the optimal recovery load distribution problem. Following this, the paper proves that the problem is NP-hard.
- We propose a greedy data placement algorithm for efficient recovery. It is experimentally demonstrated that the algorithm is able to provide a more balanced recovery load distribution. The algorithm can support low-overhead system expansion.

2 Problem Definition and Analysis

2.1 Repair Load Matrix

The utilization of both replication and erasure coding techniques serves as a means to guarantee reliability in data storage systems. Various erasure codes exist, each having distinct read patterns. For instance, LRC (Local Reconstruction Codes) [7] utilize a minimal number of nodes for repair, while regenerating codes [5, 18] necessitate the read of data from a larger number of nodes but only a fraction of the information from each node. To harmonize these techniques, the repair load matrix is employed as a means to describe the repair process for both replication and erasure coding.

The repair load matrix is a matrix that represents the cost required to repair a failed node. In scenarios where I/O is the system bottleneck, the cost typically refers to I/O expenses, and nodes are often interpreted as individual disks. Conversely, when network bandwidth is the system's bottleneck, the cost usually denotes network expenditures, with nodes commonly referring to whole servers.

Let us denote the cardinality of a placement group as n. Correspondingly, the repair load matrix is represented by an $n \times n$ matrix W. The element $W_{i,j}$ within this matrix signifies the cost incurred to retrieve data from the jth node in the placement group when the ith node within the same group encounters a failure. For example, the repair load matrix for a $(k = 3, r = 1)$ Reed-Solomon (RS) code [14] is given below, and it shows that when any node fails, data needs to be read from all other nodes, and the cost of reading data from any other node is 1.

$$W = \begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{pmatrix}$$

In the context of an RS code where the redundancy parameter r is greater than 1, there exists a multitude of plausible options for the repair load matrix W. This is contingent upon which nodes are selected for data reading during the recovery process. Any such selection can appropriately serve as the repair load matrix for the system.

For a $(k = 4, r = 2, l = 2)$ LRC code, the repair load matrix can be written as

$$W = \begin{pmatrix} 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \end{pmatrix}$$

In this matrix, when repairing a data node or local parity node, the LRC needs to read data from $\frac{k}{l}$ nodes in the same group in order to reconstruct the original data. When a global parity node requires repair, the LRC must read all data nodes' contents.

2.2 Recovery Load Graph

The repair load matrix defines the repair process for a single placement group within a distributed storage system. In contrast, the recovery load graph (or recovery load matrix) characterizes the recovery load on each node in the event of a failure within the system. This is achieved by summing the repair load for each placement group. The recovery load graph is defined mathematically as follows:

Definition 1 (Recovery Load Graph)**.** *Let W be the repair load matrix defined above. Suppose there are N nodes in the storage system, and the storage system has S placement groups, denoted $P_1, P_2, \ldots, P_S$. Each placement group P_i is an array with length n, where each value, denoted by $P_{i,k}$, represents a node id. If $P_{t,k} = i$, then we define $Index(P_t, i) = k$. The recovery load graph corresponding to this storage system is $G = (V, E)$, where V is the set of points in the graph with cardinality N, representing the nodes in the system, and E is the set of edges in the graph. Let $E_{i,j}$ denote the edge weight between node i and node j, representing the load of reading data from node j when node i fails. Let $[i \in P]$ return 1 if $i \in P$ and 0 otherwise. The edge weight is calculated as follows:*

$$E_{i,j} = \sum_{t=1}^{S} [i \in P_t] \cdot [j \in P_t] \cdot W_{Index(P_t,i),Index(P_t,j)} \qquad (1)$$

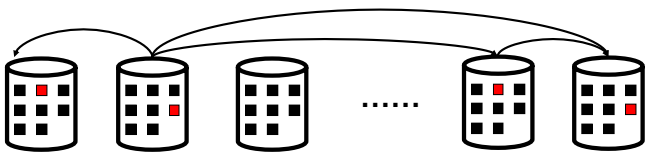

Figure 1: Recover Load Graph

2.3 Optimal Recovery Load Distribution

In this paper, we consider a system in which each placement group comprises an equal quantity of data. Placement groups that are not at capacity, as they consume a minimal amount of storage space, are disregarded. Upon the arrival of new data, the system must determine an appropriate placement group to accommodate it. The objective is to minimize the imbalanced recovery load upon the addition of a new placement group to the system. An alternative approach to this problem would be to determine the optimal recovery load distribution by considering all placement groups simultaneously, as opposed to incrementally identifying a single placement group. However, such an approach may significantly restrict the system's ability to add or remove a node, as it is hard to predict these events in advance.

An optimal distribution of recovery loads should strive to minimize the maximum recovery load after the integration of a new placement group. The definition of the optimal recovery load distribution problem is given below:

Definition 2 (Optimal Recovery Load Distribution Problem)**.** *Given a recovery load graph $G = (V, E)$, the optimal recovery load distribution problem is to construct an array P of length n such that all its elements belong to V, and the corresponding set of edges E', where $E'_{i,j} = E_{i,j} + [i \in P] \cdot [j \in P] \cdot W_{Index(P,i),Index(P,j)}$, such that the maximum value in the edge set E' is minimized. The optimal recovery load corresponding to graph G is:*

$$\min_{P} \max_{i,j \in V} E'_{i,j} \tag{2}$$

As shown in Figure 1, when node i and node j have a common placement group, the edge weight between them needs to be added to the repair cost corresponding to the repair load matrix. The optimal recovery load distribution problem then becomes a problem of selecting n nodes from the N nodes in graph G, such that the highest edge weight in the graph is minimized after the weights are added.

2.4 Complexity Analysis and Proof

In this section, we prove that the optimal recovery load distribution problem is NP-hard by reducing a known NP-complete problem, the maximum independent set problem [8], to it within polynomial complexity.

Definition 3 (Maximum Independent Set Problem)**.** *Given a graph $G = (V, E)$ and an integer n, let $N(i)$ represent the set of neighbor nodes of node i. The decision form of the maximum independent set problem is to determine whether there exists a set $P \subseteq V$ with cardinality not less than n such that $\forall i \in P$, $N(i) \cap P = \emptyset$.*

As shown in Figure 2, an independent set of a graph is a set of nodes such that no two nodes in the set have an edge between them. The red nodes in Figure 2 form an independent set of the graph because there are no edges between any two colored nodes. The maximum independent set problem is to find an independent set of cardinality not less than n in the graph.

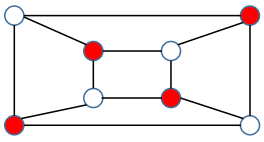

Figure 2: Maximum independent set problem

Lemma 1. *The maximum independent set problem can be reduced to the optimal recovery load distribution problem in polynomial time.*

Proof. We consider the following problem for an arbitrary graph $G = (V, E)$: Given the recovery load graph $G' = G = (V, E)$, where W is a repair load matrix with all entries equal to 1 except for the diagonal entries. The recovery load edge weight $E_{i,j} = 1$ when there is an edge in G from node i to node j. The goal is to find a placement group P that minimizes the maximum value in the updated edge set E' of graph G' after the integration of a new placement group.

We prove that the problem of finding the maximum independent set of graph G can be reduced to solving the optimal recovery load problem. Specifically, we show that the cardinality of the independent set of graph G is not less than n **if and only if** there exists a placement group P with cardinality n such that the optimal recovery load of graph G' is 1.

If there exists an independent set of cardinality not less than n in graph G, we can simply select n nodes from the independent set and place the new placement group on these n nodes in G'. Denote this set of n nodes as p. Since these n nodes are not adjacent to each other, $E_{i,j} = 0$ and $E'_{i,j} = 1$ for any node i and node j that belongs to p. Any other edges in E' remain the same as in E, which are no larger than 1. Therefore, the edge with the largest weight in E' will not exceed 1. As a result, the optimal recovery load corresponding to graph G' is 1.

Conversely, if the optimal recovery load corresponding to graph G' is 1, we assume that there is no independent set of cardinality not less than n in graph G. This means that we can arbitrarily select n nodes from the graph G, and at least two of these n nodes are adjacent. Then, if we select the same set from the graph G', the maximum edge weight of the edge $E_{i,j}$ in this set is 1. After the integration of the new placement, the edge weight of the edge $E'_{i,j}$ is at least 2 because W is a repair load matrix with all entries equal to 1 except for the diagonal entries, which suggests that the optimal recovery load for this graph is at least 2. This contradicts the premise, so it follows that there must exist an independent set of cardinality not less than n in the graph $G = (V, E)$.

Additionally, the reduction of the problem has a complexity of $O(|E|)$, as each edge of the graph G can be transformed into an edge in the recovery load graph by visiting it once. Thus, the problem of finding the maximum independent set can be efficiently reduced to the problem of determining the optimal recovery load distribution in polynomial time. □

Since the maximum independent set problem is an NP-complete problem [8], it follows from Lemma 1 that the optimal recovery load distribution problem is an NP-hard problem.

3 Algorithm Design

3.1 Data Placement Algorithm

This section presents a data placement algorithm based on a greedy strategy for the NP-hard problem of optimal recovery

load distribution. The algorithm aims to select nodes for a placement group of size n from a set of N nodes by choosing, at each step, the node whose sum of recovery costs to other nodes in the current group is smallest. While this method may not necessarily result in the optimal recovery load distribution, it can help to balance the recovery load.

The pseudocode for the algorithm is provided in Algorithm 1. This algorithm is responsible for mapping placement groups to nodes, and it is called to obtain the placement group P whenever a new placement group needs to be added to the storage system. The input to the algorithm is the current recovery load graph $G(V,E)$. The weight $WV(v)$ of a vertex v is defined as the sum of the weights of its adjacent edges, that is, $WV(v) = \sum_{e \in neighbor(v)} E(e)$. $D(v)$ is the number of data units on the node. Capital letters, such as V_0, represent sets, while lowercase letters, such as v_1, represent members of a set. For example, V_0 is a set of vertices and v_0 is a vertex within that set. The function *Pick* is used to randomly select a member from a set. The output of the algorithm is a placement group P.

Algorithm 1: Greedy Data Placement Algorithm

Input : $G(V,E)$
Output : P

1 $v_0 = Pick(\{v \mid WV(v) = min_{v' \in V}(WV(v'))\})$;
2 $P = \{v_0\}$;
3 **while** $|P| < n$ **do**
4 $\quad V_{candidates} = V - P$;
5 $\quad V_0 = V_{candidates} - \{v \mid violates\ criteria\}$;
6 $\quad V_1 = \{v \mid D(v) \leq (min_{v_0 \in V_0} D(v_0)) \cdot (1+\varepsilon) \wedge v \in V_0\}$;
7 $\quad V_2 = \{v \mid \sum_{v' \in P} E_{v,v'} = min_{v_1 \in V_1}(\sum_{v' \in P} E_{v_1,v'}) \wedge v \in V_1\}$;
8 $\quad v_{next} = Pick(V_2)$;
9 $\quad P = P \cup \{v_{next}\}$;
10 Update weight in G;

The proposed data placement algorithm based on the greedy strategy must exclude certain nodes from being placed in the same placement group. For example, nodes in the same placement group should not be on the same server or cabinet in order to reduce the risk of data loss due to systemic failures. Line 5 of the algorithm demonstrates how the candidate set V_0 is constructed based on this rule.

Heuristic rules are used to find the most suitable next node for the current placement group. This algorithm first selects the node with the smallest edge weight sum as the initial node. This process is shown by lines 1 to 2 of the algorithm. In order to achieve a uniform distribution of data, in line 6, V_1 is defined as a vertex whose number of data units does not exceed $(1+\varepsilon)$ times the minimum number of data units in the current storage system. Since the data is difficult to achieve absolute uniform distribution, this algorithm uses an adjustable parameter ε to limit the uniformity of the data placement.

To distribute the recovery load more evenly among nodes, V_2 is defined as the set of nodes with the smallest sum of recovery costs to other nodes in the current replacement group in the event of a failure, as shown in line 7 of the algorithm. Finally, a vertex v_{next} is chosen from V_2 as the next candidate for the placement group and added to the set P. This process continues until n members have been added to the set P, after which the corresponding weights in G can be updated.

When a node represents a server instead of a disk, data units for each node in the group require assignment to a specific disk. This assignment can be efficiently achieved through a round-robin strategy.

3.2 Target Node Selection

When a single node fails and requires recovery, the data stored on it must be redistributed to other nodes in order to maintain the reliability of the system. During this process, it is crucial to select nodes to receive the data units from the failed node in a manner that ensures even distribution of recovered data and maintains balance in the recovery load. The algorithm in Algorithm 2 can be used to select the location of data units to be redistributed to other nodes during the recovery process. This algorithm first excludes nodes that do not meet certain criteria as in Algorithm 1. Next, the algorithm looks for nodes with used storage space within a certain range in order to achieve a balanced distribution of data, as described in line 2. The algorithm then selects nodes that will help maintain recovery load balance after the faulty node is removed, as shown in line 3. Finally, the algorithm aims to evenly distribute the load during recovery; therefore, if the previous conditions are met, it will select the node with the least connection weight to the failed node, as shown in line 4.

Algorithm 2: Target Node Selection for Recovey

Input : $G(V,E)$, placement group P, failure node F
Output : v

1 $V_0 = V - \{v \mid violates\ criteria\}$;
2 $V_1 = \{v \mid D(v) \leq (min_{v_0 \in V_0} D(v_0)) \cdot (1+\varepsilon) \wedge v \in V_0\}$;
3 $V_2 = \{v \mid \sum_{v' \in P} E_{v,v'} = min_{v_1 \in V_1}(\sum_{v' \in P} E_{v_1,v'}) \wedge v \in V_1\}$;
4 $V_3 = \{v \mid E_{v,F} = min_{v_2 \in V_2} E_{v_2,F} \wedge v \in V_2\}$;
5 $v = Pick(V_3)$;
6 Update weight in G;

Since each node may store multiple data units, Algorithm 2 must be run for each placement group to determine the target nodes.

3.3 System Expansion

When adding new nodes to the system, the graph G must be updated to include the nodes corresponding to these new devices. The system can then continue to call the algorithm

in Algorithms 1 to automatically add new placement groups containing the new nodes to the storage system, ensuring that the recovery load remains as small as possible without requiring any data migration.

However, when adding multiple nodes at once, using the algorithm in Algorithms 1 directly can result in all the new placement groups being placed on the same batch of newly added nodes. This can lead to an imbalanced recovery load, with a concentration of recovery load and writing load on the newly added devices, even as more placement groups are added. To address this issue, the algorithm should control the rate at which data is placed on the new nodes during system expansion.

To do this, the new nodes can be placed in a separate collection. Each time the system is expanded, the user can specify a parameter c to control the placement rate of data on the new devices. When calculating data placement, at most c nodes will be selected from this collection, with the remaining $n-c$ devices being selected from other devices according to the algorithm in Algorithm 1. Once the number of data units on a node within the collection matches the number of data units on the node with the least amount of data outside of this collection, the node can be removed from the collection.

4 Evaluation

4.1 Evaluation Setup

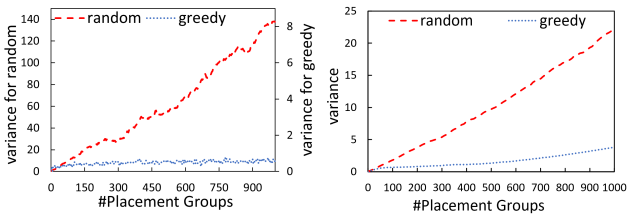
In the context of our evaluation, we designate each individual disk as a node within the system. We carry out both micro-benchmark experiments and overall performance testing to assess performance. The micro-benchmark experiments, performed outside of an actual storage system, specifically evaluate the variability in recovery load distribution and data distribution. Instead of executing actual recovery, micro-benchmark experiments provide an analysis of the recovery load distribution, which are complementary to our overall performance evaluation.

For the overall performance test, we employ a cluster of 16 servers, with each server boasting dual Intel Xeon E5 2643 v4 CPUs, 128GB of 2133 MHz DDR4 memory, a 512GB SATA3 SSD, and six 8TB 7200rpm SAS HDDs. The six HDDs are independent and not grouped by a RAID. All servers run on the CentOS 7.8 operating system. The servers are networked via a 56Gbps Infiniband connection, with an MTU size of 65520, enabling us to better utilize the high-bandwidth network in our evaluation. We set the value of ε to 0.02 for all experiments to maintain a consistent testing environment.

4.2 Micro Benchmark

We conduct micro-benchmark experiments to see how our algorithms can help to improve recovery load balance. In all experiments, N is set to 100, and RS(10,4) code is employed for each placement group.

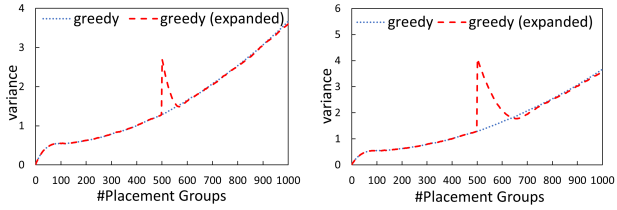
Data Distribution. Figure 3a measures the uniformity of data distribution for different data placement algorithms by calculating the variance of the number of data units. It can be seen that the greedy data placement algorithm is far more uniform than the random data placement algorithm.



(a) Data Distribution (b) Recovery Load Distribution

Figure 3: The variance of data distribution and recovery load distribution.

Recovery Load Distribution Figure 3b presents the recovery load distribution of the system when utilizing different data placement algorithms. The data depicted in the figure demonstrates that the recovery load is more evenly distributed when using a greedy data placement algorithm as compared to random data placement.



(a) Add a disk (b) Add two disks

Figure 4: The variance of the recovery load after system expansion.

Recovery Load Distribution for System Expansion We evaluate the effects of system expansion on recovery load distribution. In this experiment, the variable c is set to 1. The results are illustrated in Figure 4a and Figure 4b. Specifically, Figure 4a represents the scenario where an additional disk is added to the system when there are 500 placement groups stored, while Figure 4b illustrates the situation where two additional disks are added simultaneously.

The data illustrated in Figure 4a demonstrates that while the greedy algorithm may initially create a temporary imbalance in recovery load after system expansion, the recovery load returns to a normal state as more placement groups are integrated. This phenomenon arises due to the recovery load on newly introduced disks being zero initially, resulting in a sharp uptick in the variability of the recovery load distribution. However, as these new disks become populated with data, the recovery load re-establishes its balance.

Conversely, Figure 4b illustrates that simultaneous addition of multiple disks leads to a more pronounced imbalance in the

Table 1: The average recovery time of different data placement algorithms.

Codes	Random	Greedy	Improvement
RS code	554s	273s	2.1x
LRC	460s	192s	2.4x
Clay code	240s	141s	1.7x

recovery load of the storage system and that it takes longer for the system to return to normal.

4.3 Overall Performance

This experiment measures the recovery performance using different data placement algorithms and different erasure codes, including RS code, LRC, and Clay Code [18]. To achieve this, 96 hard disks were distributed across 16 machines, with each data unit set at a size of 10GB and a total of 175 placement groups in the system. The algorithms are integrated into the RCStor storage system [16], as it provides high recovery performance and various erasure codes. Prior to measuring recovery, data of approximately 256GB was placed on each disk, resulting in a total data size of 24.4TB. The recovery process was initiated manually by shutting down a disk, and the time required for recovery completion was recorded. To gauge the maximum recovery bandwidth, we initiated the recovery of all failed placement groups simultaneously. It should be noted that during recovery, the data from the failed disks was reconstructed on other functioning disks. We ensured there was no bandwidth cap for the recovery process. Additionally, the recovery was carried out at a time when the system was not in use, to avoid any operational interruptions. We conducted 10 trials to ascertain the average recovery time. The experimental results are presented in Table 1.

The data in Table 1 illustrates that the use of a greedy data placement algorithm can significantly enhance the recovery performance for various erasure codes. Specifically, the recovery performance is found to be 1.7-2.4 times greater than that of the random data distribution algorithm.

We have also evaluated the influence of randomness on recovery time. Our findings suggest that when utilizing the greedy data placement algorithm, the impact of randomness fluctuates within a range of ±10%. However, with the random data placement algorithm, this variability increases to ±20%.

5 Related Work

Copyset [4] proposes to reduce the probability of data loss by reducing the number of distinct placement groups, which are referred to as copysets. In contrast, the focus of our paper is to ensure recovery load balance given a predetermined small number of placement groups. This number is approximately the same as the number of copysets, contingent upon parameter configurations. In essence, we tackle the issue of data loss by balancing the recovery load given a fixed number of placement groups. This aspect marks a departure from the Copyset paper, which does not focus on recovery load balancing.

PDL [23] is a data placement algorithm that reduces imbalances in inter-cabinet network communication. SelectiveEC [24] maintains load balance during recovery by dynamically selecting nodes for reading and writing through bipartite graph matching. However, they only reduce recovery load imbalance for the network and cannot guarantee the balance of load when accessing disks.

RAID-based data placement algorithms [11, 15, 17, 19, 26] are designed for use with disk arrays, which are not appropriate for use in distributed storage systems. RAID+ [25] and D_3 [10] use orthogonal Latin squares to distribute data and ensure load balance for disk array recovery, but they lack scalability and can only be applied to arrays with tens or hundreds of disks. They also do not support dynamic system expansion.

Overall, existing data placement algorithms struggle to simultaneously provide load balancing for recovery, scalability and low migration overhead.

6 Discussion

In a storage system capable of tolerating multiple failures, resulting in numerous potential repair load matrices, a practical advantage may arise from dynamically selecting recovery sources, taking into account observed loads and stragglers. This dynamic selection aligns with our algorithm and could involve dynamically choosing k nodes from each placement group for data recovery, excluding stragglers, to minimize the maximal recovery load. The future challenge lies in developing an efficient algorithm for this process or devising other methods to account for the impacts of such dynamism.

7 Conclusion

This paper proposes a data placement algorithm based on a greedy strategy that can provide a more balanced recovery load distribution. Experiments show that using the data placement algorithm can improve the recovery performance of the storage system to 1.7-2.4 times compared to the random data placement algorithm.

LUCI: Loader-based Dynamic Software Updates for Off-the-shelf Shared Objects

Bernhard Heinloth, Peter Wägemann, and Wolfgang Schröder-Preikschat
Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Germany

Abstract

Shared libraries indisputably facilitate software development but also significantly increase the attack surface, and when using multiple libraries, frequent patches for vulnerabilities are to be expected. However, such a bugfix commonly requires restarting all services depending on the compromised library, which causes downtimes and unavailability of services. This can be prevented by dynamic software updating, but existing approaches are often costly and incur additional maintenance due to necessary source or infrastructure modifications.

With LUCI, we present a lightweight linker/loader technique to unobtrusively and automatically update shared libraries during runtime by exploiting the indirection mechanisms of position-independent code, hence avoiding severe runtime overhead. LUCI further adds no additional requirements, such as adjusting the source or interfering with the build chain, as it fully adapts to today's build and package-update mechanisms of common Linux distributions. We demonstrate our approach on popular libraries (like *Expat* and *libxcrypt*) using off-the-shelf (i.e., unmodified) binaries from Debian and Ubuntu packages, being able to update the majority of releases without the necessity of a process restart.

1 Introduction

Third-party libraries are, without doubt, an important part of software development, allowing a programmer to use functionality beyond their domain (or at least to save some time). To prevent outdated source-code copies [49], it is common to dynamically link against libraries distributed in binary format [50] – on system-level so-called shared objects, enabling independent updates. A popular example is *OpenSSL*, providing cryptographic capabilities to numerous projects. However, its infamous *Heartbleed*-vulnerability demonstrated the downside: All of a sudden, millions of systems (yet alone 24 – 55% of all HTTPS-enabled servers [13]) ran the risk of leaking highly sensitive information when the buffer over-read bug was discovered. Even though distributors quickly published fixed versions of the library, all applications directly or indirectly depending on this library had to be restarted, not only requiring immediate manual action but also causing costly downtimes of services [12, 22].

Generally, having a new library version to be responsible for the need for a service restart is all but seldom: Default server software in many popular Linux distributions like Debian is dynamically linked and depends on several shared libraries, which are usually the main reason for a service being exposed to known vulnerabilities:

For example, the currently most widely used web server [23], *nginx*, had 11 (out of 34 CVEs[1]) vulnerabilities with high severity[2] since 2010, while its basic (static) dependencies *glibc*, *OpenSSL*, *PCRE*, *libxcrypt*, and *zlib* had at the same time 70 such critical vulnerabilities (of 335 CVEs total).

It is worth noting that these numbers do not take any modules into account: the default configuration of *nginx* includes six core modules, which depend on a total of over 30 external shared libraries themselves – and have at least 98 additional critical vulnerabilities (of 474 CVEs) in the observed period.

A similar picture emerges for the second place: 14 critical vulnerabilities were found in *Apache HTTP Server* including its core modules. In contrast, its required shared libraries in basic configuration (without modules) had 81 such issues due to an additional dependency on *Expat* compared to *nginx*.

Especially for stateful software systems (e.g., database management systems) or systems with active client connections, restarting the service in case of a vulnerability is undesired [36, 37]. To address the challenges of avoiding unwanted downtimes and expensive startup costs, dynamic software update (DSU) mechanisms have been developed over the last decades [8, 11, 15, 28, 29, 42].

Although many interesting DSU techniques are available, and even Linux introduced kernel live-patching in version 4.0 more than seven years ago [20], the requirement for restarting services utilizing updated libraries has not changed since

[1] Common Vulnerabilities and Exposures: www.cve.org.
[2] CVSS (Common Vulnerability Scoring System) score with 7.0 or higher.

then. Unfortunately, common user-space live-patching has not become a reality yet.

This raises the question regarding the reasons for this shortcoming. Most approaches for DSU require modifications in the source [15, 17, 28, 29] or build system [11, 18, 42, 47], programmer-guided patch creation [34, 43, 45], and/or a virtual machine [5, 7, 35] for execution. While the modification of a single project can be rather easy, it would have to be applied to almost every software package in a system for practical usage of dynamic updates – and yet the vast amount of different software prevents any broad application.

That is why we believe that system-wide automatic live updates in user space will only succeed if the requirements are limited to the bare minimum: We argue that *unmodified (i.e., off-the-shelf) binary files* already built and deployed by distributors have to be sufficient input for base and updated versions.

In addition, imposed runtime overhead and stability concerns due to the complexity of existing approaches further hinder any attempts to establish general live-patching in user space. Nevertheless, these penalties are inevitable fallout of the effort to provide a general approach allowing to transform almost any program state – which is usually not required for security fixes: Since the vast majority of system-level software is still written in programming languages not ensuring memory safety (like C and C++) [6], patches for critical vulnerabilities commonly introduce small local code changes like bounds checking (e.g., the fix for the mentioned *Heartbleed* bug). Such patches usually do not alter any function output for valid inputs [24].

The situation for logic errors is similar: Most common bugfix patterns affect only the function scope [32] without side effects beyond its borders. Especially system-level shared objects have to maintain the *application binary interface* (ABI) to which other software binaries are dynamically linked, making structural changes rather seldom. New feature improvements altering the library's *application programming interface* (API) can usually only be used in depending software after modifying its source code as well. Since adjusting projects to the libraries' updated semantics may take time [21], distributors tend to backport bugfix patches while retaining API & ABI compatibility [39].

These insights help us to define the necessary scope required for dynamic software updates based on binary files under practical conditions: First, we focus on supporting the mentioned changes required for error correction instead of enabling updates to introduce arbitrary modifications. Second, we argue that a practical DSU solution has to update off-the-shelf binaries without requiring access to or modifications of the source code or build process.

With LUCI, we present a DSU approach for unmodified shared libraries utilizing features already enabled by default in today's build chains without inducing runtime overhead. In this sense, the paper makes the following contributions:

- A lightweight loader-based DSU mechanism targeting security fixes that is based on relinking dynamic ELF binaries by leveraging its metadata
- Design and implementation of an open-source, dynamic linker/loader with *glibc* compatibility for the x86_64 architecture supporting automatic and transparent updates of off-the-shelf shared libraries
- Evaluation of popular, binary-distributed shared libraries of recent Debian and Ubuntu releases to assess the live-patching approach's practicality

The remainder of the paper is organized as follows: After giving an overview of DSU techniques in Section 2, Section 3 describes the details of ELF binaries that we utilize for our approach in Section 4. To verify the results, we back-test LUCI with popular shared libraries in Section 5 while classifying the results in Section 6. Section 7 concludes the paper.

2 Related Work

Research of dynamic software updates in user-space dates back four decades, with *DYMOS* [11] presenting the first notable approach beyond manually live-patching machine code. The approach allows updates of programs written in a Modula dialect while using a custom compiler and runtime system. Thereby, this approach involves restrictions with respect to the source-code development and its build system, which correspond to Ⓐ and Ⓒ in Figure 1. Many sophisticated approaches that evolved since then share these restrictions:

Ginseng [28, 29] allows changes in function prototypes and data representation but is limited to source code written in C while also requiring code adjustments Ⓐ. Patches are generated by comparing the source files Ⓑ in conjunction with analysis information emitted by a custom compiler Ⓒ and loaded with a custom runtime system. The approach involves significant performance overhead of up to 30% in updated functions. Although being a powerful approach, *Ginseng* illustrates the massive adjustments required to support generic dynamic updates. LUCI avoids these requirements as it hot-swaps code while not supporting data modification.

With *Kitsune* [15] (successor of *Ekiden* [17]), developers have to manually specify update points, add control-flow and data-migration code to their C source Ⓐ, and use a custom compiler Ⓒ. After waiting for all threads to reach the update point, it replaces the whole program and performs all migrations. The approach causes a service disruption on update time but reduces overhead costs during normal execution.

POLUS [8] constructs a patch for a successive version using a source-to-source compiler Ⓑ. This patch can be applied at any time by employing `ptrace`, with old and new versions residing in memory. *POLUS* places redirection instructions

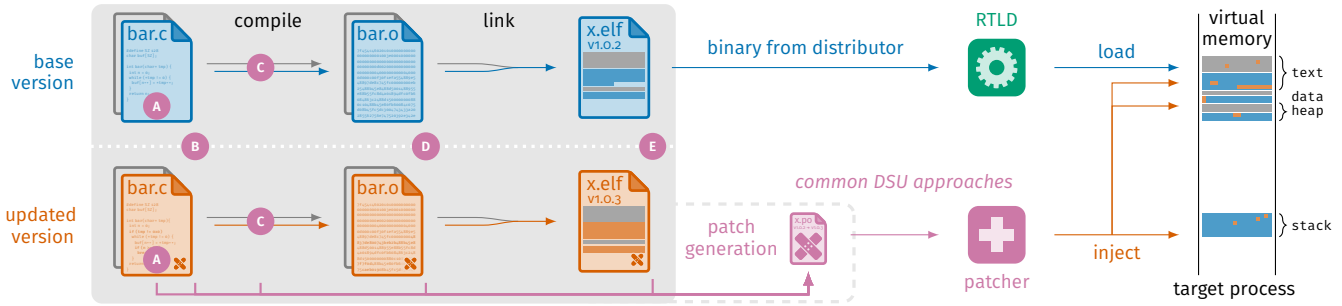

Figure 1: Common DSU approaches require either certain (higher-level) programming languages [11], modification of the code [29], or the changes in the build toolchain [42] (unless the patch is handcrafted from the resulting binaries [5]), as highlighted by the gray area on the left side. Due to the sheer amount of different software projects, it is not feasible to adjust each of them – hence preventing live-patching in user-space for today's real-world software. A generic automatic update mechanism must not interfere with these steps but merely use the resulting binaries, usually built by distributors.

into the old functions and keeps track of global-state modifications. LUCI adapts the idea of having multiple versions of a binary in the virtual memory and extends it by shared data.

In contrast to previous approaches, *Katana* [42] is language-agnostic and works on object-file level (D). While improving applicability, it still requires interfering with the build chain.

For LUCI, the feature of coping with off-the-shelf shared libraries is essential – a feature also provided by a few other approaches: Using dynamic binary translation, *DynSec* [34] can patch code of unmodified binaries while having a significant runtime overhead (11% in benchmarks) and requiring programmer-guided patch generation (E). *Piston* [43] is trying to exploit vulnerabilities in order to fix them. It works on a binary level and can automatically generate repair routines for stack-based buffer overflows, but such routines must be manually provided (E) for other vulnerabilities. With the process virtual machine *DynamoRIO* [5], binary-level code modification (E) is possible at the cost of runtime overhead. Based on this tool, *ClearView* [35] is able to learn normal application behavior and automatically generate patches for certain types of bugs, however, causing massive overheads (depending on the configuration 47% – 303% baseline overhead, and up to 30 000% while learning).

Different methods to update active functions have been proposed: *UpStare* [26] (C) and *StrongUpdate* [51] (B) using stack reconstruction and *ISLUS* [9] (B) with checkpoint-based rollback, all require C source (A). For LUCI, this is not needed since we expect shared library functions to return eventually.

While live updates for Linux [7, 27] and other operating systems [1, 3] were already an important research topic, *kSplice* [2], *kPatch* [38], and *kGraft* [33] (C)(D) initiated kernel live-patching in Linux [20]. The latter two can only perform changes on functions, not on data, similar to LUCI. In contrast, *kSplice* is not only able to support data changes but can also be used for certain specially prepared user-space libraries [31].

A few other approaches focus on live-patching of shared libraries as well: *LibCare* [47] generates patches from assembly emitted by a compiler wrapper script (C) and applies them using `ptrace`: After acquiring storage for changed code (and new data, if required), relocations in the existing code are updated while using stack unwinding to prevent modifications of currently executed functions.

A rather less-intrusive approach is used by *libpulp* [45], requiring specially prepared/compiled libraries with an additional `nop`-prologue at each function (C) to be able to dynamically insert trampoline code. A manually created description file (E) guides the updater (using `ptrace` in conjunction with a preloaded library) through the symbols to be replaced.

The *libDSU* [30] concept also targets unmodified shared libraries. However, *libDSU* would require an actual implementation of the approach to find and update all locations of pointers in the process' memory – including heap chunks, which is quite complex and error-prone to identify. LUCI avoids this requirement by keeping memory locations valid.

All existing approaches either require modifications during building, for both base and updated version, or programmer-guided patch generation. To the best of our knowledge, no approach yet exists that can provide an update on shared libraries without interfering in the build process (gray area in Figure 1). With LUCI, we close this gap.

3 Background

On Unix-based systems, a machine-code–generating compiler produces relocatable objects from the source code, nowadays in the *executable and linkable format* (ELF). With ELF being the fulcrum for executables, LUCI exploits this format.

The ELF meta information lists available and required symbols (e.g., functions and static variables) accompanied by relocation information, enabling the linker to fix destination-address parameters of memory-access and branching instructions in the machine code. For static (position-dependent) executables, the target addresses of all symbols can and must

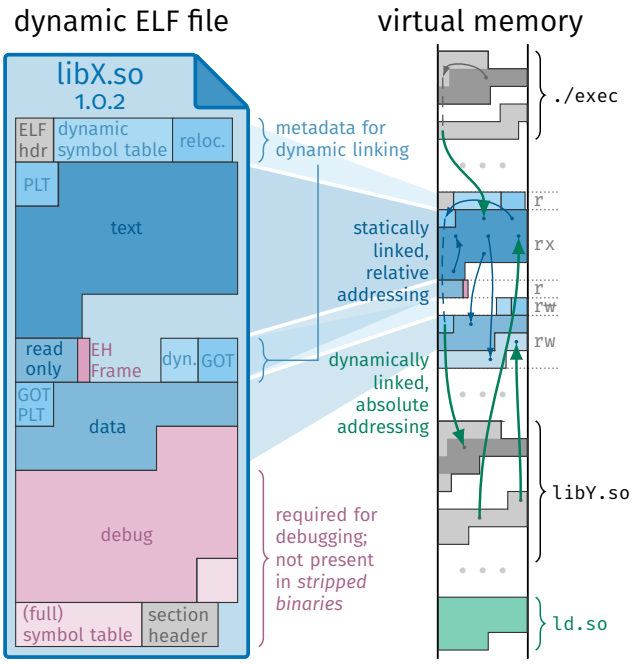

Figure 2: Shared library loaded and relocated in process' virtual memory by the dynamic linker/loader (`ld.so`).

be resolved during static linking, hence, the *executable ELF* contains a complete image of the process's virtual memory. However, for shared objects and dynamic executables, some symbols may remain undefined in the resulting *dynamic ELF* binary. Therefore, the `dynamic` section references their meta information, so symbols can be resolved during execution by the dynamic linker/loader (also referred to as *runtime linker*, RTLD) – allowing the use of other shared libraries.

To simplify the execution of such binaries, the compiler (e.g., with `-fPIC` for position-independent code) references local symbols using relative addressing, while emitting instructions and function stubs (like the *procedure linkage table*, PLT) for indirect addressing to access external symbols. The PLT itself is closely tied to a *global offset table* (GOT) section introduced by the static linker, which stores the actual target addresses during runtime. Therefore, the dynamic linker/loader is not required to modify the machine code in the `text` section itself but only the GOT and, if required, data sections. This strategy improves load performance and security since no executable pages are mapped with write permission in the process' virtual memory, while also maintaining a low memory footprint. Additional techniques like *relocation read-only* (`data.rel.ro`) further contribute to security by removing the write permission after the initial linking steps where applicable (e.g., constants referencing external symbols).

The dynamic linker/loader is responsible for finding all required shared libraries of an application on the file system. The tool places libraries in the process' virtual memory, resolves and fixes undefined symbols while retaining a defined search order (to deterministically handle symbols having the same name). Eventually, the dynamic linker/loader performs initialization and passes control to the application's entry point. For lazy binding (i.e., resolving undefined function symbols on the first call), the dynamic linker/loader has to reside in memory during the entire lifetime of the process. The same holds for the dynamic metadata of each shared library (for symbol lookup and relocation). Figure 2 visualizes a mapping of an ELF file into the virtual memory of a process.

Since a POSIX-conform dynamic linker/loader also provides an interface allowing the process to load additional shared objects at runtime, it is itself an executable, self-contained shared object (`ld.so`) with a tight connection to the C standard library (*libc*) used on the target system. In fact, the dynamic linker/loader is usually an integral part of the standard library (e.g., *glibc*, *musl libc*).

4 Approach

When a modification of a shared object used in a process is detected, we first compare the old and new version. A crucial requirement for our approach is having identical writeable sections: The same symbols have to be stored at the same position having the same size and the same initial content, for both initialized and uninitialized data (`data` and `bss` section). Only then the new version can safely be loaded and linked into the process. We found in practical applications (see Section 5) that this requirement is not a major restriction as modifications on writable sections are rare, as detailed in the following.

While analyzing typical bugfixes for common weaknesses in dominating system programming languages[3], we noticed that newly introduced static variables are rare. Further, modern compilers and linkers work in a deterministic manner (including reordering of variable allocations in an optimization step) and most distributors have optimized their build chains for reproducible builds[4]. Therefore, the probability is high that code changes do not affect the data section of the binary. Consequently, our DSU mechanism checks for alterations in sections containing writeable data, including the *thread-local storage* (TLS), which would prevent an update. While modifications of the writable sections are rare, changes to the read-only data section are more likely, for example, due to introduced strings for error messages. However, these `rodata` updates do not hinder the update process but are inherently supported by our approach, as well as newly introduced automatic variables, which are stored in the stack memory.

[3]The common weakness enumeration (CWE) list at cwe.mitre.org maintains a good overview, including views explicitly focusing on C/C++.

[4]For reproducible builds any indeterminism in the build process is removed, allowing to reproduce a binary-identical file on every build with same source code revision as input. Further information at reproducible-builds.org.

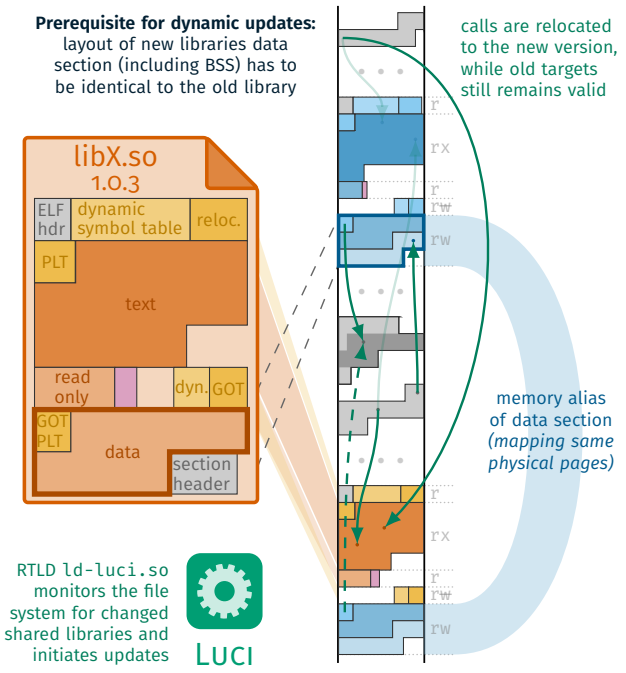

Figure 3: LUCI's core principle is to map the updated shared library to unused space of the processes' virtual memory. Thereby, it exploits *memory aliasing* in order to map the newly introduced data section to the physical memory of the previously active data section.

Segment Layout Requirements In both the old and new version, our approach additionally requires the `data` section to have identical page alignment. However, due to the page-level granularity of permissions in memory-management units, it is already standard in linker scripts to place the writable segment at a page border. The GOT dedicated to the PLT for lazy runtime linking is put at the beginning, followed by the `data` section. The writeable segment is usually preceded by the segment containing the relocation-read-only section, which also includes the standard GOT (for external variables) and is only writeable during the initial dynamic linking stage – but neither its alignment nor its content affects the updateability.

After the updater has ensured the availability of all currently required symbols in the new shared object, it loads all non-writeable data sections into the process' virtual memory, placing it at some previously unused address range. Instead of loading the data section from the ELF file, a *memory alias* of the old version's data section is created (see Figure 3): Both old and new versions' data sections use the same page frames, allowing changes to a variable in the old data section to be immediately visible in the new one and vice versa. Since Linux currently lacks a direct way to create such an alias, we have to use an anonymous in-memory file created by the `memfd_create` system call for the data.

Relinking using GOT Then, all executables and other shared objects utilizing the changed library are updated: The dynamic software updater relocates the affected entries in every GOT to the corresponding symbols in the new library. In addition, it is possible that data sections need relocation as well, for example, when function pointers are used. In this case, the LUCI updater must first ensure that the target memory still contains its original value and is compatible before replacing it with the new value.

Since function calls are performed indirectly (using single instruction reads of the GOT PLT) and both old and new functions coexist in the process, there is no need to alter the `text` section. Hence, the update can be initiated at any time without requiring quiescence [8], reaching a certain update point in code, or modifying the process stack. Furthermore, there are no limitations regarding updates of multithreading applications as there are basically no other runtime modifications than the default RTLD performs when lazy binding. Having the code of an old library function be executed at the time of update is not a problem; it continues accordingly until completed (`return` instruction) with the old code, but future calls will be redirected to the new library function, thus leading to a gradual update. Since shared libraries should provide a collection of subroutines and, therefore, frequently return to the caller, proper software engineering prohibits remaining in an endless loop inside the old version.

In order to apply changes, the dynamic software updater needs access to the process' virtual memory. Since the dynamic linker/loader resides in the process, it is a comfortable target to house the update mechanism, not only avoiding the need for additional permissions but also providing easy access to a list of all loaded objects and their relocation information.

RTLD with DSU Capabilities In order to assess the applicability of the approach to real-world libraries, we have implemented our own dynamic linker/loader LUCI for the x86_64 architecture with the ability to perform the described update procedure while maintaining binary compatibility (to some extent) to the *glibc* equivalent `ld-linux.so`, allowing loading and live-patching of unmodified binaries from a distributor: LUCI can run common executables when passed as a parameter or transparently if LUCI is set as the interpreter in the corresponding ELF section of the executable. This fully circumvents `ld-linux.so` but still supports most *glibc* libraries (including `libc.so` and `libpthread.so`) while providing compatible interfaces for RTLD-specific functionality (e.g., `libdl.so` and tunables).

If dynamic updates are enabled (e.g., by the corresponding environment variable), LUCI creates an observer thread on start and uses the `inotify` API to detect modifications of all loaded shared objects (or their symbolic links, respectively). In case of a `fork`, LUCI intercepts it in order to decouple the data memory alias and create a new observer thread in the child process. Besides the `fork` and thread creation, our

live-updating mechanism introduces no runtime overhead.

On detected changes, the observer thread autonomously compares the update compatibility of both versions and, on success, initiates the update process. In addition, LUCI can output status information, for example, notifying about required restarts due to incompatible changes.

A successful update currently does not necessarily prevent the execution of old versions: If the library dynamically stores a pointer to local functions during runtime (e.g., in heap-allocated memory), these could result in reusing old code after an update. LUCI cannot statically identify (and fix) them since there is no relocation information. Nevertheless, it provides an optional method to detect such access at runtime: After a user-defined time following an update, LUCI hides all pages containing executable sections in old libraries and installs a user-space page-fault handler (using `userfaultfd`). If the non-present page is accessed, LUCI makes it available again while using the status output to inform about the failed update and the requirement for a manual restart.

The virtual memory layout of the updated shared object is as intended by the linker and described inside the ELF file, hence not limiting debugging capabilities with standard tools like *GDB*. Furthermore, C++ exception handling (and unwinding in general) works as expected, even in updated libraries, since LUCI provides a version-agnostic interface for dynamic linker introspection: Therefore, requests from exception/unwinding routines will be passed to the exception handling frame (`eh_frame`) of the corresponding library.

Checking Basic Compatibility To safely create a memory alias of the old writeable data section in an updated shared library, the section must match in alignment, layout, and content. The meta information of the ELF file (`data` section address and size, its initial values plus the dynamic symbol table) can be sufficient – unless the writeable data has local relocations: For each static variable pointing to a local symbol, LUCI ensures the target's equivalency in the old and new version. Otherwise, an update could lead to undesirable behavior, for example, because of changed variable semantics.

The dynamic update is straightforward as long as the target is located in the `data` section, because LUCI simply compares the contents and follows the relocations. However, when considering the executable section, we cannot just compare the machine code since changed offsets (e.g., due to added code) likely result in a different byte stream. With the help of the capstone engine [41], LUCI disassembles the code and (using relocation information, instruction-pointer–relative addressing, and branch instructions) creates a dependency graph. This graph is similar to a call graph but also contains references in the data section. To enable fast comparisons, LUCI calculates a fingerprint for each function: Similar to techniques used in malware analysis [10], LUCI creates a hash based on the machine instructions while excluding relocated immediate operands and `%rip`-displacements – they are replaced instead with corresponding symbolic equivalents. This allows LUCI to find identical functions independently from their location.

For dynamic updates, LUCI considers a target symbol to be compatible if the fingerprint (for symbols in the executable section) or contents (for data) in old and new versions match, as do the targets of all references.

After ensuring the update compatibility in principle, LUCI further checks if the process has not altered the memory targeted by the relocation entry. Consequently, LUCI keeps track of previous values used for fixing relocations and aborts the update process on detected changes while notifying the user about the requirement for a manual restart.

Improving Compatibility Detection So far, stripped binaries – containing only essential parts – are sufficient. However, access to binaries' full symbol table and debug information can contribute to detecting whether an updated version can be applied: While its full symbol table contains storage information for local variables, the *DWARF* debug sections allow an even deeper inspection. Not only type information for all variables can be gathered here, but also the fields of records (`struct`) and enumerated values can be compared.

For debug purposes, many distributors like Debian and Ubuntu offer additional debug information for the binaries, due to size considerations usually distributed in separate packages. With `libdebuginfod`, there is even a web service for easy retrieval of debug symbols, using the unique *BuildID* of the binary located in the `note` section.

Although modification of records (e.g., `unions`) and additional `enum` values do usually not interfere with a successful update, they are still quite rare in non-feature-updates. Thus, we prefer a pessimistic approach for the sake of stability: If either variable location or type, any internal record field, or enumerated value has changed, the update is not applied. This limitation has the ability to simplify the version comparison drastically: By suitably hashing the information about the internal structure, the hash value is sufficient to determine compatibility. We have implemented a service (similar to `libdebuginfod`) that LUCI queries. An alternative to LUCI's approach is to include the value directly in the ELF file, for example, in an additional `note` section inserted by the post-processing steps of the packaging toolchain.

Dynamically Loaded Libraries The POSIX function `dlopen` enables one to load libraries during runtime. By default, both functions and global symbols are retrieved as pointers using `dlsym`. To effectively support dynamic updates for such runtime-loaded files, LUCI creates an indirection for function types: Similar to the PLT, the address of a helper function is returned, which redirects the call to the latest version of the symbol – introducing the overhead of an additional `jmp` instruction. Using this trampoline technique, LUCI can even update dynamically loaded libraries.

5 Evaluation

We successfully validate the previously described functionality of our implementation with a custom test suite written in C/C++ consisting of small examples (targeting especially the corner cases) using different compilers and versions (*GCC* v6 – v12, *LLVM/Clang* v11 – v15) on several distributions (including RHEL/AlmaLinux, Fedora, and openSUSE Leap). Other tests demonstrate the ability to update code changes in libraries written in Ada (*GNAT*), Fortran (*GNU Fortran*), Go (`c-shared` using the *GNU Go Compiler*), Rust (*Rust compiler* with `prefer-dynamic` flag), and, with some limitations, Pascal (*Free Pascal Compiler*).

However, to demonstrate the practicability of our approach, as well as its limitations, this evaluation focuses on popular shared libraries without any custom modifications. To provide a realistic scenario [44], we do not perform updates of individual patches/commits but on the level of full official release versions, which usually contain multiple changes.

For each library, we independently build (without using any artifacts of a previous compilation) each version of a reasonable range having a compatible API. As far as possible, we use the suggested toolchains and default configuration for each library according to the corresponding documentation. Neither changes to the source nor custom tools are used during the build process. In order to evaluate their impact on LUCI's compatibility detection, we manually enable debug symbols.

Then, a program – preferably a test suite with high code coverage – linked against this library interface is executed, while a supervisor script subsequently, with a certain delay, exchanges the library version on the file system in the background. Moreover, this supervisor listens to the status interface of LUCI in order to be notified about incompatible or failed updates (the communication is strictly uni-directional) – which will cause a restart of the test program, enabling it to use the latest library version in the traditional way.

In addition to self-compiled vanilla versions, we also test the corresponding binary releases in popular distributions the same way. We choose Debian and Ubuntu as they are considered to be the most widely used Linux distributions (at least for web servers [48]). Additionally, we are able to retrieve outdated packages from previous releases[5]. We focus on their two most recent versions: *Focal Fossa (20.04)* and *Jammy Jellyfish (22.04)* in the case of Ubuntu (LTS) and *Buster (10)* and *Bullseye (11)* for Debian. However, as debug symbols for some versions are missing in the archives, LUCI solely relies on the (stripped) ELF files when evaluating external builds.

It is worth noting that Debian carefully tries to prevent any breaking changes in their stable package releases, often backporting security fixes to the library version used initially in a particular Debian version. Therefore, its library versions may differ from custom builds having the same version number.

Suitable libraries must meet the following criteria:

- Enough *recent development* to compare different version releases – especially different binary releases in the mentioned distribution versions.
- *Independent libraries* providing distinct functionality rather than just an interface to a service. To simplify testing, it should not be tightly entangled with system components.
- Availability of a *test tool or suite* with reasonable coverage of the library interface and its code. It must not use internals beyond the public/official interface since this might prevent it from running with other releases. To demonstrate the dynamic update, we further need a long-running process (ideally executing the tests in an endless loop) – scripts executing individual tests in subprocesses are unsuitable.
- *High popularity* in both local installations and software depending on it. The Debian popularity contest [40] tracks the installations of their users and can act as an indicator.

Taking those requirements into account, we have selected the libraries *Expat*, *libxcrypt*, *OpenSSL*, and *zlib* for evaluation, all of them within the top 150 packages (out of 70 000) in the Debian popularity contest. This also covers main dependencies of the *nginx* and *Apache HTTP server*.

Environment

We perform all tasks in container environments with a minimal base system installed, running on an x86_64 architecture (Intel Core i5-8400 with four cores and 16 GiB of RAM).

For all tests, LUCI is configured to automatically detect changes in library files or their symbolic links on the file system, check compatibility, and, if applicable, update libraries during runtime. A few seconds after applying an update, the executable section of older library versions is unmapped. Any subsequent access to the old library would trigger the user-space page-fault handler, which marks the update as failed and results in a restart by the supervisor script several seconds later. The delay before a restart allows us to ensure that the program correctly continues even after a failed update, not producing unexpected results or aborting. Incorrect results or abnormal program terminations, regardless of whether the library release or the update causes them, are explicitly noted.

5.1 Expat

Since the *Expat XML parser* is used in numerous applications [46] and hence part of all popular *Linux* distributions, its dozen critical vulnerabilities discovered within the last decade make it a good target and test candidate for LUCI. We focus on major version 2, having 27 version releases since 2006 – with 29 CVEs (including 11 critical vulnerabilities).

[5] Using launchpad.net for Ubuntu and snapshot.debian.org for Debian.

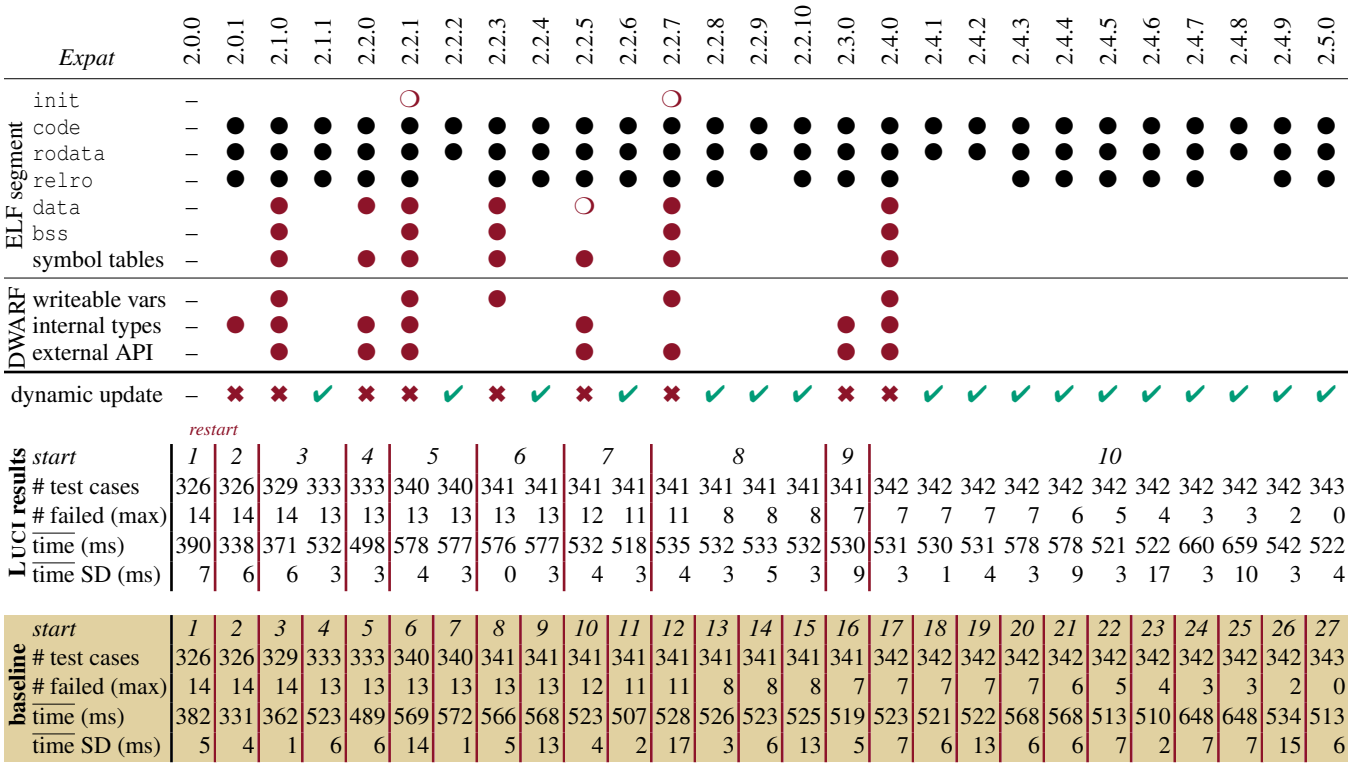

Table 1: Successively (every 25s) replacing the *Expat* library on the filesystem with all vanilla version 2 releases in chronological order while running the test suite (in an endless loop). The upper part of the table shows LUCI's internal analysis of each changed library binary compared to the previously loaded version. ● denotes detected changes of symbols in the corresponding segment, while ❍ marks identical segments having symbols with modifications in their dependencies (at other segments). When non-updatable changes (highlighted with red color) are detected, the library version is incompatible (✖) and the test suite gets restarted (marked by a vertical bar: |). Compared to the baseline (using the default RTLD, shown on the bottom), LUCI can prevent two thirds of restarts while providing the same results (as shown in the middle row).

The developers maintain a good and regularly updated test suite in a single program, which we have to slightly modify: Tests causing segmentation faults and double-frees in older releases are dynamically omitted in those vulnerable versions. Further, due to a slight API change (new symbols in 2.1.0 and 2.4.0), the corresponding tests are only enabled if those symbols are available in the currently active library release (using weak linkage). The LUCI-loaded program now executes all eligible tests sequentially in an endless loop while measuring the duration and the number of executed and failed tests[6].

Vanilla The results in Table 1 show that LUCI is able to perform 17 dynamic updates (67%) during runtime – with 11 subsequent updates (starting with version 2.4.0) without requiring any restart. During those patches, we observe a steady decrease in failed test cases due to the bugs fixed in newer releases, identically to manually executing the test suite with the corresponding library version using the default RTLD.

[6]A use-after-free bug (CVE-2022-40674) causes jitter in the results for versions prior to 2.4.9, as the corresponding test only sometimes fails.

The average duration of a test iteration in LUCI is slightly worse (about 2%), but this is caused by our RTLD implementation itself since it is not as optimized as the *glibc* counterpart and needs to use some workarounds/indirections for compatibility with standard `libc.so.6`: The timings with LUCI are consistent regardless of whether the DSU functionality is enabled or disabled. Furthermore, the raw data does not show any notable increase while updating a library to a new version.

Most failed updates have obvious reasons, like changes in the writeable data section, which LUCI automatically detects in both binary and DWARF debug information. However, LUCI rejects the updates to 2.0.1 and 2.3.0 only due to debug information. A detailed look reveals that in both cases only a single enumeration value was added. This causes a different hash of the datatype (and, in the latter case, the API as well) even though an update would be possible – which we validate in additional tests. However, the currently strict setting safely allows certain update directions: It is not only possible to skip several releases (e.g., 2.4.4 → 2.4.9), but rolling back to an earlier release is also possible – as long as the hashes are identical and the requirements of the binary are met.

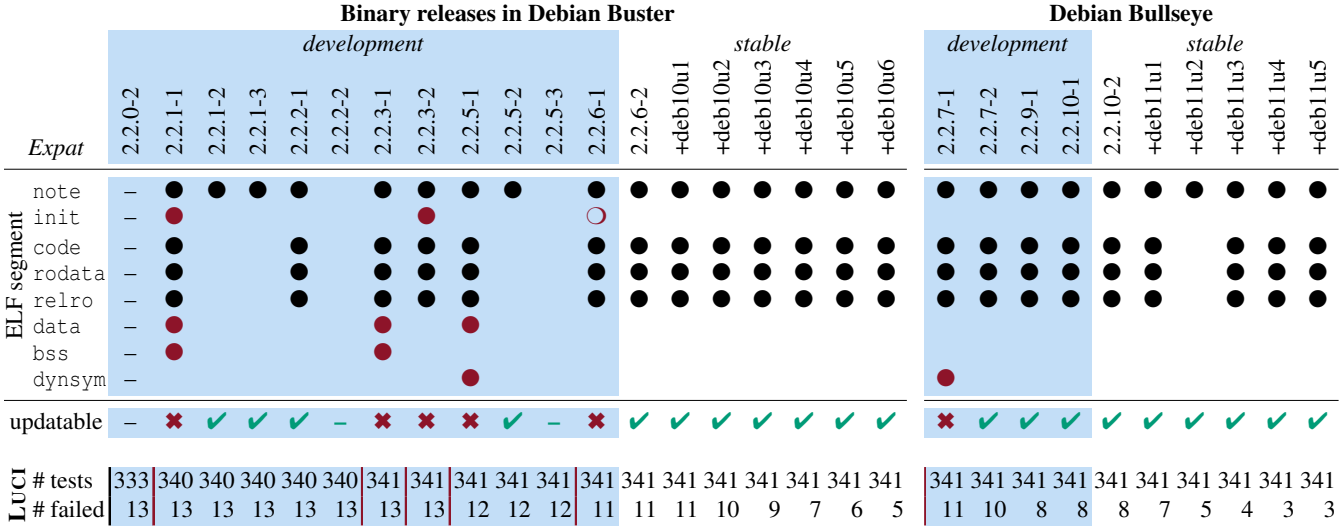

Table 2: *Expat* test suite running with binaries retrieved from the official Debian repository – including development builds.

Backtesting Additionally, we back-test the approach using prebuilt packages from distributors. For Debian, we can retrieve the binaries from the snapshot archive, which is not limited to updates for stable releases but includes all development builds as well. The implications become apparent when considering the Debian workflow: Whereas during the development phase latest library versions are maintained – having the same update incompatibilities as our vanilla builds above – the versions are frozen after the Debian release gets stable. However, that does not mean a standstill at all: The Debian team puts effort into backporting fixes for issues, like the decreasing number of failed test cases in Table 2 shows: While *Debian Buster* uses *Expat* 2.2.6 in its stable release 2019, their latest package `2.2.6-2+deb10u6` fixes several vulnerabilities found in 2022. Since they usually do not include feature changes but only minor changes in the code section, the stable phase is an ideal situation for LUCI: all package releases are eligible for dynamic updates. When also considering development builds, LUCI can prevent 72% of restarts in Buster and 90% in Bullseye.

Although the stable phase used in productive environments is our main focus for LUCI, the development builds offer interesting insights about the applicability of our approach: Several different versions of the build utils were used during that time; however, this does not necessarily cause incompatibilities. For example, package 2.2.9-1 was built with *GCC* 9.2, while 2.2.10-1 used *GCC* 10.2, but a dynamic update is still possible. It can also happen that a newer release build results in identical code and data segments, which may or may not produce a different *BuildID* stored in the `note` section. For example, the unequal *BuildID* between 2.2.5-1 and 2.2.5-2 requires LUCI to analyze the file, while the subsequent update to 2.2.5-3 is binary identical, allowing LUCI to safely skip any further processing quite early.

Ubuntu is similar regarding the version freeze after stable release, as shown in Table 3: Even with development libraries, 83% of restarts can be omitted with LUCI in *Jammy*. Library updates published for the stable release can all be dynamically applied; the same is true for all library releases in *Focal*. In both versions, there is only one update each, simply differing in the *BuildID* compared to its predecessor; all other updates have actual code changes.

These results highlight the effectiveness of LUCI in a real-world scenario, as it can update the majority of all *Expat* versions, even off-the-shelf libraries built with different compilers and without access to debug information.

Build		*Expat*	updatable
custom (vanilla)		2.0.0 – 2.5.0	17 / 26 (65%)
Debian Buster	*all*	2.0.0 – 2.2.6	13 / 18 (72%)
	stable	2.2.6	6 / 6 (100%)
Debian Bullseye	*all*	2.2.7 – 2.2.10	9 / 10 (90%)
	stable	2.2.10	5 / 5 (100%)
Ubuntu Focal	*all*	2.2.7 – 2.2.9	6 / 6 (100%)
	stable	2.2.9	4 / 4 (100%)
Ubuntu Jammy	*all*	2.4.1 – 2.4.7	10 / 12 (83%)
	stable	2.4.7	2 / 2 (100%)

Table 3: Summary of LUCI executing the *Expat* test suite using different library builds (including off-the-shelf binaries).

5.2 libxcrypt

The *extended crypt library* [14] is a modern replacement for *glibc* `libcrypt.so.1`, providing various one-way hashing methods that are frequently used for user authentication. Several test cases are included in the source. Most of them solely

Build	*libxcrypt*		updatable		
custom (vanilla)	4.0.0 – 4.4.33	*all*	35 / 47	(74%)
		unqiue	19 / 31	(61%)
Debian Bullseye	4.4.10 – 4.4.18	*all*	7 / 7	(100%)
		unqiue	3 / 3	(100%)
Ubuntu Focal	4.4.10	*all*	8 / 8	(100%)
		unqiue	0	–
Ubuntu Jammy	4.4.18 – 4.4.27	*all*	4 / 4	(100%)
		unqiue	4 / 4	(100%)

Table 4: Program running all *libxcrypt* tests in parallel (using multithreading) on LUCI while exchanging library builds.

use the shared library interface without any knowledge about the internal structure and are therefore suited for our evaluation. However, we have to exclude three test cases because of severe memory leaks and division-by-zero bugs in conjunction with older releases. Our test program endlessly repeats each eligible test case in a distinct thread without any synchronization whatsoever, requiring LUCI to apply updates to a process with several active threads.

When building and testing all 48 releases of version 4, LUCI is able to dynamically update 74% of them. However, 11 builds are binary identical to the previous one (e.g., 4.4.28), and 5 builds only differed in their *BuildID* – still enabling LUCI to update 19 out of 32 unique builds with actual code changes during runtime.

During updates, we also observe a steady decrease in failing tests: While 9 (out of 25) test cases report errors when running with the first release of the library (version 4.0.0), there are no more unsuccessful tests after the latest update.

While *Debian Buster* still retains the *glibc* crypt library, *Bullseye* moved to this replacement library (package name `libcrypt1`), which can be fully dynamically updated as stated in Table 4. In *Ubuntu Focal*, one can find 9 different packages, but their code and data are all identical (having 5 different *BuildID*s). In contrast, *Jammy* has 5 actual different builds that are all compatible. Due to the fact that *Bullseye* and *Jammy* only have a single *stable* release, we consider *all* releases, including *development*.

The approach of LUCI does not restrict the update of a library concurrently employed by several dozen active threads in a multithreaded application, as these results show.

5.3 OpenSSL

Because of its broad application – and several severe vulnerabilities in recent years – the secure communication library *OpenSSL* has achieved a certain degree of brand awareness. We focus on its two main libraries `libssl.so` and `libcrypto.so` and set up a client-server environment using the `openssl` utility for testing.

Of 20 releases in OpenSSL 1.1.1, only 6 versions of `libssl.so` seem to be updatable and none of `libcrypto.so`. Further investigation showed that the `ssl3_undef_enc_method`-structure could be blamed: Its members point to functions that can reach `ERR_raise` using an array containing error messages, which are frequently edited in the source. This would not be a problem if the structure in question, which is – to the best of our knowledge – never modified, were marked as constant. However, since it is currently writeable and hence placed in the `.data` section, LUCI requires all of its references recursively to be identical to the previously loaded library for updates. Although LUCI's decision to reject such changes works just as intended, when temporarily relaxing this constraint, 9 releases in both libraries meet the requirements for an update.

However, after every update during testing, LUCI detects code usage in superseded libraries and hence reports it as failed. Again, the reasons for this shortcoming are function pointers in writable data: Instead of statically initializing a variable, *OpenSSL* does this during runtime[7] – taking over the work originally intended for the RTLD and hence leaving LUCI with no clue about those relocations, unable to correct them to the updated version.

Using `uprobes`, we can verify that only old code referring to unchanged functions was executed and the updates are effectively applied. However, LUCI is currently not meant to handle such code as further discussed in Section 6.

5.4 zlib

The library *zlib* is used in many software dealing with data compression and was not exempted from serious vulnerabilities. We are testing version 1.2 – since the version numbering switches between three and four places, there are 49 releases from 1.2.0 to 1.2.13 (the latest at the time of writing). Since the full code coverage test of the inflate algorithm cannot be used due to its interference with internal structures, we run the various de- and inflation tests of the *zlib* example file in an endless loop while updating the libraries.

Of all releases in the past two decades, only half are suited for dynamic updates, as the results in Table 5 show. The main reasons preventing an update are the 19 interface extensions during that time, which are often accompanied by additional data structures – both creating different debug hashes. The binary builds show an ambivalent picture as well: due to the interface changes and the fix for CVE-2018-25032 modifying internal structures, none of *Debian Buster*'s builds can be updated. The same CVE applies to *Debian Bullseye* and *Ubuntu Focal*, which have around half their packages eligible for dynamic updates. Only for *Ubuntu Jammy* (whose development began after discovering this CVE), all releases can be applied dynamically.

[7] For example, `names_lh` in `crypto/objects/o_names.c` is initialized with `NULL` and assigned once with a fixed value in a custom `RUN_ONCE` function during start.

Build	*zlib*	updatable		
custom (vanilla)	1.2.0 – 1.2.13	*all*	24 / 48	(50%)
		unqiue	24 / 48	(50%)
Debian Buster	1.2.8 – 1.2.11	*all*	1 / 3	(33%)
		unqiue	1 / 3	(33%)
Debian Bullseye	1.2.11	*all*	4 / 5	80%)
		unqiue	3 / 4	(75%)
Ubuntu Focal	1.2.11	*all*	5 / 7	(71%)
		unqiue	2 / 4	(50%)
Ubuntu Jammy	1.2.11	*all*	4 / 4	(100%)
		unqiue	2 / 2	(100%)

Table 5: *zlib* de- and inflations tests using LUCI while exchanging library builds.

6 Discussion

Unlike several other DSU approaches, LUCI does not aim for general updateability and deliberately sacrifices some features: Most notably, the requirement for identical writeable data segments, which allows multiple library versions to coexist concurrently in memory, prevents changes of static variables. In case the library maintains some sort of state, it must not differ between the old and new versions for the same reason. Hence, changes to the initialization functions are prohibited. Consequently, record types have to be equal as well since they might be used in a shared state during the update transition (e.g., `structs` in heap or stack memory). If the lifetime of a pointer to an internal function outlasts the execution time of the function in which it was assigned, old code may be executed after an update. Furthermore, a related case can occur when a library function resides for a long time on the call stack, possibly because of an endless loop.

Accordingly, LUCI statically verifies the compatibility of data and interface before starting the update, while afterward dynamically detecting the execution of old code: To prevent abnormal terminations, LUCI takes a strict course, favoring false positives over false negatives. If a new version of a library does not meet all requirements and therefore is not eligible for dynamic updates, the process remains running in a valid state while LUCI notifies users about the non-updatable version, so they can manually restart the service. However, in case any subsequent update is again compatible with the currently active library, the update will be applied.

For many libraries, this pessimistic approach is sufficient to update most library versions, especially when it comes to minor (patch-level) changes like stable release branches of distributions: The approach's restrictions rarely apply to bugfixes, which most frequently require a timely deployment. The decreasing number of failures in the *Expat* test suite in Section 5.1 demonstrates the immediate effect of bugfix updates. However, extensive bugfixes and feature changes with cross-cutting changes cannot be applied, as seen in major version updates (e.g., *Expat* 2.3.0 → 2.4.0).

A notable exemption is *OpenSSL*: Although it is an interesting target for DSU due to its wide distribution, it is notorious for its code quality [4, 19], and hence the failing results are not surprising. While a first examination suggests that a few changes in its code (which we rather categorize as coding-standard fixes) would considerably improve its updateability, there are possibilities for LUCI to handle such libraries: By using a fine-grained code-access–detection method like `uprobe` and `ptrace`, further conclusions about the actually executed symbols in old libraries can be drawn. Accordingly, LUCI can ignore accessed symbols that are identical to their corresponding newer version. However, in contrast to the currently employed coarse-grained user-space page-fault mechanism, this would require additional permissions and induces overhead. Nevertheless, if a function pointer actually refers to a symbol that has been modified in the updated library, countermeasures are possible: LUCI could alter the old library's code in such a way that it redirects the control flow to the corresponding new version of the symbol (e.g., by using a `nop` slide) – but at the same time losing the advantage of simplicity and safety while not having to modify the `text` section.

It is worth mentioning that function pointers to symbols in other shared libraries do not point directly to the target but to the corresponding PLT entry – which LUCI fixes on update. Moreover, the use of virtual inheritance in C++ is not affected as well: Such objects are internally extended by an additional `vpointer` attribute, which references the `vtable` stored in the (relocation-)read-only section and is updatable.

A crucial limitation that LUCI shares with other automatic DSU approaches is the application of structural changes, which can become arbitrarily complex due to the semantic gap between (the intentions at) the source code level and the information available at the binary level after compilation. They are generally unrecognizable on a binary level without further context.

Listing 1 shows a contrived example of a change in a spinlock implementation: The semantic change of the value signaling the holding of a lock from `1` to `0` is only reflected in

```
1  typedef int lock_t;
2
3  void lock(volatile lock_t * var) {
4  -     while(!CAS(var, 0, 1)) {}
5  +     while(!CAS(var, 1, 0)) {}
6  }
7
8  void unlock(volatile lock_t * var) {
9  -     *var = 0;
10 +     *var = 1;
11 }
```

Listing 1: A contrived example of a code modification that LUCI cannot automatically reject, due to changes at a higher semantic level.

the functions' machine code. It is indistinguishable from a valid (i.e., bugfix) code change, and it does not change the interface. Consequently, LUCI cannot automatically detect this as an incompatible update. Even restrictions such as *activeness safety* [16], which prevents active functions (on the call stack) from updating, would allow an update point inside the critical section: For example, if one thread can hold the `lock` and the incorrect update is applied, then another thread can incorrectly acquire the `lock` a second time. However, proper software-engineering techniques requiring `lock_t` to be an `enum` with constants `LOCKED` and `UNLOCKED` would enable LUCI to detect the incompatibility using *DWARF* information and reject the update.

Data structures can pose similar issues regarding the detection of incompatible changes: While changes in `structs` are reflected in the debug information, a semantic modification of the access using only pointer arithmetic and casting is not detectable by LUCI. This lack of further information about the data layout is especially true for dynamically allocated memory. Further problems may arise if the modification of function parameters can have an impact on the process environment (e.g., adding a write-protection flag in `mmap`).

The problems described can be tackled with carefully chosen manual update points and hand-crafted (or test-cases–assisted [25]) state transformations. However, this would involve a significant amount of work for each library. For LUCI, we instead propose a more pragmatic solution by analyzing the change set at the source code level and explicitly marking a binary as *compatible* or *incompatible* with the previous version. Maintainers or distributors usually have the knowledge to perform this compatibility review. The resulting information can be included in the metadata of the binary (`note` section) or the package. Alternatively, the compatibility check can be carried out independently by third parties (e.g., by providing the information along with the debug hash).

To facilitate the compatibility review, LUCI has tooling support to automatically identify obviously incompatible versions (e.g., different writeable section). A further LUCI tool for simplifying the review shows the associated source-code lines that belong to the modified code in the resulting binary (using the *DWARF* symbols). With LUCI, we argue that less knowledge is required to decide on the update compatibility compared to manually writing update routines (e.g., introducing update points or writing state transformers).

In summary, Listing 1 illustrates that corner cases exist that circumvent LUCI's automatic compatibility check. Therefore, as mentioned, LUCI's tooling infrastructure assists the user in performing manual compatibility checks. However, all the libraries we have analyzed so far have well-structured code that does not require manual intervention. From this practical observation, we argue that LUCI's approach solves numerous real-world code-patching problems.

Regarding the aspect of LUCI's memory demand, we argue that having multiple coexisting versions of the library in memory is rather unproblematic: Non-writable segments are file mappings and, therefore, do not permanently reside in memory. The data segments exist only once due to LUCI's memory-aliasing technique.

7 Conclusion

Even though dynamic software updates are a well-received research topic and the benefit due to security concerns is undisputed, they barely made their way to user space on our everyday systems due to the required effort for software developers. In this paper, we propose a concept addressing the existing obstacles, hereby focusing on the most frequently reused kind of software: shared libraries.

Analysis of common bugfix patterns, including their effect on the resulting ELF files, allows the conclusion that the metadata is sufficient to enable a dynamic linker/loader to update today's binary-distributed shared libraries without requiring any changes or inducing additional runtime overhead.

To validate this claim, we have implemented our own dynamic linker/loader LUCI, which acts as an evaluation platform for live-patching common binaries: LUCI dynamically updates many versions of popular shared libraries like *Expat*, *libxcrypt*, and *zlib*. But even in the case of incompatibilities, normal execution is maintained: In no case does an update, neither successful nor failed, lead to an abnormal program termination or incorrect behavior during our evaluation.

The presented results suggest that the proposed approach is practicable and can play a part in paving the way for the common use of live-patching of user-space applications.

Although binary-compatible and supporting several of its interfaces, LUCI is not deemed a replacement for the existing default dynamic linker/loader (e.g., from the *glibc* project) but is intended to support further investigation and research for loader-based dynamic software updates. We hope that LUCI will help DSU become a reality in user space – and, for example, be supported by the standard RTLD some day.

A Artifact Appendix

Abstract

Our artifact includes the source of the dynamic linker/loader LUCI itself, alongside with a script to evaluate its live-update capabilities on the libraries *Expat*, *libxcrypt*, *OpenSSL*, and *zlib* using suitable tests. For building and testing, container environments (based on *Docker*) are employed. The artifact contains scripts to support automatically building these libraries from their official source and tools to download the corresponding Debian and Ubuntu packages. LUCI is intended for a recent Linux environment on an x86_64 architecture.

Scope

We aim to achieve two main goals with the artifact: Firstly, we want to encourage reproducing the results presented in this paper, the artifact therefore supports

- building the dynamic linker/loader LUCI, which is implemented according to Section 4,
- building several release versions of the libraries *Expat*, *libxcrypt*, *OpenSSL*, and *zlib* using the source from official repositories,
- validating the changes of the test suites, and
- running all experiments described in Section 5. This enables one to reproduce the results referred to in text and listed in further detail in Table 1, Table 2 and Table 3 for *Expat*, Table 4 for *libxcrypt*, and Table 5 for *zlib*.

Secondly, since we are aware that there is a lack of "hackable" dynamic linker/loaders (especially when it comes to *glibc*-compatibility), we provide LUCI for academic purposes, mainly but not limited to research on loader-based DSUs.

Contents

The dynamic linker/loader consists of the following internal sub-projects (each distributed in a separate repository):

`dlh` provides basic functionality similar to libc/STL for creating static freestanding applications (without *glibc*).

`elfo` is a lightweight parser for the Executable and Linking Format, supporting common GNU/Linux extensions.

`bean` binary explorer/analyzer to compare shared libraries and detect changes, which uses the Capstone Engine.

`luci` dynamic linker/loader with DSU capabilities and *glibc* compatibility (`ld-linux-x86-64`).

To build LUCI, it is sufficient to recursively clone the repository with its submodules and run `make` in the main folder. Further details are provided in the `README.md`.

For each shared library used in Section 5, there is a corresponding subfolder in the evaluation repository. With `gen-lib.sh`, the desired version(s) are built, `gen-test.sh` compiles the test program (located in `src-test`), and `run-test.sh` runs the experiments with automatic library exchanging in a containerized environment.

Hosting

Both LUCI's source code and the evaluation environment are available at github.com/luci-project/eval-atc23.

The utilities for building the shared libraries retrieve the source code from the following official repositories:

- github.com/libexpat/libexpat
- github.com/besser82/libxcrypt
- git.openssl.org
- github.com/madler/zlib

To acquire the Debian and Ubuntu packages released for each library, the utilities use the web services launchpad.net, metasnap.debian.net, and snapshot.debian.org.

Requirements

We have written all parts of the dynamic linker/loader in C/C++. A standard GCC (version 9 & 10) is sufficient to compile the project. While LUCI has no further restrictions on its build environment, its execution is currently limited to distinct versions of certain distributions, since LUCI must conform to the corresponding *glibc* interface (see Table 6).

To enable all features of LUCI, a Linux kernel 4.11 or newer with a default configuration is required. We recommend a Debian Bullseye installation using its standard kernel image.

We use *Python 3*, *GNU make*, and *Bash* for helper scripts. The tests are executed in a *Docker* container using the official Debian and Ubuntu images. The hardware platform should be an x86_64 architecture with at least 16 GiB of RAM and 6 GiB of storage.

Distribution	Release	glibc
Debian	Stretch (9)	2.24
	Buster (10)	2.31
	Bullseye (11)	2.31
	Bookworm (12)	2.36
Ubuntu	Focal Fossa (20.04)	2.31
	Jammy Jellyfish (22.04)	2.35
AlmaLinux Oracle Linux RedHat Enterprise Linux	9	2.28
Fedora	36	2.35
	37	2.36
openSUSE Leap	15	2.31

Table 6: Distributions currently supported by LUCI.

Abstract

Compilers today provide a plethora of options to optimize and instrument the code for specific processor extensions, safety features and compatibility settings. Application programmers often provide further instrumented variants of their code for similar purposes, controlled again at compile-time by means of preprocessor macros and dead-code elimination. However, the global once-for-all character of compile-time decisions regarding performance-, debugging-, and safety/security-critical features limits their usefulness in heterogeneous execution settings, where available processor features or security requirements may evolve over time or even differ on a per-client level.

Our *Multivariant ELF (MELF)* approach makes it possible to provide multiple per-function compile-time variants within the same binary and flexibly switch between them at run-time, optionally on a per-thread granularity. As MELFs are implemented on binary level (linker, loader), they do not depend on specific language features or compilers and can be easily applied to existing projects. In our case studies with SQLite, memcached, MariaDB and a benchmark for heterogeneous architectures with overlapping ISAs, we show how MELFs can be employed to provide per-client performance isolation of expensive compile-time security or debugging features and adapt to extended instruction sets, when they are actually available.

1 Introduction

Modern compilers provide a plethora of options to statically optimize and instrument the code. Natural examples for such at-compile-time tailoring include support for hardware-specific processor extensions, but also compiler-specific debugging, program instrumentation, and sanitizing aid. These options commonly do not alter the semantics of the code, but influence its *nonfunctional* properties with respect to performance, safety, security, and compatibility. They are put under the control of the developer, because they reflect important tradeoffs: Exploiting special instruction-set extensions can greatly improve performance [1], but at the cost of losing compatibility to smaller or older processors. Letting the compiler instrument the code with extra sanity checks increases safety and security [2]–[6], but comes at a significant performance cost. This also holds for many higher-level instrumentations that are inserted manually by the developers, often by means of the preprocessor: Typical examples are executable asserts [7], [8], tracing, and logging support, which have been shown to actively increase safety [9] and security [10], but are commonly disabled at compile time in production builds due to their performance overhead.

However, in a world of increasing dynamic hardware and use-case heterogeneity, the global once-for-all character of compile-time decisions regarding performance-, debugging-, and safety/security-critical features limits their usefulness: In heterogeneous cloud environments or on machines with heterogeneous ISAs, the availability of processor features may change over time, even for individual threads. The performance costs of the extra sanity checks might be acceptable while processing input from external users, but not in general. In a DevOps setting, it would be useful to temporarily enable tracing and logging, but only for that specific client who is having troubles.

In short: It would be useful to decide at run time, depending on the dynamic context, on features that are technically bound at the compile time of the code. We call this flexibility *semi-dynamic variability*, which conceptually lays between static and dynamic variability in that the code of all variants is still generated at the compile-time of the project (thus, facilitating whole-program optimization), but the actually used variants can be decided on at run time.

While there are special-purpose solutions for semi-dynamic variability in some domains (e.g, math libraries [11] or the Linux kernel [12]) that adapt at load or initialization time to the actually available hardware features, these solutions are limited in scope, require manual intervention, and typically involve costly extra indirections via proxies [13] or inherently fragile means of fine-grained run-time code patching [12]; often they have to prevent inlining.

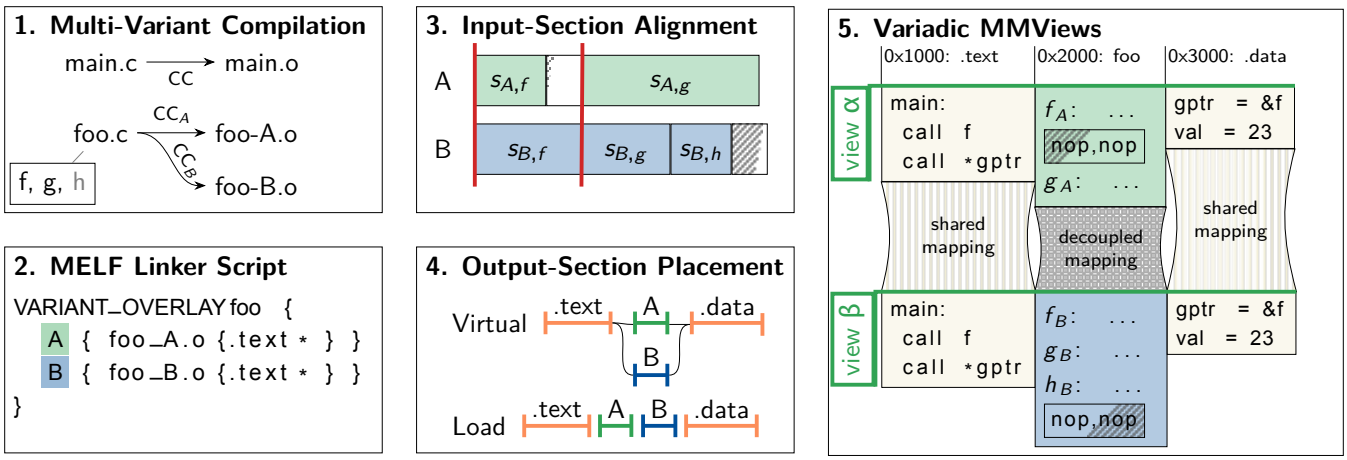

Figure 1: Overview about the MELF approach. At compile time (1), parts of the program are compiled into multiple variants (A and B), which are captured and organized in the linker script in the variant overlay `foo` (2). In the linker, the matched input sections are aligned (3) and the resulting output sections (4) are placed in the virtual- and load-address space. At run time (5), the variants are loaded into different MMViews, which share everything but the decoupled regions; common symbols and pointers are stable across views.

About this Paper

We present *multivariant ELF (MELF)* as an easy-to-apply approach for the inclusion of multiple compile-time variants within the same binary and flexible switching between them at run time on function/section granularity. MELFs are implemented solely on binary level, hence mostly independent of the employed languages and compilers (as long as they produce ELF-compatible objects), which also makes them easy to apply to existing software projects. Function variants are aligned by the MELF linker to the same virtual address, so that existing pointers or relocations remain valid even in case of a variant switch at run time. They can optionally be loaded by the MELF loader into additional in-process address spaces (with the MMViews kernel extension, taken from [14]), where multiple variants can coexist at the same time to be applied on a per-thread level.

In particular, we claim the following contributions:

- We provide the MELF concept, as an end-to-end solution for semi-dynamic variability.
- We describe our MELF linker (an extension to LLVM's LLD linker) and the MELF loader.
- We demonstrate the MELF benefits and costs in four case studies from different domains.

2 The MELF Approach

The MELF approach (see Fig. 1) provides semi-dynamic variability on function granularity for compiled functions by aligning functions (and data) with a modified LLD at link time. At run time, either one of variants is loaded into the process's address space or, with the help of the MMViews, multiple variants can coexist simultaneously. We describe our approach for *executable and linking file format (ELF)* and Linux processes, but are confident that our approach is generalizable to other binary formats (e.g., COFF, Mach-O) and process models.

2.1 System Model

We target programs written in compiled languages (e.g., C, C++, Rust, ...) that organize their binary code in regular, hierarchically-called functions (e.g., unlike Haskell, Forth). For a subset of all functions (i.e., not `main()`), it is intended to include multiple function variants in the final binary. For these functions, the signature (including the mangled symbol name) must be equal and their side effects on the program's object space must be compatible. The compiler must be able to put functions into their individual binary section.

2.2 Compile-Time: Static Variant Generation

First (Fig. 1, step 1), we have to statically generate multiple variants of our functions at compile time. These static variants can, for example, originate from translating the same translation unit multiple times with different compiler flags or CPP configurations. But also, manual variant encoding (e.g., directly in assembler) or programmatically in the compiler via guided-function specialization [15] is possible.

In Lst. 1, we show that this variant generation is simple with modern build systems, like CMake [16]. In the example, which is taken from our SQLite3 case study (Sec. 3.1), we compile the SQLite source files twice into two static

libraries.[1] Both libraries are compiled with different predefined CPP macros and linked into the `main` executable.

```
# Collect SQLite 3 Source files
file(GLOB SRCS sqlite3/*.c)

# The Non-Debug Version
add_library(sql-ndebug STATIC ${SRC})
target_compile_options(sql-ndebug -DNDEBUG=1)

# The Debug Version
add_library(sql-debug STATIC ${SRC})
target_compile_options(sql-debug -DSQLITE_DEBUG=1)

# Case-Study Executable: main
add_executable(main main.cc melf_loader.c)
target_link_libraries(main sql-ndebug sql-debug ..)
```

Listing 1: Multi-Variant compilation with CMake

Besides the multi-variant compilation, the ELF [17] standard forces us to put each function and each data object into their own section. In order to understand this requirement, we now take a quick detour into the ELF standard, which is also necessary to understand the MELF linker.

Excursus: ELF Sections vs. Functions The *executable and linking file format (ELF)* is a format that is used for linking *and* for loading programs. An ELF contains multiple byte streams (code, data, debug info, ...) that are arranged in two views: In the link view, those byte streams are called *sections*, while they are called *program headers* (or segments) in the load view. Additionally, the link view makes use of *symbols* as named offsets into a section. Further, *relocations* specify how to edit a byte stream while linking it to a virtual address. In a nutshell, the linker arranges the link-time sections into load-time segments while resolving (most) relocations.

The basic unit of linking is the section and not a (language-level) function or (global) data object. In fact, the linker has no idea about those, and it cannot (due to compile-time resolved relocations) break up a section back into smaller pieces. Therefore, as we want to align the function's start address, we have to instruct the compiler[2] to put each function (and data-object) into its own section, named like the (mangled) function name. For example, the C++ function `void foo(int)` will end up in the section `.text._Z3fooi`.

For data objects (i.e., global variables and read-only data), we require that all variants share the same (data-) object space. For this, the linker has to throw away all but one instance, which requires each variable to be located in its own section[3]. Furthermore, we restrict the program's interpretation of the shared data objects: As objects can be accessed from different variants, we *require* that the interpretation of objects, statically *and* heap allocated, must be compatible across all variants. This means that matching `struct` fields have to be aligned, that language-level types have to be of equal size, and that variants must have a common understanding of the object state. Nevertheless, this restriction holds for many automatically-applied program transformations as they are nonfunctional by design. In Sec. 4, we will discuss this topic further.

After the multi-variant compilation, we end up with a set of ELF object files whose sections s can be categorized as follows: A *variant* $v = \{s_{v,1} \dots s_{v,n}\}$ is a collection of sections that should be visible together; all sections of one variant have to have the same *section type* (e.g., code, read-only data, ...), which becomes the *variant type*. A *variant overlay* (overlay, o) is a collection of $|o|$ equally-typed *variants* and a *variant-overlay group* (group) is a set of overlays that are semantically connected. For a program, multiple independent overlays and groups can exist. For example, besides a math-code overlay (non-AVX vs. AVX2), there can another overlay group (code and read-only data) for the SQLite library that allows to en/disable executable assertions. We call all sections that are not covered by a variant the *remaining* sections.

2.3 Link-Time: Virtual-Address Alignment

After the compile-time preparation, the linker generates the multi-variant ELF (Fig. 1, steps 2-4), for which it must match and align sections from the different variants within an overlay such that they end up with the same virtual address. For our implementation, we modified `LLD` [18], the linker of the LLVM project that is a drop-in replacement for the GNU `ld` and `gold`. We will describe the required linker modifications on base of this implementation. However, they should be easily generalizable to other linkers as well.

First (Fig. 1, step 2), the developer must be able to express the relationship between sections, variants, and overlays. For this, we add a `VARIANT_OVERLAY` statement to the linker-script language, which is the command language of `ld` (and `gold`/`lld`). The statement contains multiple variant statements, which define, similar to other commands, patterns that are matched against the *input sections*, which the linker extracts from the object files. The lexically first variant of an overlay is its *primary* variant. In the overview example, we see a linker-script fragment that defines an overlay `foo` with two variants (`A`, `B`), which collect the code (text) sections from the respective `foo_{A,B}.o`.

Thereafter (Fig. 1, step 3), we align the input sections within an overlay: For this, we first match sections from the different variants and identify those sections that occur only in one variant: Starting with all sections captured by the overlay, we group the sections by the key (variant, section name) and select a single section as representative for that key. While there is usually only one candidate section, ELF

[1] Static libraries are fundamentally different from dynamic libraries. They are only collections of object files, (nearly) transparent for the linking process, and induce no run-time overhead.

$v \backslash n$	f	g	h	X	J
A	$s_{A,f}$	$s_{A,g}$		$s_{A,X}$	$s_{A,J}$
B	$s_{B,f}$	$s_{B,g}$	$s_{A,h}$	$s_{B,X}$	$s_{B,J}$
C	$s_{C,f}$	$s_{C,g}$			$s_{C,J}$

Figure 2: Input-Section Table (extended running example)

section groups[4] and weakly-defined functions[5] can result in multiple candidates. In the former case, we can choose any section as the group representative, in the latter case we apply the usual override semantic for weakly-defined functions, but only within the group. With the representatives, we end up with one section $s_{v,n}$ per (variant, name)–pair and form the overlay's *input-section table*, which tabularizes the results. In the table (Fig. 2) for the (extended) running example, we see that f and g are present in all variants and h is private to variant B. For partially-filled columns (e.g., X) that contain more than one entry, we report an error.

With the table in place, we validate and manipulate the symbol table. With multivariant compilation, the linker will encounter the same symbol, which is a named pointer into a section, multiple times. Instead of reporting an error, we collect duplicate symbols and delete all but the symbol that points to the primary variant. In this process, we verify that each variant's symbol points to the same column and has the same offset.

While we usually report an error if this check fails, some compiler optimizations (e.g., function-body deduplication) can result in two aliased symbols pointing to the same section in one variant but not in the other. However, as we cannot align this section to two different sections in the other variant, we have to solve this rare situation differently: We equip each variant with a jump table (e.g., $s_{A,J}$ in Fig. 2) and insert a `jmp` instruction for one of the aliased symbols. In each variant's jump table, the instruction jumps to the correct section and offset, while we globally redirect the original symbol to the jump-table entry in the primary variant.

With all symbols being aligned within their column, we align the columns by padding each $s_{v,n}$ to $\max_{v_i \in o} s_{v_i,n}$. As this can induce large padding gaps, we use variant-local sections as *gap-filler sections*. Currently, we perform the filling greedy as we did not encounter a situation where a (more) optimal algorithm would be required. In the example (Fig. 1, step 3), the gray areas are padding and $s_{B,h}$ is used for filling the gap in B that $s_{A,g}$ provokes.

After column alignment, we place the variants in the ELF's virtual address space (Fig. 1, step 4). For this, we utilize the fact that the load address (where the loader will copy the section to) and the virtual address (where the section "thinks" it is) can disagree. We combine all sections for a variant (table row) in an *output section*; an established linker-internal concept that acts as an intermediate step between input sections and segments. Each output section is linked (i.e., relocated) to the virtual address of the primary variant, while we load them, by default, sequentially. Thereby, load and virtual address only match for the primary variant. All remaining sections can be linked as usual.

The result of MELF is a regular ELF binary, which is only special with regard for the non-primary output sections, whose load and virtual addresses do not match.

2.4 Run-Time: Multivariant Loading

With the MELF binary constructed, it is time to bring our multi-variant program to execution. As this depends on the indented usage scenario, this section will only provide the necessary primitives from which different use cases can be constructed (see Sec. 3).

First, we have to decide which variant(s) will execute and initialize the program state. As primary variants are loaded to their virtual address, the program automatically starts executing in those variants, and it also loads their data-segment contents. This also requires us to only run the constructors for global variables of the primary variant, which is done by discarding the initialization-array entries of the other variants.

For the usage of MELF's, we provide two operation modes by the MELF run-time loader library: With the *base mode*, only one variant per overlay is active at the same time, which the developer can replace with an explicit call into the run-time library. For this, we use the `mprotect()` system call to make the respective overlay region writable and copy the contents of the desired variant to the primary virtual address. To make overlay and variant regions known to the MELF loader, the linker places symbols with virtual and the load addresses before and after each output section; with these, the program can reference all variants in the program. Usually, the developer will only replace text and other read-only sections, as switching data variants would reinitialize the global variables. Also, for this mode to work, we demand that no thread currently executes or has a call frame for a function from the replaced overlay. This program state is called *global quiescence* [14].

As the base mode is of limited use for multithreaded programs, we also provide the *MMView mode*, based on MMViews [14]. Thereby, multiple variants can be active simultaneously and threads can switch *their* variants for which they only have to be *locally quiescent* (i.e., they do not execute a replaced function). As this mode requires the MMView kernel extension, we give a brief overview of its semantic.

Excursus: MMViews With MMViews, a process can have *multiple*, closely-synchronized, concurrently-active address spaces, which have the same structure: all mappings are equally placed and address-space modifications work si-

[4] e.g., used for deduplicating functions from C++ template expansions.
[5] Weak functions are only used if no non-weak counterpart is defined

multaneously on all MMViews. Also, the contents of most mappings are synchronized by sharing the physical page frames. Only for mappings that the user explicitly marked as *decoupled*, the kernel will establish a copy-on-write mapping, whereby those mappings contain MMView-local memory. Also, threads can switch between MMViews and can create a new MMView by cloning their current view.

The existing [14] MMView Linux extension implements MMViews as separate page-table trees. So, since an MMView is technically a separate address space, they induce higher memory overhead (for the page tables) and increase the TLB pressure if two MMViews are active on the same core. Also, page-table modifications, although the extension synchronizes them lazily, have a higher run-time overhead. However, switching views is rather cheap as the kernel only exchanges a single CPU register.

Coming back to MELF, we use the described extension to execute multiple variants in one process concurrently: We decouple all primary-variant regions, allowing the user to create one MMView for each desired variant combination. With the described base-mode primitives, the user can load different variants into the MMViews. Thereby, an MMView can combine these variants from the variant-overlay groups.

In Fig. 1, step 5, we see two MMViews α and β, which currently have loaded variant A resp. B. We see that the non-multivariant text and data remain shared and only in the overlay region (0x2000-0x3000) is decoupled. Since MMViews have a synchronized structure and the MELF linker aligned the start address of the multivariant functions, all common symbols (e.g., `call f`) and function pointers (e.g., `gptr`) are globally valid and threads in different views can easily co-operate.

With MMViews in place, a thread can switch variants on function-call granularity, for which call and return edges have to perform inverse MMView switches. For this, the run-time library provides a trampoline function (Lst. 2) that switches to the desired MMView, forwards arguments, restores the previous MMView and returns the return value. As the trampoline is not part of an overlay, it can also transfer the control flow between two multi-variant functions. The call protocol for MELFs defines the following call-chain:

1. Call `call_with_helper` with a variant index, function pointer and its arguments
2. Switch to the variant, save old return pointer and replace it by `call_return`
3. Jump to provided function pointer
4. Return from provided function pointer (now returns to `call_return`)
5. Switch back to the variant before the call-chain started
6. Jump to saved, original return pointer, ending the call-chain

```
_threadlocal variant_id_previous = 0;
_threadlocal variant_return = nullptr;
variant_id = 1;
func_pointer = &do_work;
func_arg = 10;
// 1. Call trampoline.
call_with_helper(variant_id, func_pointer, func_arg){
    asm {
        // 2. Switch view
        push variant_id
        syscall_variant_switch
        // Syscall result is old variant id. Save it.
        xchg %rax, variant_id_previous@threadlocal
        // Load new return pointer "call_return".
        leaq call_return(%rip), %r10
        // Exchange return pointer with "call_return".
        xchgq    %r10, (%rsp)
        // Save old return pointer.
        xchgq   %r10, variant_return@threadlocal
        // 3. Jump to function pointer.
        jmp func_pointer
    }
}

// 4. "func_pointer" will return to this function.
call_return(){
    asm {
        // 5. Load old variant id and switch back.
        mov variant_id_previous@threadlocal, %rax
        push %rax
        syscall_variant_switch
        // 6. Return to original return pointer.
        jmp    variant_return@threadlocal
    }
}
```

Listing 2: Trampoline function `call_with_helper` ensures to call `call_return` at the end of the call chain to switch back to the caller's original application variant.

Since the protocol always requires jumping back to the original application variant, we only demand local quiescence per thread.

3 Case Studies

As the MELF approach is a general semi-dynamic–variability method for compiled languages, we now provide multiple case studies to demonstrate the potential of our approach. We will justify, for each case study, its relevance, describe the usage of MELF, and show its benefits with a quantitative evaluation. Thereby, we will only focus on the MMView mode as we consider it the more interesting application mode for MELF.

Benchmark Setup

We cover the server-centric scenarios with a dual-socket system (Intel Xeon Gold 6252, 2.10GHz, 2×24 physical cores, 2 NUMA nodes, 384 GiB DRAM, hyperthreading disabled). Additionally, we use a smaller machine with more restricted hardware (Intel i5-6400, 4 cores, 32 GiB DRAM, no hyperthreading). On the software side, we used Debian

Table 1: Overview over the SQLite case-study binary

GNU/Linux 11 with an MMView-enabled Linux 5.15 kernel with Spectre and Meltdown mitigations enabled.

3.1 Case-Study: SQLite Asserts

With this case study, we demonstrate that MELF is able to overlay multiple handwritten code variants and that we can performance-isolate both variants for thread-contextualized execution (with MMViews). More concretely, we build a MELF binary that contains two variants of the SQLite library: (1) the *debug view*, where `assert()` statements and additional sanity checks are enabled, and (2) the *performance view*, where these are disabled. Within the same process, multiple threads execute read-only SQL queries, either with the debug view or the performance view. We vary the total number of threads and the number of threads in the debug view, as well as the benchmark machine.

Scenario Justification Unlike compiler-based security measures, executable asserts [7], [8] are inserted manually by the developers to test high-level invariants at run time. They are an intrinsic part of debug builds, which often include extended data structures and code paths to check application behavior. Thereby, assertions not only assist the development of safer programs [9], but they are also an active security measure [10]. However, due to their complexity, size and performance impact, they are usually disabled in production in favor of a performance/release build. With MELF, we can provide a more restricted debug view with enabled assertions, for example, for SQL queries that handle user input. Technically, this case-study is of interest as it shows how to manage multiple variants that interpret data differently.

Workload We use a geospatial proximity search, since handling two-dimensional data requires complex algorithms and data structures. On the list of 2856 UK postcodes, we issue SQL queries that find the geographically closest code that is not further away than 25 km for randomly chosen coordinates in the UK. For handling coordinates, we use SQLite's R-Tree plugin.

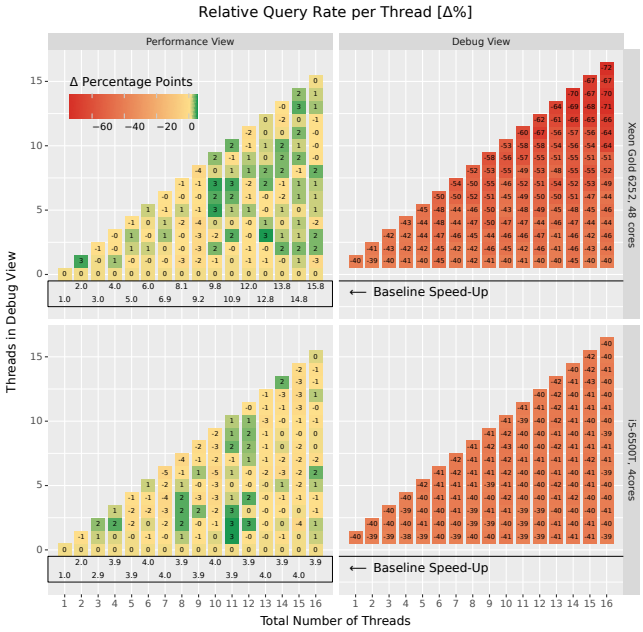

Figure 3: SQLite Performance Measurements

Benchmark In Tab. 1, we provide a comprehensive overview about the used benchmark binary. Since SQLite's default configuration did not scale beyond a single core, we had to disable some statistic features to limit contention. While running both views concurrently worked out-of-the-box for most parts, we had to unify the `struct sqlite_mutex` as the debug view requires additional fields to track mutex ownership. Without a unified data type, the address calculation for array elements differed and provoked a crash. In total, we had to change 30 lines of code.

For a seamless interoperability, MELF aligns 1 310 functions by inserting a total of 372.3 KiB of padding, which is 13.48 percent of the combined size in the virtual address space. MELF already optimized the required padding by using 109/202 view-private functions in the performance/debug view as gap fillers. For the mutable global data in (.data, .bss), we align both variants but only use the debug view's data.

Performance Isolation In order show that the MELF approach is able to isolate the impact of the debug view on threads in the performance view, we run the benchmark with 1 to 16 threads, whereby 0 to 16 threads execute permanently in the debug view, while the others execute in the performance view. We also execute the benchmarks on our 4-core and on our 48-core machine in order to determine if core contention has a significant impact. We execute each benchmark for 60 seconds, record the number of completed SQL queries

In Fig. 3, we show the per-thread SQL-query rate and normalize it to the results where all threads execute in the

performance view (y-axis = 0), which we consider the baseline for this experiment. For the baseline case, we also show the speedup to confirm that contention within SQLite itself is not the cause of performance degradation but only the usage of MMViews and MELF. As expected, we see near perfect speedup on the 48-core machine, while the speedup caps around 4 on the 4-core machine. Please note the highly asymmetric color scale in this figure.

In the debug view, we see a significant impact of the additional assertions and sanity checks on the query rate. As the slowdown on the 48-core machine (-39 % to -72 %) is significantly worse for more threads in the debug view than on the 4-core machine (-38 % to -43 %), we conclude that the additional sanity checks provoke more contention due to additional state locking.

In the performance view, we see that the number of threads in the debug view has no consistent impact on the other threads, and some results even indicate better indicate a higher performance with using MMViews. Therefore, we take a look at the relative standard deviations for the baseline case to determine if these results stem from SQLite itself. While we cannot derive any conclusions from the relative standard deviation for the 4-core machine (0.3 %–12.4 %), the 48-core machine (rel. stdev.: 0.3 %–1.7 %) suggests that the MELF approach also has a small impact on the performance view. If compared to the observed relative query rates (-4 % to 3.4 %), we conclude that MELF has a negative performance impact of around 1 percent and adds around 2 percent of jitter. Nevertheless, in relation to the impact of globally-enabled assertions, the MELF approach isolates the impact of additional sanity checks in SQLite successfully.

3.2 Case-Study: Thread Pools on Heterogeneous Instruction-Set Machines

With this case study, we show that MELF eases the programming of non-homogeneous multicore machines where cores share a common subset *instruction-set architecture (ISA)* but have additional heterogeneous ISA extensions. More concretely, we provide a thread-pool abstraction (see Fig. 4) that accepts jobs together with a hint on which core type the job will run best. Depending on the current load, the pool schedules the job (preferably) on a hinted core where it uses a MELF-prepared code view that exploits the core-specific ISA extensions or on another core with a different code view that is optimized for that core. Thereby, the thread-pool user fully utilizes her heterogeneous architecture without the need for adapting her code paths for the specific architecture.

Scenario Justification While the first non-uniform multicores (e.g., , ARM big.LITTLE [19]) came with a unified ISA, recent work [20]–[22] investigates on the performance and energy benefits of heterogeneous ISAs. However, ISA diversity poses a programmability challenge as programmer are not keen to distribute their program/data

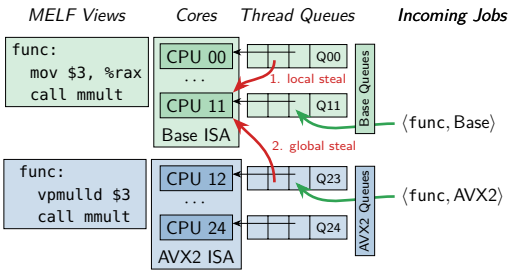

Figure 4: Heterogeneous-ISA Thread Pool

flow manually over different ISAs. Therefore, researchers proposed fault-and-migrate [23], cross-core invocation [24], and multi-kernel [25] methods to manage this variability. With MELF, we take a step towards the seamless integration of heterogeneous ISAs into our programs. Technically, this case-study is of interest as we make use of different cross-cutting compiler options on instruction level, something that is not easily expressible on a language or ifdef level.

System Model As we have no heterogeneous-ISA machine at hand, we simulate one by virtually dividing one NUMA node of our 48-core machine into two partitions (see Fig. 4): On the 12 AVX2 cores, modern AVX/AVX2 vector instructions are available, while the other 12 cores lack this ISA extension.

Work Load For our benchmark, we choose two job types that benefit differently from the AVX2 instructions: While jobs with a recursive Fibonacci (n=36, Base/AVX: 57.9 ms) do not benefit at all, the duration of a Matrix-multiplication (565×565) job drops from 58.3 ms to 38 ms on the AVX2 core. For the matrix multiplication, we use the Eigen C++ library (v3.4), which uses explicit ISA specialization according to the given compiler flags. Please note, that we have chosen the parameters such that the base-core execution time match. As work load, we submit 1000 jobs with 0 to 100 percent of the jobs being matrix multiplications (see Fig. 5) and record the end-to-end latency of those 1000 jobs as well as the accumulated job execution time.

Thread-Pool Variants Based on Eigen's non-blocking thread pool, which already implements thread-local queues and work stealing, we build three thread-pool abstractions that all take a function pointer and a scheduling hint as a job description: The **1 Pool, Base only** variant executes all jobs on a single 24-worker thread pool and only uses code without AVX2 instructions; the scheduling hint is ignored. The **2 Pool** variant uses two 12-worker thread pools, one for the base cores and one for the AVX2 cores; each core executes code specialized for its ISA and workers are pinned to its core; *no* stealing happens between the pools; and the scheduling hint selects the thread pool. The **1 Pool, MELF** variant uses a single 24-worker pool that utilizes MELF: Each worker thread is pinned to its core and executes in a MELF code view that is specialized for its ISA. If a worker

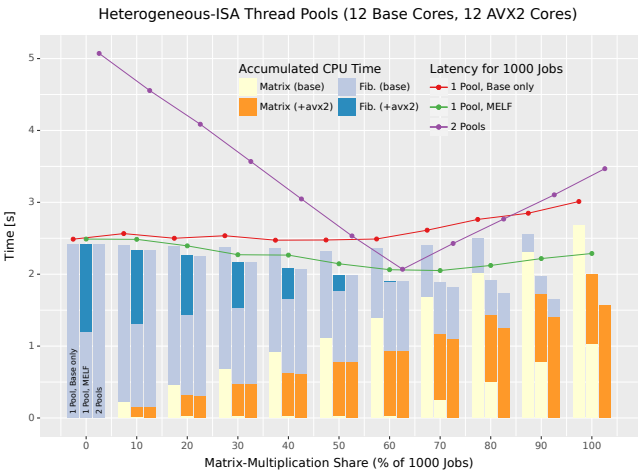

Figure 5: Latency and accumulated processing time for a mixed work load on a 24-core heterogeneous-ISA machine with different thread-pool configurations. To scale latency and processing time, the processing time was divided by 24.

queue runs empty, the worker first tries to steal from workers with the same ISA (see Fig. 4, 1. local steal) before stealing from other ISAs (2. global steal). Please note that stealing from a foreign ISA queue works seamlessly as the local MMView exposes the same functions but implemented with different instructions.

Results In Fig. 5, we show the evaluation results on one NUMA node of our 48-core machine, where we compare the three pool variants with respect to required processing time. Please note, that we divided the accumulated processing time by 24 to match its scale to the end-to-end latency. The remaining difference between latency and processing time stems from pool overheads and execution phases where not all workers execute jobs.

For the Base only variant, processing time is, as expected, only spent in the base code view (less bright colors). The slight increase in both curves stems from the increased cache pressure if 24 cores execute matrix multiplications in parallel compared to executing recursive Fibonacci calls on the (cached) stack. Although the 2 Pool variant spends the least amount of processing time, its end-to-end latency for 1000 jobs is significant at both ends as it only utilizes 12 cores at 0 and 100 percent matrix-multiplication jobs. Also, it achieves its best latency at 60 percent multiplications, which is expected from the ratio between a Fibonacci job (57.9 ms) and an AVX2-Matrix multiplication (38 ms).

Finally, the MELF-enhanced 1 Pool variant, performs better in both dimensions: Compared to Base only, it uses less processing time as it actually utilizes the AVX2 instructions, whereby also its latency is better. Compared to the 2 Pool variant, it always utilizes all cores resulting in a consistently low latency and only when more than 60 percent of the submitted jobs are Matrix-multiplications requires more processing time.

3.3 Case-Study: Profiling in memcached

In this case study, we dynamically en-/disable compiler-introduced function-level profiling on a per-thread basis with MELF and MMViews in `memcached` (v1.6.10). Similar to the SQLite study, we combine two memcached variants in one binary:(1) In the *profiling view*, the compiler (with the `-pg` flag) introduced `mcount()` calls into function prologues that record the invocation, while (2) the *performance view* contains the same functions but without profiling code. On a per-connection basis, worker threads either select the profiling or the performance view. For our benchmark, we gradually change the number of profiled connections and measure the request handling time within `memcached`.

Scenario Justification As developers cannot emulate complex production environments, it is often up to the DevOps team to detect and explain performance anomalies after deployment. For this function-level profiling, as provided by `gprof` [26], would provide precise insights about call frequencies and caller–callee relationships, but its cost prohibits us to have it permanently enabled. Also, in a multi-tiered environment, where only some clients incur a certain anomaly, it is desirable to enable profiling only selectively for certain threads and requests. Because `gprof` consists of both, a compiler instrumentation to modify function translation and a statically-linked profiling library, developers are unable to define exclusive code paths they want to profile. They can either profile the whole application or nothing at all. Thanks to MELF, the DevOps team can enable `gprof`-profiling dynamically and selectively, thus limiting the impact to a minimum.

Technically, this case-study is of interest as we reduce contention on cross-cutting features.

Work Load As a work load for our multi-variant `memcached` server, we use the `memtier` benchmark, which is a specialized benchmark for key-value databases [27]. On the client side, we use its default SET–GET ratio of 1:10 and start 16 threads with 50 clients each, resulting in 800 clients with 800 active connections to *memcached*. We execute the benchmark on the same machine, but pin `memcached` to one NUMA node, while pinning `memtier` onto the other. We record data request latencies until each view has serviced 100 million requests.

Benchmark Unlike other servers, `memcached` has an event-based design and the worker threads execute a state machine for each connection. Thereby, connections can be easily rebalanced between workers and one worker routinely handles many connections. To match the 16 `memtier` threads, we start `memcached` with 16 worker threads that, together, service all client requests.

For new connections, we decide whether it will execute in the performance or the profiling view, mimicking scenar-

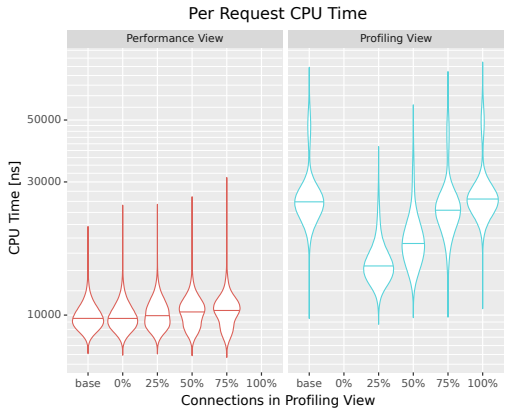

Figure 6: Memcached Performance Measurements for 1M sampled Data Points per Violin

ios where certain IP ranges or customers are profiled. In our benchmark, we use enable profiling for the first N (0 %-100 %) connections to demonstrate the impact of profiling. As long as the profiling percentage threshold is not met, each connection will be profiled. Because `memcached` distributes connections round-robin across workers, each worker thread will serve both, profiling and performance connections. Consequently, every worker thread switches between performance and profiling view continuously across the whole benchmark, which increases TLB pressure since they live in distinct address spaces. Nevertheless, as we will show, this penalty is still better than to enable profiling globally and could even be improved by a profiling-aware connection scheduling.

For our measurement, we record the execution time of the `drive_machine()` function, which is responsible for executing the per-connection state machine, making the function crucial for the request latency. For each benchmark run, we record request latencies until we reach 100M data points for each view. Therefore, for the mixed-mode benchmarks (25 %-75%), we will end up with 200M data points.

Results In Fig. 6, we show violin plots for the `drive_machine()` execution times separated by requests serviced that were serviced in the profiling or the performance view. Please note, that the 25% performance violin on the left matches the 25% profiling violin on the right as both stem from the same benchmark run. Also, we include the *base* variants, which show the results for a `memcached` server with statically enabled or disabled profiling without MELF or MMViews. For preparing the violin plots, we limit each data set (100M data points) to the [0.01%, 99.99%]-interval to remove outliers and randomly sample 1 million representative data points.

By comparing the base variants, we see that profiling has a significant impact on `memcached`'s most important function and increases its execution time by 175 percent. Further, for both views, the violin with the maximum number performance/profiling connections match the results of the base variant (i.e., performance base $\leftrightarrow$ 0% performance). From this, we can conclude that MELF enables us to enable and disable profiling dynamically at run-time without having a continued run-time impact.

For the profiling view, we see that the impact of profiling *per request* increases if more connections use the profiling path. This behavior can be explained by looking at the `gprof`-induced into the code: For each function, `gprof` allocates a counter variable that the compiler-introduced `mcount()` function uses to keep track of the number of invocations. As the activated `memcached` logic is rather small and executed by 16 threads in parallel, all workers in a profiling view access the same small set of per-function counters. Together with the fact that `gprof` does not even cache-align these counters, profiling results in many cross-core cache invalidations. Further, this effect scales with the percentage of threads working in the profiling view as more cache conflicts happen.

For the performance view, we see a slight increase in the median and tail latencies if more connections are shifted to the profiling view. Since workers need to switch views if the currently active MMView does not match the next processes connection, MELF increases the TLB pressure, impacting also workers in the performance view. Also, the frequent cache invalidations in the neighboring profiling view increases the cache-coherence traffic and puts a burden on the memory bandwidth. Nevertheless, even with 75 percent of all connections being profiled, the median over the base variant only increases by 7.6 percent for performance connections, which is far less than activating profiling globally. Inspired by these results, one could restrict profiling to a single worker thread or a small set of connections to get a statistic picture of the whole `memcached` process without inflicting the described cache conflicts from invocation counters.

In total, the MELF approach was able to make the static `gprof` method dynamically and selectively applicable without requiring a restart of the process and without touching the compiler.

3.4 Case-Study: ASAN in MariaDB

With this case study, we demonstrate that MELF is able to handle multiple variants in complex C++ projects. We compile MariaDB (> 20000 functions) once with (`-fsanitize-address`) and once without address sanitizer [5] and use the MELF linker to overlay both variants in the same binary. At run-time, we decide on a per-user basis whether a client's SQL queries are executed with sanitized or unsanitized MMView.

Scenario Justification Sanitizers [28], like AddressSanitizer [5] and UBSan [29], are often implemented as compiler transformations and they are usually used at de-

Table 3: Query Latency for Sysbench `oltp_point_select` benchmark on MariaDB with and without AddressSanitizer (ASAN).

velopment time to find bugs. However, due to their high overheads, they are then disabled in production, although they could provide an additional level of sanity checking for code that handles user input. With MELF, we enable AddressSanitizer, which was found to be the most common sanitizer [28], for individual database users in MariaDB, whereby we mimic a trusted–untrusted customer model. Technically, this case-study is of interest as MariaDB is a multi-threaded, large server application. With ASAN being strongly invasive on the code and data path, it helps to understand how MELF scales for large code bases.

Work Load As a work load, we use the `sysbench` [30] `oltp_point_select` benchmark. On our 48-core machine, we execute and pin MariaDB to NUMA node 1, while sysbench runs on NUMA node 2. We start MariaDB in the one-thread-per-connection mode, and always have 24 concurrent sysbench connections. To satisfy the mentioned trusted–untrusted customer model, we execute two sysbench instances, each of which connects as different database user. To vary the load between the ASAN/no-ASAN view, we vary the distribution of the 24 connections between both instances. We use the output of sysbench, which records the end-to-end latencies per transaction, as our result data.

Results In Tab. 2, we see an overview of the MariaDB binary produced by the MELF linker. First, we see that the application of ASAN increases the number of functions, as the compiler cannot inline and eradicate some of the smaller functions. We also see that the ASAN variant's text section is 2.6 times larger than the normal text section. Together with the fact that 98 percent of the normal view's functions had to be aligned and, therefore, could not be used for gap filling, explains the larger percentage of padding bytes (33.87 %).

In Tab. 3, we show the end-to-end latency results for the `oltp_point_select` benchmark. First of all, we see that AddressSanitizer has a significant impact on the performance of MariaDB as it increases the median latency by 89 percent. This latency penalty is also inflicted on clients whose queries are processed in the ASAN view. However, also clients in the normal view have a 36 percent increased query latency. This increase can be explained by the fact that the ASAN run-time library still has to intercept and wrap heap allocations, which are known to have a major impact on query performance[31], in order to keep its shadow-memory map up to date. However, in the normal view, MELF only removes the additional checks from the query processing and the additional overhead from the run-time library remains.

4 Discussion

In the following, we discuss limitations and benefits of the MELF approach.

Multi-Variant Data As we have discussed in Sec. 2.3, the MELF approach is currently limited to a strict data-object sharing semantic, where all variants share the data sections of the primary variant. For this, the data and its interpretation have to be compatible in all variants, which can, as we have seen with SQLite (Sec. 3.1), require some manual program modifications.

The following program demonstrates this limitation as it is incompatible in three different dimensions: (1) If a lock is allocated in A, the object would be too small to usage in B, (2) the field `L` has different offsets, and (3) both variants have a different idea about the lock state (`1` vs. `-1`).

```
// Variant A                    // Variant B
struct lock { int L; }          struct lock {int 0; int L;}
#define LOCKED 1                #define LOCKED (-1)
```

Supporting these cases in general is impossible, as it would require complete program understanding on the language level. However, for many cases, one could use semi-automated transformer functions [13], [32], [33], known from dynamic software updates, to synchronize two copies of the data.

For data initialization, we use the variant that is active at the initialization time. Therefore, we use the global data segment and invoke all global constructors in the primary variant. Function-local static variables are, in line with C/C++ semantics, initialized at the first call of the respective function and, thus, in the context of the then active variant.

Besides strict data sharing, the MELF linker also supports a strict data-object partitioning. For this, the linker has to keep all data sections, let each variant only reference its own

data sections, and we would run the constructor of all variants at program start. In this use case, the developer has to ensure that objects do not flow (i.e., across the univariant parts of the program) across variant boundaries. This mode could be useful for using multiple incompatible versions of libraries that make heavy use of global state.

MMView Dependency We acknowledge that MELF plays out its benefits particularly in combination with MMViews, which we use to back the same virtual-address range with different contents depending on the active thread of a process. The MMView approach has disadvantages, such as memory overhead and increased TLB pressure [14]. Because the exact runtime overhead of MMViews highly depends on the size of virtual memory and its physical data (plain data in RAM, file-backed mappings), a general overhead cannot be quantified. Furthermore, the measurable effect on the TLB directly correlates to a thread's view switch frequency and memory access patterns, which is individual to every application. For view creation and switching, a mean runtime penalty of 7µs with a standard deviation of 6µs has been measured on earlier benchmarks for memcached and MariaDB [14]. In another recent study of memcached, the cost of MMViews were only measurable for context-switches between different views. In general, however, a transition from one view to another is comparable to a context-switch between two threads of two different processes. As an alternative, multithreaded MELFs could be facilitated through CPU-assisted segmentation [34], such as supported by the IA-32 architecture [35]. With segmentation, we would load every variant into its own segment and each thread could select its variant by setting its code-segment selector register accordingly. On the IA-32 platform, where call and jump instructions implicitly use the code segment, this would be equivalent to MMViews. Without the separate address-space clones, the memory and TLB overheads would be replaced by a minor offset calculation overhead that segmentation entails.

Although segmentation contradicts Linux's flat memory model, MELF binaries could easily be supported if (a) the kernel provides means to initialize and switch hardware segments and (b) if the code-segment register is preserved between thread switches. Unfortunately, segmentation as a virtual memory primitive is currently not in fashion on modern platforms. Particularly, it has been removed from AMD64 [35] and was never available on RISC architectures. Given that segmentation has other advantages, such as safety benefits, we would applaud a renaissance of this virtual memory primitive. However, even without segmentation, we could theoretically implement text variants, using position-independent code coupled with the segmentation remnants in AMD64 (FS/GS register) to facilitate variant-adherence for indirect jumps. However, this would require intrusive linker and compiler modifications.

Switching For both modes (base and MMView), we demand that switching the variant takes only place at function boundaries. This limitation stems from the fact that MELF only aligns function start addresses, but all other intra-function addresses could be unaligned. For example, saved return addresses may not be valid in the other variant. However, with additional compiler support, this quiescence requirement could be weakened: For example, if the compiler would also align call sites and would make the call frames at those call sites compatible across variants, we could switch variants flexibly at every call and return edge. Such an extension could be beneficial for supporting workloads on heterogeneous ISA as it would, for example, ease thread migration between different ISAs without stack rewriting [36].

Applicability and Benefits With our case studies, we have shown that the MELF approach is applicable to a wide range of programs. By covering not only C but also C++ projects, which result in more complex object files (e.g., C++templates are a main user for COMDAT), we have demonstrated that MELF works on multiple programming languages. Further, as our approach only requires a compiler to produce "sectioned" object files, we are in principle language agnostic and widely applicable.

Also, MELF is agnostic to the source of the code modification. As shown, we support automatically-introduced compiler transformations (e.g., profiling) as well as manually-encoded variants (e.g., SQLite). Thereby, MELF covers more scenarios than pure language-based methods, like *aspect-oriented programming (AOP)* [37]. Further, as MELF prepares everything at link time, static binary validation could make MELF safer than dynamic-binary instrumentation (e.g., Intel Pin [38]), which was criticized to ease an exploiter's life [39].

Further, we have shown that MELF's semi-dynamic approach to variability is able to cover a wide range of use cases that are security-related (assertions, ASAN), provide DevOps with deeper insights (profiling), and ease the support of coming hardware generations (heterogeneous ISAs). We believe that especially the DevOps and the heterogeneous-ISA scenario will require semi-dynamic variability, since: (1) We need more dynamically-observed metrics to understand our complex systems down to the individual hot path. (2) Extensible architectures, such as RISC-V platform [40], with its many ISA compatibility levels, will boost the spreading of heterogeneous-ISA machines. (3) In many settings, we simply have not the choice to drop existing applications in favor of from-scratch developed software.

Although three of our four case-studies do not dynamically switch views during runtime, we were able to gain reasonable performance isolation in each application scenario: For profiling in memcached we achieved performance isolation of profiling connections and do dynamically switch a thread's view based on the connection currently being

served. In the other case-studies, we were able to obtain: (a) Performance isoliation and improved robustness for dynamic assertions in SQLite. (b) Performance maximization via ISA-specialized function variants with thread-pools. (c) Performance isolation and improved security for ASAN in MariaDB. Additionally, function pointers work "out-of-the-box" for MELF, which eases a programmer's life.

We also imagine that MELF can be used in an embedded setting, where no MMU is available to implement MMViews: For these machines, MELF can prepare variant overlays of in-flash text segments, which then can be exchanged at run-time by partially rewriting the flash memory. Thereby, multiple software variants can be supported in one device without inducing indirection overhead.

Also, we have seen that MELF's function alignment only induces moderate memory overheads (see Tab. 1), while the run-time overhead in combination with MMViews depends on the concrete case study. Nevertheless, even in the `memcached` case study, where threads switch on a regular basis between views, the run-time overhead was limited to less than 8 percent. Furthermore, Fig. 6 shows that the median runtime latency in the performance view is equal for the base and 0% variant.

Summarized, MELF is a cheap, language-agnostic method to lift static code variability to the semi-dynamic level. MELF is widely applicable and provides us with a framework for further explorations of semi-dynamic variability.

5 Related Work

Technically, text overlays [41], [42] are a closely related topic: They were used to reduce a program's primary-storage requirement by loading only the currently used subset of functions into the memory. While overlays have a renaissance [43], [44] for managing complex memory hierarchies, they are fundamentally different as they partition one program to fit it into a smaller memory. In contrast, MELF overlays multiple but similar programs in one binary and, with MMViews, execute those variants concurrently.

On the language level, aspect-oriented programming [45] if applied dynamically [46], [47] is similar to MELF. However, as aspects only add code before, after, or around function (calls), it does not support variants that stem from generic and cross-cutting code transformations.

Function Multiversioning [48] is a GCC extension to generate multiple versions per function, each of which specialized for the availability of different instruction-set extensions. The loader selects one variant on function granularity, which, unlike with MELFs, cannot be changed later on.

Fat binaries support multiple processor architectures by embedding program versions for the different processor types into one executable or library [49]–[54]. The variant to execute can be either selected directly by the operating system [54] or through a polyglot opcode string that is interpretable by both architectures [52]. Nextstep's *Mach-O* format, which was later adopted by Mac OS X, even supports "multifat" binaries that allow more than two different architectures (68K, x86, HP PA-RISC, SPARC) [50], [53], [54]. Going one step further, Cha et al. propose a system for generating multi-architecture binaries that, in contrast to fat binaries, use the same program string which is transformed in a way to be correctly interpretable by multiple processor types [55]. Similarly to the architecture heterogeneity of fat binaries, the *Windows Portable Executable* format has support for multiple platforms as it contains a DOS and Windows program in parallel [56]. Whereas the DOS part is usually just a small stub nowadays, it has been used to ship binaries that work under DOS and Windows in the past. In contrast to MELF, in all these approaches the variant selection covers the whole program, that means it is determined at process start, and cannot be changed later.

6 Conclusion

Multivariant ELF (MELF) is as a binary-level approach for the inclusion of multiple compile-time variants within the same binary and flexible switching between them at run time on function/section granularity. This facilitates the implementation of *semi-dynamic variability*, that is, dynamic switching between feature-variants at run time that are nevertheless generated and known at compile time, whereby even highly cross-cutting compiler features become configurable at run time. In combination with a kernel extension for in-process address spaces, this even works on the level of individual threads.

MELFs are implemented solely on binary level and mostly independent of the employed languages and compilers. Function variants are aligned by the MELF linker to the same virtual address, so that existing pointers or relocations remain valid even in case of a variant switch at run time. Thereby, MELFs are relatively easy to apply to existing projects. We demonstrated this on the example of four case studies, ranging over a wide range of multithreaded C and C++ projects. In all cases, MELF was able to isolate the costs and benefits of the compiler/developer-induced code variants to those threads, that use it at run time.

A Artifact Appendix

Abstract

This artifact includes all tools and a documentation to run the evaluation for multivariant ELFs, a binary-level, language-agnostic approach to semi-dynamic variability. It details how to run and modify four case studies using the provided artifact package, which includes benchmark scripts, a virtual disk file and the MMView kernel and its initrd. Users run the virtual machine via QEMU and execute scripts, which allow to generate and display benchmark data for each case-study. The four case studies are: (a) MariaDB ASan, (b) SQLite assertions, (c) Heterogeneous-ISA thread-pool, and (d) memcached profiling to prove the wide applicability of MELFs. Each case study includes instructions on running, exporting results, and modifying the benchmark. Next to the case-studies, users can also modify the provided MELF linker, the crucial component in creating MELFs, to examine the generation and placement of variant generation.

Scope

Users investigating the MELF benchmarks are able to verify that the only dependencies and changes to-be-made to make use of MELFs in applications are: (1) Express the existence of multiple application variants inside an application-specific linker script file (2) Extend existing application code to declare and load variants. (3) Use the llvm-based MELF linker to link application modules (object files) to the final MELF executable.

For each individual case-study, users can reconstruct the claimed benefits of MELFs described within the paper, which is mainly performance isolation and increased binary size depending on the workload. All evaluators, however, need to keep in mind that running those benchmarks in a virtualized environment will not provide the same results we were able to get for our paper. Your final result highly depends on the hardware your host machines use. But the main concept of performance isolation shall be visible in each benchmark executed.

Contents

This archive provides the user with every evaluation resource needed to run our evaluation setup. Namely, this archive consists of:

- run.sh. A script that starts a virtual machine via QEMU.
- hda.qcow2. The virtual disk file of the virtual machine which includes the whole artifact evaluation, based on debian 11.7.
- linux-mmview-vmlinuz-5.15. A Linux kernel fork of version 5.15 which includes the operating system abstractions for MMViews.
- initrd-linux-mmview-vmlinuz-5.15. The corresponding initrd of the MMView kernel fork.

- README.txt. A documentation file giving a detailed explanation of every benchmark setup and how to build, modify and draw benchmark data.

To start artifact evaluation, the user has to have QEMU installed onto their execution environment and to start run.sh. After the VM booted, the user can get access to the system by logging in either as the user "user" or as "root". The user has a Makefile inside his home directory which contains a target for each benchmark to generate the data and export that data into different formats.

Hosting

The artifact evaluation archive is hosted on the domain of our institution and can be downloaded from there: `https://sra.uni-hannover.de/Publications/2023/melf-usenix-atc23/`

Requirements

Most of our artifacts do not require specialized hardware. For the heterogeneous-ISA artifact, we execute code making use of AVX512 instructions. In order to run this artifact your host machine has to support AVX512, but most of modern hardware does that by default. Otherwise, the list of requirements is:

- Modern CPU with at least 16 cores. If you have less you have to adjust the run.sh script and the benchmarks inside the VM.
- At least 8GB RAM, the more the better.

For software requirements, you need to have installed:

- KVM module installed and loaded on your host machine.
- QEMU virtualization software stack.

Users can deviate from the given requirements, but doing so requires manual modification of run.sh and the benchmark inside the virtual machine.

APRON: Authenticated and Progressive System Image Renovation

Sangho Lee
Microsoft Research

Abstract

The integrity and availability of an operating system are important to securely use a computing device. Conventional schemes focus on how to prevent adversaries from corrupting the operating system or how to detect such corruption. However, how to recover the device from such corruption securely and efficiently is overlooked, resulting in lengthy system downtime with integrity violation and unavailability.

In this paper, we propose APRON, a novel scheme to renovate a corrupt or outdated operating system image securely and progressively. APRON concurrently and selectively repairs any invalid blocks on demand during and after the system boot, effectively minimizing the system downtime needed for a recovery. APRON verifies whether requested blocks are valid in the kernel using a signed Merkle hash tree computed over the valid, up-to-date system image. If they are invalid, it fetches corresponding blocks from a reliable source, verifies them, and replaces the requested blocks with the fetched ones. Once the system boots up, APRON runs a background thread to eventually renovate any other non-requested invalid blocks. Our evaluation shows that APRON has short downtime: it outperforms conventional recovery mechanisms by up to 28×. It runs real-world applications with an average runtime overhead of 9% during the renovation and with negligible overhead (0.01%) once the renovation is completed.

1 Introduction

Ensuring the integrity and availability of an operating system is crucial to the security of a computing device which is repeatedly threatened by adversaries. Specifically, the adversaries might compromise the operating system by exploiting unpatched vulnerabilities contained in its kernel, system applications, or shared libraries and, if exists, underlying systems software like a hypervisor. Then, they would permanently tamper with the system image (or files) stored in local storage to persist their control over the device (i.e., persistent malware [24, 29, 81]) or destroy it (i.e., destructive malware [53,77,82]). The computing device is no longer available in a valid form and demands *a recovery* as soon as the corruption is recognized [51, 98, 125].

Secure boot is a mechanism to boot a system while checking its integrity [8, 13, 52, 104, 124]. A trusted bootloader—whose authenticity is ensured by cryptography and hardware-based mechanisms [9, 102, 122]—measures (i.e., calculates a cryptographic hash over) the operating system and compares the measured value with an expected value before loading and passing control to the operating system. Any mismatch between them means that the operating system is in an invalid state. Specifically, the operating system might be (a) manipulated to embed a persistent backdoor, (b) destroyed to no longer work, or (c) downgraded to run a vulnerable old version. All these invalid states require an urgent fix.

Secure boot is suitable for securing devices with *image-based management*. They consistently deploy and update devices with *read-only* immutable system images built on the server-side and maintain their integrity on devices. However, such write protection is typically enforced within the kernel and adversaries can bypass it if they compromise the kernel [46,58,87]. Thus, operating systems require secure boot to verify the system image integrity, which is straightforward as expected measurement values are consistent or updated with coordination in image-based operating systems. Many modern operating systems for containers [36,39,45,61,86,96,105], Internet of Things (IoT) and edge devices [25, 37], mobile phones [6], mixed reality headsets [74], and personal computers [1, 10, 83, 117] adopt both.

System recovery is a logical next step when secure boot has found any corruption from a system image. Numerous security systems [3,4,17,26,51,79,98,108,125] even frequently reboot and recover (or reprovision) devices to protect them against persistent security and privacy threats and failures. However, to the best of our knowledge, all existing recovery mechanisms suffer from the following problems:

- **Downtime.** If a system recovery is necessary, a computing device enters a recovery environment [18,75,94,120]. The recovery environment does not support any other regular tasks. That is, the system is *unavailable during recovery*, which is especially unacceptable to reboot-based security

systems [3, 4, 17, 26, 51, 79, 98, 108, 125] and mission-critical tasks like edge computing [12, 84].

- **Inefficiency.** A recovery is inefficient because *it does not know which files or blocks it must fix in advance*. Existing mechanisms either (a) overwrite the entire system image to the local storage [40, 50, 51, 98, 125], which not only takes long but also is bad for storage lifetime [73, 103], or (b) verify each file or block to selectively fix corrupt one [54, 91], which is slower than the former.
- **Staleness.** A recovery typically relies on a system image backup stored in the local storage [50] which can be *outdated or corrupt*. To avoid this problem, it might fetch the latest system image from a reliable source, but this downloading prolongs the overall recovery time.

In this paper, we propose APRON, a novel approach to securely and progressively renovate an operating system image on a device. Unlike existing recovery mechanisms that fully repair a corrupt system image in a recovery environment and then boot into the recovered system, APRON securely boots into the system while repairing it, minimizing the downtime. It runs in the fresh kernel context to concurrently and selectively renovate any corrupt blocks which are requested during the system boot and after the startup of the operating system.

APRON *intervenes* between applications or kernel threads and the local storage containing a system image to verify and renovate invalid blocks on demand. To verify a requested block, APRON uses a Merkle hash tree [72] which is computed against an up-to-date system image and certified by an authorized entity (i.e., an administrator or an operating system vendor). Any hash verification error implies that a requested block is invalid (i.e., corrupt or outdated). Then, APRON renovates it by retrieving a corresponding block from a reliable source such as a remote server, verifying it, and overwriting it at the correct storage location. Once the system boots up, APRON additionally runs a background thread to renovate any other non-requested invalid blocks in the end. Also, it deduplicates any redundant network transfers.

We prototype APRON for Linux. We use device mapper [95] for intervening storage access and `dm-verity` [112] for hash tree verification. We also use Network Block Device (NBD) [22] as our remote storage protocol and its client, `nbdkit` [60], for userspace operations including HTTPS.

APRON ensures short system downtime and low runtime overhead. For a recovery with a 10 GiB system image in the servers with fast (local 1 Gbit/s) and slow (remote 100 Mbit/s) networks, APRON adds at most 5 s and 32 s to the downtime, respectively. It outperforms the full recovery by up to 28× and 12× and the delta recovery by up to 120× and 23×. APRON incurs an average runtime overhead of 9% on diverse real-world application tests from the Phoronix Test Suite [89] during renovation. Once the renovation is completed, the runtime overhead becomes negligible (0.01%).

In summary, this paper makes the following contributions:

- APRON is the first system that securely and progressively renovates a device's system image. It effectively minimizes the downtime due to recovery or update.
- APRON suggests a unified way to fix various types of invalid blocks including corrupt and outdated blocks.
- APRON shows its effectiveness (i.e., short downtime and low runtime overhead) in various configurations.

The source code of our prototype is publicly available at `https://github.com/microsoft/APRON`.

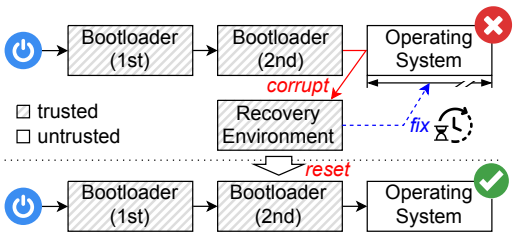

Figure 1: Secure boot with a normal recovery.

2 Background and Motivation

We will explain the background and motivation of APRON.

2.1 Secure Boot and Recovery

Secure boot ensures that a valid operating system will start to run on a device when it is powered on or reset. It has various synonyms, such as authenticated, measured, trusted, and verified boot, depending on security policies enforced or emphasized. Trusted or verified boot typically stops the boot procedure if it recognizes any verification failures, and initiates a recovery procedure. Authenticated or measured boot proceeds with the boot procedure while extending measurement values to a hardware component like Trusted Platform Module (TPM) [119] to report them to a system administrator for a later decision. In this paper, secure boot denotes trusted boot.

Figure 1 shows a procedure of secure boot with a recovery. When a device is powered on or reset, its CPU starts to execute the first-stage bootloader or boot firmware (e.g., Unified Extensible Firmware Interface (UEFI) [121], coreboot [30]) typically stored in a boot ROM. The first-stage bootloader verifies and loads the second-stage bootloader (e.g., GRUB [41], BOOTMGR [38]) stored in a specific location of local storage (e.g., EFI System Partition (ESP)). The second-stage bootloader verifies an operating system image stored in local storage. If the verification fails or a recovery has been requested, it boots into a recovery environment.

The recovery environment runs an agent program for recovery. The agent either downloads the latest system image from a known source and validates it or uses a local backup image to re-image the device [4, 18, 40, 50, 51, 98, 108, 125]. Finally, the agent reboots the device or directly loads the recovered kernel (using `kexec` in Linux [47] or Kernel Soft Reboot (KSR) in Windows [76]) and lets the kernel proceed the remaining boot procedure.

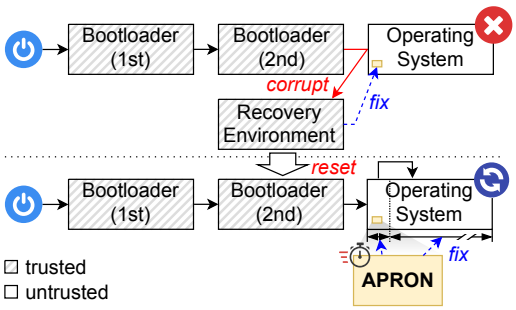

Figure 2: Secure boot with APRON.

2.2 Image-based System Management

Modern operating systems for specific use cases or casual end-users, such as container, IoT, edge, mobile phone, and personal computers [1, 6, 10, 25, 36, 37, 39, 45, 61, 74, 83, 86, 96, 105, 117] adopt image-based management to confine and simplify their deployment and update procedures. They split device storage into at least two different partitions including *read-only system partition* and *read-writable user partition*.

The system partition contains security-critical data which must not be modified, including kernel, drivers, and shared libraries. The kernel prevents any processes from modifying the partition [11, 112]. Administrators or operating system vendors generate or update a golden image for the system partition, sign it, and deploy it to devices. Instead of deploying the entire image, they can calculate and deploy the *delta* between the new and old images [34, 70, 91]. The device either fully overwrites the received image into its system partition or selectively updates it based on the delta. Later, a trusted bootloader verifies whether the system partition contains a valid, up-to-date system image before loading it.

The user partition contains casual applications and data populated by a user, which are not related to the device's critical operations. These user applications and data can be backed up by cloud storage, which is out of this paper's scope.

2.3 Motivation and Goal

Secure boot and image-based operating systems are widely deployed to real-world computing devices. However, their recovery mechanisms suffer from three important problems, motivating us to design a new approach that progressively recovers the device not only during its secure boot but also after the startup of its operating system (Figure 2).

Downtime for recovery. While the recovery environment repairs the system image, a computing device cannot conduct any regular operations that it is expected to do. That is, it cannot ensure a critical requirement, *availability*, for a long time. It is critical especially if the device leverages frequent reboots and recoveries to mitigate attacks and failures [3, 4, 17, 26, 51, 79, 98, 108, 125] or is deployed for mission-critical or time-sensitive tasks like edge computing [12, 84]. We cannot simply get rid of the recovery environment because we need a separate environment to securely trigger a recovery procedure at least. Instead, what we aim to achieve is

G1. Two-stage progressive recovery
Our approach progressively recovers the system image during and after the system boot. Its validity is ensured by a separate recovery environment.

Inefficient recovery due to unknown state. Existing recovery approaches are inefficient as they do not know which portions of the system image are corrupt in advance. Inspecting the entire image to identify invalid blocks and calculate delta takes long (§6.2). Instead, what we aim to achieve is

G2. State-aware on-demand recovery
Our approach identifies whether certain portions of the system image are corrupt and recover them on demand.

Insecure recovery due to stale image. Existing recovery approaches rely on a system image backup stored in local storage to recover the system image, which might be outdated or corrupted by adversaries. Fetching the latest image from a reliable source is a viable solution, but it is slow even if the image is compressed. Instead, what we aim to achieve is

G3. External up-to-date recovery
Our approach fetches authenticated portions of the system image on demand from a reliable external source.

3 Threat Model and Assumption

We consider how to recover a computing device from a remote adversary who can compromise the device's operating system including its kernel and system binaries as well as the underlying systems software (e.g., hypervisor and host operating system) if exists. The adversary can bypass the attack detection or prevention mechanisms for the device using unknown attack vectors, enabling initial compromise. After they compromise the system, they tamper with its storage to persist their control over it or corrupt it [24, 29, 53, 77, 81, 82].

We assume that the adversary cannot tamper with the boot firmware like other bare-metal recovery or reprovision systems [17, 51, 79, 108, 125]. Existing hardware components (e.g., boot ROM [66], TPM [119], and security coprocessors [9, 102, 122]) protect the boot firmware and its configuration data including the public key certificate of the authorized entity (i.e., administrator or operating system vendor) and a signed system version number for rollback prevention. We assume that a user or an administrator can recognize system compromise (e.g., by monitoring its external behaviors) and recover the system by forcefully rebooting it [14, 40, 118, 125] to let the boot firmware initiate a recovery procedure. In addition, the authorized entity generates and signs system images and metadata as well as operates servers for device management.

4 Design

In this section, we explain the design of APRON. It consists of (a) *storage layer* to authentically and progressively renovate

the system partition during the system boot and after the startup of the operating system, (b) *server* to maintain and deploy valid, up-to-date system images, (c) *client* to fetch specific portions of the system image and deliver them to the storage layer for renovation, and (d) *recovery environment* to initiate APRON.

Storage layer. The APRON storage layer is responsible for on-demand renovation of invalid blocks (§4.2), background prefetching (§4.3), and deduplication (§4.4). All these tasks are securely performed based on a Merkle hash tree computed over a valid, up-to-date system image.

Server and client. The APRON server manages and updates operating system images, generates metadata for them (e.g., a Merkle hash tree), signs them, and deploys them to clients. The APRON client establishes a secure session with the deployment server to fetch data blocks based on the APRON storage layer's requests and deliver them to it (§4.5).

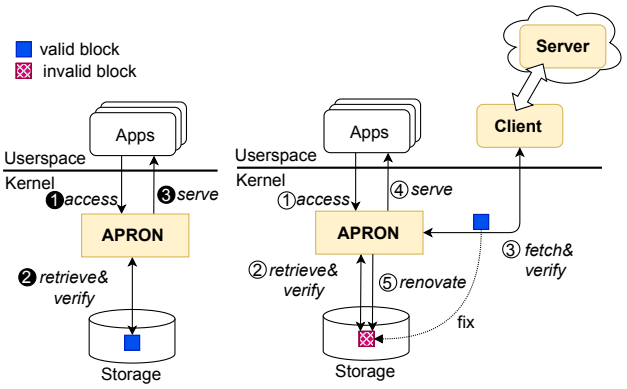
Recovery environment. The APRON-aware recovery environment prepares a minimal environment to initiate an operating system with APRON including operating system kernel and APRON metadata (§4.6).

4.1 Initialization

APRON is integrated into the operating system kernel and can be configured via boot parameters and APRON metadata. The APRON metadata includes a root hash value concatenated with a version number and Merkle hash tree calculated over the system partition. This metadata is prepared and signed by the APRON server (§4.5). APRON stores critical system files (e.g., kernel and device drivers) in the system partition and APRON metadata in a separate partition (to avoid circular dependency when calculating a hash tree). The APRON-aware recovery environment verifies this setting (§4.6).

During the system boot, APRON updates and verifies the APRON metadata. In particular, APRON attempts to download the latest APRON metadata from the APRON server. Then, it verifies the metadata's signature using the authorized entity's public key and checks whether the metadata's version number is greater than or equal to the reference version number. Both public key and reference version number are secured along with the boot firmware (§3). If the downloaded metadata is new and valid, APRON replaces the locally stored one with it and proceeds the system boot. If the version number in the new metadata is greater than the reference version number in the secure storage, APRON monotonically increases the reference version number accordingly as it means there is a legitimate update. Otherwise, APRON discards the downloaded one and proceeds the system boot with the local metadata.

When the operating system sets up a root filesystem, APRON prevents it from directly using the system partition. Instead, APRON places a *layer* (i.e., a virtual storage device or partition) over the system partition and makes the operating system use the storage layer as a read-only root filesystem. This layer allows APRON to intercept any accesses to the system partition, verify the individual accesses, and selectively fix the corresponding blocks using the Merkle hash tree.



(a) Valid access (b) Invalid access

Figure 3: On-demand renovation. Access to a valid block is verified and served using local storage (❶–❸). Access to an invalid block is served with the help of a remote server (①–⑤).

4.2 On-Demand Renovation

If any process or thread (except for APRON itself) requests a portion of the system partition, APRON transparently provides valid data either as they are or after renovating them. Figure 3 shows the overall on-demand renovation procedure. When a userspace application or kernel thread attempts to read data contained in the system partition via a filesystem or block device interface (❶), APRON retrieves a corresponding disk block expected to contain the requested data and verifies it using the Merkle hash tree (❷). If the retrieved block is valid (Figure 3a), APRON provides it to the requester (❸). To avoid repetitive storage retrieval and validation (i.e., to skip ❷), APRON maintains retrieved read-only blocks in an in-kernel cache and serves them to requesters later without re-validation until the blocks are evicted from the cache. Also, APRON identifies whether a requested block is a *zero block* (i.e., a data block filled with zeros) by checking the hash tree (i.e., a corresponding leaf node). In that case, it quickly provides a zero buffer to the requester without accessing the storage device at all. These two performance optimization methods are motivated by `dm-verity` [112].

If the retrieved block is invalid (Figure 3b), APRON fetches a corresponding block from the deployment server via the client and then verifies it (③). If the fetched block is valid, APRON provides it to the requester (④) to proceed with its execution immediately. Then, APRON overwrites the content of the fetched block into the corresponding location at the local storage device (⑤). If the fetched block is invalid due to network error, server error, or some other reason, APRON retries the block fetching up to a predefined number of times. If APRON fails to obtain the block eventually, it reboots the device to re-initiate the renovation.

In addition, APRON concurrently retrieves the same block

from the local and remote storage (i.e., conduct ② and ③ in parallel) to effectively hide network overhead. APRON activates this concurrent fetching only if it confirms that the storage device is corrupt (i.e., it finds at least one invalid block during previous storage accesses) to avoid sending meaningless network requests.

4.3 Background Prefetcher

The on-demand renovation might fail if the network connection between a device and the deployment server becomes unreliable or slow during execution. To avoid such failures, APRON has *background prefetcher* that is a kernel thread to detect and renovate invalid blocks of the system partition in advance. Background prefetcher only inspects unidentified blocks which exclude verified or renovated blocks and zero blocks according to the hash tree. To support the former, APRON maintains a verified block bitmap and updates its bits when certain blocks are verified or renovated by either the on-demand renovation or background prefetcher.

Background prefetcher inspects unidentified blocks if it does not interfere with storage accesses from other applications or kernel threads. Specifically, it wakes up if there is no in-flight access to the local storage device, checks and renovates a limited number of unidentified blocks, and sleeps.

Background prefetcher detects consecutive invalid blocks and renovates them together (i.e., a batch renovation) to improve the renovation throughput. It is different from the on-demand renovation which repairs each urgently required block with low latency. When background prefetcher wakes up, it inspects the system partition from the first unidentified block according to the verified block bitmap to detect the first invalid block. Next, it inspects the following blocks until it encounters a valid block or the number of inspected blocks exceeds a threshold, resulting in a sequence of consecutive invalid blocks. Then, it fetches corresponding blocks from the remote storage together, verifies them, overwrites them to the local storage device for batch renovation, and updates the verified block bitmap accordingly. It uses an exponential backoff algorithm to dynamically adjust the threshold.

Disconnection. If background prefetcher has fully inspected the entire system partition, APRON can be completely disconnected from the deployment server until the device gets reset or it needs to renovate or update the system image (§4.6).

4.4 Deduplication

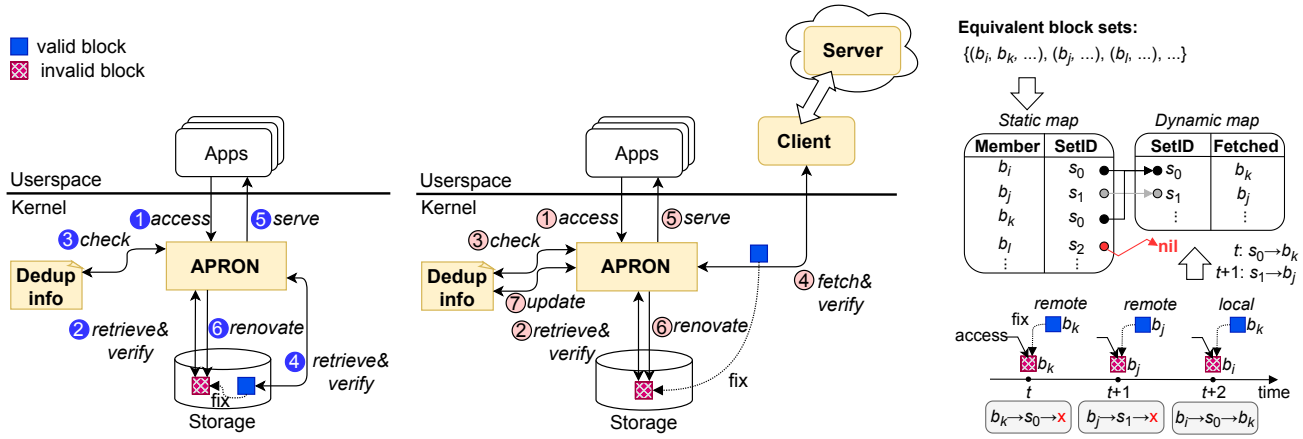
APRON might repetitively fetch equivalent blocks from the deployment server for renovation, which meaninglessly stresses both server and network. APRON avoids it using a data deduplication technique. APRON fetches a corresponding block from the server to renovate an invalid block only if it is unique or no other equivalent block of it has been fetched. If not, APRON uses the fetched equivalent block (in the local storage) for renovation. The APRON server creates deduplication metadata representing equivalent block sets in the system image. Specifically, the APRON server analyzes the system image (or the leaf nodes of its hash tree) to find equivalent blocks with the same content, forms sets by grouping equivalent blocks, assigns a unique identifier to each set, and adds this information to the deduplication metadata. The APRON server deploys and maintains the deduplication metadata together with the hash tree. To minimize the metadata size, APRON excludes unique blocks and zero blocks from it.

On the device, APRON maintains deduplication information consisting of two data structures for maintaining equivalent block sets and tracking whether and which block belonging to each set has been fetched, respectively. During initialization, APRON retrieves equivalent block set information from the deduplication metadata and constructs a *static block map* which associates each non-unique block (member) with its set identifier ($member \mapsto setID$). Later, APRON confirms whether a block is unique by looking up the static block map. If APRON fetches any non-unique block belonging to an equivalent block set for the first time (during the on-demand or background renovation), it adds this information to a *dynamic block map* to reversely associate the fetched block's set identifier with the fetched block ($setID \mapsto fetched$). This dynamic block map allows APRON to serve a duplicated block request using an equivalent block stored in the local storage.

Figure 4 shows the on-demand renovation with deduplication. The deduplication neither affects access to any valid blocks nor any invalid but unique blocks. Thus, we do not re-explain them (refer to §4.2). Instead, we focus on access to an invalid non-unique block that might have an equivalent block fetched and stored in the local storage device. If APRON confirms that a requested invalid block is not unique and its equivalent block is stored in the local storage device according to the deduplication information (i.e., the dynamic block map) (Figure 4a ❸), APRON retrieves the equivalent block from the local storage device and verifies it (❹). If the retrieved equivalent block is valid, APRON provides it to the requester (❺) and fixes the invalid local block (❻). In addition, it skips ❹ if the equivalent block is in the cache.

If the requested invalid block has no fetched equivalent block or the retrieved equivalent block is invalid (Figure 4b), APRON fetches a corresponding block from the deployment server and verifies it (④), provides it to the requester (⑤), and renovates the invalid local block (⑥). APRON updates the deduplication information (⑦) by adding the requested block as a fetched one to the dynamic block map.

Figure 4c depicts how deduplication works. In the beginning, APRON constructs a static block map using equivalent block sets and an empty dynamic block map. At time t, a thread requests an invalid and non-unique block b_k with the set ID of s_0. APRON fetches a corresponding block from the deployment server since the dynamic block map has no entry for s_0 and adds $s_0 \mapsto b_k$ to the dynamic map. At time $t+1$, a thread requests b_j with the set ID of s_1. Again, APRON fetches a corresponding block from the server and adds $s_1 \mapsto b_j$ to



(a) Invalid access with fetched equivalent block (b) Invalid access without fetched equivalent block (c) Deduplication management

Figure 4: On-demand renovation with deduplication. Access to an invalid block with a local equivalent block is served and renovated using the equivalent block (❶–❻). Access to an invalid block without a local equivalent block is served with the help of a remote server while renovating the requested block and updating the deduplication information (①–⑦).

the dynamic map. At time $t+2$, a thread requests b_i with the set ID of s_0. This time, APRON retrieves b_k from the local storage to renovate b_i because the dynamic map has $s_0 \mapsto b_k$.

Background prefetcher with deduplication. Background prefetcher prioritizes unique or never-fetched invalid blocks which must be remotely renovated over other invalid blocks which can be locally fixed. To this end, it treats invalid non-unique blocks as semi-valid if their equivalent blocks have been fetched and does not renovate them urgently. At the end of storage inspection, it spawns another kernel thread, *duplicator*, to renovate all semi-valid blocks using their local equivalent blocks. Like background prefetcher, duplicator wakes up if there is no in-flight access to the local storage device, renovates a single set of consecutive blocks, and sleeps.

4.5 Server and Client

The APRON servers are responsible for two major tasks: generating and maintaining operating system images as well as their associated metadata; and deploying them to the APRON client running in computing devices via a secure channel.

Management server. The management server is a trusted server operated by administrators or operating system vendors. It generates APRON metadata when a system image is newly generated or updated. First, it analyzes the system image to zero out unallocated data blocks—to handle sparse images—and then calculates a hash tree over the image. Next, it generates deduplication metadata (i.e., figures out equivalent block sets) using the hash tree's leaf nodes. Then, it monotonically increases the hash tree version number, and signs a concatenation of the root hash value and version number. Lastly, it stores the system image and APRON metadata in a dedicated place to be accessible to the deployment server.

Deployment server. The deployment server provides system images and APRON metadata to APRON devices. It interacts with devices via secure channels (i.e., TLS) to prevent external entities from manipulating or eavesdropping on communication. To handle data block requests, it uses a remote storage protocol (e.g., iSCSI, NBD) or a regular data transfer protocol (e.g., HTTP, FTP). The former lets it efficiently and transparently handle requests but is bad for portability. The latter introduces overhead including bloated packet headers and extra translation but ensures portability and proximity (e.g., with Content Delivery Network (CDN)). They respectively have pros and cons, and which one we are expected to choose one of them according to system configurations.

Client. The APRON client is a userspace service that interacts with the deployment server. It establishes a secure channel with the server and uses either a remote storage protocol or a regular data transfer protocol to receive data blocks.

Unlike the management server, APRON does not trust both the deployment server, which could be operated by a third party like a CDN, and the userspace client, which might be compromised by an attacker. The in-kernel APRON storage layer always verifies received blocks with the versioned APRON metadata signed by the management server. Even if the deployment server or the userspace client arbitrarily tampers with or downgrades the system image or metadata, the in-kernel APRON layer identifies such attempts based on signature and version mismatch.

4.6 First-Stage Recovery and Update

APRON can start to work only if a device has critical system files (i.e., kernel and device drivers for storage and network) and APRON metadata in valid forms. APRON relies on a first-stage recovery environment to ensure it. If any of them are invalid, the trusted bootloader enters the recovery environment to obtain their latest versions from the deployment server. A conventional APRON-unaware recovery environment would fully download both critical system files and APRON meta-

data from the deployment server via HTTPS. In contrast, an APRON-aware recovery environment only needs to download the metadata via HTTPS while selectively renovating invalid portions of the critical system files via APRON. It is possible because a recovery environment typically shares the same (or minimized) kernel with the main operating system, so we modify its kernel to incorporate APRON.

Scheduled update. APRON works as an update mechanism for non-compromised operating systems. If APRON recognizes an update during system execution, it stages updated APRON metadata on the APRON partition. Through a reset, the recovery environment replaces APRON metadata with the staged one. Finally, APRON progressively updates the system during its execution. Unlike existing update mechanisms [5,7,16], APRON does not need to reserve extra storage to temporarily store a (potentially large) update file and apply multiple update files in a proper order.

5 Implementation

In this section, we explain how we develop APRON for Linux.

Initialization. We use `initramfs` to configure and initialize the APRON storage layer as the root filesystem. Our `initramfs` checks whether the signature and version number of a given root hash value are valid using the public portion of our signing key and reference version number we provision to TPM NVRAM indexes. If they are valid, it initializes the APRON storage layer and mounts it at a specific point. Further, it creates a `tmpfs` filesystem to use it as a writable overlay for the storage layer using `overlayfs` [23] to support applications that only work with a writable root filesystem. Lastly, it sets up the overlaid storage layer as the root filesystem. We store the `initramfs` in the system partition, so it is secured by APRON as well.

Storage layer. We implement the APRON storage layer as a loadable kernel module written in approximately 1,200 lines of C code on Linux kernel version 5.11. The storage layer prototype consists of two virtual block devices representing local and remote block devices, respectively.

The local virtual block device intervenes with any access to the system partition and is exposed as a regular block device to the outside (to work as the root filesystem). It is based on the device mapper framework [95]. The storage layer verifies all accesses to the local block device using a Merkle hash tree based on `dm-verity` [112]. It also spawns background prefetcher as a kernel thread to inspect the local block device while maintaining and using the deduplication information. If the storage layer finds any corrupt blocks from the local block device, it renovates them by copying corresponding blocks from the remote virtual block device to the local virtual block device while verifying them using the hash tree. That is, it securely makes the content of the local block device equivalent to that of the remote block device. This approach also allows APRON to use a local backup device for renovation instead of a remote device if the network condition is bad or a new system image is buggy. Background prefetcher uses `kcopyd` [114] to efficiently copy a sequence of data blocks between block devices. In addition, APRON's every storage access is cached by the `dm-bufio` interface.

The remote virtual block device interacts with the deployment server via the APRON client based on NBD [22]. We use NBD because it is easy to configure (both in client and server) and has a small code base. If needed, APRON can work with other advanced remote block storage such as Ceph [123] for better efficiency, reliability, and scalability.

Server. The APRON server has a program to identify equivalent block sets written in 170 lines of Rust code, Bash scripts to automate the creation, management, and deployment of system images and APRON metadata, and other server applications. It uses `zerofree` [126] to zero out the unallocated blocks of system images, `veritysetup` [112] to calculate Merkle hash trees over them, and `openssl` [115] to sign the root hash value concatenated with a version number. Also, it uses `nbdkit` [60] and `lighttpd` [65] to operate an NBD server with TLS and an HTTPS server, respectively.

Client. We prototype the APRON client using `nbd-client` [32] and `nbdkit` [60]. It uses `nbd-client` to connect to the APRON server via NBD over TLS and configure this session as the storage layer's remote block device. Also, to interact with the APRON server via HTTPS, it uses `nbdkit` to spawn a device-local NBD server backed by the HTTPS server and lets `nbd-client` connect to this local NBD server (via a Unix domain socket). `nbdkit` relies on its `curl` plugin to fetch specific portions of system image files from the HTTPS server using HTTP `range` requests.

Recovery environment. The APRON recovery environment is based on the Linux kernel with APRON and `initramfs`. It includes `curl` [107] to download APRON metadata from the APRON server, and both `nbd-client` and `nbdkit` to renovate essential system files (i.e., kernel and `initramfs`) in the system partition on-demand. Unlike the main operating system, we decide not to spawn background prefetcher in the recovery environment because it only runs for a short amount of time. In addition, it contains `kexec` [47] to directly load the renovated operating system's kernel.

Bootloading. We decide not to manipulate the first-stage bootloader (UEFI [121]) of our computing device (e.g., replace it with coreboot [30] or replace its platform key with our own key [52]) because it is too intrusive and does not affect the core functionalities of APRON. Instead, we rely on the current UEFI-based Linux boot procedure that securely loads the second-stage bootloader, GRUB [41], signed by Linux vendors (i.e., Canonical in our case) through Shim [68] signed by Microsoft. We modify GRUB's configuration to make it load either the operating system with APRON or the APRON recovery environment.

6 Evaluation

We evaluate APRON by answering the following questions:

- **RQ1.** Does APRON ensure short system downtime when it needs to renovate the system during boot? (§6.2)
- **RQ2.** How much overhead does APRON add to other workloads during renovation? (§6.3)
- **RQ3.** What is the network usage of APRON for renovation? (§6.4)
- **RQ4**. Does APRON complete renovation within a reasonable time? (§6.5)

6.1 Setup

Device. We use a desktop computer featuring an Intel Core i5-8500 CPU (six cores) at 3 GHz, 8 GiB of RAM, and 1 TB of PCIe 3.0 NVMe SSD as an APRON device.

Server. The APRON device frequently downloads small data packets to selectively renovate the system image, subject to network performance. To evaluate it, we use two APRON servers with fast and slow network configurations. The fast-network server is a mini computer connected to the 1 GbE switch that the APRON device is also connected to. It features an Intel Pentium Silver J5005 CPU (four cores) at 1.5 GHz, 8 GiB of RAM, and 500 GB of SATA SSD. The slow-network server is a Virtual Machine (VM) in Microsoft Azure. It features two Intel vCPUs at 2.6 GHz, 8 GiB of RAM, and 30 GiB of Premium SSD. According to `netperf` [49], the median TCP latencies between the device and two servers are 0.24 ms and 5.45 ms, and the TCP throughputs between them are 934 Mbit/s and 931 Mbit/s, respectively. We additionally throttle the slow-network server's bandwidth to 100 Mbit/s to evaluate low-throughput cases.

Configuration. We install Ubuntu Server 20.04 on the device while replacing its kernel and modules with ours, computing a hash tree over the system partition, and changing its GRUB configuration. We do not use existing image-based operating systems because they are highly customized for specific platforms (e.g., VM, mobile phone). We reserve 10 GiB for a device's system partition formatted with `ext4`. Ubuntu Server 20.04 occupies 5.5 GiB of the system partition. It becomes 1.6 GiB with `gzip`. We also reserve 100 MiB to store the APRON metadata. We use 4 KiB as the data and hash block size and SHA-256 for constructing the hash tree, and RSA-4096 to sign the root hash. The sizes of the hash tree and deduplication metadata are 81 MiB and 1.6 MiB, respectively. We install Ubuntu Server 20.04 to our servers. We repeat all experiments at least 10 times and report their average values except for benchmark tools with internal repetitions (§6.3) and an experiment with deterministic results (§6.4).

6.2 System Downtime (RQ1)

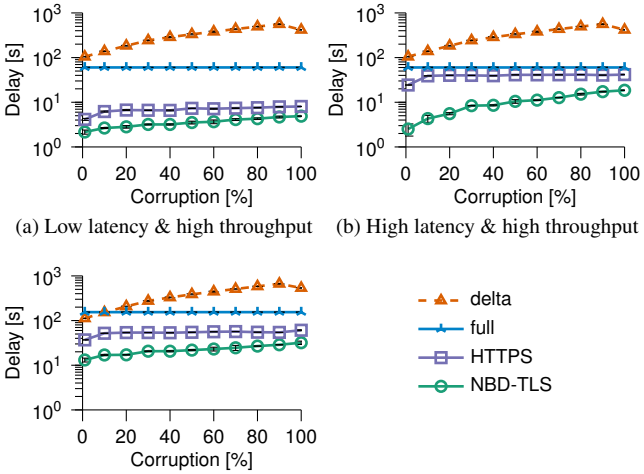
To minimize system downtime, APRON boots into a system while renovating its invalid blocks requested during the boot. We compare it against existing recovery mechanisms which repair all invalid blocks before the system boot. In general, both attacks and legitimate updates change a portion of the system image (which will be explained later), but what and how many blocks they will change are unpredictable. Thus, we randomly corrupt 1%–100% of the system partition for evaluation (i.e., zero some of or all its 4 KiB blocks). Whether we use zero or non-zero blocks does not affect APRON's performance (§6.6). We measure the delay solely introduced by APRON; that is, we exclude any other delays due to hardware initialization, bootloader loading and execution, and operating system loading, which are ∼16 s in total on our device, because they are independent of APRON. We use `systemd-analyze` [64] for this measurement. In addition, we omit the case without corruption because APRON does not delay it.

Full recovery. For comparison, we implement a full recovery mechanism like existing mechanisms [4, 40, 50, 51, 98, 108, 125]. In a recovery environment (i.e., before the system boot), an agent downloads the compressed image via HTTPS while concurrently decompressing it to the local storage. Then, it boots into the recovered system. We omit additional image validation because we trust TLS. The recovery takes ∼60 s (high throughput) and ∼154 s (low throughput), which is 4× and 10× longer than the system boot time. It is independent of the corruption ratio and marginally affected by network latency.

Delta recovery. We implement a delta recovery mechanism using `rdiff` [91] that the SWUpdate project [16] uses. `rdiff` consists of (a) signature computation, (b) delta computation, and (c) patch adoption. Delta update is efficient because it can pre-compute (a) and (b) on the server-side, but the delta recovery cannot leverage such pre-computation (details are in Appendix B.) In total, it takes 105–561 s (high throughput) and 112–665 s (low throughput), which is 7–35× and 7–42× longer than the system boot time. It depends on the corruption ratio and is marginally affected by network latency. The delta recovery is slow, but it reduces network traffic (31 MiB–1.6 GiB) and unnecessary storage writes.

APRON. Figure 5 shows APRON's boot-time delay while varying the network latency, network throughput, and corruption ratio. The delay is 2.2–4.9 s (NBD over TLS) when latency is low and throughput is high, which is 14%–31% of the boot time. It becomes 0.2–1.2× longer than the boot time when latency increases and 0.8–2.0× longer than the boot time when latency increases and throughput decreases. They are up to 27.8×, 23.9×, and 11.8× shorter than the full recovery, and up to 119.8×, 41.6×, and 23.1× shorter than the delta recovery, respectively. In addition, as expected, APRON with HTTPS is 1.6–9.7× slower than APRON with NBD over TLS due to extra translations.

Summary. APRON ensures short downtime because it apparently repairs the blocks required to boot the system first and the remaining blocks later once the system boots up. It outperforms existing mechanisms especially when (a) the network latency is low, (b) the network throughput is high, and (c) the number of invalid blocks is small. These conditions are satis-



(a) Low latency & high throughput (b) High latency & high throughput

(c) High latency & low throughput

Figure 5: Boot-time delay comparison between APRON and other recovery mechanisms.

fied in practice. The network performance is improving. Also, the number of invalid blocks is generally small in both attack and update cases. For example, a persistent backdoor usually consists of a few small executables [29, 81]. We further analyze how Flatcar Container Linux [39] (an image-based operating system) and Fedora Cloud [93] (a pre-installed cloud image) change over their releases. Across 36 Flatcar releases for two years (version 2512.2.0 to 3139.1.2 for QEMU x64), 9.7%–12.2% of their 8.5 GiB images change. Also, across 11 Fedora Cloud releases for five years (version 26 to 36 for QEMU x64), 12.5%–21.7% of their 4.5 GiB images change. Thus, APRON is effective in decreasing the system downtime.

6.3 Runtime Overhead (RQ2)

APRON verifies and renovates the (remaining) system partition during system execution. We evaluate how its **verification** and **renovation** processes affect the runtime performance of other workloads using benchmark programs. We ensure the benchmark programs terminate before renovation is completed. Otherwise, they run on the recovered system which hides renovation overhead. To this end, we prolong renovation using a fully corrupt system image and the slow-network server and select benchmark programs which take shorter than the renovation (§6.5). We install them in another system image copy and execute them via APRON. We compare APRON to a **pristine** environment with the same hardware and operating system except that it runs an unmodified kernel.

Microbenchmark. Figure 6 shows LMbench [71] system call execution times normalized to those from the pristine environment. Both in a verification condition and during the renovation, the overheads of the APRON device over the pristine device are 0%–40%. As expected, APRON affects system calls related to filesystem and network (e.g., `stat`, `fstat`, `open`/`close`, UNIX socket). On a geometric mean, the overheads of the APRON device in a verification condition and during the renovation are 7% and 8%, respectively.

The APRON device might download a lot of data from the deployment server to renovate the system partition, so it might affect the network performance of other applications. We use LMbench's network throughput evaluation results to identify whether and how APRON affects LMbench's network throughputs (Figure 7). In a verification condition, the network throughput of LMbench on the APRON device is 3.6% (geometric mean) lower than that on the pristine device. During the renovation, the network throughput of LMbench on the APRON device is 11.8% (geometric mean) lower than that on the pristine device. Consequently, APRON's renovation noticeably affects the network throughput of other applications only during renovation. In addition, if we turn off APRON's verification once the renovation is completed, the overhead becomes almost zero.

Macrobenchmark. We evaluate APRON with 11 real-world application tests from Phoronix Test Suite [89] (Figure 8). The overheads of APRON during renovation over the pristine environment are 1.9%–21% (geometric mean: 9%). As expected, renovation affects I/O-intensive workloads (e.g., 7-Zip, Apache, and Memcached) whereas less affects compute-intensive workloads (e.g., Crafty, FLAC, and PyBench). Without renovation (i.e., the verification condition), APRON's overhead over the pristine environment is negligible (0.01%).

6.4 Network Usage (RQ3)

During renovation, APRON fetches blocks required for recovery from the deployment server. We evaluate this network usage. We use the randomly corrupt system images again (§6.2). We count the number of bytes the server sends to the APRON device at the server (using `lighttpd` logs) while enabling APRON's optimization (i.e., zero block ignorance and deduplication). This network usage is independent of network latency and throughput.

Figure 9 shows how many bytes APRON downloads from the server while varying the corruption ratio. It downloads 44.6%–94.0% of the corrupt blocks, which are only 1.1–2.9× larger than corresponding `rdiff` deltas. APRON's optimization is effective especially when the number of invalid blocks is large. This is because it increases the probability that multiple invalid blocks are equivalent such that no repetitive downloads are needed due to deduplication (§4.4).

6.5 Complete Renovation Time (RQ4)

Once the system boots up, APRON performs both on-demand and background renovation. We measure how long it takes to complete the renovation when the system is idle or busy. Hastening the complete renovation is not our goal and that is why we assign a low priority to background prefetcher to minimally affect other workloads (§6.3). We compare it against the full and delta recovery to check whether it is reasonable.

Idle system. Figure 10 shows APRON's complete renovation time in an idle system while varying the network latency,

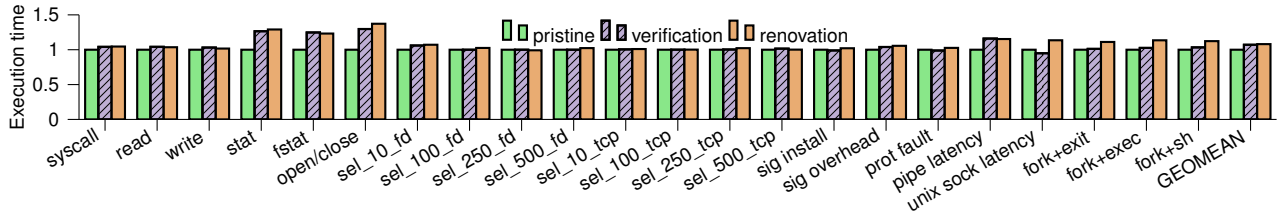


Figure 6: LMbench system call execution time normalized to the pristine cases (**pristine**: Ubuntu Server 20.04 without APRON; **verification**: APRON without a renovation process but with hash-tree verification; **renovation**: APRON with a renovation process).

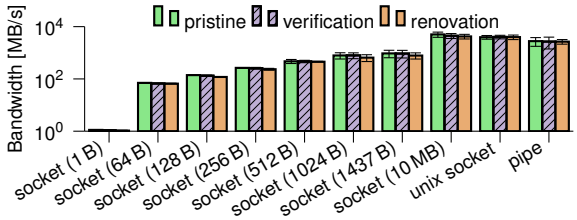

Figure 7: LMbench network throughput.

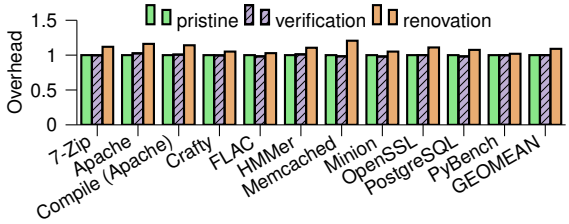

Figure 8: Normalized Phoronix Test Suite overhead.

network throughput, and corruption ratio. The complete renovation (NBD over TLS) demands 47.4–104.5 s when latency is low and throughput is high, 50.2–190.4 s when latency increases, and 84.0–504.3 s when latency increases and throughput decreases. They take 0.8–1.7×, 0.8–3.2×, and 0.5–3.3× longer than the full recovery, and 2.2–5.5×, 1.9–3.1×, and 1.1–1.4× shorter than the delta recovery, respectively. In addition, APRON with HTTPS takes 1.1–2.1× longer than APRON with NBD over TLS. APRON's complete renovation is subject to network latency and throughput because it does not benefit from bulk network transfer and compression.

Busy system. We make the system busy by running the Memcached test from Phoronix [89], which heavily contends with APRON (Figure 8), once the system boots up. The complete renovation is delayed by at most 7.0% (low latency) and 2.5% (high latency and low throughput). Overall, the renovation is moderately affected by the system's busyness. The renovation with the slow-network server suffers less from the busyness than that with the fast-network server since the slow network performance dominates the renovation overhead.

Summary. Although APRON renovates the system during its execution in the background, it finishes the renovation within a reasonable time—i.e., it is at most 3× slower than the full recovery. Further, it is comparable to or even faster than the full recovery if the network is fast and the number of invalid blocks is small. Both are satisfied in practice (§6.2).

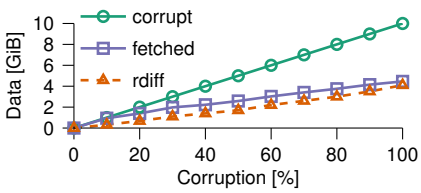

Figure 9: Network usage of APRON.

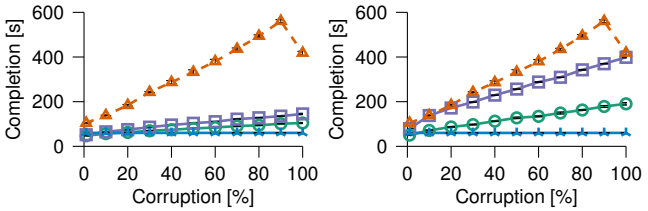
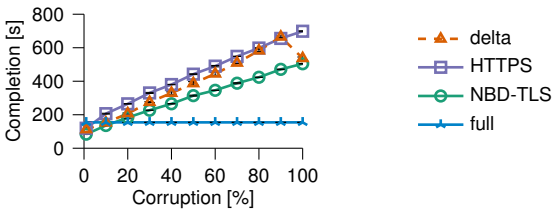


(a) Low latency & high throughput (b) High latency & high throughput



(c) High latency & low throughput

Figure 10: Complete recovery time comparison between APRON and other recovery mechanisms.

6.6 Miscellaneous

Non-zero corruption. We confirm whether we use zero or non-zero blocks to corrupt the system image does not affect APRON's performance. If a block is expected to be a zero block, APRON does not touch it regardless of corruption. If not, APRON renovates it regardless of whether it is overwritten by a zero or non-zero erroneous block. Non-zero corruption slows down the delta recovery as it complicates `rdiff` signatures, but showing its worst case is not our interest.

Deduplication. The deduplication decreases not only network usage but also renovation time to some extent. Without it, the renovation is delayed by up to 2.2% (low latency) and 9.0% (high latency and low throughput). The renovation with the fast-network server marginally benefits from the deduplication because it aims for reducing the network overhead (§6.4). In contrast, the system downtime does not benefit from the deduplication because only a few blocks are requested during the system boot.

Memory usage. APRON uses at most ∼120 MiB of additional memory when it renovates a fully corrupt system image to cache fetched blocks and maintain its data structures. This memory is reclaimed once the renovation is completed.

7 Security Analysis

In this section, we analyze the security of APRON. We focus on how APRON mitigates persistent kernel attacks. Also, we explain how APRON detects or prevents less severe but frequent userspace and network attacks.

Kernel attack. APRON efficiently recovers a computing device from advanced adversaries who have compromised the device with critical kernel vulnerabilities. APRON runs in the kernel and it does not assume any other non-standard kernel integrity protection or monitoring technologies [15, 44, 69, 78, 88, 128] to protect itself. To this end, if adversaries compromise the kernel, they can *temporarily* deactivate APRON and corrupt the system image. However, APRON eventually defeats them based on a system administrator's input: the administrator can detect a misbehaving device using device or network monitoring tools and forcefully reset it using existing, standardized techniques [40, 118, 125]. This reset eliminates in-memory exploits and activates APRON via secure boot again. If the administrator prepares an updated image fixing the exploited vulnerability, APRON prevents the adversaries from reusing the vulnerability by rapidly recovering the system with the updated image. Even if no patch is prepared, APRON causes hardship to the adversaries since they must repeatedly compromise the operating system across forceful device resets to persist their control or system destruction. Such repetitive attack attempts are highly visible and thus can be detected and mitigated by network-level techniques [3].

Userspace attack. APRON prevents or detects userspace attacks against it through all four attack surfaces userspace attackers can access (§5): (a) filesystem containing operating system files, (b) APRON storage layer, (c) storage device storing the system image, and (d) APRON client. First, APRON prevents or detects the modification of its filesystem. APRON mounts the filesystem for the operating system as read only, preventing non-privileged attacks. Adversaries with a root privilege can remount the filesystem and modify it. However, such modifications only remain in memory and are not reflected in the underlying write-protected APRON storage layer. Second, APRON prevents the modification of its storage layer. The APRON storage layer ignores any block write requests via block IO interfaces. Thus, both non-privileged and privileged adversaries cannot modify it. Third, APRON prevents or detects the modification of its storage device. Non-privileged adversaries cannot access the storage device. In contrast, privileged adversaries can tamper with the storage device using block IO interfaces. However, the APRON storage layer identifies and reverts such manipulation based on the signed hash tree. Fourth, APRON detects a misbehaving APRON client. Privileged adversaries can compromise the userspace APRON client to deliver manipulated data to the APRON storage layer. However, APRON identifies and ignores such manipulated data based on the signed hash tree.

Network attack. APRON detects network attacks including traffic manipulation. Adversaries might tamper with the network traffic between the APRON client and deployment server to deliver a manipulated system image. However, since APRON traffic is secured with TLS, the adversaries cannot arbitrarily manipulate it unless they break TLS or compromise the deployment server. Even if they succeed, APRON drops such manipulation because it verifies fetched data using the signed hash tree.

8 Discussion

In this section, we discuss some possible alternatives to APRON's design.

Advanced deduplication and compression. APRON currently uses a simple block-based deduplication (§4.4) without network traffic compression, resulting in relatively high network usage (§6.4). APRON can reduce it using advanced deduplication techniques like content-defined chunking [31, 67, 80] and seekable compression [116], but there are two tradeoffs. First, their computational overhead is higher than block-based deduplication, increasing the overall recovery time and runtime overhead. Second, they are incompatible with the efficient, block-level hash tree [112] APRON leverages. To maintain the compatibility, APRON requires a fine-grained hash tree with complicated data structure and computational complexity. We leave balancing these tradeoffs to future work.

File-based recovery. APRON verifies and renovates the entire storage or partition as it assumes the image-based system management (§2.2). Instead, it can focus on a set of critical files if it separately maintains their root hashes using techniques like Integrity Measurement Architecture (IMA) [62] and `fs-verity` [113]. This file-based recovery potentially reduces the overhead of APRON, but it must overcome two problems. First, it requires a separate technique to recover the kernel and filesystem itself. Otherwise, it even cannot identify whether certain files exist in the device. Second, it must maintain and update a set of root hash values in a scalable and consistent manner. This is because there are many critical files depending on each other (e.g., system binaries and shared libraries). APRON is free from such problems because it is independent from the filesystem and it only maintains a single root hash value for the entire image.

Mutable data. APRON leverages and ensures the read-only property of the image-based system management, but it does not prevent users from storing any data in the device. Like other image-based operating systems, APRON can maintain a separate read-writable user partition (§2.2). Then, APRON can let users use it as a writable overlay for the storage layer (as explained in §5) or mounting it at specific writable directories (e.g., `/etc`, `/home`) [33].

Single point of failure. APRON can suffer from a single-point-of-failure problem because its recovery task relies on a server which is remote in most cases. To overcome it, APRON needs other techniques like a load balancer [21] to mitigate this problem. Especially, the HTTPS version of APRON seamlessly benefits from such load balancing (§4.5).

9 Related Work

In this section, we explain existing studies related to APRON.

Network boot. Datacenter administrators frequently provision operating systems on new or failed server machines. They use the Preboot eXecution Environment (PXE) boot [55] to make each server boot into a small operating system stored in a storage server within the same local network. This small operating system downloads a full operating system to the local storage and, finally, boots into it. However, the PXE boot neither efficiently downloads system images nor ensures any network-level security because it relies on TFTP [106]. Thus, it can only be used within a well-managed local network. To overcome these problems, iPXE and UEFI support HTTP(S) boot [56, 59]. Still, they must download an entire operating system image to local storage to boot into it unlike APRON.

Diskless boot. Administrators can configure an operating system to use network storage as its root filesystem via remote block storage protocols (e.g., iSCSI and NBD) or network file systems (e.g., NFS and Samba). It is known as diskless boot [35,48,79,97]. It makes much more sense in a data center where servers are connected through the same high-bandwidth and low-latency local network [20]. However, since this approach fully relies on network storage, it cannot avoid repetitive fetching of the same blocks from storage servers if the blocks are evicted from the cache due to memory pressure. Further, a lack of required blocks due to potential network errors can result in significant system malfunctioning. Data block caching [26, 100, 101, 109, 110] might mitigate these problems, but cached blocks can be evicted according to the cache replacement policy unlike APRON. Also, all cached blocks should be accessed via a translation layer and discarded when any recovery or update is needed. Advanced distributed file systems [2, 101, 123] can avoid some of the problems, but they have large code bases and require complicated server- and client-side configuration. Unlike them, APRON only requires maintaining a simple file or web server.

Operating system streaming deployment. An operating system streaming deployment [28,42,43,85,111] uses both local and network storage. While serving block requests from kernel threads and other applications using network storage, the operating system streaming deployment stores downloaded blocks at the corresponding locations of local storage. These stored blocks will be used to resolve further requests to avoid repetitive downloading of the same blocks. The operating system streaming deployment also copies not-yet-downloaded blocks from network storage to local storage in the background to eventually mirror the network storage to the local storage. However, unlike APRON, existing operating system streaming deployment mechanisms neither consider secure operating system deployment nor support selective renovations of invalid blocks. Thus, it must deploy the entire operating system image from scratch if it recognizes any corruption or the operating system image has been updated.

Efficient update. Updating an operating system or its kernel with minimal downtime is heavily studied [5, 7, 16, 19, 27, 63, 90, 99, 127, 130]. A/B update [5, 7, 16] has a separate partition to download an updated system image during execution and reboot into it. Live kernel patching [19, 27, 90, 130] hot fixes the kernel without rebooting it. Since live kernel patching cannot handle complicated changes (e.g., data layout), other schemes [63, 99, 127] leverage memory snapshot and soft reboot. However, all these mechanisms work only if an operating system or underlying systems software (i.e., hypervisor [99], System Management Mode (SMM) [130]) is not compromised or corrupt. For example, a privileged attacker can tamper with both A/B partitions, hinder hot-patching, or corrupt memory or storage snapshots. Thus, they should rely on recovery mechanisms APRON to fix corrupt systems.

Multi-node progressive recovery. Multi-node progressive recovery [3, 57, 92, 129] is another way to recover or update a system with minimal or zero downtime. To maximize the availability of a critical service, these schemes operate redundant copies of the same service in multiple physical or virtual computing nodes. If the service needs to be recovered or updated, they first deal with a part of the nodes while running the other part of nodes to keep alive the service. They handle the latter part of nodes after they have recovered or updated the former part of the nodes. These schemes can achieve zero downtime if at least one node is always running. However, their resource costs are high because they require multiple nodes. In addition, we note that they can benefit from APRON because, in the end, they recover or update each node—reducing node recovery or update time is important to maintain their overall fault tolerance.

10 Conclusion

APRON is a novel approach to authentically and progressively renovate an operating system image during the system boot and after the startup of the operating system, minimizing the system downtime needed for a recovery. It is especially effective for the reboot-based security systems that frequently reset and repair devices to deal with attacks and failures, and mission-critical systems which are sensitive to the downtime. APRON renovates the entire operating system image with negligible runtime overhead and small network usage.

Acknowledgment

We would like to thank the anonymous reviewers and our shepherd, Eric Eide, for their helpful feedback.

A Merkle Hash Tree

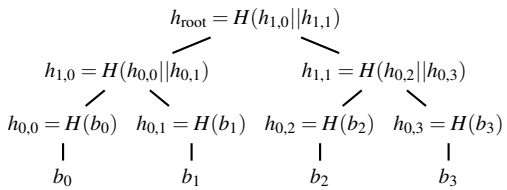

Figure 11: Merkle hash tree

A Merkle hash tree [72] is a method to efficiently and securely verify whether any part of data is corrupt. It is constructed by recursively computing hashes over data and their hashes (Figure 11). Its root hash summarizes the entire data. Thus, we only need to ensure the root hash's authenticity and integrity (i.e., sign it) to verify data and node hashes. For example, to verify a data block b'_1, we compute $h'_{0,1} = H(b'_1)$, $h'_{1,0} = H(h_{0,0}||h'_{0,1})$, and $h'_{root} = H(h'_{1,0}||h_{1,1})$ with leaf and internal node hashes $h_{0,0}$ and $h_{1,1}$—which have been verified in the same manner—and compare h'_{root} with signed h_{root}.

B Delta Update

The detailed procedure of the delta update is below. First, we compute an `rdiff` signature which is a structured summary of a base file (i.e., a corrupt system partition) to compute delta. In our APRON device, it takes ∼21 s to compute an `rdiff` signature over the system partition regardless of how many portions of it are corrupt. The signature size is 181 MiB without compression. Once we compress it with `gzip`, it becomes between 72 MiB (1% corruption) and 0.5 MiB (100% corruption). Next, we upload the compressed signature to the server, decompress it, and compute the delta between the signature and the valid system image. The delta computation takes 55–273 s and the size of the delta is between 91 MiB and 4.1 GiB (between 31 MiB and 1.6 GiB after compression). Both depend on how many portions of the system partition are corrupt. We only use the Azure VM for this delta computation to ignore the CPU performance difference between the two servers. Finally, we download the compressed delta—which take 1–16 s (high throughput) and 9–135 s (low throughput), decompress it, and patch the system partition with it. Patching itself takes ∼12 s regardless of the number of corrupt blocks.

zpoline: a system call hook mechanism based on binary rewriting

Kenichi Yasukata[1], Hajime Tazaki[1], Pierre-Louis Aublin[1], and Kenta Ishiguro[2]
[1]*IIJ Research Laboratory*
[2]*Hosei University*

Abstract

This paper presents zpoline, a system call hook mechanism for x86-64 CPUs. zpoline employs binary rewriting and offers seven advantages: 1) low hook overhead, 2) exhaustive hooking, 3) it does not overwrite instructions that should not be modified, 4) no kernel change and no additional kernel module are needed, 5) source code of the user-space program is not required, 6) it does not rely on specially-modified standard libraries, and 7) it can be used for system call emulation. None of previous mechanisms achieve them simultaneously.

The main challenge, this work addresses, is that it is hard to replace `syscall`/`sysenter` with `jmp`/`call` for jumping to an arbitrary hook function because `syscall` and `sysenter` are ***two-byte*** instructions, and usually more bytes are required to specify an arbitrary hook function address.

zpoline resolves this issue with a novel binary rewriting strategy and special trampoline code; in a nutshell, it replaces `syscall`/`sysenter` with a two-byte **`callq *%rax`** instruction and instantiates the trampoline code at virtual address 0. We confirmed zpoline is functional on the major UNIX-like systems: Linux, FreeBSD, NetBSD, and DragonFly BSD. Our experiments show that zpoline achieves 28.1~761.0 times lower overhead compared to existing mechanisms which ensure exhaustive hooking without overwriting instructions supposed not to be modified, and Redis and a user-space network stack bonded by zpoline experience only a 5.2% performance reduction compared to the minimum overhead case while the existing mechanisms degrade 72.3~98.8% of performance.

1 Introduction

System calls are the primary interface for user-space programs to communicate with Operating System (OS) kernels. Since user-space programs almost always go through system calls to perform important actions, system call hooks can be the vantage point to trace and change their behavior. Therefore, there are many use cases, such as tracing tools [6, 19], sandboxes [18, 25], OS emulation layers [1, 8], and binary compatibility supports of new OS subsystems [22, 29, 30, 33, 36, 37].

Motivating use case. Past studies demonstrated that user-space OS subsystems [10, 13, 17, 23, 24, 27], backed by kernel-bypass frameworks [15, 34, 38], are highly performant. In principle, system call hooks enable us to *transparently* apply user-space OS subsystems to the legacy software artifacts through the POSIX standard (as demonstrated in § 3.3), and the transparency is an important factor for the applicability of user-space OS subsystems.

Problem and related work. However, in UNIX-like systems on x86-64 CPUs, the representative platforms for server systems, there is no perfect system call hook mechanism.

1. Existing kernel supports (e.g., `ptrace` (§ 3.1.1) and Syscall User Dispatch (SUD) [20] (§ 3.1.3)) and the legacy binary rewriting technique using `int3` signaling (§ 3.1.2) **cause unacceptable performance degradation** to hook-applied user-space programs (§ 3.3).
2. Other binary rewriting mechanisms (e.g., instruction punning [7], E9Patch [9], and the technique applied in X-Containers [36]) (explained in § 2.1) and function call replacement (e.g., LD_PRELOAD (§ 3.1.4)) **cannot exhaustively hook system calls**. Thus, they cannot be used for systems requiring reliability.
3. Another type of binary rewriting technique (e.g., Detours [14]) **overwrites instructions that are supposed not to be modified** (explained in § 2.1).
4. Solutions based on specific changes to the kernel or additional kernel modules such as Dune [3], which are not merged to the mainline, substantially **diminish the portability** of applications relying on them.
5. Approaches requiring recompilation of the source code of a user-space program, typically seen in Unikernel [26] systems [5, 21], are **unusable in many cases** because users often do not have access to the source code.
6. The approach, which links application binaries with a standard library (e.g., libc) specially modified for replacing the invocations of system calls with function calls of specific OS subsystems [22, 29, 30, 33, 37], **narrows down the range of choice for applicable standard**

library implementations, moreover, **cannot hook system calls which are invoked from the outside of standard libraries**.

7. Although BSD Packet Filter (BPF) [28] and its extended version, eBPF, allow users to apply hooks to the kernel-space functions, they **cannot be used for changing and emulating the behavior of system calls without modifying the kernel source code**.

In summary, every existing system call hook mechanism has a significant downside. Due to the lack of an ideal system call hook mechanism, there have been no practical means of transparently applying user-space OS subsystems to existing user-space programs. Consequently, the applicability of user-space OS subsystems has been significantly limited, regardless of their great advantages.

Contributions. To solve this problem, we present a novel system call hook mechanism for x86-64 CPUs named *zpoline* that is free from all drawbacks mentioned above (§ 2). We demonstrate the benefits of zpoline through microbenchmarks (§ 3.2) and experiments transparently applying user-space OS subsystems to user-space programs (§ 3.3).

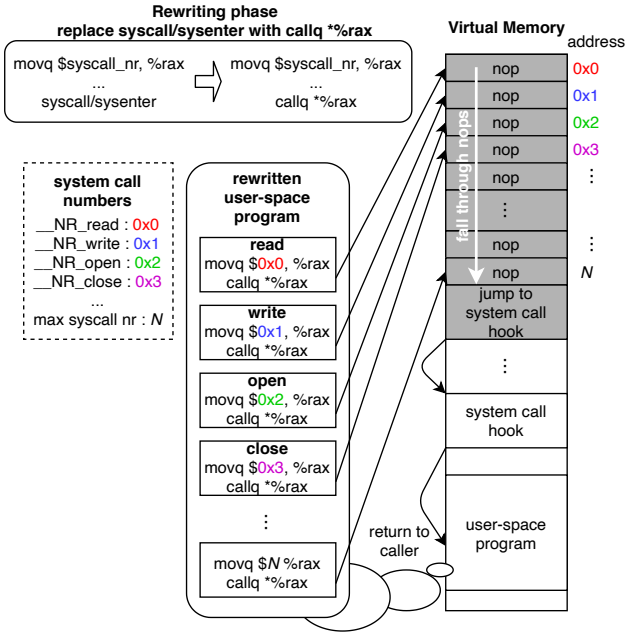

Figure 1: zpoline overview. The trampoline code is shaded.

2 zpoline

zpoline is based on binary rewriting; it replaces `syscall` and `sysenter`, which are ***two-byte*** instructions (`0x0f 0x05` and `0x0f 0x34` in opcode respectively) that trigger a system call, to jump to an arbitrary hook function address.

2.1 Challenge and Goal

The challenge of this work is that the two-byte space, originally occupied by a `syscall`/`sysenter` instruction, is too small to locate a `jmp`/`call` instruction along with an arbitrary destination address; typically, two bytes are occupied by the opcode of `jmp`/`call` and eight bytes are necessary for a 64-bit absolute address, or another possibility is one byte for a `jmp`/`call` instruction and four bytes of a 32-bit relative address. Due to this issue, existing binary rewriting techniques give up the replacement in some cases and fail to ensure exhaustive hooking [7, 9, 36], exceed the two-byte space originally occupied by `syscall`/`sysenter` to put the code bigger than two bytes while a jump to the exceeded part causes unexpected behavior [14], or take the `int3` signaling approach (§ 3.1.2) that imposes a significant overhead (§ 3.2). The goal of zpoline is to be free from these drawbacks.

2.2 Design

The overview of zpoline is shown in Figure 1.

System call and calling convention. zpoline employs the calling convention of system calls. In UNIX-like systems on x86-64 CPUs, when a user-space program executes `syscall`/`sysenter`, the context is switched into the kernel, then, a pre-configured system call handler is invoked. To request the kernel to execute a particular system call, a user-space program sets a system call number (e.g., 0 is `read`, 1 is `write`, and 2 is `open` in Linux on x86-64 CPUs) to the `rax` register before triggering a system call, and in the kernel, the system call handler executes one of the system calls according to the value of the `rax` register.

Binary rewriting. To hook system calls, zpoline replaces `syscall`/`sysenter` with **`callq *%rax`** which is represented by two bytes `0xff 0xd0` in opcode. Since the instruction sizes of `syscall`/`sysenter` and `callq *%rax` are the same two bytes, *the replacement does not break the neighbor instructions*. What `callq *%rax` does is to push the current instruction pointer (the caller's address) to the stack, and jump to the address stored in the `rax` register. Our insight is that, according to the calling convention, the `rax` register always has a system call number. Therefore, the consequence of `callq *%rax` is the jump to a virtual address between 0 and the maximum system call number which is more or less 500[1].

Trampoline code. To redirect the execution to a user-defined hook function, zpoline instantiates the trampoline code at virtual address 0; in the trampoline code, the virtual address range between 0 and the maximum system call number is filled with the single-byte `nop` instruction (`0x90`), and at the next to the last `nop` instruction, a piece of code to jump to a particular hook function is located.

[1] In Linux 5.15, the maximum system call number of the x86-64 ABI, seen in `unistd_64.h`, is 448.

Execution flow. After the trampoline code instantiation and binary rewriting are completed, the rewritten part (`callq *%rax`) will jump to one of the `nop`s in the trampoline code while pushing the caller's address on the stack. The execution slides down the subsequent `nop`s; after executing the last `nop`, it jumps to the hook function. Here, the hook function will have the same register state as the kernel-space system call handler. The return of the hook function jumps back to the caller address that is pushed on the stack by `callq *%rax`.

Security notes. We note that, like other system call hook mechanisms based on binary rewriting, zpoline itself does not offer security enhancement. On the other hand, if users wish to improve the security of zpoline-applied systems, they can employ existing mechanisms; for instance, seccomp [2] can filter the execution of kernel-space system calls triggered by a zpoline-applied user-space program, and CPU supports such as Memory Protection Keys (MPK) [16] can isolate the implementation of a hook function.

2.3 Implementation

Our current prototype focuses on Linux. The core implementation of zpoline consists of trampoline code instantiation and binary rewriting. We implement these in a shared library called `libzpoline.so` and a special loader named `zpoline_loader`; we assume a user uses either[2]. They perform the setup procedure of zpoline (§ 2.3.1) before the main function of a user-space program starts.

2.3.1 Setup Procedure

The trampoline code setup procedure first allocates memory at virtual address 0 by using the `mmap` system call[3]. Afterward, it fills the allocated memory region with the content described in § 2.2. The binary rewriting procedure initially obtains the memory mapping information from `procfs`. Then, it traverses CPU instructions on the executable memory regions, and replaces `syscall`/`sysenter` with `callq *%rax` (§ 2.2). The memory regions for the trampoline code and the code binary of the user-space program are configured to be writable during this setup phase, and they are restored to be non-writable before the setup procedure exits. After the setup completes, the main function of the user-space program starts as usual, but, all system calls are hooked by zpoline. We note that this implementation does not change the binary files of user-space programs since binary rewriting is done on the code binary loaded onto the memory.

2.3.2 Hook Function Development

zpoline users can implement an arbitrary system call hook function as part of `libzpoline.so` or `zpoline_loader`. However, there is an issue that the hook function falls into an infinite loop when it calls a function that originally executes `syscall`/`sysenter` because the replaced code (`callq *%rax`) brings the execution back to the hook function. Users encounter this issue especially when they use `libzpoline.so` because the default dynamic linker/loader automatically associates library calls used in the hook function with the libraries whose `syscall`/`sysenter` instructions are replaced with `callq *%rax`.

Use of `dlmopen`. We avoid this issue by using `dlmopen`, an extended version of `dlopen`. `dlopen` loads a library file onto the memory of a user-space process. On top of this basic feature, `dlmopen` allows users to specify a *namespace* where the library is loaded, and it conducts the association in the same namespace. Thus, `dlmopen` enables us to avoid the automatic undesired association by loading the hook function in a new namespace. To use `dlmopen`, we assume a zpoline user builds the core of the hook implementation as an independent shared library. During the setup phase, `libzpoline.so` loads the library using `dlmopen`, and obtains the pointer to the core implementation of the hook function by using `dlsym`. The hook function, implemented in `libzpoline.so`, calls it through the obtained pointer.

2.3.3 NULL Access Termination

Typically, a memory access to virtual address 0, namely the NULL pointer access, causes a page fault because of the lack of physical memory mapping at virtual address 0, and it results in the termination of the user-space program. The NULL access termination is important for stopping buggy programs. On the other hand, the use of virtual address 0 in zpoline brings about the issue that the NULL access of a user-space program does not cause a fault. To cope with this issue, zpoline employs a set of techniques.

Terminate NULL read and write. To terminate NULL read and write, zpoline configures the trampoline code to be the eXecute-Only Memory (XOM)[4]; a user-space program, that attempted a read/write access to XOM, will be terminated by the kernel because of a fault.

Terminate NULL execution. To trap unintentional NULL execution, zpoline collects the virtual addresses of `syscall`/`sysenter` which are replaced during the setup phase of zpoline (§ 2.3.1), and it checks, at the entry point

[2] `libzpoline.so` assumes to be loaded through LD_PRELOAD and used when the application binary is dynamically linked. LD_PRELOAD allows `libzpoline.so` to run the setup procedure before the main function of the user-space program starts. `zpoline_loader` is complementary and assumes to be used when the application binary is statically linked and the LD_PRELOAD feature does not work.

[3] In Linux, by default, the memory mapping to virtual address 0 is only allowed for the root user, but it can be permitted for all non-root users by setting 0 to `/proc/sys/vm/mmap_min_addr` (confirmed in Linux 5.15).

[4] In Linux running on a CPU supporting the Memory Protection Keys (MPK) [16] feature, the `mprotect` system call configures XOM when only `PROT_EXEC` is set in the access flag; if MPK is not supported by the CPU, `mprotect` does not configure XOM.

of the hook function, if the caller of the hook function is one of the replaced virtual addresses or not. If it is not, zpoline terminates the user-space program because it is not the jump from the replaced `callq *%rax`, meaning an unintentional jump to NULL. To maintain the replaced virtual addresses while achieving a low-overhead NULL execution check, we use a bitmap that covers the entire 256 TB (48-bit) virtual address range that is typical in x86-64 CPUs. This bitmap allows us to conduct the NULL execution check with a few bit operations, and this cost is evaluated in § 3.2. The bitmap occupies 32 TB of virtual address space, however, its physical memory consumption is substantially smaller because the virtual address pages, whose all bits are clear, do not need to have underlying physical memory pages[5]. We note that if a user prefers to avoid occupying 32 TB of virtual address for the bitmap, we can alternatively use a hash table at the cost of the higher overhead of the NULL execution check.

2.4 Limitations

Here, we discuss the limitations of zpoline.

`syscall`/`sysenter` loaded at runtime. The current prototype of zpoline cannot hook `syscall`/`sysenter` loaded or crafted after the completion of the setup (§ 2.3.1). We can resolve this issue by borrowing the idea of online binary rewriting presented in the X-Containers [36] work that traps an invocation of a system call and rewrites, on the fly, the `syscall`/`sysenter` instruction that triggered the system call.

vDSO (virtual dynamic shared object). Kernels provide user-space programs with several system calls by directly exposing the code for them through vDSO. Like other system call hook mechanisms, zpoline cannot hook vDSO-based system calls by default; however, we can enable zpoline to hook them by disabling vDSO[6].

Unusable virtual address 0. zpoline is not applicable if memory at virtual address 0 is unusable; for instance, the virtual address 0 is already used for other purposes, or the kernel does not allow the mapping at virtual address 0.

Other OSes. We confirmed that zpoline is functional on FreeBSD 13.0, NetBSD 9.2, and DragonFly BSD 6.0[7]. We could not use zpoline on OpenBSD 7.0 because the minimum mappable virtual address is hard-coded as the page size. In Windows, `VirtualAlloc` is conceptually equivalent to `mmap`. On Windows 10, `VirtualAlloc` fails when the specified virtual address is lower than 0x10000, therefore, we could not apply zpoline. But, Windows offers a compatibility layer for Linux called Windows Subsystem for Linux (WSL). We confirmed that zpoline works on WSL2 while it did not on WSL1 whose `mmap` to virtual address 0 returns successfully but actually does not conduct the memory mapping. On macOS, the virtual address 0 of a user-space program is used by a special segment named `__PAGEZERO`, therefore, we could not apply zpoline on macOS.

Other CPU architectures. zpoline is not compatible with CPU architectures which assume the instructions to be aligned by architecture-specific sizes on the memory and consider a jump to an unaligned virtual address as an invalid operation (e.g., ARM); this is because, when zpoline is applied, the execution can jump to an unaligned virtual address between 0 and the maximum system call number (§ 2.2)[8]. However, we believe zpoline is applicable to a large number of servers because x86-64 CPUs are very popular.

3 Evaluation

This section evaluates zpoline through a comparison with existing hook mechanisms (§ 3.1). Particularly, we quantify the hook overhead of zpoline (§ 3.2) and the performance penalty experienced by application programs and user-space OS subsystems bonded by zpoline (§ 3.3).

Experiment setup. For the experiments, we use two machines; each has two 16-core Intel Xeon Gold 6326 CPUs clocked at 2.90 GHz and 128 GB of DRAM. The two machines are directly connected via Mellanox ConnectX-5 100 Gbps NICs. In the experiments in § 3.3, we use one of the two as the *server machine*, and the other as the *client machine*. Both machines run Linux 5.15.

3.1 Comparison

We compare zpoline with `ptrace` (§ 3.1.1), `int3` signaling (§ 3.1.2), SUD (§ 3.1.3), and LD_PRELOAD (§ 3.1.4). Here, we describe the mechanisms and properties of them.

3.1.1 `ptrace`

UNIX(-like) OSes offer the `ptrace` system call that enables a *tracer* process to hook system calls attempted by a *tracee* process. Since `ptrace` is a kernel feature, it can hook system calls exhaustively. However, its hook overhead is enormous due to the context switch between the tracer and tracee; the tracer sleeps while the tracee is running, and the tracee sleeps during the tracer runs its hook function. Therefore, at every system call invocation, the tracee experiences a long latency that includes the wake-up time of the tracer, the execution time of the hook function, and the wake-up time of the tracee. This latency results in *significant performance degradation of the user-space program running on the tracee.*

[5] In many cases, most of `syscall`/`sysenter` instructions come from libc and ld.so. We found the bitmap uses 22 and 5 physical 4 KB pages to maintain 544 and 50 of `syscall`/`sysenter` in libc and ld.so respectively (glibc-2.35).

[6] Linux disables vDSO when the kernel boot option specifies `vdso=0`.

[7] In FreeBSD and NetBSD, users can use `sysctl` to permit memory mapping at virtual address 0. DragonFly BSD allows it by default.

[8] Besides the issue of the instruction alignment, binary rewriting techniques need to pay attention to architecture-specific factors; for example, on ARM CPUs, the simple replacement from `SVC` to `BL` overwrites/breaks the return address saved in a specific register [31].

3.1.2 `int3` Signaling

`int3` is a one-byte instruction (`0xcc`) that invokes a software interrupt. On Linux, the kernel handles it and raises `SIGTRAP` to the user-space process that executed `int3`. The `int3` signaling technique exploits this behavior to hook system calls; it replaces `syscall`/`sysenter` with `int3` and employs the signal handler for `SIGTRAP` as the hook function. Since `int3` is one byte, it can replace an arbitrary instruction without breaking the neighbor instructions. This technique is traditionally used in debuggers to implement breakpoints. However, *signal handling incurs a large overhead* because it involves context manipulation by the kernel.

3.1.3 Syscall User Dispatch (SUD)

Syscall User Dispatch (SUD) [20] was added in Linux 5.11, and it offers a way to redirect system calls to arbitrary user-space code. For the SUD feature, the kernel implements a hook point at the entry point of system calls. A user-space process can activate SUD via the `prctl` interface. When SUD is activated, the hook point raises `SIGSYS` to the user-space process. This mechanism allows a user-space program to leverage the `SIGSYS` signal handler as the system call hook. However, similarly to the `int3` signaling technique, SUD *imposes a significant performance penalty on the user-space program due to the overhead of the signal handling.*

3.1.4 Function Call Replacement by LD_PRELOAD

The dynamic linker/loader (`ld.so`) offers the LD_PRELOAD feature that allows users to specify shared objects to be loaded before the main part of a program starts, and it can be used for selectively overriding function calls implemented in other shared objects. Users can employ this mechanism to replace the system call wrapper functions, which are typically implemented in standard libraries, with arbitrary function calls. The performance penalty of LD_PRELOAD is very small because the hooks are applied through function pointer replacement.

A function call hook is not a system call hook. However, precisely, the function call replacement for a system call wrapper function is not the hook for a system call; in the first place, the `syscall` and `sysenter` instructions are not directly associated with any function calls, and LD_PRELOAD cannot hook a `syscall`/`sysenter` instruction which does not have a dedicated and exported wrapper function.

The case where LD_PRELOAD fails to hook. glibc [11] is a representative example where LD_PRELOAD cannot apply system call hooks exhaustively. In many cases, glibc does not use the well-known system call wrapper functions to invoke system calls; instead, glibc directly embeds `syscall`/`sysenter` in its internal functions which are marked as invisible from the outside of glibc, and LD_PRELOAD cannot apply hooks to `syscall`/`sysenter` instructions wrapped by such internal function calls.

Mechanism	Time [ns]
`ptrace`	31201
`int3` signaling	1342
SUD	1156
zpoline	41
zpoline (no NULL execution check (§ 2.3.3))	40
LD_PRELOAD	6

Table 1: The overhead for hooking a system call.

Potential but impractical approach. Although it is possible for users to apply hooks using LD_PRELOAD by entirely replacing library calls that contain `syscall`/`sysenter` instructions, this approach does not scale because users must give up the use of the original library call implementations; in other words, they need to reimplement the equivalent functionalities by themselves, however, it is not realistic to reimplement large part of glibc. Moreover, this reimplementation approach cannot be applied if, unlike glibc, the source code of a shared library file is not available.

Limitation of LD_PRELOAD. In short, *LD_PRELOAD cannot exhaustively hook system calls*, thus, is not an appropriate option to apply user-space OS subsystems to existing user-space programs; for instance, a file descriptor, which is opened by a user-space OS subsystem, will be passed to a kernel-space OS subsystem if a system call is not properly hooked, and it leads to unexpected behavior of the system.

Similarity to binary rewriting techniques. We note that, in our experiments, the cases of other binary rewriting techniques [7, 9, 14, 36] are represented by the LD_PRELOAD case because they share the same characteristics: their performance overhead is very small, however, as described in § 2.1, they cannot hook system calls exhaustively.

3.2 System Call Hook Overhead

We quantify the system call hook overhead by measuring the time to hook `getpid`, one of the simplest system calls. Our primary interest here is the hook overhead itself; to avoid the overhead of the kernel-crossing system call, we use a hook function that returns a dummy value without actually executing the `getpid` system call. Table 1 shows the results. First, the overhead of LD_PRELOAD is negligible as expected (§ 3.1.4). The overhead of zpoline is 6.8 times higher than LD_PRELOAD, and this is primarily due to the `nop`s in the trampoline code (§ 2.2). The cost of the NULL execution check (§ 2.3.3) is 1 ns out of 41 ns. zpoline is 761.0, 32.7, and 28.1 times lighter than `ptrace`, `int3` signaling, and SUD respectively. The major overheads of `int3` signaling (§ 3.1.2) and SUD (§ 3.1.3) derive from the signal handling for `SIGTRAP` and `SIGSYS`. `ptrace` exhibits the biggest overhead due to the cost of scheduling between the tracer and tracee processes (§ 3.1.1).

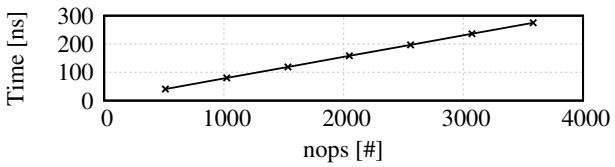

Figure 2: The overhead to hook a system call depending on the number of `nop`s at the beginning of the trampoline code.

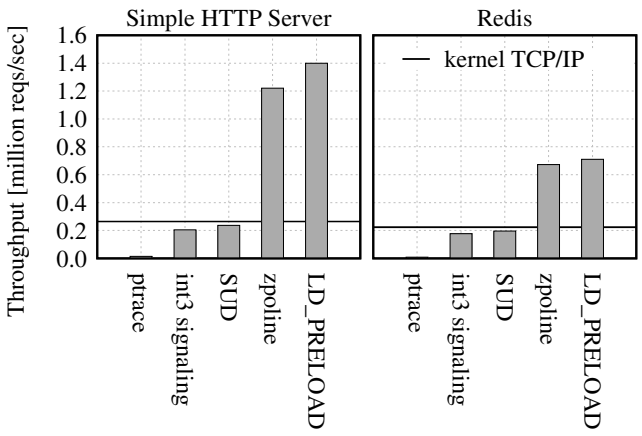

Figure 3: Performance of applications running on lwIP and DPDK with different system call hook mechanisms. For reference, the throughput of the Linux kernel TCP/IP stack is shown by the non-dotted horizontal line.

nop overhead. In zpoline, `nop`s in the trampoline code increase the hook overhead. The number of `nop`s depends on the number of system calls implemented by the kernel (§ 2.2). To see how the overhead grows, we run the same `getpid` test above while changing the number of `nop` instructions in the trampoline code. Figure 2 shows that the overhead linearly increases according to the number of `nop`s. However, in the first place, the kernel development communities are very wary to add system calls. Therefore, we believe the `nop` overhead of zpoline will not increase drastically in the future. Moreover, although 3.5 K `nop`s are located, the overhead of zpoline is still 113.4, 4.8, and 4.2 times lower than that of `ptrace`, `int3` signaling, and SUD respectively.

3.3 User-space OS Subsystem Performance

This section evaluates how zpoline affects the performance of application programs backed by user-space OS subsystems; we employ zpoline and the existing hook mechanisms described in § 3.1 to *transparently* apply a portable TCP/IP stack, lwIP [10], backed by Data Plane Development Kit (DPDK) [15], to a simple HTTP server and Redis [35]. Normally, kernel-bypassing lwIP achieves higher networking performance than the kernel TCP/IP stack of Linux [4, 32]; for reference, we run the same benchmarks using the kernel TCP/IP stack of Linux and report its performance by non-dotted horizontal lines in Figure 3. We note that the simple HTTP server and Redis are chosen for the experiments because LD_PRELOAD could apply hooks to them, and as explained in § 3.1.4, LD_PRELOAD can fail to hook system calls in other systems.

Simple HTTP server. Commonly, a server program triggers network-relevant system calls more frequently when its application logic gets lighter because it can serve a lot of requests in a short time. To stress the hook mechanisms with lightweight application logic, we made a simple HTTP server that replies a static 64-byte content; we run it on the server machine. As the benchmark client, we run wrk [12] on the client machine; it sends requests through 32 persistent concurrent connections. The results are shown in Figure 3 (left). First, the LD_PRELOAD result represents the minimum overhead case (§ 3.2), and it demonstrates the potential of lwIP on DPDK, which is 5.2 times faster than the Linux kernel TCP/IP stack whose throughput is shown by the non-dotted horizontal line in Figure 3 (left). Comparison with the LD_PRELOAD case sheds light on the overhead of each hook mechanism. The percentages of performance reduction in `ptrace`, `int3` signaling, and SUD compared to LD_PRELOAD are 98.9%, 85.3%, and 83.0% respectively. Contrarily, zpoline causes only 12.7% of performance reduction. These results are explained by the hook overheads shown in Table 1.

Redis. We evaluate how a real-world application performs on zpoline. For benchmarking, we use Redis [35], a widely used key-value store; we run a Redis server process on the server machine. As the benchmark client, we use `redis-benchmark`, which is distributed as part of the Redis source, on the client machine; we run the GET 100% workload so that the Redis server will spend most of its time on networking operations rather than disk operations. Requests are sent over 32 persistent concurrent connections. Figure 3 (right) shows a similar trend to the simple HTTP server experiment, and the overall results reflect the overheads shown in Table 1. Compared to LD_PRELOAD, the throughput results of `ptrace`, `int3` signaling, and SUD are 98.8%, 75.0%, and 72.3% lower respectively. In contrast, zpoline imposes only 5.2% of throughput reduction.

4 Conclusion

This paper has presented zpoline, a system call hook mechanism for x86-64 CPUs, that can exhaustively hook system calls at a low overhead without overwriting instructions that are supposed not to be modified. zpoline is a practical means of transparently applying user-space OS subsystems to existing user-space programs and contributes to the applicability of user-space OS subsystems.

Abstract

Streaming workloads deal with data that is generated in real-time. This data is often unpredictable and changes rapidly in volume. To deal with these fluctuations, current systems aim to dynamically scale in and out, redistribute, and migrate computing tasks across a cluster of machines. While many prior works have focused on reducing the overhead of system reconfiguration and state migration on pre-allocated cluster resources, these approaches still face significant challenges in meeting latency SLOs at low operational costs, especially upon facing unpredictable bursty loads.

In this paper, we propose Sponge, a new stream processing system that enables fast reactive scaling of long-running stream queries by leveraging serverless framework (SF) instances. Sponge absorbs sudden, unpredictable increases in input loads from existing VMs with low latency and cost by taking advantage of the fact that SF instances can be initiated quickly, in just a few hundred milliseconds. Sponge efficiently tracks a small number of metrics to quickly detect bursty loads and make fast scaling decisions based on these metrics. Moreover, by incorporating optimization logic at compile-time and triggering fast data redirection and partial-state merging mechanisms at runtime, Sponge avoids optimization and state migration overheads during runtime while efficiently offloading bursty loads from existing VMs to new SF instances. Our evaluation on AWS EC2 and Lambda using the NEXMark benchmark shows that Sponge promptly reacts to bursty input loads, reducing 99^{th}-percentile tail latencies by 88% on average compared to other stream query scaling methods on VMs. Sponge also reduces cost by 83% compared to methods that over-provision VMs to handle unpredictable bursty loads.

1 Introduction

Stream queries continuously process real-time data to extract insights and make business-critical decisions, such as analyzing real-time logs to extract statistics, detect anomalies, and provide notifications [2, 6, 29, 48, 52]. Latency is an essential service level objective (SLO) in these streaming workloads, as faster up-to-date results mean more value. Stream systems are expected to run 24/7 while meeting their SLOs [53].

Meanwhile, stream systems regularly face significant challenges due to sudden, unpredictable bursts of input loads caused by random events, e.g., influencer tweets, breaking news, and natural disasters [46, 47]. These bursts can abruptly increase the input load by more than 10× in just a few seconds [11, 17, 26, 37, 56]. If stream processing systems do not quickly acquire additional computing resources that can handle the bursty loads and do not promptly redistribute the load to the newly allocated computing resources, events will soon pile up on the existing resources, leading to cascading impacts on query latencies that can have fatal consequences such as reduced user satisfaction and revenues [48].

One approach to quickly acquiring additional computing resources is to over-provision resources. Existing work such as Rhino [18], Megaphone [25], and Chronostream [55] builds efficient stream load redistribution mechanisms by harnessing over-provisioned resources to minimize latency spikes on load bursts. For instance, Megaphone [25] smoothly migrates stream query loads to extra resources during stable load in preparation for load spikes. However, over-provisioning solutions can be *costly* and inefficient, as a significant amount of resources will remain idle for most of the time.

Cloud services can reduce operational costs by offering on-demand resource allocations. Existing scaling approaches for on-demand resources dynamically migrate stream operator instances, in units of parallel *tasks*, to the allocated on-demand virtual machines (VMs). They redistribute the tasks and their states, which are key-value pairs of aggregated intermediate results [7, 15, 16, 19, 36, 49]. However, migrating tasks and their states incurs extra overheads (e.g., (de)serialization), which increase proportionally to the state size (e.g., a large number of key-value pairs), and can violate low latency SLOs. Moreover, using VMs, which are popular on-demand cloud resources, can further exacerbate latency spikes due to the considerable launch delay of VM instances which can take

* Corresponding authors.

dozens of seconds (i.e., 25-30 secs) with conventional cloud providers [21, 31, 44].

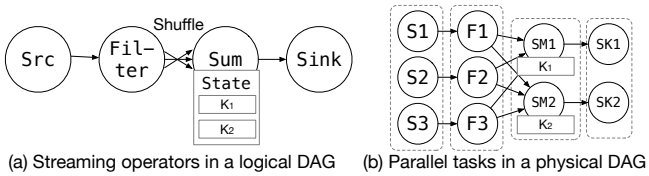
In this paper, we design Sponge, a new stream processing system that requires low operational costs and keeps low latency upon sudden bursty loads. Sponge is designed with the following three design principles:

Combining two heterogeneous cloud resources to have the best of both worlds: Sponge harnesses two heterogeneous cloud resources: VMs and serverless function (SF) instances. Serverless solutions provided by conventional cloud providers [11, 17, 26, 37, 56] only take hundreds of milliseconds (i.e., 300-750 ms) to launch and prepare and are designed to achieve high scalability, while the operational costs are much higher than those of VMs. Therefore, to achieve low latency and low operational costs, Sponge uses VMs for processing stable streaming loads for longer periods of time, while quickly invoking SF instances and using them for short periods of time to handle bursty loads. If the bursty input loads persist, we may consider launching new VM instances to permanently offload the tasks with existing state migration techniques [16, 18, 19, 23, 25, 28, 36, 45, 49, 55]. In such cases, on-demand SF instances can be used to accomplish system SLOs by hiding the launch overhead during the preparation of the new VM instances.

Keeping tasks with high migration overheads on VMs, while quickly redirecting data to SFs: When VMs process streaming data with stable loads over long periods of time, the states of stream tasks are materialized, and the state size may increase on the existing VMs. To avoid the state migration overheads from VMs to SFs, Sponge incorporates the *redirect-and-merge* mechanism: Sponge immediately redirects the increased load to SFs, which are imminent to offload, so that each SF instance can build small partial states and periodically send them back to the VMs to merge with the original states. This approach allows Sponge to promptly exploit fast-launching SF instances and bypass the prohibition of direct network communication between SF instances. For quick data redirection, Sponge exploits SF properties to prevent cold start latencies and pre-initiates copies of VM tasks on SFs to keep its runtime, process, and pre-initiated tasks readily available on time.

***Fast reactive scaling*:** On top of the fast resource scaling mechanisms on SF instances, Sponge identifies bottleneck tasks *reactively* and makes precise decisions on which part of the query to offload and how much of the compute resources to request. At runtime, Sponge continuously monitors the CPU usage, the major resource constraint of task execution, to quickly react to the changing input loads. Our offloading policy determines the fraction of input loads to offload based on excess events accumulated in the input queue and accounts for the optimal time to recover from load increases to meet the SLOs for a given query.

Sponge is built atop Apache Nemo [51, 57] with about 10K lines of code. We evaluate Sponge on EC2 instances (5× r5.xlarge) and AWS Lambda instances (up to 200 Lambda instances of 1,769MB memory with one full CPU core) with NEXMark [42], a popular benchmark for stream processing. The effectiveness of our optimizations varies according to the characteristics of queries (e.g., dataflow pattern, # of tasks, and state size). Our evaluations show that Sponge exhibits similar performance to costly over-provisioned approaches, and reduces input event 99^{th}-percentile tail latencies by 88% on average compared to scaling queries on VMs and by 70% compared to scaling on SFs without our techniques.



(a) Streaming operators in a logical DAG (b) Parallel tasks in a physical DAG

Figure 1: (a) Logical DAG of four operators including a stateful `Sum` operator with two key groups. (b) The corresponding physical DAG with parallel tasks.

2 Background

In this section, we describe the resource demand characteristics of stream processing and different on-demand resource provisioning methods provided by current cloud services.

2.1 Stream Processing

Execution model. A stream processing query processes an unbounded number of timestamped events to derive specific results (e.g., top K, statistics) on every temporal window. The execution of the query is generally expressed as a directed acyclic graph (DAG) of operators and data dependencies. As shown in Fig. 1, a vertex represents a stream operator that transforms input events and emits output events, and an edge represents how data flows between its adjacent operators. Popular stream engines like Flink [15], Spark Streaming [7], and Beam [12] aid users with high-level languages (e.g., declarative language) to facilitate query expressions. To provision compute resources over stream operators in response to the input data rate, the stream engine generates an optimized physical DAG (Fig. 1(b)) after translating a user query into a logical DAG (Fig. 1(a)). In a physical DAG, each logical operator is expanded into n parallel tasks, $p_0, ..., p_{n-1}$, where each task processes a disjoint data partition.

Streaming operators and resource demands. A stream operator is either stateless or stateful. Stateless operators, such as `map` and `filter`, are typically used to compute individual events or drop unnecessary events or fields by applying predicates. Due to their simplicity, stateless operators can be pipelined together within a single node to leverage data locality and reduce network overheads. On the other hand, stateful operators, such as `groupByKey` and `join`, perform data

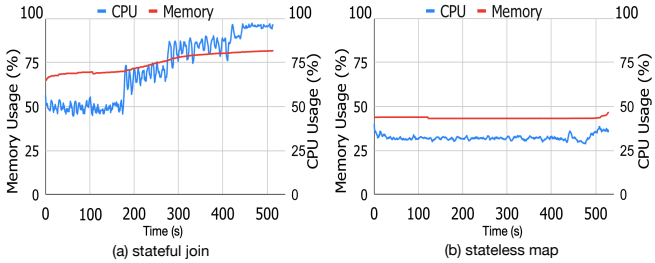


Figure 2: CPU and memory usage patterns for (a) stateful windowed `join` and (b) stateless `map` operators upon processing a fixed input rate of 80K events/s on identical 4 vCore nodes. The CPU and memory usage of the stateful operator increase until the window is full.

grouping within a window boundary to organize unbounded streaming events into disjoint groups based on timestamps and aggregation keys, requiring computationally extensive key lookups. Thus, most streaming engines apply parallelism specifically to stateful operators such that a single stateful task p_i processes events that only belong to a non-overlapping key partition group K_i out of the entire key space $K = \cup_{i=0}^{n-1} K_i$.

Stateful operators are often the major source of system bottlenecks [38, 50]. In particular, since each parallel stateful task is assigned to a key partition group, it incurs shuffle communication for the events in its key group that are collected from the preceding (upstream) operators. Shuffle communication often requires the data to travel across different nodes, requiring data serialization and deserialization on top of the computation performed for the key lookups. As a result, as shown in Fig. 2, it is prevalent to provision more CPUs to execute stateful operators rather than stateless operators [28, 54].

2.2 On-Demand Resource Provisioning

Several real-world stream analytics systems report high temporal variability in the event count of data streams, even across one-minute time windows [34, 36, 43, 48]. This means that stream processing may need to frequently adjust resource provisioning and query execution plans in response to changes in input loads. Upon facing increased input loads, the system needs to allocate more resources to avoid operators being congested and maintain stable query latency.

Cloud providers offer primarily two options for on-demand resource allocation: virtual machines (VM) and serverless functions (SF). We compare three representative characteristics between these two options in more detail.

Resource size. VMs are machine-isolated by bare-metal hypervisors, whereas SFs are process-isolated by OSes. Therefore, SFs are much more flexible in allocating resources. Cloud providers typically provide VMs in chunks of a predefined, fixed amount of resources (e.g., r5.xlarge with 4 vCores and 32GB memory). In contrast, SFs are allocated based on a specified memory size. For the memory size, cloud providers assign a certain number of CPU power (e.g., vCores)

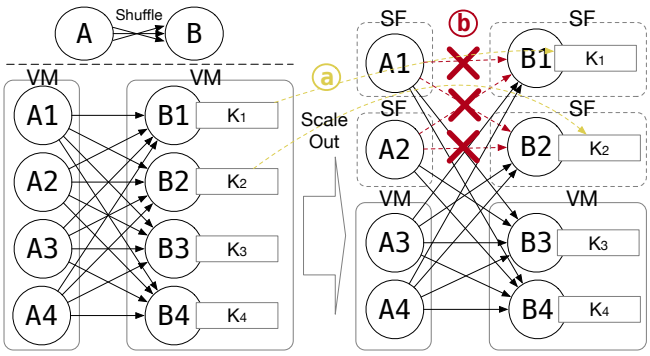

Figure 3: While scaling out on SF instances, the system must be aware that ⓐ task state migration overheads lead to latency spikes, and ⓑ direct data communication among adjacent tasks is prohibited between SF instances.

guided by their pricing model [8]. We observe that network bandwidth per SF instance is about 100Mbps and concurrently using multiple SFs can increase the bandwidth up to GBs of effective bandwidth, which VMs already support, providing enough capacities to handle most streaming workloads.

Start-up time. VM instances take a significant amount of time to launch and to prepare the runtime stack for query workload as they virtualize resources using bare-metal hypervisors. We observe that provisioning a new VM instance in major cloud service providers, like AWS, Azure, and GCP, mostly has a latency of over 25 seconds. On the contrary, SF instances provided by these cloud vendors take only 300-750 ms to launch and be ready to run because SF instances share runtimes and resources at the OS level.

Usage cost. SF instances are much more expensive to use than VM instances, e.g., 4× more expensive when running a 1GB SF instance with AWS Lambda (with $<$ 1 vCPU) compared to a t2.micro EC2 instance, which is equipped with 1 vCPU and 1GB RAM. However, temporarily using SF instances primarily for frequent short-lived bursty loads that constitute only a small fraction of time throughout the day [26] does not significantly increase the operational cost (§ 6.5).

3 Challenges

Based on these observations, we propose to use a combination of VMs and SFs to have the best of both worlds. To achieve low latency and cost, we use cheap and stable VMs for handling continuous loads for long periods of time, and costly and reactive SFs for bursty loads during short periods of time. In this section, we describe several challenges in scaling streaming loads from VMs to on-demand SF instances.

C1. Migration with large operator states. For stream scaling in the cloud, existing approaches trigger resource adaptation primarily by re-scaling operators (i.e., increasing or decreasing parallelism) and migrating the bottlenecked tasks to the instances with available resources (i.e., load redistribution) [7, 15, 16, 19, 28, 36, 49]. Thus, even if we can set

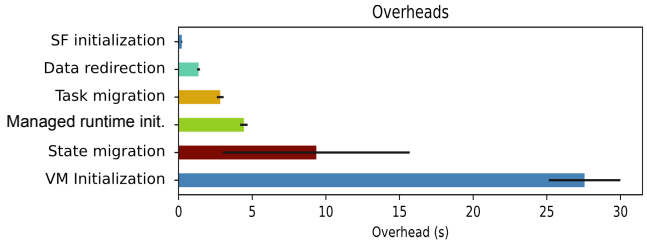

Figure 4: A comparison of the overheads of different steps of workload scaling on stream processing systems in the cloud. The VM, SF, and managed runtime initialization overheads are averaged across all instances, and the data redirection and task/state migration overheads are averaged across all single-scaling operations for the 5× input load experiment in § 6. Error bars indicate the 95% confidence interval.

up SF instances quickly, the task state migration overhead is inevitable with existing systems, as shown by Fig. 3ⓐ, and paradoxically often inflicts damage to system performance.

Fig. 4 illustrates the various overheads that occur during a single workload scaling for the queries evaluated in § 6. As shown in this figure, the task migration and reconfiguration require a few extra seconds (3-4 seconds) to resume the work after the migration. Also, the state migration takes several seconds (e.g., from 4 to 17 seconds) depending on the state size because of the (de)serialization overheads of states. These task and state migration overheads lead to increased query latency due to the delay in receiving events from upstream tasks. The system that aims to meet low-latency SLOs must correctly and rapidly carry out task offloading to SFs. In particular, some use cases are expected to generate outputs even in order of seconds or less, without query accuracy loss [36, 48].

C2. Indirect data communication between SF instances. As SFs are designed to be provisional and temporary, cloud vendors usually prohibit running a server process that can accept inbound network connections on an SF instance. Hence, direct data communication across SF instances is prohibited. This prevents neighboring stream operators (parent and child operators) from being offloaded to SFs simultaneously, as these operators require direct shuffle data transfers to group data by its key partitions, as shown in Fig. 3ⓑ.

Therefore, we can choose to migrate only certain tasks to SFs (e.g., either operator A or B in Fig. 3), but this eventually leads the bursty input load to end up on VMs on the adjacent operators and fails to alleviate latencies. Alternatively, we can offload all the tasks involved in the shuffle communication on a large SF instance. However, this forces parallel tasks to be located on a single SF instance, which can lead to network pressure while leaving VMs idle. Consequently, it is essential to design the system to be able to offload adjacent operators together to SFs while bypassing the prohibited direct communication across SF instances.

C3. Quick decision making and scaling. With frequent unpredictable changes in input events, offloading decisions must be made quickly at runtime. Stream systems often detect symptoms of bottlenecks from system metrics and decide on whether and how much to scale. However, existing approaches can be too slow, as they require multiple iterations of optimization that scale bottleneck operators one after another [19]. Other work prevents such iterations by providing a global optimum after collecting all metrics from all executors to redistribute tasks [28]. While these approaches effectively find the target throughput and may be suitable for throughput-oriented workloads, they only work in intervals of multiple 10s of seconds and may not be suitable for latency-oriented workloads. For a stream system operating with diverse intervals and window sizes, it is important to have a uniformly fast and effective optimization level to prevent window outputs from being delivered too late.

4 Sponge Design

In this section, we describe the key pillars of our system design and explain the details by illustrating our graph rewriting algorithm, dynamic offloading policy, and the mechanisms that prevent cold start latencies and enable system correctness.

4.1 Design Overview

Latency spikes occur when the input rate r_i exceeds the maximum throughput m_i on a particular task p_i. When this happens, data starts to accumulate on the event queue, along with the operator state in memory, leading to high CPU usage and memory pressure. In a cloud environment, the maximum throughput m_i often depends on the CPU capacity allocated to the task, regardless of the operator type. This is because most cloud providers are equipped with GBs of network bandwidths, and memory pressure starts to increase when the CPU becomes saturated, and the input data builds up in the event queue with $r_i > m_i$. Therefore, our goal is to primarily focus on relieving CPU pressure. To achieve this, we design a system that accurately estimates the amount of additional resources needed and provides fast mechanisms for offloading CPU computation from VMs to SFs through two design principles: *redirect-and-merge* and *fast reactive scaling*.

Redirect-and-merge. Sponge is designed to rapidly forward increased input load to available resources in SF instances. To ensure speed, we bypass expensive query optimizations during runtime by performing DAG optimizations during compile time, i.e., when the application is launched (Fig. 5ⓐ). During compile time, there are no concerns yet about runtime synchronization and progress, so it only takes about 200ms upon workload initialization to perform the DAG optimizations. After the optimization, Sponge scheduler places tasks on appropriate executors (Fig. 5ⓑ). This allows Sponge to focus on which operators and how much of their data volume

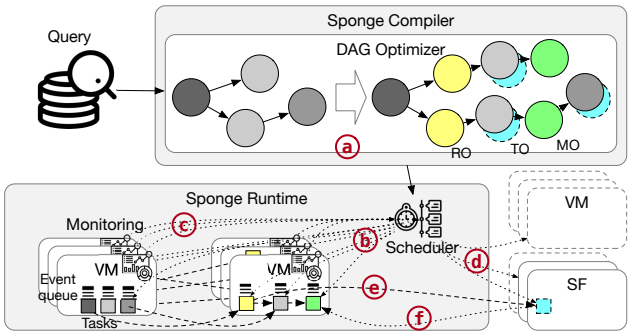

Figure 5: Sponge architecture.

to offload to SFs based on monitoring CPU usage (Fig. 5ⓒ) without having to relaunch queries at runtime.

While stateful operators are our primary focus as initial bottlenecks, any operator can become a subsequent bottleneck. Thus, we enable offloading for any operator, regardless of its type and statefulness. We design transient operators (TOs) so that operator logic can be prepared on SF instances to receive events immediately after detecting an increase in the input load and CPU usage on VMs (Fig. 5ⓓ). We also enable offloading to be activated at any time with high efficiency and responsiveness. To meet these requirements, we introduce a set of new proxy operators: router operators (ROs) and merge operators (MOs). ROs supervise the data communication to downstream VM and SF instances, in order to enable the system to rapidly and elastically *forward* data from any existing operators to the designated instances (Fig. 5ⓔ). To minimize state migration overhead, which is a major bottleneck in task migration [18, 23, 25, 55], the states, exclusively for the offloaded input load, are maintained separately on SFs. MOs enable the system to later *merge* the corresponding states of offloaded workload created on SFs with the states on the original VMs for any stateful operators (Fig. 5ⓕ). This way, the offloading overhead for both stateful and stateless operators is substantially reduced, as we only have to offload the computational logic, and not the states. The proxy operators are inactive during non-scaling periods to avoid extra costs and are only activated when needed.

Fast reactive scaling. With the principle above, we provide a fast reactive approach that prevents inaccurate predictions on resource provisioning by monitoring local performance metrics within the executors. Bottlenecks often occur individually on VMs, so it is sufficient to mitigate them *locally* within each VM. As briefly mentioned, relieving CPU pressure when the input rate r_i is greater than the operator throughput m_i is key to reducing CPU and memory strain in stream processing systems. Sponge has low monitoring overhead, with less than *10ms per observation*. Based on input rate and CPU usage observations, Sponge estimates the amount of CPU resources needed to increase operator throughput and meet our SLOs under increased input loads.

Algorithm 1: DAG rewriting for operator insertion.

```
1  Function OperatorInsertion(dag)
2      for vertex, inedges in dag.topological_sort() do
3          t_op = TransientOp.for(vertex)
4          for inedge in inedges do
5              if inedge.comm != 1to1 then
6                  r_op = RouterOp.create()
7                  dag.remove_edge(inedge)
8                  e1 = {inedge.src→r_op, inedge.comm}
9                  e2 = {r_op→vertex, 1to1}
                   // connect transient operators
10                 e3 = {inedge.src.t_op→r_op, inedge.comm}
11                 e4 = {r_op→vertex.t_op, 1to1}
12                 dag.add_edges([e1, e2, e3, e4])
13             else
14                 e = {inedge.src.t_op→t_op, 1to1}
15                 dag.add_edges([e])
16             if inedge.src.is_stateful() then
17                 m_op = MergeOp.create()
18                 dag.remove_edge(inedge)
19                 e1 = {inedge.src→m_op, inedge.comm}
20                 e2 = {m_op→vertex, 1to1}
21                 e3 =
                    {inedge.src.t_op→m_op,inedge.comm}
22                 e4 = {m_op→vertex, 1to1}
23                 dag.add_edges([e1, e2, e3, e4])
24     return dag
```

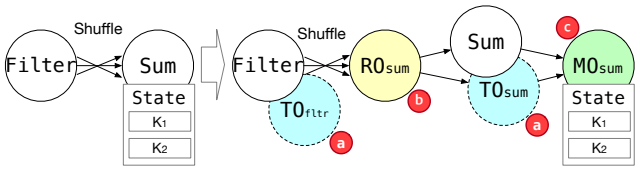

Figure 6: DAG transformation after graph rewriting.

4.2 Compile-time Graph Rewriting Algorithm

At the start of the application, our compiler applies the graph rewriting algorithm (Algorithm 1) to the application DAG, which produces a new DAG based on a set of conditional rules, as shown in Fig. 6. In our algorithm, TOs, ROs, and MOs are inserted as follows. *TOs* are cloned stream operators with additional features to run on SF instances, such as maintaining partial states for stateful operators. Since all original operators are potential candidates for offloading, we first create TOs for all operators (line 3, Fig. 6ⓐ). This way, all operators causing CPU bottlenecks can scale on SFs with TOs. *ROs* enable data communications between VM and SF instances when the communication pattern involves a shuffle or a broadcast (as one-to-one communications typically occur locally between pipelined operators) (§ 2). ROs run on existing VMs to redirect the input data to the downstream tasks running on either VMs or SFs without performing additional

computations (line 5-12, Fig. 6ⓑ). If the communication pattern involves the same number of partitions and tasks between two operators, we pipeline the corresponding TOs with a one-to-one edge (line 13-15). ROs incur almost no costs as they simply redirect events to the tasks on target instances (e.g., conventional or TO tasks). Lastly, we insert an *MO* after each stateful operator for every edge, so that the partially aggregated states on the TOs can be merged back into the original states on VMs (line 16-23, Fig. 6ⓒ), where the details of the merging mechanisms are provided in § 4.5. Stateless operators do not need to merge states, so they simply pass on their output to the following operators (e.g., filter operator in Fig. 6). During non-scaling periods, ROs are not activated and TOs and MOs do not receive any data, adding no computational costs to the runtime. The operators are only activated upon offloading actions.

4.3 Dynamic Offloading Policy

In this section, we describe when Sponge triggers offloading, how many SF instances it uses, and how many events it offloads. Our goal is to constantly maintain low query latencies while keeping CPU utilization stable across all active cloud instances. To achieve this, Sponge quickly calculates the total number of CPU cores needed to meet this goal and the Sponge scheduler redistributes the workload accordingly among the tasks placed on VMs and SFs.

Overall workflow. The Sponge runtime, shown in Fig. 5, is a main system component that performs monitoring of the resources and operator states to take immediate scaling actions as needed. Each executor continuously monitors CPU resources and input rates, typically every second, and observes if the CPU load falls outside a stable range for consecutive periods. If so, the Sponge runtime initiates the scaling phase by first calculating the target system throughput, based on the over-subscription period of CPUs and the current input rates (that jointly decide the number of events in the queue), and the recovery deadline (the time remaining to clear the events and return the system to a stable state). Subsequently, the Sponge runtime adds new SF instances as needed to meet the recovery deadline by sending requests to the Sponge scheduler. The number of new SF instances is chosen to be minimum to neither over-subscribe nor under-subscribe the active cloud instances, minimizing operational costs. After a scaling action is taken, the Sponge runtime returns to the monitoring phase. It is possible that the Sponge runtime may go through multiple monitoring-scaling phases before the system becomes stable.

4.3.1 Detailed Offloading Process

CPU utilization goals. Along with system metrics, such as the input rate and operator latency, Sponge measures the CPU load of the executor in order to maintain adequate CPU loads on individual nodes. Through extensive experiments, we have observed that the input rate r_i exceeds operator throughput m_i and event queues start to build up (i.e., $r_i > m_i$) when the CPU is occupied at around 75-80% of its capacity. We have also seen symptoms of over-provisioned system resources when the CPU load falls under 50-60%. Due to such reasons, we aim to maintain the CPU utilization range between 60-80%.

Events in the queue. Assuming $r_i(t) > m_i(t)$ between times t_p and t_{p+1} ($t_p < t_{p+1}$), the number of excess events accumulated in the queue can be formulated as $\int_{t_p}^{t_{p+1}} (r_i(t) - m_i(t))\,dt$. Obviously, the accumulated events in the queue will be smaller if the duration $d = t_{p+1} - t_p$ is smaller. This is the main reason for using SF instances over VMs – to reduce the duration of $r_i(t) > m_i(t)$.

Recovery deadline. Recovering from this event backpressure is achieved by providing the system with additional resources to achieve higher throughput, m_{i_o}. If additional resources are available from time t_o, we should set a deadline t_{o+1} until which we aim to empty the queue to return to a stable state for our streaming system. We base the deadline on the window interval of the query (e.g., 10 seconds) so that we can deliver the query results within the query's next output boundary. Then, the number of additional events that can be processed from the queue can be expressed as $\int_{t_o}^{t_{o+1}} (m_{i_o} - r_i(t))\,dt$, where the increased throughput is larger than the input rate ($m_{i_o} > r_i(t)$). As a result, we should adjust our throughput m_{i_o} with sufficient additional resources to meet our recovery deadline t_{o+1} (e.g., $t_{o+1} - t_o \leq 10$) such that the following equation holds:

$$\int_{t_p}^{t_{p+1}} (r_i(t) - m_i(t))\,dt \leq \int_{t_o}^{t_{o+1}} (m_{i_o} - r_i(t))\,dt \qquad (1)$$

The approximation of the integrals is based on Simpson's rule provided by [5], which turns complex calculations into simple arithmetic that incurs trivial overheads.

Stable throughput per VM CPU core. To calculate the target number of SF instances required to achieve our target throughput, we maintain records of the CPU usage rate of the VM node during stable loads. Assuming that a task p_i runs on a single VM core with an average usage rate of $\overline{u_{cpu_i^{VM}}}(\%)$ and an average task input rate of $\overline{r_i}[events/sec]$ based on the records, we scale and approximate the input rate and throughput for 100% utilization of the VM core $rpc_i^{VM}[events/(sec \cdot core)]$ for task p_i, as follows:

$$rpc_i^{VM} = \frac{\overline{r_i}}{\frac{\overline{u_{cpu_i^{VM}}}}{100}} \qquad [events/(sec \cdot core)] \qquad (2)$$

Required number of SF instances and data redistribution. Based on the approximation of how much input throughput a VM core can handle, we can calculate the number of required SF instances to achieve our target throughput m_{i_o} with a simple division. We offload tasks from VMs to SFs to keep the CPU utilization of VM clusters between $60-80\%$ in order to prevent resource over-provisioning. Hence, we target the VM CPU core usages at 70%, for our approximation to solidly fall

into our target with a ±10% buffer even when our profiling measurements exhibit minor errors on time-varying variables like $r_i(t)$.

Assuming the CPU capacity of each SF instance core is different from that of a VM core, we can derive a relation between them with profiling: $capa^{SF}_{core} = \rho * capa^{VM}_{core}$. Correspondingly, $rpc^{SF}_i = \rho * rpc^{VM}_i$ because the throughput is proportional to the CPU capacity. Altogether, the number of total SF cores c that we need to prepare to meet our latency goal for task p_i can be derived with Equation 2 as follows:

$$c = \lceil \frac{m_{i_o}}{0.7 \cdot rpc^{SF}_i} \rceil = \lceil \frac{m_{i_o} \cdot \overline{u_{cpu_s}}}{0.7 \cdot 100 \cdot \rho \cdot \bar{r}_i} \rceil \quad (3)$$

where the number of required SF instance cores increases as ρ decreases. Finally, the number of SF instances can be calculated with $\frac{c}{k}$ where k is the number of cores per SF instance ($k = 1$ in our evaluation).

When offloading stateless or stateful tasks, Sponge evenly redirects data or redistributes keys to the $\frac{c}{k}$ SF instances, while processing remaining events on VMs to keep 70% CPU usage in average. If the event distribution is skewed across the key space, the solution can be extended to use key histograms for more accurate key partitioning, as in existing approaches [13, 30]. Both during scaling up and down, the target CPU usage is set at 70% within our target range.

4.4 Reducing Cold Start Latency

In order to timely gain access to SFs, Sponge provides two options: (1) warm-up SF workers in advance by sporadically processing short events [21, 39, 58] to minimize the managed runtime initialization overheads [35], and (2) use solutions like AWS SnapStart [32], which bring shorter initialization times of SFs by taking a snapshot of the initialized SF instance environment and caching it for low-latency access [1]. As SFs are charged based on the memory usage time and the number of requests [9, 10, 22], prices for pre-warming SFs are trivial (nearly zero). By default, Sponge prepares and keeps enough SFs warm to handle up to 5× the stable load during the workload. For bursty loads that exceed 5× the stable load, Sponge timely prepares new instances with SnapStart [32] on AWS. SFs on AWS SnapStart [1, 32] show a slightly worse start-up time compared to the instances that are kept warm in advance, but the overhead is reduced by more than 80% compared to unoptimized JVM initializations, resulting in a sub-second total start-up time for SFs (§ 6.4). As a result, by enabling both methods for initializing the managed runtime, Sponge can timely gain access to SFs upon facing unpredictable bursty input loads.

4.5 Correctness

As stream systems are designed to be long-running, progress is tracked by the positions of the *watermarks* that flow along

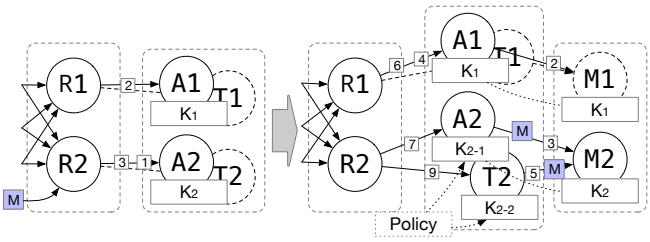

Figure 7: Once an operator (A2) tries to scale, an offload message (M) is generated at the RO (R2) to activate its TO (T2) and MO (M2). The offload message acts as a boundary among input events (1-9) for operator scaling and state merging.

with stream events [12, 15, 51, 57]. Based on the intuition, Sponge maintains correctness by (1) introducing a watermark in the event stream as a control message upon (de)activating an operator and (2) ensuring that all events between two watermarks are processed in the original system (i.e., without offloading) or on the offloaded operators [23, 36].

Concretely, upon detecting a possible bottleneck in an operator task p_i on an executor, Sponge fires a watermark message `M` into the data channel (Fig. 7). Upon receiving watermark messages, operators checkpoint their states to later recover from the checkpointed states, guaranteeing exactly-once processing. Sponge scales after temporarily pausing operators upon control messages and delivering messages to downstream tasks. Once all on-the-fly events in the data plane are consumed, downstream tasks send acks back to the upstream tasks to guarantee no event and state loss.

Thus, the events that arrive after `M` are immediately redirected to the tasks of the TOs on SFs, where partial states are aggregated if the operator is stateful. For stateful operators, TOs send the aggregated states to the following MOs placed on VMs, which know where to start merging the partial states with the original ones. Both incremental and appended aggregation can be mergeable with partial states, similar to how Flink [15] manages shared states, which causes moderate overhead on VMs. Even if events arrive out-of-order in the merge operators, they wait for the same watermark to arrive from the task in VM and its transient tasks so that the states can be synchronized. This ensures that all input data before and after `M` are processed according to the proposed optimizations.

5 Implementation

We have implemented Sponge with about 10K lines of Java with support for AWS Lambda, as follows:

Programming interface: To express a stream query as an application DAG, we use Apache Beam [12] application semantics, which is a widely used dataflow programming interface for various systems (e.g., Spark [7], Flink [15], Cloud-Dataflow [3]). In addition, as Beam provides APIs for developers to build associative and commutative operations (e.g.,

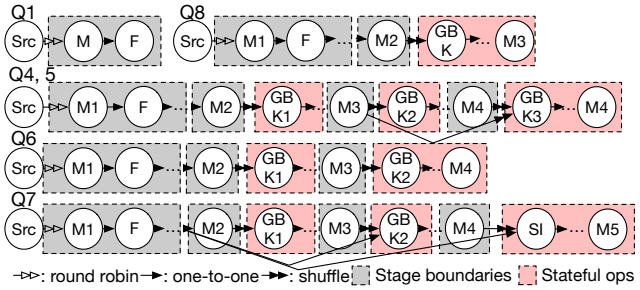

Figure 8: A simplified application DAG of stream queries used in our evaluation. `M` and `F` are map and filter operators, `GbK` is a stateful group-by-key operator for incremental aggregation on windows, and `SI` is a non-mergeable stateful operator for the join operation.

combiners), Sponge can extract this information to build the merge operators.

Compiler: Apache Nemo [51, 57] provides the intermediate representation and optimization pass abstractions, with which we can flexibly optimize application DAGs. We split our operator insertion into three separate optimization passes for inserting ROs, TOs, and MOs on Nemo to reshape the application DAG, defined by Apache Beam semantics.

Runtime: We modify the Nemo runtime [51, 57] to support the migration of tasks and the redirection of the data from VMs to SFs. Sponge executes worker processes on VM and SF instances, which each manages a thread pool that contains a fixed number of threads and assigns tasks to the threads. VM workers set up Netty [41] network channels and communicate with other VMs and SF workers, while there are no network channels set up between SF instances due to the communication constraint. For launching new VM and SF instances, as well as for deploying the worker code on AWS Lambda, we use boto3, the AWS SDK API for controlling AWS instances [14].

6 Evaluation

In our evaluation, we observe Sponge performance compared to other scaling mechanisms (§ 6.2), distinguish the factors that contribute to the Sponge performance (§ 6.3), compare the cold start latency reduction mechanisms (§ 6.4), and observe the latency-cost trade-off between SFs and VMs (§ 6.5).

6.1 Methodology

Environment. We use AWS EC2 r5.xlarge instances (32*GB* of memory and 4 vCores) as VM workers, and AWS Lambda instances as SF workers. As AWS Lambda offers one vCPU per 1,769*MB* and provides constant network bandwidth (i.e., $\sim$ 100Mbps) regardless of the instance size, we use single-core SF instances of 1,769*MB* to provision each instance with enough network bandwidth to achieve the throughput of the CPU core. VMs generally provide 10Gbps networks, which effortlessly cover the traffic generated by the CPU

Query	Stateful	State Size	# of Tasks (per Op.)	Stable input rate
Q1	X	-	120	550 K/s
Q4	O	~90 MB	60	190 K/s
Q5	O	~2.4 GB	70	19 K/s
Q6	O	~73 MB	70	230 K/s
Q7	O	~1.5 GB	90	15 K/s
Q8	O	~7 GB	60	60 K/s

Table 1: Characteristics of different NEXMark stream queries.

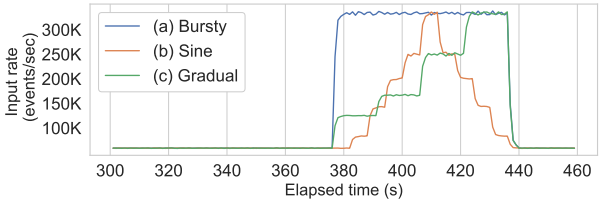

Figure 9: Examples of different bursty input patterns used in some experiments, where input rates increase at time $t = 380$. (a) shows a sudden increase from $60K$ to $300K$ ($5\times$) for 60 seconds, (b) shows a sine-curve increase and decrease, and (c) shows a gradual increase.

core throughput (i.e., $< 10\%$ bandwidth utilization when offloading 450K events/sec). We set up Amazon Virtual Private Cloud (VPC) for the data communication between the VM and SF instances for stable network connections.

Workloads. NEXMark [42] is a widely used streaming benchmark [28, 33] that analyzes auctions and bid data streams. NEXMark contains diverse stream queries with complex dataflow and stateful operations. Among the 8 (Q1-8) NEXMark queries, we choose 6 queries as shown in Table 1 because they represent distinctive data communication patterns and stateless and stateful operations. We omit Q2-3 because Q2 is a stateless query similar to Q1, and Q3 is a non-associative stateful query like Q7.

Fig. 8 illustrates the simplified original DAG of NEXMark queries, and Table 1 summaries the characteristics of the queries. The queries except for Q1 contain windowed operations. We configure the window size of queries as 60 seconds and the window interval as 1 second. While the system throughput declines with larger and more frequent windows, we evaluate under a frequent window interval to test Sponge under requirements for frequent, time-critical resource scaling. The throughput of the evaluated engine [51, 57] is similar to the performance of other stream processing engines [7, 15] when the same window size and interval are used. Nonetheless, in our evaluation, the bursty traffic is increased by up to $10\times$ events/sec and represents a wide range of realistic input rates in the field (§ 6.2).

Baseline. We compare Sponge with the following baselines:

- **NoScaling** executes stream queries on static VMs without scaling out stream queries.
- **VMBase** dynamically creates new VMs and migrates tasks

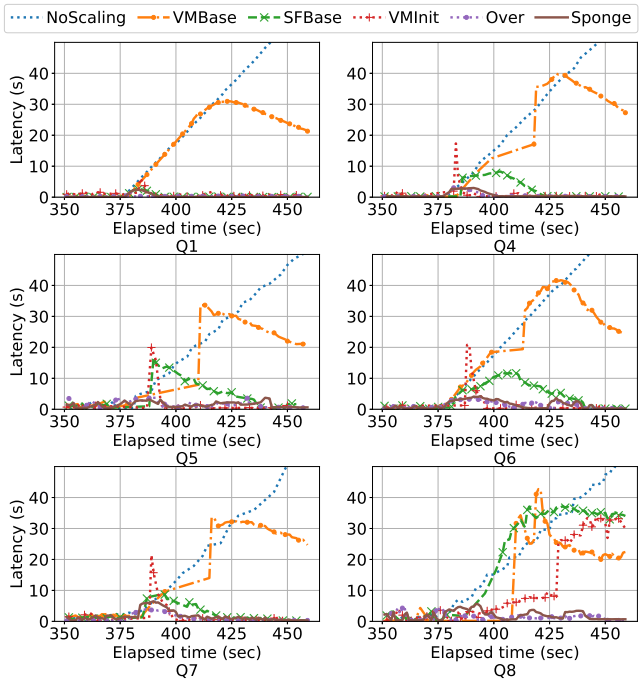

Figure 10: The tail latency graph, under a bursty load (Fig. 9(a)) at $t = 380s$ and scaling is triggered at $t = 381s$.

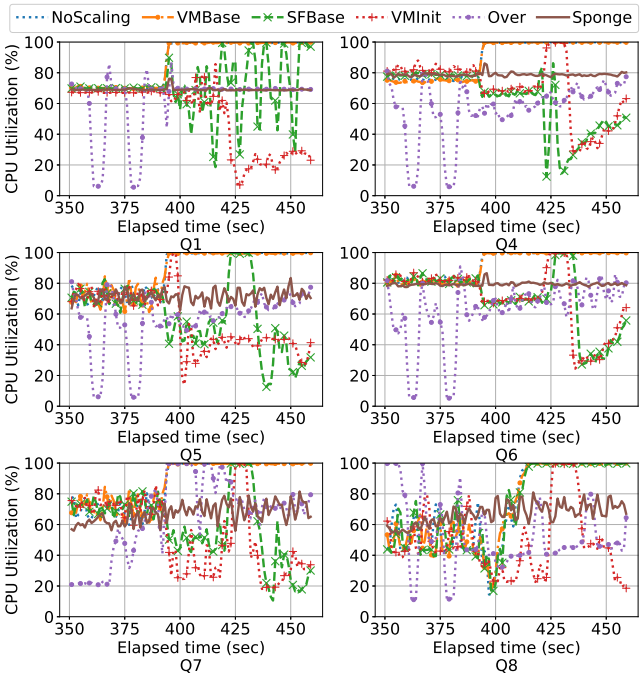

Figure 11: The CPU utilization graph, under a bursty load (Fig. 9(a)) at $t = 380s$ and scaling at $t = 381s$.

to the new VMs for scaling without dataflow reshaping.

• **SFBase** dynamically creates SF instances and migrates tasks to SFs for scaling without dataflow reshaping. For SFBase and Sponge, we prevent cold start latencies on SF workers as described in § 4.4.

• **VMInit** initializes new VMs in advance and migrates tasks to the new VMs for scaling without dataflow reshaping.

• **Over** over-provisions VMs and already has enough resources to cover input loads without dataflow reshaping.

Bursty traffic and resource allocation. We emulate bursty traffic by increasing the input rate over a short period of time, as shown in Fig. 9. In this traffic pattern, we first generate stable input streams where the input rate is stable and does not fluctuate. At a specific point (e.g., $t = 380s$ in our evaluation), we increase the input rate for a short period of time (e.g., 60 seconds) to emulate an increased load and then decrease the rate back to the stable input rate. In § 6.2, we observe the average performance of the different systems under up to $10\times$ burstiness ($\frac{\text{bursty input rate}}{\text{stable input rate}}$), and we provide detailed analysis on the effects of the burstiness rising from $3\times$ to $6\times$ in § 6.3. By default, the burstiness is set to $5\times$, as it distinctly shows the limitations of existing approaches comparatively. For example, as the stable CPU load is kept at $60-80\%$, most baselines already experience high latencies from $2\times$ burstiness, but the performance results are more clearly distinguishable between the baselines under the $5\times$ burstiness.

During the stable load, we run 5 VM workers. We generate events (per second) for the stable load such that all 5 VM workers undergo CPU usage between 60% and 80%, preventing the VM cluster from being under-loaded or overloaded. As queries have different computational complexity, the stable input rate is configured differently for each query as shown in the last column of Table 1. Once bursty loads occur, we dynamically allocate up to 200 single-core SF instances for *Sponge* and *SFBase*, and up to $50(10\times)$ new extra VM instances for *VMBase* depending on the query load.

6.2 Performance Analysis

Fig. 10 and Fig. 11 illustrate the 99^{th}-percentile tail latency and CPU utilization, respectively, of the different systems across different queries for the Burst traffic pattern in Fig. 9. Overall, *Sponge* and *Over* exhibit lower latencies compared to others during bursty periods and successfully keep the CPU utilization stable. The latency of *NoScaling* continuously increases with full CPU utilization as the existing VMs are overloaded and never perform offloading. Henceforth, we discuss Sponge and other baselines that perform scaling. For SF-based strategies that are restricted by the prohibited direct communication between SF instances, we profile their operator costs and manually configure them to make the best scaling decisions.

Sponge. Sponge reduces the tail latency on average by 88% compared to *VMBase* and 70% compared to *SFBase* and performs comparably to *Over*. Sponge also keeps the CPU utilization relatively stable across time, as shown in Fig. 11. Subsequently, we illustrate below why other scaling strategies cannot deliver the same benefits as Sponge in further detail.

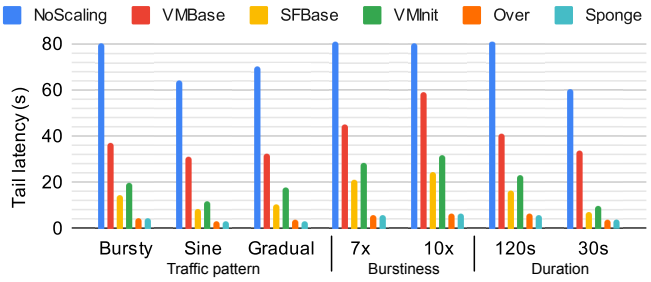

Figure 12: Summarized results of the experiments, with similar settings as in Fig. 10, displaying the average peak tail latency across the different NEXMark queries under diverse input patterns and burstiness.

VMBase. The latency of *VMBase* in Fig. 10 increases by at least 30s due to the slow start-up time of the VMs. Specifically, we observe that it takes around 25-30 seconds for the VMs to start, and around 4 extra seconds for managed runtime (i.e., JVM) worker processes to start on the newly started VMs. Moreover, as JVM processes are cold at the beginning and JIT compilation is not triggered, the processing throughput is low in the beginning, which causes extra latency of up to 44 seconds. After new VMs are instantiated, tasks are migrated to new VMs, and the latency of the VM decreases as the throughput eventually becomes larger than the input rate. Nevertheless, the CPU utilization of *VMBase* shown in Fig. 11 is continually kept high after the peak load, as it tries to climb down from the latency peak by heavily processing the data in the event queue.

SFBase. The slow start-up time of VMs can be mitigated by using SFs as shown in *SFBase*. Upon scaling out Q1 (a simple stateless query), *SFBase* significantly reduces the latency and CPU compared to *VMBase*, as the start-up time of an SF instance only takes a few hundred milliseconds in our evaluation. This result suggests that only by using SFs instead of VMs, we can significantly improve the latency for scaling out a simple stateless query, similar to MArk which handles bursty loads of stateless inference jobs [58].

However, for scaling out other complex queries with N-to-N shuffle data communications and stateful operations, the performance gain of *SFBase* compared to *VMBase* declines. It indicates that naïvely scaling queries on SFs without any operator insertion has limitations due to the challenges explained in § 3. In Q4 and Q6, latency increases by up to 12 seconds because the operators with shuffle edges cannot be redistributed to SFs and VMs become the bottleneck. In Q5, Q7, and Q8, latency and CPU spikes are caused by task and state migration overheads.

VMInit. Like *SFBase*, *VMInit* reduces the slow start-up time of VMs by starting them in advance. For *VMInit*, queries with N-to-N shuffle data communications can be offloaded, but we can see that it still incurs task and state migration overheads resulting in short steep peaks of tail latencies and CPU usage, which is highlighted in Q8.

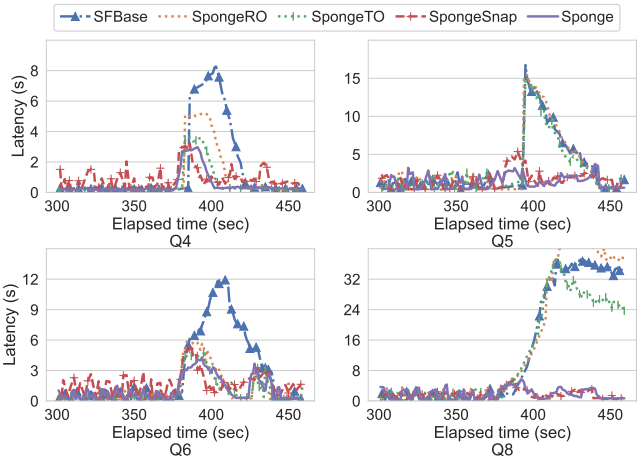

Figure 13: The latency graphs for SF, *SpongeRO*, *SpongeTO*, SpongeSnap, and Sponge to analyze and break down the performance improvements of Sponge.

Over. The over-provisioned case is the most expensive solution, providing enough resources for the peak loads without considering an upper bound for runtime costs. In Fig. 10, we can see a slight increase in latency as the input load increases, but it soon stabilizes back. The CPU usage in Fig. 11 displays an under-utilization before the peak load, but shows an adequate utilization rate afterward, as it is allocated with an adequate amount of resources for the peak load.

Input patterns. In Fig. 12, we can see the average tail latency among the different queries along the different input patterns. We can see that *Sponge* and *Over* show good performance among all settings, and *NoScaling* continuous increases in most cases. The sine and gradual bursts show a relatively mild effect compared to others, as their bursts are more gentle. We can see that while 120s and 30s bursts show somewhat similar results, 7× and 10× bursts show higher tail latencies due to the increased load.

6.3 Graph Rewriting Effect

To validate our design, we analyze the performance gain on Sponge with the following additional baselines:

- **SpongeRO** scales queries on SFs while allowing direct communication between SF instances with ROs only.
- **SpongeTO** scales queries on SFs by adding event redirection atop *SpongeRO* with ROs *and* TOs.
- **SpongeSnap** shows performance for Sponge, with ROs, TOs, and MOs, on SnapStart, without pre-warming instances.

Fig. 13 illustrates the tail latencies of *SFBase*, *SpongeRO*, *SpongeTO*, *SpongeSnap*, and *Sponge* in more detail. Q1 and Q7 are omitted in the figure, as Q1 is a simple stateless query, and Q7 is represented by Q5 and Q8.

Router operator effect. Comparing *SpongeRO* with *SFBase* shows the effect of router operators. In Q4 and Q6, SFs exhibit higher latencies as VMs are bottlenecked while processing

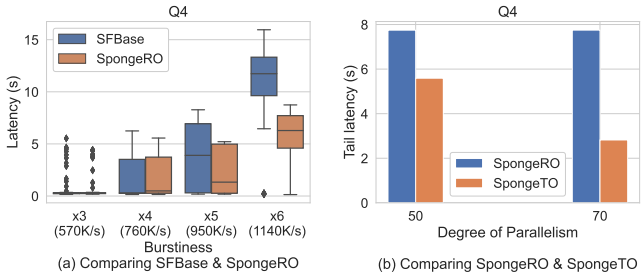

Figure 14: Comparison on Q4 for (a) *SFBase* and *SpongeRO* on diverse burstiness, and (b) *SpongeRO* and *SpongeTO* on different degrees of parallelism (# of parallel tasks).

events for `M` operators (Fig. 8) on VMs (only 3% of input events are filtered before `M2`). As naive SFs can only offload one of `M` and `GbK`, we choose to offload `GbK`, as the amount of computation on `M` is smaller than that of `GbK` due to the additional aggregation. However, the input rate of `M` on VMs becomes higher than the maximum throughput on the VMs with 5× bursts in Q4 and Q6, and events pile up in `M` operators, incurring latency increases in SFs. In Q5 and Q8, the latency of *SFBase* is similar to *SpongeRO* as VMs sufficiently handle the load on `M` operators. The main bottlenecks in Q5 and Q8 are `GbK` operators, which incur large aggregate computations. This result indicates that the RO is effective when the input rate and the overhead caused by the operators running on VMs are high.

We also evaluate when VMs become bottlenecks on `M` operators, by varying the burstiness ($\frac{\text{bursty input rate}}{\text{stable input rate}}$ from 3 to 6 in Q4 (Fig. 14(a)). In the figure, the bottom and top of the box are the 25^{th} and 75^{th} percentiles, the line indicates the median, error bars are the 95% confidence interval, and outliers are dotted as rhombi. VMs sufficiently handle 3× and 4× burstiness, and the latency of *SFBase* does not increase and is similar to *SpongeRO*. However, when the burstiness increases to 6×, VMs become the bottleneck in processing the input events of `M`. Unlike *SFBase*, *SpongeRO* adds an RO between `M` and `GbK`, and migrates both `M` and `GbK` to SFs while keeping the RO on VMs. As an RO does not (de)serialize events and does not perform computation, the amount of computation of RO is always smaller than that of `M`, and reduces latencies by up to 70%.

Transient operator effect. Transient operators enable Sponge to redirect data without stopping the workload for rescheduling. The effectiveness of transient operators increases as the number of tasks to be migrated (or redirected) increases. Q4 requires a large number of tasks to be migrated or redirected. For Q4, we had to migrate or redirect 85% of total tasks to SFs to mitigate the bottleneck in the VMs in *SpongeRO* and *SpongeTO*. *SpongeRO* takes around 2.8 seconds for migrating its tasks. In contrast, *SpongeTO* takes around 1.4 seconds for redirecting its tasks. Due to the fast redirection mechanism, *SpongeTO* additionally reduces the latency by up to 28% compared to *SpongeRO*.

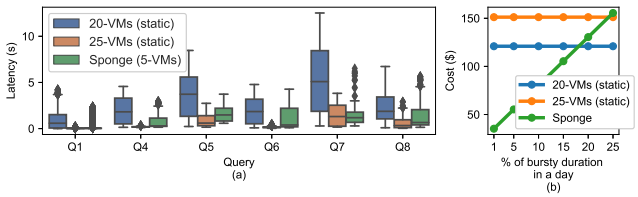

Figure 15: (a) The latency during a bursty period, and (b) a rough calculation of the cost according to the % of the bursty duration throughout the day.

When the degree of parallelism increases, the number of tasks to be migrated or redirected also increases. Fig. 14(b) illustrates the tail latency under different degrees of parallelism in Q4. With 50 parallel tasks for each operator, the task migration/redirection overhead is small, but the latency increases after the migration and redirection in both *SpongeRO* and *SpongeTO*, as a smaller degree of parallelism makes the system more prone to unevenly skewed tasks. With 70 parallel tasks, the overall latency decreases but the task migration overhead increases in *SpongeRO*. As a result, the peak latency increases by up to 8 seconds. In contrast, due to the lightweight redirection optimization, the peak latency of *SpongeTO* is kept at around 3.5 seconds, which is 56% smaller than *SpongeRO*.

Merge operator effect. Even with ROs and TOs, *SpongeTO* still suffers from high latencies in Q5 and Q8 due to the state encoding/decoding overheads. The state migration overhead is trivial in Q4 and Q6 (< 100MB), but the overhead increases with the state size. The time to encode/decode the states of Q5 and Q8 takes around 13s (for ∼2.4GB state) and 35s (for ∼ 7 GB state), respectively. As a result, the latency of *SpongeTO* increases by up to 15 and 38 seconds in Q5 and Q8. In contrast, Sponge significantly reduces the latencies to 4 seconds in Q5, and to 6 seconds in Q8, preventing state migration overheads with MOs.

6.4 Cold Start Latency Reduction Methods

In § 4.4, we describe two methods for reducing the cold start latency: by keeping warm SF instances and by using snapshots of SFs through tools like SnapStart [32]. In Fig. 13, we can see that the performance of *SpongeSnap*, which solely bases its initialization method on SnapStart [32], is slightly worse, but comparable with *Sponge*, which uses a hybrid of both methods in optimizing the managed runtime (e.g., JVM) initialization overhead. Since the overhead is reduced by more than 80% with SnapStart [32], and > 90% with warm SF instances compared to the original managed runtime initialization methods on SF instances, both methods succeed to timely supply SFs within a sub-second total start-up time.

6.5 Latency-Cost Trade-Off

The cost of using SF instances may be higher than overprovisioning VMs when the bursty input persists. In such cases, it makes more sense to launch new VMs while Sponge

handles the bursty traffic and offload our tasks to the VM. To investigate the latency-cost trade-off and figure out when it is more beneficial to launch new VMs, we compare the following two VM over-provisioning approaches with Sponge in terms of latency and cost on the workload shown in Fig. 9(a). One is *20-VMs (static)*, where 20 VMs are statically allocated without dynamic scaling, and the other is *25-VMs (static)*, where 25 VMs are statically allocated. As the default number of VMs used in *Sponge* is 5, *20-VMs* and *25-VMs* allocate 4× and 5× more VMs compared to *Sponge*, respectively.

Fig. 15(a) illustrates the latency of *20-VMs*, *25-VMs*, and *Sponge* during the bursty period. The latency of *Sponge* is in between *20-VMs* and *25-VMs*. Compared to *25-VMs*, which has enough resources to handle 5× bursty loads, Sponge has inherent scaling overheads due to the redirection and migration protocols. This is why the latency of *Sponge* is slightly higher than *25-VMs*.

In terms of cost, Fig. 15(b) shows a rough calculation of cost according to the bursty duration in a day. For instance, 1% of bursty duration represents that bursty loads happen for $24hr * 0.01$ during a day. Basically, the cost of *Sponge* is smaller than others when bursty loads occur in short durations. When the duration of the bursty load is less than 15%, *Sponge* has lower latency and cost compared to *20-VMs*. When the bursty load persists (at more than 25% in Fig. 15(b)), the cost of *Sponge* exceeds *25-VMs* due to the high cost of the SF instances. In this case, it is more beneficial to statically over-provision VM resources in terms of latency and cost. Nevertheless, as presented in existing works [36, 40], bursty loads are mostly short-lived, and persistent peaks are comparatively much rare, resulting in their duration generally falling much below 15% of the total time. Sponge provides mechanisms to initially provide prompt scaling with fast-starting SFs regardless of the peak duration and later expands the cluster to additional slow-starting VMs if the peaks persist, making the solution effective with any bursty traffic in terms of both cost and latency.

7 Related Work

To the best of our knowledge, Sponge is the first work that addresses all technical challenges described in § 3. There are some existing works that partially address the challenges, and we compare them with Sponge.

Data communication across SF instances. Researchers have exploited fast-starting SF instances for various workloads such as interactive data analytics [27, 44], video analytics [4, 21], and daily applications [20]. These applications are also represented as DAGs, and shuffle operations are required between SF instances. Their solutions to enable data communication across SF instances enable using additional VM relay servers [21], using HDFS in VMs [27], building an ephemeral storage service [31], and using a NAT-traversal technique [20]. Sponge router operators enable data communication across SF instances preserving event-based stream processing with low latency, without requiring any of the additional VM resources or NAT-traversal technique.

Optimizing state migration. Rhino [18] and ChronoStream [55] replicate states of stream queries across extra (over-provisioned) machines to minimize state migration overheads. Replicating and holding states requires costly over-provisioning of long-running resources like VMs. Holding states on SFs will cause additional state recovery and cost when SFs are reclaimed by cloud vendors. Megaphone [25] proposes fluid migration that smoothly migrates states from source to destination resources for a long period to reconfigure system configurations. However, when bursty loads happen, the reconfiguration must be executed in a short period of time. As a result, a large amount of state migration is inevitable to quickly migrate the load on VMs. In contrast, Sponge avoids state migration from VMs to SFs by just forwarding data to SFs and merging partial states in SFs into the existing VMs.

Scaling policy. Regarding scaling policies, SEEP [16], StreamCloud [24], and Dhalion [19] use metrics like CPU utilization for their decisions. Systems such as DS2 [28] aim to measure the processing and output rates of individual dataflow operators through system instrumentation. Many of these scaling policies are designed to be agnostic to the underlying scaling mechanisms and resource acquisition schemes. In contrast, the Sponge scaling policy also explicitly considers the characteristics of SF instances and offloads the right amount of computations to keep the CPU utilization high.

8 Conclusion

Sponge harnesses SF instances for offloading bursty loads from existing VMs in streaming workloads. Sponge minimizes task migration overheads and addresses data communication constraints on SF instances by inserting new stream operators in the application DAG: router, transient, and merge operators. Sponge also provides an offloading policy that determines when and how to offload the increased input loads. Our evaluation on AWS EC2 and Lambda shows that the Sponge operators are effective in significantly reducing tail latencies in stream processing upon unpredictable bursty loads, compared to existing scaling mechanisms on VMs and SFs.

Amazon Web Services

Abstract

AWS Lambda is a serverless event-driven compute service, part of a category of cloud compute offerings sometimes called Function-as-a-service (FaaS). When we first released AWS Lambda, functions were limited to 250MB of code and dependencies, packaged as a simple compressed archive. In 2020, we released support for deploying container images as large as 10GiB as Lambda functions, allowing customers to bring much larger code bases and sets of dependencies to Lambda. Supporting larger packages, while still meeting Lambda's goals of rapid scale (adding up to 15,000 new containers per second for a single customer, and much more in aggregate), high request rate (millions of requests per second), high scale (millions of unique workloads), and low start-up times (as low as 50ms) presented a significant challenge.

We describe the storage and caching system we built, optimized for delivering container images on-demand, and our experiences designing, building, and operating it at scale. We focus on challenges around security, efficiency, latency, and cost, and how we addressed these challenges in a system that combines caching, deduplication, convergent encryption, erasure coding, and block-level demand loading.

Since building this system, it has reliably processed hundreds of trillions of Lambda invocations for over a million AWS customers, and has shown excellent resilience to load and infrastructure failures.

1 Introduction

AWS Lambda is a serverless event-driven compute service, part of a category of cloud compute offerings sometimes called Function-as-a-service (FaaS). First launched in 2015, today AWS Lambda functions run millions of times per second over millions of unique customer workloads. One factor that attracts customers to Lambda is its ability to scale up to handle increased load, typically in less than one second (and often as quickly as 50ms). This scale-up time, which customers have come to refer to as *cold-start time*, is one of the most important metrics that determine the customer experience in FaaS systems. When we launched AWS Lambda, we recognized that reducing data movement during these cold starts was critical. Customers deployed functions to Lambda in compressed archives (*.zip* files), which were unpacked as each function instance was provisioned. As Lambda evolved, and customers increasingly looked to deploy more complex applications, there was significant demand for larger deployments, and the ability to use container tooling (such as *Docker*) to create and manage these deployment images. Customers also wanted Lambda to support these images without compromising on cold-start performance.

Adding container support to AWS Lambda without regressing on cold-start time presented a significant technical challenge for our team. The core challenge is simply one of data movement. Today, Lambda can start up to 15,000 containers a second [18] for production workloads, and we expect to scale further for future workloads. Simply moving and unpacking a 10GiB image for each of these 15,000 containers would require 150Pb/s of network bandwidth. To achieve scalability and cold-start latency goals, we needed to take advantage of three factors which simplify this problem:

Cacheability While Lambda serves hundreds of thousands of unique workloads, large scale-up spikes tend to be driven by a smaller number of images, suggesting that the workload is highly cacheable.

Commonality Many popular images are based on common base layers (such as our own AWS base layers, or open source offerings like Alpine). Caching and deduplicating these common base layers reduce data movement for all containers that build on them.

Sparsity Most container images contain a lot of files, and file contents, that applications don't need at startup (or potentially never need). Harter et al [15] found that on average only 6.4% of container data is needed at startup.

Our solution combines caching, deduplication, erasure coding, and sparse loading to take advantage of our needs. With-

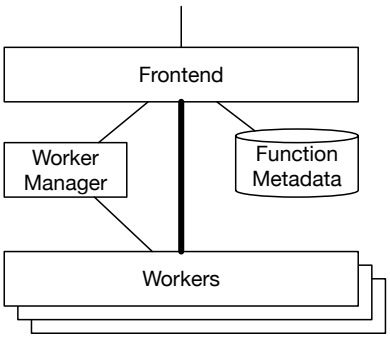

Figure 1: Architecture of the AWS Lambda invoke path

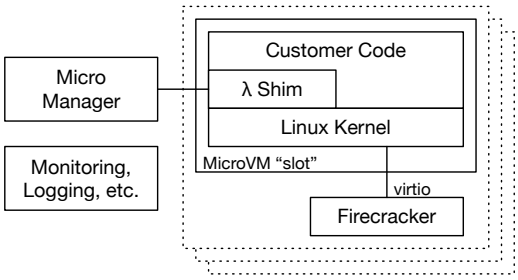

Figure 2: Architecture of the AWS Lambda worker

out adding any customer visible complexity (they simply upload a container image to a convenient repository), we were able to achieve our scale and cold-start latency goals, while having significant headroom for future scaling.

In this section, we present the existing architecture of AWS Lambda, and the overall architecture of our system. Section 2 presents the low-level implementation of our sparse loading solution. The cache architecture, and use of erasure coding to improve scalability and tail latency is presented in Section 4. Section 3 presents our convergent encryption-based secure deduplication architecture. Finally Section 6 compares our solution to other approaches from academia and industry.

1.1 Existing Architecture Overview

To reduce risk and optimize time-to-market, we wanted to introduce these new capabilities to Lambda with the minimum amount of change to the existing architecture, as shown in Figure 1. Requests to execute a certain function (we call these *invokes*) arrive via a load-balanced stateless frontend service. This service loads the metadata associated with the request, performs authentication and authorization, and then sends a request to the *Worker Manager*, requesting capacity. *Worker Manager* is a stateful, sticky, load balancer. For every unique function in the system, it keeps track of what capacity is available to run that function, where that capacity is in the fleet, and predicts when new capacity may be needed. If capacity is available, the Worker Manager instructs the frontend to forward the request payload to a Worker, where the function is executed. If no capacity is available, the Worker Manager identifies a Worker with available CPU and RAM, and sends a request to start a sandbox for the relevant function. Once this is complete, the frontend is notified and the function is executed.

Each Lambda worker, as shown in Figure 2, includes a small controller process, the Micro Manager, some additional agents for logging and monitoring, and a large number of MicroVMs. Each MicroVM, based on our Firecracker [3] hypervisor, contains the code for a single Lambda function for a single customer. Inside the MicroVM is a minimized Linux guest kernel, a small shim that provides Lambda's programming model, any provided runtime (e.g. the JVM for Java or CoreCLR for .NET), and the customer's code and libraries. As described in our Firecracker paper [3], the key concern here is security: customer code and data is not trusted, and the only communication between the workload inside the MicroVM and the shared worker components is over a simple, well tested, and formally verified implementation of *virtio* [27, 32] (specifically *virtio-net* and *virtio-blk*).

In the first generation architecture (before this work), when a new MicroVM is created with new capacity for a particular function, the Worker downloads the function image (a *.zip* file up to 250MiB in size) from Amazon S3, and unpacks it into the MicroVM guest's filesystem. This model is simple, and works well for small images, but requires the full archive to be downloaded and unpacked before the new MicroVM can do any work. To support larger images, we wanted to avoid this blocking download, and avoid the storage cost of unpacking the entire archive if only part of it is used.

2 Block-Level Loading

To take advantage of the *sparsity* property of containers, we needed to allow the system to load (and store) only the data the application needs, ideally at the time it needs it. Approaches like Slacker [15] and Starlight [8] have approached this problem at the filesystem level - a natural fit for containers, which are built as an overlayed stack of file-level archives. This approach isn't the right one for our environment. We believed that the inherent complexity of filesystems, and additional complexity of overlaying multiple filesystems, would unacceptably increase the attack surface of the shared components in Lambda. Instead, we decided to keep the block-level *virtio-blk* interface between the MicroVM guest and the hypervisor, perform all filesystem operations inside the guest. This requires performing sparse loading at the block, rather than file, level.

Figure 3 shows our high-level architecture, showing the Lambda worker (shown in detail in Figure 4) where customer's code is run, container registry which contains the primary copy of customer's container images, and the chunk

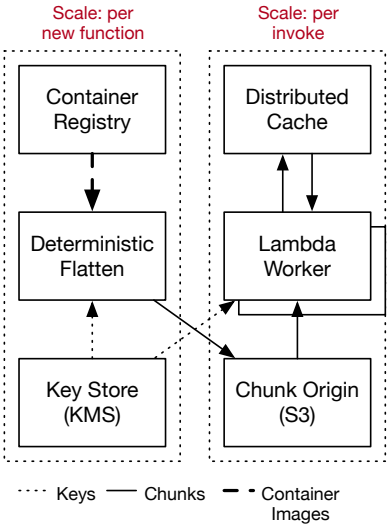

Figure 3: High-level system architecture.

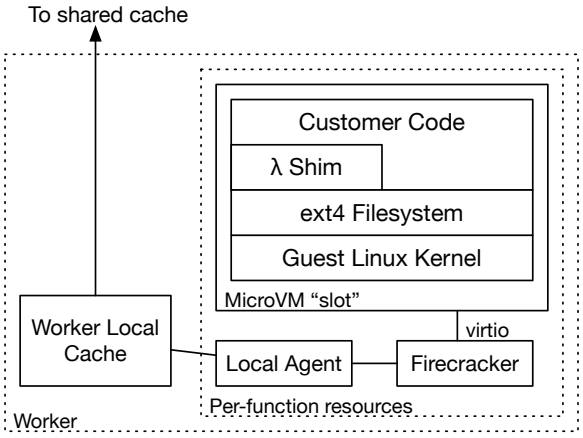

Figure 4: Lambda worker with per-worker, per-customer, and in-guest components

creation and caching infrastructure.

Our first step in supporting block-level loading is to collapse the container image into a block device image. As described in the OCI image specification [1], a container image is a stack of tarball *layers*. In the typical container stack, these layers are overlayed at at runtime using *overlayfs*. In our implementation, we perform this overlaying operation at the time the function is initially created, following a deterministic flattening process which applies each tarball in order to create a single *ext4* filesystem. Function creation is a low-rate control-plane process, that is typically only triggered by customers when they make changes to their code, configuration, or architecture. Even the most aggressive adoptees of continuous integration only make these changes on the order of minutes, while function invocation can happen up to millions of times a second.

The flattening process is designed so that blocks of the filesystem that contain unchanged files will be identical, allowing for block-level deduplication of the flattened images between containers that share common base layers. We'll revisit this in Section 3, but the high-level reason is that differences between functions (and even more so between versions of the same function) are typically much smaller than the functions themselves. The flattening process proceeds by unpacking each layer onto an *ext4* filesystem, using a modified filesystem implementation that performs all operations deterministically. Most filesystem implementations take advantage of concurrency to improve performance, introducing nondeterminism. Ours is serial, and deterministically chooses normally-variable parameters like modification times.

Following the flattening process, the flattened filesystem is broken up into fixed-size chunks, and those chunks are uploaded to the origin tier of a three-tiered cache for later use (we use S3 as this origin tier). Chunks in the shared storage are named according the their content, ensuring that chunks with the same content have the same name and can be cached once. This scheme, described in detail in Section 3, allows efficient deduplication of chunk content in storage and cache layers without requiring a central directory or index of chunks.

Each fixed-size chunk is 512KiB. Smaller chunks lead to better deduplication by minimizing false-sharing, and can accelerate loading for workloads with highly random access patterns. Larger chunks reduce metadata size, reduce the number of requests needed to load data (hence improving throughput), and provide natural read-ahead for sequential workloads. The optimal value will change over time as the system evolves, and we expect that future iterations of the system may choose a different chunk size as our understanding of how customers use the system evolves.

2.1 Per-MicroVM Snapshot Loading

Once chunks are created, the system needs to be able to access the data they require from the chunks that contain that data. As shown in Figure 4, we added two new components to support this loading:

- A per-function *local agent* which presents a block device to the per-function Firecracker hypervisor (via FUSE), which is then forwarded using the existing virtio interface into the guest, where it is mounted by the guest kernel.
- A per-worker *local cache* which caches chunks of data that are frequently used on the worker, and interacts with the remote cache (see Section 4 for details)

When a new Lambda function is started on a worker, the Micro Manager creates a new *local agent*, and a new Firecracker MicroVM which contains two *virtio* block devices: a

root device which is the same for all MicroVMs, and a block device backed by the FUSE filesystem exposed by the *local agent*. The MicroVM boots, starts some supervisory components, and then starts executing the customer code in the container image. Each IO that this code performs (unless it can be served from the page cache kept by the guest kernel) turns into a *virtio-blk* request, which is then processed by Firecracker, and handed off to the local agent.

The local agent handles reads by reading directly from the local cache, if the chunk that contains the requested offset is already present there. If not, the relevant chunk is fetched from the tiered cache, as described in Section 4. The local agent handles write by writing them to block overlay, backed by encrypted storage on the worker. A bitmap is maintained at page granularity, indicating whether data should be read from the overlay, or from the backing container image. The page granularity of the bitmap requires a read-modify-write for writes from the guest which don't cover an entire page.

This page-level copy-on-write approach allows the MicroVM guest to handle both reads and writes, while keeping the data in the local cache (and all other caching tiers) immutable, allowing it to be shared across multiple guests.

3 Deduplication Without Trust

Base container images, such as the official Docker *alpine*, *ubuntu*, and *nodejs* are extremely widely used: each boasts over a billion aggregate downloads from the popular DockerHub container repository[1]. Starting from one of these base images, and customizing it to the special needs of the application, is a common way to create new container images. When a popular base image is used, the deterministic flattening process described in Section 2 produces unique chunks for the customized parts, and chunks for the common parts that are identical to those produced for other images with the same base. These shared chunks create a significant opportunity for deduplication: if only a single copy of these chunks is stored, less data movement is needed, less storage is consumed, and caches are more effective.

Approximately 80% of newly uploaded Lambda functions result in zero unique chunks, and are just re-uploads of images that had been uploaded in the past. This appears to be primarily driven by automated testing and deployment (CI/CD) systems. Of the remaining 20% of functions that create at least one unique chunk (and therefore aren't just trivial re-uploads), the mean upload contains 4.3% unique chunks, and the median 2.5% unique chunks. Trivial all-zero chunks are not included in these numbers: they are excluded entirely from images at creation time.

Figure 5 shows the distribution of deduplication effectiveness, for the top quartile (by image size) and remainder of the population. This breakdown shows that the majority of functions of all sizes are heavily deduped, and a significant tail where deduplication is not as effective. While large functions are still effectively deduplicated, they have a smaller tail of unique chunks. This data clearly suggests that deduplication is worth the complexity, reducing storage by as much as 23x, and improving effectiveness of the cache tiers (how much cache effectiveness is improved depends on the correlation between probability of deduplication and frequency of access). While the 80% of functions with no unique chunks aren't statistically interesting, deduplicating these has a large practical benefit, including reducing storage costs by another 5x, and boosting cache effectiveness.

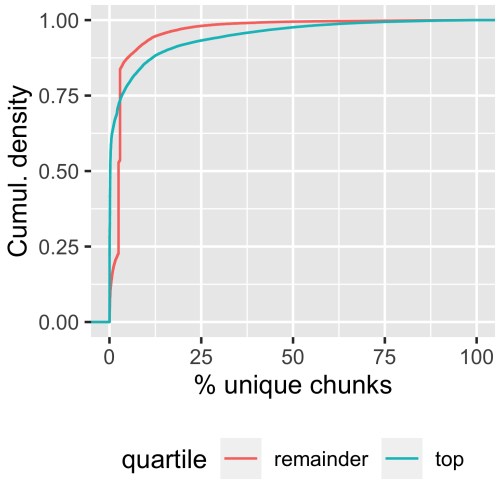

Figure 5: Empirical CDF of deduplication effectiveness at chunk creation time, among functions that aren't trivial re-uploads.

3.1 Convergent Encryption

Deduplication of plaintexts is relatively straightforward. Venti [30], dating back to 2002, used a hash of block contents and a separate index to deduplicate blocks. Introducing encryption, however, significantly complicates deduplication. As Storer, et al [33] write:

> Unfortunately, deduplication exploits identical content, while encryption attempts to make all content appear random; the same content encrypted with two different keys results in very different ciphertext. Thus, combining the space efficiency of deduplication with the secrecy aspects of encryption is problematic.

One solution is to have a shared key, or keys, that can be used to decrypt shared blocks, but this either introduces single keys that can access a large number of blocks, or a significant key management problem. Perhaps the hardest problem is

[1] statistics from https://hub.docker.com/, accessed July 2022

minimizing trust. While AWS Lambda runs user code with strong isolation [3], we still wish to restrict each Lambda worker host to only being able to access the data it needs for the functions that have been sent to it.

The authors of Farsite [2, 11] developed *convergent encryption* as a solution to this problem. A cryptographic hash of each block (in the case of Farsite a file block, in our case a chunk of a flattened container image) is used to deterministically derive a cryptographic key that is used for encryptng the block. We follow this same scheme, but mix additional metadata into the key derivation (as described in Section 3.3).

The flattening process described in Section 2 takes each chunk, derives a key from it by computing its SHA256 digest, and then encrypts the block using AES-CTR (with the derived key). Here, AES-CTR is used with a deterministic (all zero) IV, ensuring that the same ciphertext always leads to the same plaintext. Using a deterministic IV in this context is safe, because due to the collision resistance of SHA256, a *key, IV* pair is only used on for one plaintext block [12]. A manifest of chunks is then created, containing the offset, unique key, and SHA256 hash of each chunk[2]. The manifest is then encrypted, using AES-GCM, using a unique per-customer key managed by AWS Key Management Service (AWS KMS). Chunks are then named based on a function of the hash of their ciphertext, and uploaded to the backing store (AWS S3) using that name if no chunk of that name already exists.

In our scheme, we do not encrypt the entire manifest with the customer's unique key. Instead, only the key table (the keys of each encrypted chunk) is encrypted, and the whole document is authenticated (i.e. included in the calculation of the AES-GCM tag as additional data). This allows the garbage collection process to access the list of chunks in the manifest, while having no access to the chunk keys. The size of manifests, stored in an efficient binary format, is negligible: less than 3MiB for a 16GiB container image, or 0.02% overhead.

This approach provides a number of desirable properties:

- Data can be deduplicated with no sharing of keys: the keys to decrypt the customer's manifest are unique to that customer, and access to them (via AWS KMS) is only provided to the workers that that particular customer's functions are placed on.
- Data can be deduplicated with no coordination or special access provided to the flattening process. Flattening processes operate independently, and the only special operation they need is "upload this file to storage if it doesn't already exist".
- The scheme provides strong end-to-end integrity protection for chunks. Workers check the chunks they download against the MAC in the manifest, ensuring that modified ciphertexts can be detected and rejected.

[2]It may appear attractive to use an AEAD mode like AES-GCM rather than the more expensive SHA256 in this application, but these modes do not commonly provide collision resistance against attackers who know the data key [10], an important property in our security scheme.

3.2 Compression

Our system does not compress chunk plaintexts prior to encryption. This is for two reasons. First, given the network bandwidth available to our caches and workers the additional latency of decompression, and difficulty of allowing random access to compressed data, makes the latency benefit of compression marginal. Second, compression before encryption allows potential attackers to infer plaintext contents from compressed sizes, a *compression side channel*. This risk, and the relatively small expected benefit, means that we decided not to implement compression (beyond trivial elision of all-zero chunks).

3.3 Limiting Blast Radius

While deduplication has value in cost and cache performance, it also adds some risks. Some popular chunks are widely referenced, meaning that anything that causes access to those chunks to break or become slow, also has a very wide impact on the system. Risks include partial (gray) failures of cache nodes, operational issues that cause unavailability of data, bugs in garbage collection, or corruption of data in the cache hierarchy. Highly popular chunks also cause hot-spotting in distributed storage. While our cryptographic scheme detects corruption and will prevent readers from seeing corrupt data, it does not correct it, and so corrupted data will become unavailable.

To solve this problem, we include a varying *salt* in the key derivation step of our convergent encryption scheme. This salt value can vary in time, with chunk popularity, and with infrastructure placement (such as using different salts in different availability zones or datacenters). Otherwise-identical chunks with different salt values will end up with different keys, and therefore difference ciphertexts, and will not deduplicate against each other. By controlling the frequency with which the salt is rotated, we can continuously trade off deduplication efficiency with blast radius. Salt allows us to encapsulate the control of deduplication entirely within the chunk creation layer, without any other component needing to be aware of its decisions. Salt rotation is an operational concern, and is not needed for the security of the deduplication scheme.

3.4 Garbage Collection

A key challenge of any distributed deduplication scheme is garbage collection: removing data from the backing store when it is no longer actively referenced. Garbage collecting the wrong chunk could cause wide impact across multiple customers. Our deduplication scheme does not maintain a central

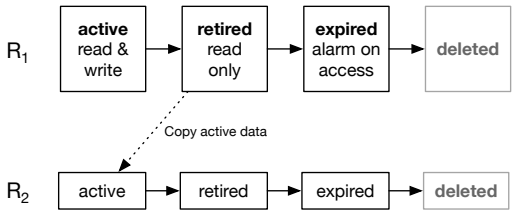

Figure 6: Lifecycle of data chunks used by the generational garbage collector.

directory of chunk references or manifests, making exact reference counting infeasible. Past experience with distributed garbage collection has taught us that the problem is both complex (because the tree of chunk references is changing dynamically) and uniquely risky (because it is the one place in our system where we delete customer data). The approach we took to garbage collection is based on this experience.

Our approach to garbage collection is based on the concept of *roots*. A *root* is a self-contained manifest and chunk namespace, analogous to the *root*s used in traditional garbage collection algorithms. Unlike traditional GC roots, in our system we periodically create new roots (which then get all new data), and retire old roots (after moving any still-needed data into a fresh root).When a customer's container image is converted, the manifest and set of chunks are placed in an *active* root, for example R_1. An active root handles both reads and writes of data. Periodically, a new root R_2 is created and becomes active, while root R_1 enters a *retired* state at which point it only serves reads of data. While R_1 is retired, any manifest that is still referenced in R_1 is migrated, along with any chunks it references, to R_2. Over time the manifests and chunks in R_1 that are in active use will be migrated to R_2, allowing R_1 to be safely deleted. This process is repeated: R_2 is retired and R_3 becomes the active root and so on. Figure 6 shows this lifecycle. Moving chunks along with their manifest ensures that if a manifest exists in root R, then all the chunks it references do to. A unique identifier for the currently active root is also included in the deduplication salt (Section 3.3), ensuring that newly-created chunks in the active root are not shared with previous roots.

Instead of deleting roots immediately after data migration is complete, we put them into an *expired* state. In this state, data is still allowed to be read, but any attempt to access data leads to an alarm. These alarms both engage an operator and automatically stop further deletion of data. This approach allows us to robustly detect garbage collection issues (especially incomplete copying) in production, and quickly and automatically stop any data from being deleted. While this mechanism is inexact (data could be accessed after the period the root is *expired*), it provides a valuable additional layer of protection against data loss. While software bugs are rare, and we test garbage collection changes carefully, multiple layers of protection against customer data loss are critical in any distributed storage system.

Having data in multiple roots does drive up storage costs, however that additional cost is palatable for Lambda as customers often update their functions and a large majority of data is never migrated to a new root. The system is also capable of having multiple roots active simultaneously, which reduces the blast radius of bugs and provides the ability to roll out new garbage collection changes and algorithms to a subset of manifests and their chunks.

4 Tiered Caching

When workers don't have chunks in their local cache, they attempt to pull them from a remote availability-zone-level (AZ-level) shared cache (as shown in Figure 3). If chunks aren't in this cache, workers download them from S3, and upload them into the cache. This AZ-level cache is a custom implementation of a fairly standard design: chunks are fetched over HTTP2, data storage is two-tiered with an in-memory tier for hot chunks and a flash tier for colder chunks, and eviction is LRU-k [29] (a scan-resistant variant of Least Recently Used). Chunks are distributed to the AZ-level cache using a variant of a consistent hashing [19] scheme, with optimizations to improved load spreading (similar to the approach of Chen et al [7]). The caching tier improves fetch performance considerably: from the worker's perspective, a hit on the AZ-level cache takes a median time of 550μs, versus 36ms for a fetch from the origin in S3 (99.9th percentile 3.7ms versus 175ms).

Figure 7 shows the effectiveness of these three cache tiers. Over a week of production usage in one large AWS region, a median of 67% of chunks were loaded from the on-worker cache, 32% from the AZ-level distributed cache, and the remaining 0.06% from the backing store.

The per-worker cache has a median hit rate of 67%, and a 10th percentile low hit rate over the week in question of 65%. The in-AZ cache is even more effective, with a median hit rate of 99.9% and 10th percentile low hit rate over the week of 99.4%. Figure 8 shows the empirical CDF of the hit rate of the in-AZ cache over the week, measured in one-minute buckets across one at-scale production availability zone. The left tail of the distribution is associated with large spikes in traffic to newly created functions. We are evaluating priming the in-AZ caches during the chunk creation process to flatten this left tail and further improve hit rates, primarily with the goal of reducing load-time latency for new functions.

4.1 Optimizing for Tail Latency

While data in the AZ-level cache is not required to be durable (durability is ensured using S3 as the origin), a simple unreplicated cache scheme (where each object is stored in a single node) didn't meet our needs for three reasons.

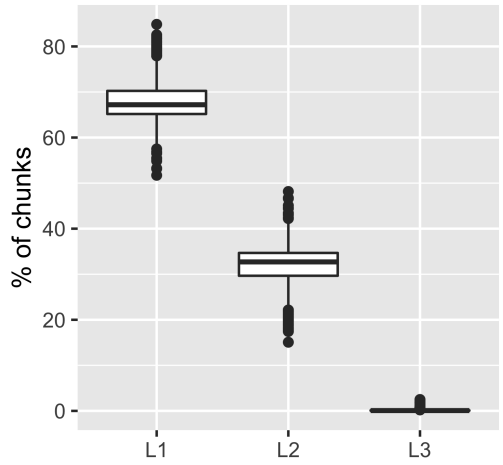

Figure 7: One week of hit rates on each of the cache tiers: on-worker (L1), distributed in-AZ (L2), and backing store (L3)

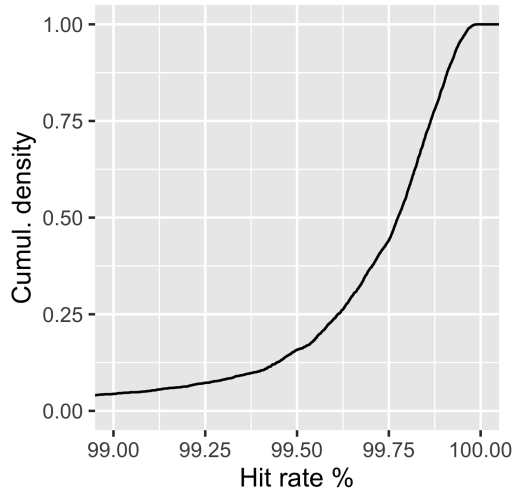

Figure 8: Empirical CDF of in-AZ cache hit rate

Tail latency A single slow cache server can cause widespread impact. Slowness could be caused by congestion at the host or in the network, or by partial hardware or software failure.

Hit Rate Drops Having each item cached in a single server means that the hit rate drops if that server fails, or is taken down for deployment.

Throughput Bounds Having each item cached in a single server means that the bandwidth available to fetch the object is bounded by a single server's bandwidth.

Of these, tail latency is the largest practical concern. Our experience operating these types of systems suggests that debugging slowness and partial failure is much harder than debugging outright failure. Even if this slowness is only in the long tail, it still matters in production because each container start needs to fetch a large number of chunks. For example, a start which fetches 1000 chunks will experience the 99.9th percentile tail latency of the cache on 63% of tasks. The difference is material: in one deployment of the cache we observe a median client-measured latency of 500μs, and a 99.9th percentile latency of 4ms.

Replication, combined with redundant requests is a well-established [13, 37, 39] technique to drive down tail latency, and would also solve our throughput and hit-rate problems. Unfortunately, replication increases costs proportionally to the replication factor, an important concern in a primarily in-memory cache. Instead, we chose erasure coding, following a similar scheme to EC-Cache [31]. Erasure coding is not widely used in caches, but provides compelling solutions for all three of our concerns. When a worker misses the cache, it fetches the chunk it needs from the origin, then uploads erasure-coded stripes of that chunk into the cache. When a worker needs to fetch a chunk, it requests more stripes than are strictly needed to reconstruct the chunk, and then reconstructs the chunk as soon as enough stripes are returned. Our current production deployment uses a *4 of 5* code, achieving 25% storage overhead, and a 25% increase in request rate in exchange for a significant decrease in tail latency. Figure 9 compares the empirical latency CDF of the *4 of 5* code versus a hypothetical *4 of 4* scheme using latency measurements from one deployment of our production system.

This scheme prevents any drop in hit rate from occurring when cache nodes fail, or are taken down for deployment. A common approach in similar systems is to use retries to hide the effects of deployments and failed nodes, an approach which is known to lead to metastable failure modes in large systems [5, 17]. Erasure coding allows us to achieve a similar level of resiliency while performing the same amount of work in success and failure cases (a design philosophy we call *constant work* [23]).

4.2 Stability and Metastability

Caches with high hit rates, such as ours, are desirable from a latency and efficiency perspective, but have a hidden downside. If the cache becomes empty (such as due to power loss or operational issue), or the hit rate suddenly drops (such as due to a change in customer behavior), the downstream services can see significantly more traffic than they are used to. In the case of our cache, with an end-to-end hit rate typically exceeding 99.8%, this downstream traffic increase could be up to 500 times normal. S3 is an extremely scalable backing store, and can tolerate the full uncached load. However, the increased latency leads to higher concurrency demand from customer's applications (due to Little's Law [21]), and therefore higher demand for new Lambda slots, increasing load and changing

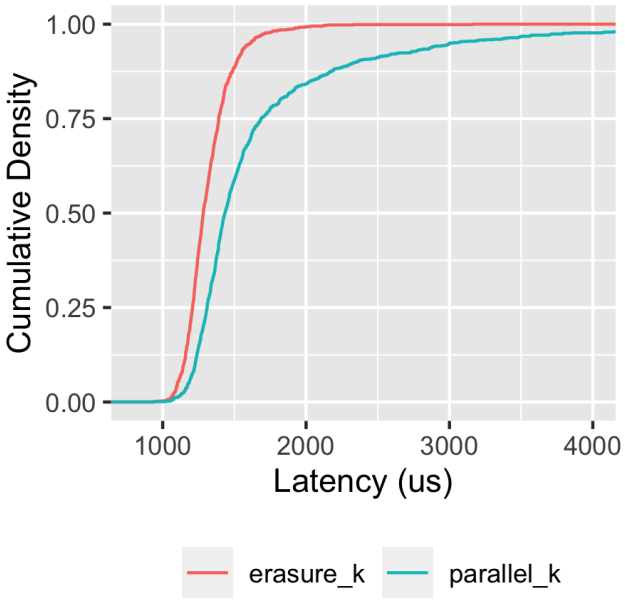

Figure 9: Comparative empirical CDFs of client-side latency of 4-of-4 parallel cache load, versus 4-of-5 erasure coded cache load.

the size and composition of the system's working set. This can lead to metastable behavior [5, 6, 17], where the system isn't able to refill the cache when it is empty[3].

We have built mitigations for this risk into higher layers of Lambda. Primarily, the system is designed to be concurrency-limited. When container starts slow down and the number of concurrent tasks exceeds this limit, new starts are rejected until in-flight ones complete. We also actively test the system's ability to *cold start* from an empty cache at the maximum concurrency. This testing allows us to be confident that the system is able to restart from a cold cache, or tolerate workload changes that significantly reduce hit rate.

4.3 Cache Eviction and Sizing

Traditional cache replacement policies like Least Recently Used (LRU) and First In First Out (FIFO) are simple and easy to implement, but have a significant downside for this application: a lack of *scan resistance*. In our case, this means that a large number of infrequently used functions starting up can replace all the hot entries in the cache with recently-used entries belonging to those functions, dropping cache hit rates for more frequently-used entries, and filling the cache with entries that will never be read again. This happens periodically in our environment, driven by weekly, daily, and hourly spikes of periodic *cron job* functions. These functions are large in number, but each runs at a low scale (typically only using one sandbox), making caching their chunks relatively unimportant. To avoid the hit-rate drops caused by this periodic work, we use the LRU-k [29] eviction algorithm, which tracks the last k times an item in the cache was used, rather than only the most recent time.

Eviction and hit rates are also related to the size of our local and AZ-level caches. Following the logic of Gray and Putzolu's classic *Five Minute Rule* [14], the minimum desirable cache size is the one that makes the cost of cache retention equal to the cost of fetching chunks from S3. However, because our cache is not only aimed at reducing costs but also improving customer-observed latency, we also set a hit rate goal and increase the cache size if we fall below that goal. The total cache size, then, is the larger of the size needed to achieve our hit rate goal, and the size needed to optimize costs.

5 Implementation and Production Experience

We built the local agent (the FUSE implementation that backs the sparse block device for each MicroVM), the worker-local cache, and the remote cache server in the Rust programming language. We used the *tokio* runtime, and *reqwest* and *hyper* for HTTP. At the time we started this project, the invoke path of AWS Lambda includes components written in Java, Go, C, and Rust. We chose Rust because of our good experiences with the Rust components we had built in the past, especially around performance and stability, and have again been happy with our choice of Rust, encountering no major production bugs in the libraries we chose. We were also attracted to Rust because of the successes other AWS teams (such as the Amazon S3 team [4]) have had applying formal methods to verify code correctness in Rust, even with non-expert programmers.

One interesting stumbling block with Rust (version 1.46.0, current at the time of implementation) is brittle optimization, especially autovectorization, of hotspots. Unsurprisingly, we found that the parity calculations we use for erasure coding are nearly 5x faster when performed 64 bytes at a time (with AVX512) or 32 bytes at a time (with AVX or NEON) than when performed 8 bytes at a time, and 10x faster than when performed byte-at-a-time. Unfortunately, the naive Rust loop emitted the byte-at-a-time code (as shown in Listing 1), despite the compiler being capable of autovectorization. Small changes to the code would change autovectorization behavior, even changes outside the function of interest. Reluctant to move to assembly for this code, we finally settled on the code in Listing 2, which robustly emits appropriately unrolled

[3] Related effects have been observed in computer systems since at least the 1960s. In the 1968 paper 'The Working Set Model for Program Behavior' [9], Peter J Denning observed a similar effect in paging systems:

> This can create a self-intensifying crisis. Programs, deprived of still-needed pages, generate a plethora of page faults; the resulting traffic of returning pages displaces still other useful pages, leading to more page faults, and so on.

AVX, AVX512, or vectorized ARM code depending on the target platform. Seemingly small changes to this function (such as removing the *assert*, changing any of the assignments, or allowing it be inlined) cause autovectorization to be disabled. This is a small issue with Rust, and one that we expect to be improved in future compiler versions.

Listing 1 Naive byte-by-byte x86 assembly code as emitted by the Rust compiler for straightforward loop implementation (with annotations by *perf* showing percent of runtime). Note significant missed opportunities for optimizations like vectorization and loop unrolling.

```
  0.08 |350:   cmp    %rax,%rsi
       |     ↓ jae    3f4
 49.18 |       movzbl (%rdi,%rsi,1),%ebx
  0.13 |       xor    %bl,(%rcx,%rsi,1)
 50.52 |       lea    0x1(%rsi),%rbp
  0.08 |       mov    %rbp,%rsi
       |       cmp    %rax,%rbp
       |     ↑ jb     350
```

Listing 2 Implementation of parity calculation in Rust, showing extra lines needed for reliable autovectorization.

```
#[inline(never)]
fn parity(target: &mut [u8], source: &[u8]) {
    assert_eq!(source.len(), target.len());
    let len = target.len();
    let _ = target[len-1];
    let _ = source[len-1];

    for i in 0..len {
        target[i] ^= source[i];
    }
}
```

On the other hand, the Rust ecosystem's support for build-time microbenchmarks (such as with the *criterion* crate) makes it fast and easy to iterate on this type of performance work, and even assert at build time that autovectorization has succeeded (effectively stopping regressions from entering production). This is a significant boon in a cloud environment, where performance regressions can cause production outages, and performance is tied to both cost and carbon efficiency.

5.1 Latency and Multimodality

As with any storage system, performance was an important goal for the design and implementation of our snapshot chunk loading system. While throughput, CPU efficiency, and other bandwidth measures contribute to the cost of running the system, its scale-out nature make latency and scalability the most important factors of performance. The local agent and on-worker caches trivially scale out, due to the fact that they do not communicate off their worker, except in interacting with S3 (to pull chunks from the origin), and the L2 AZ-level cache.

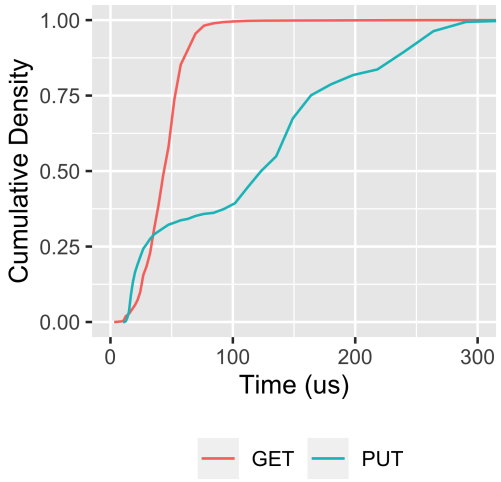

Figure 10: Empirical CDF of server-side measured latency of the L2 cache server

Figure 10 shows the latency for GETs and PUTs on this cache, measured from the server side, across all of the cache nodes in a production deployment over the course of one week. Each GET or PUT is of a 512kB chunk. As discussed in Section 4, the L2 cache is a flash-based cache with a significant local memory tier (about 10% of cache size). GET latency is very consistent, with a median of below 50μs. PUT latency is less consistent, with some multi-modality apparently caused by writeback behavior on the cache host. Despite this multi-modality, performance is still excellent, with a median latency of 125μs, a 99th percentile latency below 300μs, and a 99.99th percentile of 413μs[4]. When building this cache server, we chose HTTP2 as a wire protocol for convenience with the intention of replacing it with an efficient binary protocol later. In production, we've found the overhead of HTTP (implemented with *hyper* and *reqwest*) so low that we have not yet been motivated to replace the protocol.

Figure 11 shows the end-to-end latency for returning a read from the perspective of the local agent (that is the FUSE implementation). This doesn't show the end-to-end IO latency experienced by guests, because it's from the perspective of the worker and does not include the (significant) hit rate on the page cache maintained by the MicroVM guest's kernel, and read-ahead performed by the guest to populate that cache. Like the L2 server latency, this end-to-end latency shows sig-

[4]Having a 99.99th percentile at less than 4x the median is a very desirable property, and difficult to achieve with garbage collected languages like Java and Go

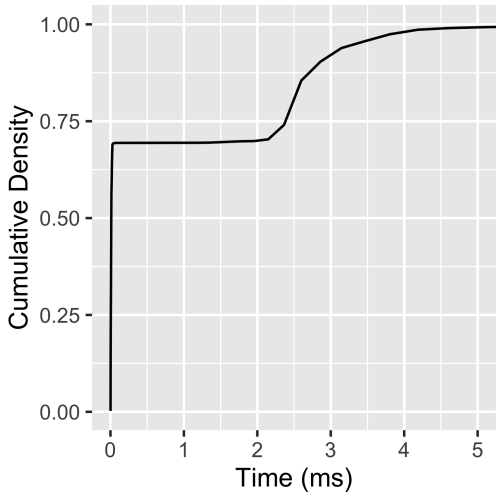

Figure 11: Empirical CDF of end-to-end read latency observed at the local agent (FUSE implementation).

nificant multi-modality: a mode below 100μs which represent local cache hits, a mode around 2.75ms which represent L2 hits (and the subsequent work like decryption), and mode (trimmed from the graph) showing rare fetches from the origin (see Figure 7 for the relative frequencies of these modes). We are working on an optimized cryptographic scheme which reduces the latency of decryption.

Multi-modality like this is the norm in storage systems, but presents a few practical challenges to operators. First, as discussed in Section 7 a small change in the relative frequencies of each mode can significantly change the mean latency observed by clients (and so change the concurrency and throughput of the system). Second, latency percentiles and trimmed means are the summary statistics most commonly used by operators at AWS, and they tend to obscure multi-modality. Plots like empirical CDFs (eCDFs, as presented here) can be valuable, but don't show change-over-time as time series of summary statistics do. We have experimented with heat maps, day-over-day eCDFs, and others, but have yet to find a succinct way to present these data to operators. Third, multi-modality makes the decision of where to spend optimization resources more complex. Which mode should the team work to improve? Or should they work to reduce the relative frequencies of higher modes?

5.2 Production experience with FUSE

Our experiences with FUSE match those reported by Vangoor et al [36], showing relatively little throughput overhead when well tuned. However, we have found that the choice to use FUSE to present a file which is then subsequently used as a block device by Firecracker's virtio-blk implementation, has introduced significant overhead. When an application running in a MicroVM reads a new chunk, control is passed to the guest kernel, then Firecracker, then the host kernel's FUSE layer, then the local agent, before flowing back through the same path. This introduces context switch overhead, but more importantly requires four different threads to be scheduled by the host kernel's scheduler. This introduces inefficiency in steady state, and significant jitter under load. We are moving away from FUSE for this application, primarily due to this effect. Our new implementation uses *userfaultfd* and *mmap*, removing two layers from the architecture.

We don't regret starting with FUSE. It provided a convenient interface, a clear security and operational isolation story, and allowed a team without deep systems-level programming experience to build an acceptably high performance system.

6 Related work

Mirroring the rise in popularity of serverless and containers accelerated container loading has been a highly active area of research, and industry implementation, over the last decade. Before that, accelerating VM loading through faster disc image movement was an active area of research. For example, Frisbee [16] in 2003. Amazon EC2 has taken advantage of common data to accelerate VM image loading, through tracking lineage of EBS snapshot chunks [28], since 2009. With Slacker [15] Harter et al studied access patterns in container loading, and presented a system which takes advantage of these patterns by performing layer-level lazy loading. Starlight [8] takes a fairly similar filesystem-orientated approach, optimized for loading at the edge where minimizing round-trips to the datacenter is a significant contributor to performance. eStargz [35] extends common container image formats to make lazy loading at the layer level more efficient, building on the approach of Google's CRFS.

DADI [20] uses a block-level approach fairly similar to our own, but with a peer-to-peer approach rather than a dedicated cache layer, and without the ability to deduplicate as widely as our system is able to. FaaSNet [38] approaches a similar problem to the one we were solving, but works on the layer level (rather than flattening images as we do), and does not appear to perform deduplication. Cntr [34] and Yolo [26] take the approach of breaking down container images into different classes of data, some needed urgently on start up and some likely to be accessed less urgently. This explicit approach may be more efficient than the simple block-based approach, but also requires a deeper introspection of the contents of the container. Wharf [41] and CFS [22] take the distributed filesystem approach, showing that can significantly improve loading performance at the cost of increased coordination between containers.

Accelerating storage performance and loading with deduplication has an even longer history, for example in 2001 with Muthitacharoen et al [25] and 2002 with Venti [30], and Farsite [2].

7 Conclusion

We present AWS Lambda's solution for accelerated loading of container images, and approach that combines deduplication, erasure coding, tiered caching, userspace filesystems, and convergent encryption. We have operated this system for several years, and are extending its use into other areas of AWS. While our solution on the surface appears to have a lot of moving parts, it is optimized for what we believe to be the realities of building massive scale cloud systems: failures are frequent, failures are often partial and complex, and security is the top priority.

7.1 Broader Lessons and Future Work

While Lambda's snapshot loading infrastructure is a specialized system for a rather specialized application, we believe that there are some broader lessons from our experiences that apply to the systems community as a whole.

- Containers are most popularly used by Lambda customers as "static linking in the large" dependency closures. Customers want to build, test, and deploy a function with all its dependencies in one atomic unit, but traditional static linking is either unavailable or inconvenient. However, containers are also highly inefficient in this context, necessitating the deduplication and sparse loading we describe here. We believe that there is a significant need for a lighter-weight dependency closure mechanism, which comes closer to traditional static linking in the size of the artifacts that it creates.

- Caches reduce costs, improve latency, and reduce load on durable storage, and are a critical component of nearly any stateful system. However, they also introduce risks such as metastable failures (due to unexpectedly empty caches, or sudden shifts in workloads), and challenges for users like multi-modal latency distributions. While work such Yang et al [40], and Huang et al [17] have made steps towards deeply understanding these effects, we believe that significantly more work is needed to understand the dynamic behaviors of caching in large systems, and to develop patterns to mitigate the risks of caches.

- MicroVMs provide an isolation mechanism which is nearly as lightweight as containers, or even processes [3, 24], while providing additional interfaces for plugging in both local and distributed operating system logic. MicroVMs provide a powerful new tool in the operating system researcher's or builder's toolbox. We believe that operating system support for virtualization, and virtualization support for applications, operating systems, and databases are ripe areas of research which are not yet receiving sufficient attention.

Our future work is focused on optimizing the system further for cost, performance, and especially customer-experienced cold-start latency. This same system is used in Lambda SnapStart, a feature of AWS Lambda which reduces cold-start latency using memory snapshots, to store and load memory snapshot contents. That use-case is especially latency sensitive, motivating significant investments in both average case and tail latency. We expect this work to include optimizing cache retention and data placement policies, optimizing client and server performance, and completing the migration from FUSE to *userfaultfd*.

Acknowledgements

Any system of this size requires a team to build and operate, and in this case we're deeply thankful to the AWS Lambda team for their work and contributions. Holly Mesrobian, David R. Richardson, Ajay Nair, and David Nasi were instrumental in supporting this work. Shay Gueron, Osman Surkatty, and Derek Manwaring helped ground our cryptographic ambitions, and provided valuable feedback.

Abstract

The Internet Computer (IC) is a fast and efficient decentralized blockchain-based platform for the execution of general-purpose applications in the form of smart contracts. In other words, the IC service is the antithesis of current serverless computing. Instead of ephemeral, stateless functions operated by a single entity, the IC offers decentralized stateful serverless computation over untrusted, independent datacenters. Developers deploy stateful *canisters* that serve calls either to end-users or other canisters. The IC programming model is similar to serverless clouds, with applications written in modern languages such as Rust or Python, yet simpler: state is maintained automatically, without developer intervention.

In this paper, we identify and address significant systems challenges to enable efficient decentralized stateful serverless computation: scalability, stateful execution through orthogonal persistence, and deterministic scheduling. We describe the design of the IC and characterize its operational data gathered over the past 1.5 years, and its performance.

1 Introduction

Recently, the technological advances in blockchain [29], cryptography [27] and consensus protocols [5, 9, 24] have enabled more and more efficient execution of decentralized Web3 [56] applications and smart contracts. Platforms that service such applications are larger than ever [42], consisting of thousands of nodes, processing billions of requests, storing large quantities of data and connecting many users. Currently, the research community lacks a clear understanding of the operational data of such large-scale platforms, their challenges and performance, beyond testnet deployments with synthetic workloads and failure patterns. In this article, we introduce the Internet Computer (IC), its design, several of its systems challenges and real-world operational performance data.

The IC is a decentralized platform for the execution of general-purpose decentralized applications (dapps). Listing 1 shows an example for such a dapp. In current serverless offerings, this application would not work without an external service, as functions are stateless. Instead, the IC enables `decentralized and stateful serverless` computing. The IC protocol [53] runs on globally distributed servers in independent datacenters. It is highly scalable and efficient in executing applications. The main goals of the IC are decentralization, security and performance.

```
use ic_cdk_macros::{query, update};
use std::{cell::RefCell, collections::HashMap};

thread_local! {
    static STORE: RefCell<HashMap<String, u64>> = RefCell::default();
}
#[update]
fn insert(key: String, value: u64) {
    STORE.with(|store| store.borrow_mut().insert(key, value));
}
#[query]
fn lookup(key: String) -> u64 {
    STORE.with(|store| *store.borrow().get(&key).unwrap_or(&0))
}
```

Listing 1: Functional key-value store canister. The update call adds a key value pair; the query call gets values by keys. State is stored on the canister heap and persisted transparently.

In particular, the IC aims to enable governance and evolution to be controlled by different parties in a trustless and fault-tolerant manner instead of a central entity. The IC must also provide strong integrity and access control guarantees for the apps running on it as well as the users interacting with it in an efficient way. Overcoming these challenges requires novel blockchain technology, cryptography and consensus protocols [9, 27, 53]. Those advances need to be combined with a carefully crafted system design. In this paper, we focus on those systems-related challenges at the application execution layer and we present our solutions and operation data.

Application developers deploy dapps (equivalent to serverless function workflows) on the IC without the cumbersome process of resource management, just like in serverless environments. The dapps interact with each other and with

end-users. Each dapp is composed of *canisters*, the smallest units containing code and data, an immediate equivalent to serverless functions. Such canisters can be combined to build complex and powerful smart contracts. Figure 1 depicts our protocol stack. The IC operates as a large-scale replicated state machine. To achieve wide-range scalability, the IC nodes are partitioned (sharded) [13, 57] into *subnets*, each running its own replicated state machine.

Central to this article is the execution environment, which ensures that the actions implemented by developers are triggered efficiently and deterministically, and that consumed resources are accounted for. For simplicity and portability, applications are programmed in a high-level language such as Rust, but compiled down to *WebAssembly* [28]. Canisters run isolated from one another inside sandboxed processes that execute code running under a WebAssembly virtual machine.

We identified significant execution layer systems challenges that we addressed when designing and building the IC. First, as opposed to serverless environments [49], our applications are long-running and **(C1)** `stateful`. The IC enables this through an efficient mechanism to track modified memory during canister call execution [39]. Coupled with canister statefulness, the IC programming model is inspired by an event-driven, actor-based model, where application programmers implement functionality that responds to messages from users or other canisters. To simplify programmer experience the IC offers `orthogonal persistence` [14, 31] – the system running the canister automatically persists the canister memory state without users taking action toward this goal. Therefore, sending messages to a canister is just like invoking multiple times a serverless function, with the distinction that function state modified by earlier calls is persisted without the programmer explicitly saving data in external services.

Second, similarly to current scalability challenges [30, 50, 58] in serverless computing, our nodes need to run thousands of canisters (or functions) per node. This entails achieving intra-node **(C2)** `scalability`. This is a must to accommodate large subnets with tens of thousands of canisters.

Third, we emphasize **(C3)** `determinism`. Since the IC is a large decentralized replicated state machine, all nodes must transition to the same next state, despite potentially malicious user input, canister code and node behavior. In a first step, this requires strict message *ordering*. Moreover, determinism is necessary in *scheduling* [2, 36, 44] actions that alter the replicated state and, of course, the actual *state changes* must be performed deterministically as well.

Of utmost importance for the IC is ensuring **(C4)** `security` for application developers and end-users. More precisely, the IC design aims to minimize the trust application developers and end users must place in individual entities. Thus, the IC relies on strong integrity, availability and access control guarantees. In particular, only valid messages will be processed and the response can be verified as long as more than two thirds of the nodes are honest. Canisters cannot inspect or change the state of other canisters or other parts of the system. These guarantees are achieved by carefully crafted low-level operating systems and runtime mechanisms as well as through the use of virtualization and sandboxing techniques.

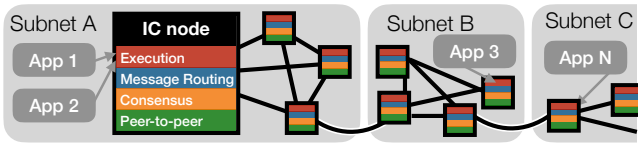

Figure 1: The protocol stack run by the nodes of the Internet Computer. The P2P layer disseminates protocol and user-generated messages. Message validation and ordering is established by the consensus layer. Messages are then routed to the execution environment and trigger efficient deterministic (replicated) computation of the apps deployed on the IC. Apps on different subnets can send messages to each other.

In this paper we show that the years-old mantra saying blockchains are slow and inefficient is coming to an end. Addressing these challenges efficiently means the IC is, to the best of our knowledge, the fastest and most efficient blockchain to date, outpacing the execution speed, transaction and execution costs [16] of other blockchains by orders of magnitude, while having significantly fewer carbon emissions [10]. More importantly, it enables decentralized stateful serverless computing. We therefore omit comparing the IC with other blockchains, but rather compare its performance with native and non-decentralized client-server architectures, whose performance we aim to achieve.

Having operated the IC for more than 1.5 years, we share our experience in designing and building the IC, with an emphasis on its systems challenges. The IC was launched in May 2021. As of January 2023, it hosts over 230,000 canisters for a total state of 2.5 TB (more than twice the size of the Ethereum blockchain) running services ranging from social media to decentralized finance. Our main contributions are:

1. We present the high-level design of the IC (Section 2).
2. We present systems challenges of the IC execution layer, with a focus on the memory subsystem, orthogonal persistence, deterministic scheduling and scalability (Section 3).
3. We showcase the performance of the IC. We introduce high-level operational data, which we open to the public. We present end-to-end application performance and study in-depth the IC performance compared to native applications. We discuss the (performance) implications of decentralization and statefulness (Section 4).

2 The Internet Computer Design

In this section we briefly introduce the IC. For a more comprehensive article explaining protocol aspects in more depth we refer the reader to the IC whitepaper [53].

Motivation. The IC aims to provide efficient multi-tenant, general-purpose, and secure computation in a decentralized

and geo-replicated manner tolerating Byzantine faults, offering developers a modern and easy to use programming model.

Overview. The nodes of the IC run a network of replicated state machines [48], which interact with each other via messages. State machine replication achieves the same output state for a service replicated on multiple machines. Each state machine generates new states by applying *deterministic* state transformations — based on the deterministic execution of the canisters' code provided by the app developers — to the previous state by processing ordered input messages from users and other canisters. The result is a new state and output messages to canisters and users.

Subnets and nodes. The nodes (term used interchangeably with replicas, machines, or servers) of the IC are partitioned into *subnets*, each subnet providing state machine replication for the set of canisters deployed on it.

Each node in a subnet runs all the canisters deployed in that subnet. Subnets can be smaller or larger: we have subnets with 80,000+ canisters and subnets with several hundreds. Most subnets have 13 nodes that are geo-replicated across the Americas, Europe and Asia. For applications in need of improved security, we have higher-replication subnets, spanning up to 40 nodes. A subnet should continue to function even if some replicas are faulty. The replicas running the IC protocol are hosted on servers in geographically distributed, independently operated data centers, bolstering security and decentralization.

Currently, the IC nodes are homogeneous. Homogeneity is important for system parts that are executing code running in the replicated state machine, as otherwise, speed may be reduced due to too many slow nodes. However, functionality outside of the replicated state machine, such as for executing non-replicated query calls can be scheduled proportionally to each machine's resource availability.

The IC supports heterogeneous subnets as long as all machines in a subnet are homogeneous. For example, certain subnets have 13 machines while others have 40, certain subnets have different disks and IO throughput and charging is based on the number of nodes in a subnet (i.e., replication factor). Overall horizontal scalability is achieved through the sharding mechanism. This effectively allows the IC to scale horizontally adding massive numbers of nodes without much additional overhead.

2.1 Failure Model

To maximize decentralization, the IC is designed for Byzantine fault-tolerance, in which faulty nodes may deviate in an arbitrary way from the IC protocol.

In any given subnet with $n \geq 3f+1$ nodes, at most f nodes may behave in a faulty manner. This is the highest number of failures which can be tolerated without additional assumptions on failures and message delivery [22, 48]. The failures account for software bugs, power outages as well as outright malicious behavior by colluding nodes. To limit the exposure and maximize decentralization, the nodes in a subnet are chosen in different geographical areas, jurisdictions and node provider organizations. In the future, trusted execution environments will further reduce the attack surface.

Traditional systems [8, 11, 38] often assume a weaker crash-stop failure model and aim to be available if a subset of nodes crash, but cannot cope with Byzantine behavior. The performance implications of Byzantine fault tolerance over crash-stop are acceptable for the applications deployed on the IC.

2.2 IC interface

The Internet Computer provides two distinct types of calls (i.e., requests sent to canisters): update and query calls. We refer to these operations interchangeably as either calls, requests, or messages. The IC also provides special calls for the canister life cycle: canister *creation*, canister *installation* and canister *upgrades*. Those are special forms of update calls.

Update calls can modify canister state. They are executed on all machines in a subnet participating in state machine replication. The calls are ordered and validated by consensus in a Byzantine fault-tolerant manner. This order, together with deterministic execution of canister code and relevant parts of the IC, provide state machine replication guarantees. Since consensus is computation and communication heavy, agreement and execution of update calls is done in batches to optimize throughput. Thus, update call latency is dependent on the time spent for consensus to reach agreement on blocks.

While update calls for different canisters may be executed in parallel, update calls for the same canister are processed sequentially. The response to an update call is threshold-signed by $2f+1$ nodes, i.e., a super-majority of the nodes created a signature collectively, hence users can verify correctness without having to communicate with multiple nodes.

The IC API guarantees atomicity for update calls as long as no further calls to other canisters are made. Updates that modify local state and run local computation are always atomic. For computation that calls into other canisters/smart contracts 2PC protocols could be implemented.

Query calls, on the other hand, do not change the canister's persisted state. As such, a query call may be processed directly by a single replica without passing through consensus. This reduces the query call latency significantly.

The correctness of query call responses from individual machines can be verified despite the Byzantine fault tolerance failure model with *certified variables*. Such variables carry threshold signatures which are generated collectively by a super-majority of the nodes in a subnet. Data elements that programmers want to verify via certified variables need to be arranged in a Merkle tree [35]. With certified variables, elements of a canister's state can be verified by clients even when talking to a single IC node.

Note that the Internet Computer does not guarantee any

order between query calls and other calls to the system (neither query nor update). If the order of calls matters, canister developers must use update calls and/or provide a versioning scheme as part of the canister code.

Applications running on different subnets can call each other by means of an asynchronous pull-based reliable communication primitive on top of consensus on both the sending as well as the receiving subnetwork.

IC Programming. Currently, developer support for applications programmed in *Rust*, *Motoko* [18], or Python [15] exists. The IC canister code is compiled down to WebAssembly, which is executed under a sandboxed virtual machine on the IC nodes. Any language that can be compiled down to WebAssembly could also be used. A detailed description of WebAssembly execution is provided in Section 3. Listing 1 shows an example of a functional 15-line key-value store canister implemented in Rust. It exports one update call to insert elements in the kv-store and one query call to retrieve them.

2.3 The IC Protocol Stack

As illustrated in Figure 1, the Internet Computer Protocol consists of four layers.

Peer-to-peer Layer. Within a subnet, nodes exchange information to achieve consensus on the replicated state and the messages to be processed next. To this end, the peer-to-peer layer offers a (prioritized) broadcast service to the layers above. To conserve bandwidth, peer-to-peer relies on an advert-based mechanism, where nodes first send a small advert to announce they have an artifact. Other nodes can then request the artifact if they need it, based on the details in the advert. Peer-to-peer relies on TLS over TCP streams between the nodes of a subnet. On top of that, it adds further reliability with notifications for unsent messages (in case of sender-side errors), and automatic connection re-establishment and requests for recent adverts.

Consensus Layer. Incoming messages must be validated and ordered so all replicas process them in the same order. The IC uses a novel consensus protocol [9] briefly described here.

The protocol proceeds in rounds. The replicas grow a tree of blocks referencing valid predecessor blocks. Their local trees form a consistent yet sometimes locally incomplete tree view. In each round, a pseudo-random process is used to assign each replica a unique rank. The replica of lowest rank is the *leader* of that round. When the leader is honest and the network is synchronous, the leader will propose a block, which the other honest nodes in the subnet will validate and add to their local tree. If the leader is not honest or the network is not synchronous, some other replicas of higher rank may also propose blocks, have them validated and added to the tree. Whenever $2f+1$ replicas report that they added exactly one block to the tree, this block and its predecessors on the path to the root are declared finalized and the non-finalized parts of the tree up to this height are pruned.

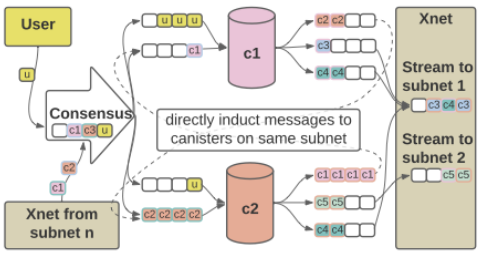

Figure 2: Routing messages through the IC protocol stack. Messages for canisters, issued by users or canisters on other subnets, are validated and ordered by consensus. Subsequently, messages are put into input queues for their destination canister. Messages created by canisters are put into output queues from where they are either transferred to their respective input queues on the same canister (bypassing consensus) or sent as part of streams to their target subnet.

One can prove that this protocol provides the consensus properties, namely *safety* (i.e., all replicas in fact agree on the same ordering of inputs) and *liveness* (i.e., all replicas should make steady progress). The IC consensus protocol guarantees safety despite asynchrony. This means that there is no assumption of an upper bound on the time to send information from one node to another. For liveness short intervals with fast message delivery are sufficient. The IC consensus protocol degrades gracefully when some replicas are malicious.

Message Routing. Once the consensus layer orders input messages, they are delivered to the message routing layer. The destination canister for each message is selected and the messages are enqueued for processing by the execution environment. During execution, the destination canister updates its state as part of the replicated state machine and generates outputs handed back to the message routing layer.

The message routing layer enqueues messages in one of multiple input queues. For each canister C running on a subnet, there are several input queues — there is one queue specifically for user-generated messages to C. Furthermore, each other canister C', from which C receives messages, gets its own queue. In each round, the execution layer will consume some of the inputs in these queues, update the replicated state of the relevant canisters, and place outputs in various output queues. For each canister C running on a subnet, there are several output queues — each other canister C', with whom C communicates, gets its own queue. The message routing layer will take the messages in these output queues and place them into subnet-to-subnet streams to be processed by a crossnet transfer protocol, whose job it is to actually transport these messages to other subnets. This is visualized in Figure 2.

Thus, the replicated state comprises the state of the canisters, as well as "system state", including the above-mentioned queues and streams. Thus, both the message routing and execution layers are involved in updating and maintaining the replicated state of a subnet. It is essential that all of this state

is updated in a completely deterministic fashion, so that all replicas maintain exactly the same state.

The consensus layer is decoupled from the message routing and execution layers, in the sense that only messages from finalized blocks of the chain reach routing and execution. Temporary block tree branches are pruned before their payloads are passed to message routing. This is in contrast to other blockchains which execute blocks speculatively, before ordering and validating them [46].

Execution Layer. The Execution Environment operates in rounds, during which it takes messages from canister input queues and executes the corresponding Wasm function with the message as payload. Based on the input and canister state, the execution environment updates the canister state, and could additionally add messages to output queues. One of the main challenges is that computation must be deterministic for state machine replication to work.

A scheduler determines in which order messages are executed in each round. The main goals of the scheduler are (see Section 3.3 for a more detailed description): (1) it must be *deterministic*; (2) it should distribute workloads *fairly* among canisters (3) optimizing for *throughput* over *latency*.

The IC offers orthogonal persistence, an illusion given to programs to run forever: the heap of each canister is automatically preserved and restored the next time it is called. Listing 1 shows an example key-value store that illustrates how easy it is to use orthogonal persistence. The key-value store in this case is backed by a simple Rust HashMap stored on the Wasm heap by means of a thread-local variable. We use a RefCell to provide interior mutability. The example would also be possible without it, but mutating the thread-local variable would be unsafe in that case, as the Rust compiler cannot guarantee exclusive access to it.

3 Systems Challenges of the IC

We focus on the execution layer of the IC and discuss the challenges C1-C4, as well as their solutions.

The IC can execute arbitrary programs. The basic computational unit in the IC is called a canister. Canister programs are encoded in WebAssembly (Wasm) [28], a binary instruction format for a stack-based virtual machine.

The main goal is to execute `deterministically`, `securely` and `efficiently` the functions triggered by messages sent to canisters. Each canister is executing under a long-running Wasm virtual machine whose state is persisted over long periods of time. In terms of efficiency IC nodes are able to sustain running tens of thousands of canisters [17]. The *memory subsystem* of the nodes addresses challenge **C1**.

The IC needs to scale up, by achieving high resource utilization on individual nodes. This is important to achieve performance comparable to native systems and to amortize the cost of state machine replication. Essential for achieving

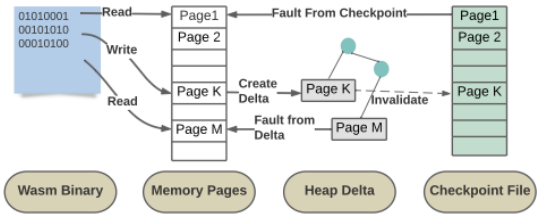

Figure 3: Memory faulting architecture, including heap delta and checkpoint file. When Wasm instructions trigger page faults, memory contents can be faulted in from the memory checkpoint. When pages are dirtied by writes, heap deltas are created, which invalidate page content in the checkpoint file. Subsequent faults are served directly from heap deltas. Periodically, heap deltas are merged into a new checkpoint.

these goals is to enable efficient execution of developer code through Wasm code execution, solving challenge **C2**.

To ensure correct and deterministic state machine replication, we designed and implemented a deterministic scheduler for the IC nodes. Our scheduler implements a deterministic time slicing mechanism, effectively solving challenge **C3**.

Security is achieved at multiple layers of the IC through trust, consensus, byzantine fault-tolerance and so forth. Details about these can be found in our whitepaper [53]. At this layer, we ensure security through operating systems and virtualization mechanisms effectively solving challenge **C4**.

3.1 C1 - Statefulness - The Memory Subsystem

Currently, canisters can use up to 52 GiB of memory to be accessed by users. Any implementation of orthogonal persistence has to solve two problems: **(1)** How to map the persisted memory into the Wasm memory; and **(2)** How to keep track of all modifications in the Wasm memory so that they can be persisted later. We use page protection to solve both problems. We divide the entire address space of the Wasm memory into 4 KiB pages. All pages are initially marked as inaccessible using the page protection flags of the OS.

The first memory access triggers a page fault, pauses the execution, and invokes a signal handler. The signal handler then fetches the corresponding page from persisted memory and marks the page as read-only. Subsequent read accesses to that page will succeed without any help from the signal handler. The first write access will trigger another page fault, however, and allow the signal handler to remember the page as modified and mark the page as readable and writable. All subsequent accesses to that page (both r/w) will succeed without invoking the signal handler.

Invoking a signal handler and changing page protection flags are expensive operations. Messages that read or write large chunks of memory cause a storm of such operations, degrading performance of the whole system. This can cause severe slowdowns under heavy load.

Versioning: Heap Delta and Checkpoint Files. A canister

Figure 4: The performance improvement given by memory faulting optimizations (lower is better). Note the logarithmic vertical axis. Speedups range from 1.25X to 3.5X.

executes update messages sequentially, one by one. Queries, in contrast, can run concurrently to each other and to update messages. The support for concurrent execution makes the memory implementation much more challenging. Consider that a canister is executing an update message at (blockchain) block height H. At the same time, there could still be a previous long-running query that started earlier, at block height $H-K$. This means the same canister can have multiple versions of its memory active at the same time; this is used for the parallel execution of queries and update calls.

A naive solution to this problem would be to copy the entire memory after each update message. That would be slow and use too much storage. Thus, our implementation takes a different route. It keeps track of the modified memory pages in a persistent tree data-structure [41] called Heap Delta that is based on Fast Mergeable Integer Maps [37]. At a regular interval (i.e., every N rounds), there is a checkpoint event that commits the modified pages into the checkpoint file after cloning the file to preserve its previous version. Figure 3 shows how the Wasm memory is constructed from Heap Delta and the checkpoint file.

Memory Faulting Optimizations. We describe below three optimizations we designed to improve memory faulting.

◊ **Optimization 1:** *Memory mapping the checkpoint file pages.* This reduces the memory usage by sharing the pages between multiple calls being executed concurrently. This optimization also improves performance by avoiding page copying on read accesses. The number of signal handler invocations remains the same as before, so the issue of signal storms is still open after this optimization.

◊ **Optimization 2:** *Page tracking in Queries.* All pages dirtied by a query are discarded after execution. This means that the signal handler does not have to keep track of modified pages for query calls. As opposed to update calls, for queries we introduced a fast path that marks pages as readable and writable on the first access. This low-hanging fruit optimization made queries 1.5x-2x faster on average.

◊ **Optimization 3:** *Amortized prefetching of pages.* The idea behind the most impactful optimization is simple: to reduce the number of page faults, we need to do more work per signal handler invocation. Instead of fetching a single page at a time, the signal handler tries to speculatively prefetch pages. The right balance is required here because prefetching too many pages may degrade performance of small messages that access only a few pages. The optimization computes the largest contiguous range of accessed pages immediately preceding the current page. It uses the size of the range as a hint for prefetching more pages. This way the cost of prefetching is amortized by previously accessed pages. As a result, the optimization reduces the number of page faults in memory intensive messages by an order of magnitude.

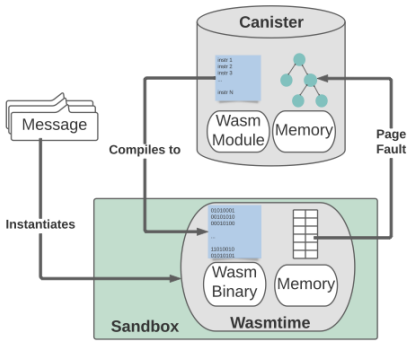

Figure 5: The execution of messages instantiates a Wasmtime instance in a sandboxed environment. Each sandbox can run multiple wasmtime instances. The Wasm module is compiled to a binary running inside the VM while memory accesses are faulted in from the memory heap deltas and checkpoint file.

These optimizations bring substantial benefits for the performance of the memory faulting component of the execution environment. Figure 4 plots the performance optimizations we achieved when enabling all three optimizations in comparison with turning them off. We measured this for a memory intensive benchmark which allocates 8 bytes, 1 MiB, or 512 MiB. The optimizations allow the IC to improve its throughput for memory-intensive workloads as depicted in the Figure and no performance degradation was observed for other workloads.

3.2 C2 - Scalability: Wasm Execution

To process a message, the canister executes the corresponding function in the Wasm module. Figure 5 depicts this process. Function execution requires a Wasm instance which is a combination of Wasm code and memory. One of the challenges is that we cannot afford to keep one Wasm instance alive for each of the canisters running in a subnet because we would run out of memory. Instead, we construct Wasm instances on demand for each message and dispose of them after the message execution. Thus, the latency of message execution depends on the instantiation time and the actual time to execute the function. Included in this instantiation time is also the time to compile the Wasm code. One optimization we deployed is to cache compilations of Wasm code.

For one of the most used canisters in production, the compilation cache optimization reduces the P99 for running non-replicated queries by 2 orders of magnitude. This is depicted in Figure 6. Therefore, for our real-world example, cold-start times are now below 10 ms for previously compiled user-code

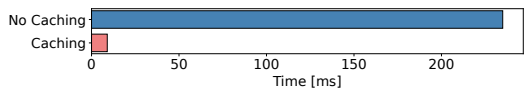

Figure 6: Compilation caching effects. P99 for running a short (1 ms), non-replicated query on a cold started canister.

and around 230 ms when compiled for the first time. This is an important achievement compared to major serverless providers where cold-start times are in the order of seconds to tens of seconds [1, 49, 51, 55]. However, compilation time varies proportionally with the complexity of the Wasm code being compiled. Therefore, for certain applications longer first-time compilation times are to be expected—subsequent calls are optimized by caching the compilations.

Section 3.1 describes how the Wasm instance manages a canister's memory in checkpoint files or heap deltas.

Instrumentation: Time-slicing and Accounting. Since Wasm is Turing-complete we need a mechanism to ensure termination of message execution. Otherwise, a faulty or malicious smart contract would be able to stall the progress of the blockchain by potentially infinitely long running messages. As everything else in the execution layer, the point at which we do that needs to be deterministic. However, execution duration is not, as execution might be slightly different on different nodes due to nondeterministic events in the system (e.g. one machine having a page fault, but not the other one).

Instead, we instrument Wasm code to count the number of instructions that have been executed for each message that is being processed by the system. To reduce the performance overhead, our compiler extension performs counting at the basic block level instead of individual instructions. Concretely, at the start of an execution round we initialize the global instruction counter of the Wasm module for each canister to the instruction limit. In each basic block of the Wasm module we insert a snippet of code to decrement the counter by the number of instructions in the basic block. In re-entrant blocks, such as function and loop headers, we insert code that aborts message execution when the counter is negative.

Another benefit of quantifying computation done via instruction counting is that we can deterministically charge canisters for performed work. The canisters are charged for the resources they are consuming, including computation, communication and storage. For that reason, the IC needs to account for resource usage of all canisters in the system. Two examples for resources being accounted are memory accesses (estimated by the number of pages read and written) as well as CPU instructions used. Memory accesses are tracked with the memory protection mechanisms as described in Section 3.1.

Resources also need to be accounted for when serving users query calls. Queries are especially complex since their execution is non-replicated due to their execution on just a single node. However, the canister still needs to be charged deterministically by all nodes as the balance of a canister is part of the canister's state which is managed by state machine replication. This is currently an open problem we are investigating.

3.3 C3 - Deterministic Scheduling

Since we are operating a replicated state machine, it is essential that each replica processes the same inputs in the same order. To achieve this, the replicas in a subnet run a consensus protocol [21], which ensures that they process inputs in the same order. If the IC code executing those messages as well as the canister code itself is deterministic, the internal state of each replica will evolve over time in exactly the same way, and each replica will produce exactly the same sequence of outputs in the absence of hardware-related problems.

Granularity. For simplicity, the scheduler works at a coarse level, scheduling canisters instead of individual messages and executing each canister until there are no more messages in its queues or the system-defined instruction limit for a round is reached. IC nodes are modern dual-socket multi-core servers. Deterministic behavior on such a machine can be achieved when canisters are pre-allocated to specific CPU cores at the beginning of each round. Our current scheduler takes this approach because it is a simple and effective design choice which is then easily proven correct (see Appendix A).

Allocation and fairness. To ensure responsiveness under heavy load, canisters have the option of paying upfront for a *compute allocation*. Since canisters are single threaded, a *compute allocation* is a fraction of one CPU core, expressed in percentage points. Only part of a subnet's compute capacity can be allocated, ensuring progress for canisters with zero compute allocation, i.e. best effort canisters. Fairness is defined as guaranteeing canister compute allocations (i.e., a backlogged canister with compute allocation A executing at least A full rounds out of every 100) and evenly distributing the remaining capacity ("free compute") across all canisters.

Given a deterministic state machine with N CPU cores (and $N \times 100$ compute capacity), we schedule (at least) N canisters to execute a *full round*: a round, in which a canister either exhaust the instruction limit or completes the execution of all their enqueued messages. The scheduling algorithm uses credits accumulated across rounds as priority: an amount of credits equal to the canister's compute allocation plus a uniform share of the *free compute* is credited to every canister at the beginning of every round; canisters in the priority queue are assigned round-robin to CPU cores (each of the first N canisters are scheduled first on a CPU core), and 100 credits are debited from each canister that executes a full round.

Our algorithm's time complexity to compute the schedule algorithm is linear in the number of canisters, which is acceptable because scheduling only happens once per round (alongside other operations that require linear time). The scheduling algorithm has the following properties:

- `Correctness wrt. compute allocation`: every backlogged canister gets a "full execution round" at least A out of every 100 rounds, where A is the canister compute allocation.

- `High throughput`: in the absence of information regarding the number of instructions required to execute each message ahead of time (which might allow for better bin packing); and given the constraint that canisters must be allocated to specific cores ahead of time; the algorithm provides optimal throughput by executing canisters allocated to each core until the round instruction limit is reached.
- `Fairness`: the credits system ensures that (backlogged) canisters with equal compute allocations get the same number of "full execution rounds" over a long enough time period.

Appendix A defines and anlyses the scheduler formally.

Deterministic Time Slicing. The scheduler, as explained above, although effective, is suboptimal for messages that trigger executions of varying length. Each subnet of the IC operates in epochs of many rounds. Messages run either to completion or to a predefined upper limit on the number of instructions per round. In the second case, the execution is aborted and returns an error. In this case, the user would have to rewrite the algorithm to make the execution of the long-running message span multiple execution rounds. This is less than ideal because of two reasons. First, it can artificially increase round duration due to stragglers, which leads to overall throughput loss and slowdown. Second, it can lead to significant CPU waste because a long-running execution that is aborted due to reaching instruction limits will be re-executed.

To solve this problem, we designed a *deterministic time slicing* mechanism on top of our scheduler, where each message execution longer than a round is `sliced` in a number of intervals with roughly equal numbers of instructions. This is akin to time slicing in modern schedulers [7], although the biggest challenge here is to enforce determinism. Time slicing also increases the amount of intermediate state, that needs to be kept while a message is preempted. The slices achieved here are then scheduled as described before.

3.4 C4 - Ensuring Security

The security model of the IC aims to provide *access control* and *integrity* of canister and system data in the presence of malicious canisters and users. Canisters can specify a method that accepts or rejects requests, e.g., based on caller ID, resource consumption etc. Only correctly signed messages are then processed. Responses to update calls and queries for certified variables are threshold-signed by the subnet nodes, so clients can verify authenticity. Canisters cannot inspect or change state of other canisters or parts of the system. This is guaranteed by eliminating the main Wasm attack vectors.

An adversary may craft Wasm code to: (1) exploit bugs in the Wasm engine to escape its protection mechanism; and (2) perform side-channel attacks to obtain data from the system or other canisters [33]. The IC protects against these attacks using OS isolation and sandboxing. Each canister is compiled and executed in its own sandboxed process that communicates only with the main replica process via security-audited IPC.

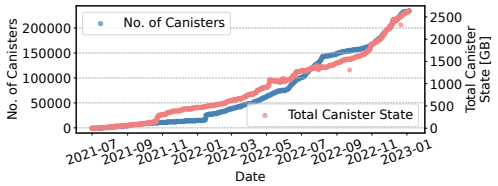

Figure 7: Total number of canisters running on the IC.

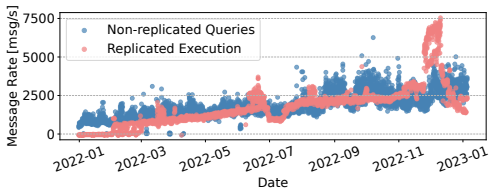

Figure 8: The rate of non-replicated and replicated messages.

Sandboxes are given minimal permissions needed to execute using object-based access control (SELinux).

In the future, hardware-based security, offering fully encrypted VMs with the possibility to attest remotely if the expected VMs are running, will increase obstacles curious and malicious node providers face.

4 The Internet Computer In Data

We present data related to the operation and performance of the IC. We show the growth and usage patterns the IC is experiencing, its overall performance (in comparison with native code) and identify sources of overhead with regard to the systems challenges presented in Section 3.

The Internet Computer Hardware. The IC currently runs on homogeneous hardware that is hosted by independent node providers. The chosen configuration makes use of dual-socket AMD EPYC 7302 processors with a total of 32 physical cores running at 3 GHz, each core having 2 hardware threads. The IC servers make use of 503 GiB of memory. AMD chips were chosen due to their secure encrypted virtualization feature to enable VM encryption across VM upgrades in combination with remote attestation.

The data presented in Sections 4.1-4.2 is gathered from production. Experiments discussed in the rest of this section are executed on an internal testnet that mimics subnets on the IC. The difference to IC machines is that two IC VMs are deployed to each host, instead of one. Testnet machines are hence expected to be slower for concurrent workloads.

4.1 A High-level View of the IC

IC Growth (C1 + C2). We focus on the high-level operational data gathered from the IC. The usage has been steadily increasing since launch, showing an acceleration of the numbers of deployed applications since the beginning of 2022. Figure 7 depicts the number of deployed canisters over time, as well as their overall allocated state, which reaches 2.5TB.

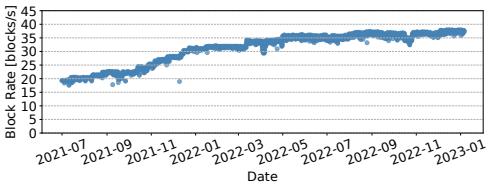

Figure 9: The block rate of the IC.

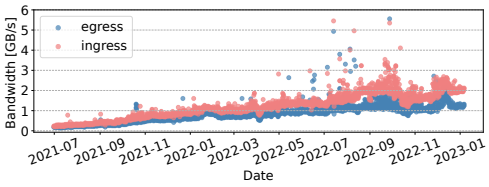

Figure 10: Aggregated IC Nodes network traffic.

Workload Growth (C1 + C2). Together with the increase in the deployed applications we also observe an increase in the workload deployed on the IC. Figure 8 plots the arrival rate of messages over time. As expected, non-replicated messages (i.e., queries), which do not pass through consensus and do not alter canister state are being triggered significantly more often than replicated messages by our users. Replicated execution, which incurs the consensus overhead is used less — we assume only for operations that need to alter application state. An interesting observation to make here is that in February 2022, we have changed the way in which we quantify the number of replicated messages. Whilst before this date, the number only sums up *update* calls, after this date the date adds also replicated execution that the canisters use for their operation (e.g., periodic heartbeats). The graph shows a significant increase in the number of replicated messages after February 2022. We note here that it is common practice that for *operational systems*, metrics sometimes change meaning over time as the systems itself is refined and continuously evolving. The significant increase in replicated execution in Dec 2022 is due to the launch of a popular application, while the later drop corresponds to a change in the call pattern of the same application.

IC Scaling Out (C2). Over time, the IC has increased its capacity to sustain increased workloads and achieve decentralization. Evidence to sustain the scaling out of the IC is given by examining the *block rate* – the number of blocks generated by the consensus layer. Figure 9 plots these data, showing an increase of 57% since launch.

Similar evidence to sustain growth of the IC in terms of higher workload demands is represented by the increased network bandwidth used to exchange messages between nodes. Figure 10 depicts the aggregated bandwidth of traffic generated: since launch, the traffic generated between the nodes has increased from around 250 MB/s to about 3 GB/s, over an order of magnitude increase over a period of a year. The amount of ingress and egress traffic is very similar, as expected.

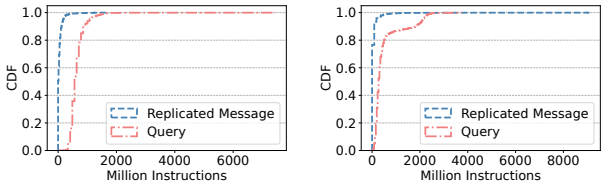
Figure 11: The time queries or replicated messages take in the execution layer, without consensus overhead.



(a) OpenChat Subnet. *(b) DSCVR Subnet.*

Figure 12: The number of instructions spent for executing queries or replicated messages.

4.2 The IC Performance

The IC has attracted the developers of several large applications, for example: *OpenChat* (a decentralized chat application), *DSCVR* (decentralized social news aggregator), and *distrikt* (a decentralized professional social media platform). These applications have added a significant increase in workload complexity for the IC. We present an in-depth analysis of the metrics of the subnet that runs the OpenChat canisters. We focus mostly on data related to the systems challenges described in Section 3.

The subnet hosting the OpenChat application is composed of 13 replica nodes distributed geographically (in North America, Europe and East Asia). The subnet hosts 80,000 canisters.

Replicated vs. Non-Replicated Execution. (C1-C3) First, we assess the duration of non-replicated queries in comparison with replicated update calls in Figure 11. We compare the data in the OpenChat subnet with the data coming from the subnet running DSCVR (and other applications). Note that this comparison does not include the overhead of the P2P, consensus and messaging layer, but only measures the time spent in the Execution layer. By analyzing the data in Figure 11 we conclude that queries run longer for the OpenChat subnet, while updates dominate on the DSCVR subnet. Figure 12 plots the number of Wasm instructions for queries compared to replicated messages. The average number of instructions executed for queries is significantly higher than for replicated messages for OpenChat, leading to longer executions. On the contrary, on the DSCVR subnet the behavior is the exact opposite. This shows that the IC runs a diverse set of applications, with varied needs and characteristics.

Memory Overhead (C1 + C2). The heap delta is used in-between checkpoints to keep track of modified memory pages. This data structure can affect the subnets' ability to scale up

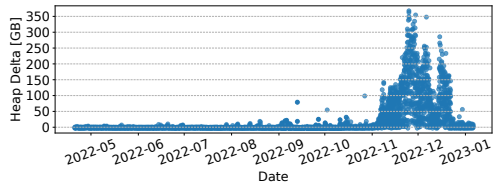


Figure 13: Heap delta for an IC subnet over time.

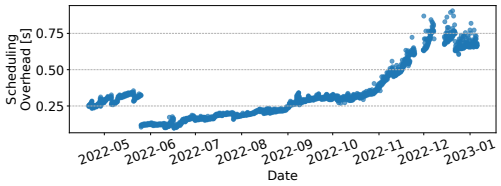

Figure 14: Scheduling overhead for an IC subnet over time.

to many concurrent canisters as tracking modifications incurs overhead. Figure 13 shows how the heap delta for all canisters on OpenChat subnet evolves over time. The data shows that on average the heap delta is below 5 GB, but more recently, since November 2022 it has significantly increased, up to 350 GB. This shows a large increase in OpenChat usage, aggregated for more than 80,000 canisters. On subnets with fewer canisters heap deltas are typically smaller.

Scheduling Overhead (C3). When scheduling replicated messages the same ordering has to be ensured on all replicas so that determinism is guaranteed. Deciding which message gets scheduled for execution and at what time is a costly operation that can affect scalability. We plot the scheduling overhead, i.e., the time to compute the schedule for one round, in the OpenChat subnet in Figure 14. The immediate conclusion is that this overhead is in the order of hundreds of milliseconds per round for this subnet. An interesting point is the overhead reduction which can be observed around the end of May 2022. This is attributed to an optimization related to the scheduling process, namely checking if a canister has messages to be run. We checked the scheduling overhead for subnets with smaller numbers of canisters as well. Our conclusion is that this overhead is proportionally smaller (as the overhead complexity is $O(N \log N)$ for N canisters). Similarly to the heap delta observation, the scheduling overhead increased significantly since November 2022. This is also because the number of users (and canisters) for OpenChat has significantly increased, leading to many more messages being scheduled for execution in this subnet. We investigate ways to reduce this overhead to support efficient scheduling with larger workloads.

4.3 The IC Virtualization Stack

We quantify the impact of the IC virtualization. In Section 3 we described how user code is executed. In short, user code is compiled to Wasm, which gets instrumented and compiled to a binary that gets executed inside a sandbox. To achieve orthogonal persistence and stateful execution we keep track of memory writes in a persistent data structure from which the Wasm VM is faulting in its pages. This indirection introduces a non-trivial overhead. We quantify this overhead for two types of workloads: compute- and memory-intensive. Each of these workloads stress different resources of the stack.

Compute Intensive Workload (C2). We implemented a workload that calculates prime numbers up to a given integer number. This is a single threaded workload, which we wrote in Rust and deployed on the IC. We ran the same workload (identical Rust code) on an IC machine natively (compiled to an x86 binary), without the entire virtualization stack. Furthermore, we ran the same Rust code on one of the top-3 serverless providers. Experiments in the IC have been measured from within the Execution Environment and hence do not contain network latency or the cost of other parts of the IC stack. We provide similar data for the serverless provider and take the latency from the provider's dashboard. The experimental data is presented in Table 1. The overhead is computed against the native execution (not against the serverless provider).

First, the Internet Computer performance compared to native execution is good for longer-running workloads considering the extra features that the IC execution environment provides: sandboxing, accounting and tracking changes. Second, we emphasize that the IC performance is in the same order of magnitude with one of the top-3 serverless providers. Considering the extra operations that the IC does to offer its users decentralization, security etc., we deem these performance data encouraging, especially taking into account the fact that the serverless execution is faster than native execution in our case. This directly implies that the hardware running the serverless platform is very likely faster than the hardware we described in Section 4.

Memory Intensive Workload (C1). We performed a similar experiment with a memory intensive workload. Here, memory is accessed sequentially in strides of 8 bytes. The totally allocated memory is 1 GB. In this experiment we only compare against a native execution because all current serverless platforms are not stateful. Therefore, the serverless functions access memory directly (i.e., without any faulting architecture, persistence, versioning) through either microVMs [1] or containers [43]. A more direct comparison would involve a serverless function that stores its state in a storage environ-

n	**IC** [ms]	**Native** [ms]	**Serverless** [ms]	**Slowdown IC / native**
0	1.40	0.02	3.53	70 X
100	1.43	0.03	1.93	47 X
1,000	2.35	0.94	2.94	2.5 X
10,000	41.54	33.85	19.65	1.22 X
50,000	718.26	610.73	347.54	1.17 X

Table 1: Median computation time for a compute intensive workload running on the IC, native execution and running on a serverless provider (average for serverless due to lack of raw data) over 30 executions. The workload identifies primes in the first n integers.

Operation	Data Size [Bytes]	IC [ms]	Native [ms]	Slowdown IC / native
Read	50,000	2.15	0.02	107 X
Read	5,000,000	26.36	1.83	14.2 X
Read	50,000,000	195.52	18.27	10.7 X
Write	50,000	2.28	0.02	114 X
Write	5,000,000	33.79	2.14	15.8 X
Write	50,000,000	277.36	19.13	14.5 X

Table 2: Median computation time over 30 executions of a memory intensive benchmark performing strided reads/writes of different sizes on the IC and native execution.

ment [32], but this is outside the scope of this article.

We therefore compare the execution time of executing the benchmark compiled to a native x86 binary on one of the IC node to the time of executing the same benchmark as canister code. Table 2 summarizes our findings. For workloads that touch up to 50 MiB of data, the overhead of running this benchmark on the IC is approximately 10 X to 15 X. Lower amounts of data touched incur larger slowdowns, with smaller data giving the largest slowdown.

Even though the slowdown compared to native execution seems large, we remind the reader that a rather deep virtualization stack is involved in memory operations. Further, the IC needs to account for resource consumption and track memory writes, which the native version does not do. Finally, update calls pass through consensus and the entire IC stack, therefore offering the users all the Internet Computer benefits: decentralization, security, and tamper-proof execution. Moreover, we remind the reader that the IC is orders of magnitude faster and more efficient than other blockchains. We are further working on improving the memory faulting layer using write barriers [6] or userfaultfd [39] so that in the future we can reach our goal of (close-to-)native performance.

The Cost of Decentralization and Statefulness (C1-C4). One of the overarching goals of the IC is to offer levels of performance as close as possible to *native* and traditional client-server architecture performance. With regard to user-perceived overhead, the factors contributing most are the consensus protocol, the networking, and the crypto primitives, as well as memory faulting. At a macro level, this overhead can be observed by re-interpreting Figures 9 and 10. All the replication protocol-related mechanisms leads to network traffic (e.g., a few MB per machine per second, see Figure 10, considering that at the moment of writing the IC runs on over 500 machines) and computational overhead for the creation and validation of blocks and the messages contained therein. This overhead is not crippling the operation of the IC and its benefits significantly outweigh its downsides.

We ran many memory-intensive *update* calls in one of our testing and benchmarking subnets. Memory-intensive updates especially stress the entire system stack because they: (i) modify significant amounts of the canister state; (ii) need replicated execution; (iii) require consensus for ordering. Therefore, we quantify the overhead of system components by running `Linux perf`. Figure 15 is an instance of quantifying

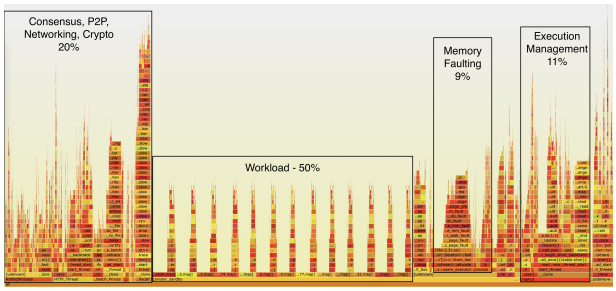

Figure 15: Decentralization and statefulness overheads when several memory-intensive `update calls` are made. Data presented as flame graphs [26].

such overhead. We observe that the actual workload takes approximately 50% of the used CPU time (not all the CPU capacity is used). A large fraction of the overhead can be attributed to the consensus and P2P protocol, networking or crypto primitives stack, together they account for roughly 20% of the CPU time. Another sizeable CPU time consumption is due to the memory faulting subsystem (9%) and the execution management stack (11%). The latter involves all processing related to canister administration, Wasm instrumentation, communication with sandboxes.

4.4 End-to-end Performance (C1-C4)

We quantify the end-to-end performance of our subnets using the default subnet size of 13 nodes. Note that for enhanced security guarantees (e.g., tolerating more malicious nodes) the IC hosts even larger subnets (i.e., 40 machines). All subnets are geo-replicated, i.e., are composed of machines running on multiple continents – the Americas, Europe, Asia. Our results are depicted in Table 3.

In contrast to other experiments we execute requests with insignificant execution overhead, so we can safely attribute the latency overhead to other layers. A geo-replicated subnet is able to run ∼78K queries per second with a latency of 50ms-200ms, given by differences in geographic location of client and targeted IC node. Since no coordination among nodes is needed for query execution, we can safely attribute this latency to the networking layers. In terms of updates (stateful and replicated execution), a geo-replicated subnet is able to serve 950 updates per second for a latency of 1-4s (which

Op	Throughput (ops / s)	Latency (s)	Overheads
Query	78,000	0.05-0.2	Networking
Update	950	1-4	Networking, Consensus, Replicated Execution, Statefulness

Table 3: End-to-End performance for the two operations supported by the IC.

includes networking, consensus and replication overheads). Note that this latency is comparable to the top-3 serverless platforms cold starts [54].

5 Related Work

The IC builds on fruitful years of research at many levels: from consensus, to peer-to-peer networking, cryptographic protocols, blockchain, and operating systems. We limit our discussion to blockchain-related technology and large-scale systems making use of it, and the value of opening up and discussing data from large-scale operational systems.

Blockchain Execution Environments. It has become a mantra that blockchains are slow. Just like for the IC, others have investigated ways in which computations and transactions running atop blockchains can be sped up. These are related to either speeding up consensus [12, 52], using software transactional memory [25,46,47], enforcing determinism and ordering [34, 52], or optimizing execution layers [2]. The performance evaluation in these works relies on synthetic workloads in test environments. To the best of our knowledge, this paper is the first to report on the performance of the execution environment of a real-world blockchain deployment.

Operational Systems and Data. Next to the more traditional workloads, such as high-performance scientific computing [20], analytics [4], cluster workloads [45], recently data centers started providing Blockchain-as-a-service offerings [23]. As Amvrosiadis et al. point out [3] data set diversity is key to understand the characteristics of workloads and to tailor new resource management schemes. The community recognizes and emphasizes the need of analyzing operational systems, such as the Microsoft Serverless platform [49], CloudLab [19], or the evolution of the Google data center network [40]. We believe our article adds significant data and insight on the design, operation and growth of systems that offer general-purpose computation capabilities on top of blockchain platforms.

6 Conclusion

The Internet Computer overcomes traditional blockchain limitations with respect to speed, storage costs, and computational capacity. We demonstrated how the novel design of the IC, coupled with solving low-level systems challenges enables decentralized stateful serverless. In particular, we presented an in-depth description of the execution layer of the IC followed by an evaluation of operational and performance data over real-world workloads as well as compute and memory-intensive benchmarks.

A Appendix – Scheduler Analysis

Notation For a vector $\mathbf{v}$ we write $\mathbf{v}_j$ for the j'th entry in $\mathbf{v}$. By overloading notation, we write $\mathbf{e}_j$ for the unit vector with 1 on the j'th position and 0 everywhere else. We write $|\mathbf{v}|$ for $\sum_j \mathbf{v}_j$ – for vectors with positive entries $|\cdot|$ corresponds to $|\cdot|_1$.

For a set S we write $|S|$ for its size. For a real number x we write $|x|$ for its absolute value. We write $x \leftarrow a$ for assigning to variable x value a. If S is a set, we write $x \leftarrow S$ for a deterministic way of assigning a value $s \in S$ to variable x.

Problem statement An allocation for t canisters is represented by a vector $\mathbf{a} = (a_1, a_2, \ldots, a_t)$, a vector in $\{1,2,\ldots,v\}^t$ for some v. Given an allocation vector $\mathbf{a} = (a_1, a_2, \ldots, a_t)$, we define a deterministic (stateful) scheduling algorithm which, for each round $k \in \mathbb{N}$ outputs some index $sch(k) \in \{1,2,\ldots,t\}$, or equivalently, some unit vector $\mathbf{e}_{j^*}$ (with $j^* \in \{1,2,\ldots,t\}$)[1].

Intuitively, a good scheduler approximates the allocation vector well, i.e. for large enough k it outputs j a number of times proportional to its allocation. We formalize this intuition as follows.

[1] To simplify notation, we ignore that the scheduler is stateful

For each $k \in \mathbb{N}$ and $i \in \{1,2,\ldots,t\}$ let $idxs(k,i) = \{j \mid j \leq k, sch(j) = i\}$ the set of indexes j such that i was scheduled in round j (i.e. $s(j) = i$). For a good scheduler, the quantity

$$\left| \frac{|idxs(k,i)|}{k} - \frac{a_i}{|a|} \right|$$

is "small" for all large enough k. Informally, the above relation states that the scheduler has allocated k rounds proportional to the desired allocation.

Scheduler description Given an allocation vector $\mathbf{a}$, we define the following scheduler. The state of the scheduler at step k is given by vectors $\mathbf{d}(k), \mathbf{p}(k), \mathbf{s}(k)$ defined as follows[2].

The initial state is $\mathbf{d}(0) = \mathbf{s}(0) = (0,0,\ldots,0)$. For $k \geq 1$ define:

$$\begin{cases} \mathbf{p}(k) = \mathbf{d}(k-1) + \mathbf{a} \\ j^* \leftarrow \{j \mid \mathbf{p}_j(k) \geq \mathbf{p}_l(k),\ \forall l \in \{1,2,\ldots,t\}\} \\ \mathbf{s}(k) = \mathbf{s}(k-1) + \mathbf{e}_{j^*}, \\ \mathbf{d}(k) = \mathbf{p}(k) - \mathbf{e}_{j^*} \cdot |\mathbf{a}| \\ sch(k) = \mathbf{e}_{j^*} \end{cases}$$

Analysis The following lemma states some invariants that hold throughout the execution of the scheduler.

Lemma A.1. *For any $k \in \mathbb{N}$ it holds that:*

$$|\mathbf{d}(k)| = 0$$

For any $k \in \mathbb{N}^*$ it holds that:

$$|\mathbf{p}| = |\mathbf{a}|$$

Proof. We prove the invariant holds true for $\mathbf{d}$ by induction on k. The invariant for $\mathbf{p}$ follows immediately.

Base case For $k = 0$ we have that $\mathbf{d}(0) = (0,0,\ldots,0)$ so the invariant holds trivially.

Induction step By definition,

$$\mathbf{d}(k) = \mathbf{d}(k-1) + \mathbf{a} - \mathbf{e}_{j^*} \cdot |\mathbf{a}|$$

for some $j^* \in \{1,2,\ldots,t\}$. We then get that:

$$|\mathbf{d}(k)| = \left|\mathbf{d}(k-1) + \mathbf{a} - \mathbf{e}_{j^*}\right| = 0 + |\mathbf{a}| - |\mathbf{a}| = 0$$

□

The following lemma establishes a relation between $\mathbf{d}$ and $\mathbf{s}$. Informally, the relation says that $\mathbf{s}(k)$ is an approximation of $k \cdot \frac{\mathbf{a}}{|\mathbf{a}|}$ – the quality of the approximation is given by the entries in $\mathbf{d}$.

Lemma A.2. *For any $k \in \mathbb{N}$ it holds that:*

$$\mathbf{d}(k) = k \cdot \mathbf{a} - \mathbf{s}(k) \cdot |\mathbf{a}|$$

Proof. Proof by induction.

[2] In fact $\mathbf{p}$ is explicitly maintained only for convenience of analysis; it can be reconstructed from $\mathbf{d}, \mathbf{s}$ and $\mathbf{a}$

Base case For $k = 0$ we have that $\mathbf{d}(k) = \mathbf{s}(k) = (0, 0, \ldots, 0)$ so the equality holds trivially.

Induction step Assume it holds for $k-1$, i.e. $\mathbf{d}(k-1) = (k-1) \cdot \mathbf{a} - \mathbf{s}(k-1) \cdot |\mathbf{a}|$. By definition, $\mathbf{d}(k) = \mathbf{d}(k-1) + \mathbf{a} - \mathbf{e}_{j^*} \cdot |\mathbf{a}|$ for some j^*. From the induction step, this can be rewritten as

$$\begin{aligned} \mathbf{d}(k) &= (k-1) \cdot \mathbf{a} - \mathbf{s}(k-1) \cdot |\mathbf{a}| + \mathbf{a} - \mathbf{e}_{j^*} \cdot |\mathbf{a}| \\ &= k \cdot \mathbf{a} - \mathbf{s}(k) \cdot |\mathbf{a}| \end{aligned}$$

□

The following lemma establishes a lower bound on the the debt which processes can accumulate throughout their lifetime.

Lemma A.3. *For any $k \in \mathbb{N}$ and $j \in \{1, 2, \ldots, t\}$ it holds that:*

$$1 - |\mathbf{a}| \leq \mathbf{d}_j(k)$$

Proof. Proof by induction.

Inductive step The inequality trivially holds for $j \neq j^*$ since by definition (and the induction hypothesis):

$$\mathbf{d}_j(k) = \mathbf{d}_j(k-1) + \mathbf{a}_j \geq \mathbf{d}_j(k-1) \geq 1 - |\mathbf{a}|$$

To prove the bound for j^*, notice that by Lemma A.1, for any $k \in \mathbb{N}$:

$$\sum_{j=1}^{t} \mathbf{d}_j(k) + \mathbf{a}_j(k) = |\mathbf{a}|$$

Since j^* is such that $\mathbf{d}_{j^*}(k-1) + \mathbf{a}_{j^*} \geq \mathbf{d}_j(k-1) + \mathbf{a}_j$ for all j and $t \leq |\mathbf{a}|$, it holds that

$$\mathbf{d}_{j^*}(k-1) + \mathbf{a}_{j^*} \geq \frac{|\mathbf{a}|}{t} \geq 1.$$

So, we have that

$$\begin{aligned} \mathbf{d}_{j^*}(k) &= \mathbf{d}_{j^*}(k-1) + \mathbf{a}_{j^*} - (\mathbf{e}_{j^*} \cdot |\mathbf{a}|)_{j^*} \\ &\geq 1 - |\mathbf{a}| \end{aligned}$$

□

Finally, the following theorem establishes that in $|\mathbf{a}|$ rounds, job i is scheduled $\mathbf{a}_i$ times.

Theorem A.4.

$$\mathbf{s}(|\mathbf{a}|) = \mathbf{a}$$

Proof. By Lemma A.2, it holds that:

$$\mathbf{d}(|\mathbf{a}|) = |\mathbf{a}| \cdot \mathbf{a} - \mathbf{s}(|\mathbf{a}|) \cdot |\mathbf{a}| = (\mathbf{a} - \mathbf{s}(|\mathbf{a}|)) \cdot |\mathbf{a}|$$

Since $\mathbf{d}_{j^*} \geq 1 - |\mathbf{a}|$ (by Lemma A.3) and $\mathbf{d}_j(|\mathbf{a}|)$ is an integer divisible by $|\mathbf{a}|$ (by the above equality) then, it holds that $\mathbf{d}_j(k) \geq 0$. Since $|\mathbf{d}(|\mathbf{a}|)| = 0$ then $\mathbf{d}(|\mathbf{a}|) = (0, 0, \ldots, 0)$ and the desired equality follows.

□

PINOLO: Detecting Logical Bugs in Database Management Systems with Approximate Query Synthesis

Abstract

DBMSs (Database Management Systems) are essential in modern enterprise software. Thus, ensuring the correctness of DBMSs is critical for enterprise applications. Among various kinds of bugs, logical bugs, which make a DBMS return an incorrect result set for a given SQL query, are the most challenging for detection since they typically do not result in apparent manifestations (e.g., crashes) and are likely to go unnoticed by users. The key challenge of detecting logical bugs is the test oracle problem, i.e., how to automatically characterize the expected results for a given query. The state-of-the-art approaches focus on generating the equivalent forms of queries via the customized rules, which rewrite a seed query to achieve the equivalent transformation. This dramatically limits the forms of SQL queries fed to the DBMS and thus leads to the under-reporting of many deeply-hidden logical bugs. In this paper, we propose a novel approach, PINOLO, to constructing a test oracle for logical bugs. Instead of generating the equivalent mutants of a seed query, our idea is to synthesize the queries that theoretically should return a superset or a subset of the result set of the seed query, forming the over-approximations or under-approximations of the seed query. A logical bug is detected if the result set returned by our synthesized query does not follow the expected approximation relation. We implemented our idea as a DBMS testing system and evaluated it on four widely-used DBMSs: MySQL, MariaDB, TiDB, and OceanBase. By the time of writing, PINOLO has found 41 unique logical bugs in these DBMSs, 39 of which have been confirmed by developers.

1 Introduction

Database Management Systems (DBMSs) are widely used as a key component in modern enterprise software. Their correctness and reliability are critical for many enterprise applications, such as online banking, e-shopping, e-payment, etc. Therefore, DBMS testing has attracted considerable attention in the industry [14, 23, 38, 41] and academia [10, 34–36]. For example, fuzzing, a widely-used testing technique, has been extensively applied to DBMSs [14, 38], showing its effectiveness in detecting crash bugs. However, as another typical kind of bug, logical bugs would cause DBMSs to return an incorrect result set for a given query but can easily go unnoticed by developers since they would not behave with apparent manifestations like system crash.

The predominant approach to detecting logical bugs consists of various automatic testing techniques. However, designing effective automatic testing techniques is non-trivial. One of the fundamental technical challenges is to characterize a correct result concerning a given query for comparison, which is a classical problem in testing, i.e., *test oracle problem* [12]. To tackle this challenge, researchers have proposed various ways to obtain the test oracle. The first category is based on differential testing [39]. It provides the same generated SQL query to multiple DBMSs for execution and resorts to the querying results to construct the test oracle. More concretely, the inconsistency among the result sets returned by different DBMSs indicates the presence of a potential logical bug. However, as pointed out by the existing studies [34, 36, 39], differential testing cannot be applied when a generated SQL query cannot comply with the grammar of all selected DBMSs or contains operations that have different semantics between different DBMSs. Although all the DBMSs support the common core syntax of SQL, each of them provides various extensions and forms its own dialect [39], which dramatically limits the generality of differential testing.

The second category is the oracle-guided synthesis approach [36], which does not rely on multiple DBMSs and thus mitigates the limitation of differential testing. It first specifies a randomly-selected row in a database table, namely, *pivot row*, as the test oracle and then synthesizes the query whose result set should contain this pivot row. The failure of fetching the row with the synthesized query evidences a potential bug underlying the tested DBMS. However, since such an approach considers only one row each time and the synthesis merely focuses on the *where* clause generation, it would miss logical bugs in various scenarios [34, 35]. For example, those rows that are duplicated to the pivot row are wrongly fetched or omitted, or the values processed by performing operators on the original row data are mistakenly computed and returned. Moreover, as pointed out by some recent studies [34, 35], the synthesis requires domain knowledge of the database dialect's supported operators and functions, and thus the implementation effort is high.

The third category is the metamorphic testing based approach [34, 35]. It first transforms a given query q into another query q' such that their querying results satisfy a specific relation, which is referred to as a *metamorphic relation*. The violation of the metamorphic relation upon the querying results indicates the wrong result of evaluating q or q'. For example, TLP [35] decomposes a query q into three partitioning sub-queries, each of which computes the result sets for a boolean predicate to be evaluated as **TRUE**, **FALSE**, and **NULL**, respectively, and then constructs an equivalent query q' by performing the union operation on these three sub-queries. NoREC [34] transforms an optimized version of a query into a non-optimized one by the customized rule, e.g., changing "**SELECT** * **FROM** t **WHERE** p" into "**SELECT** (p **IS TRUE**) **FROM** t." Compared with the aforementioned two categories of approaches, metamorphic testing based approaches are much more lightweight to implement and have been proven to be more effective in detecting logical bugs [34, 35]. However, existing studies instantiate the metamorphic relations as equivalent relations, which are still insufficient to detect many deeply-hidden bugs. This is because it is highly possible that, owing to the limited search space of mutations, the pair of equivalent queries would still share common buggy operators and functions and eventually return the same results. In such a case, the oracle from the equivalent query cannot provide any hint to detect logical bugs.

In this work, we present a new metamorphic testing based approach, named PINOLO, to detect logical bugs. Our idea to instantiate the metamorphic relation originates from the observation that the querying result of a given query is essentially a multi-set of tuples. The inclusion relation between the multi-sets, which is the foundation of set theory, is a good choice to characterize the metamorphic relation of two queries. Therefore, we try to mutate a given seed query to obtain the queries over or under-approximating it, of which the querying results are the superset or the subset of the one of the seed query. Based on the approximation relations, we can reveal a logical bug if the actual results violate the approximation relation. To systematically synthesize the two kinds of mutants, we introduce a series of approximate mutators, e.g., strengthening or weakening the predicates in *where* clauses, and propose an approximate query synthesis algorithm to generate the queries that have the over and under-approximation relations with the seed queries. Benefiting from our approximation relation and flexible approximate mutators, PINOLO can seize more opportunities to reveal logical bugs, as it can perform more aggressive mutations over the seed queries (e.g., discarding several functions), which explore the mutants of a seed query thoroughly. We also prove the correctness of our test oracle to solidify the theoretical foundation of PINOLO.

We implemented our idea as a DBMS testing system and evaluated it using four widely-used and comprehensively tested DBMSs, including MySQL, MariaDB, TiDB, and OceanBase. Compared with the state-of-the-art approaches, PINOLO is more effective in detecting logical bugs. During the 24-hour run, PINOLO can find 41 unique logical bugs, while the three state-of-the-art approaches together can only discover 14 bugs. Upon the submission, 39 out of 41 bugs have been confirmed by developers, showing the great impact of PINOLO on the four real-world DBMSs. In summary, this paper makes the following contributions:

- We introduce the concept of the approximation relation and a series of approximate mutators to resolve the test oracle problem in testing logical bugs in DBMSs.
- We propose a systematic metamorphic testing based approach PINOLO to detecting logical bugs in DBMSs, which leverages the approximate mutators to synthesize approximate queries for a seed query.
- We implement our idea as a DBMS testing system and systematically evaluate it using four widely-used DBMSs. The evaluation results demonstrate the effectiveness of PINOLO in detecting logical bugs.

2 Background

As discussed in § 1, this paper focuses on finding logical bugs in the DBMSs. This section provides several preliminaries as the background, including the concept of the DBMS, the logical bugs in the DBMSs, and the metamorphic testing based approaches for DBMS testing.

2.1 Database Management Systems

The DBMSs are widely used in many modern software systems. They enable the developers to perform various data manipulations, namely insertion, removal, update and search, according to their demands. Here, we concentrate on the relational DBMSs in our work as our target, which are one typical kind of DBMSs. Basically, they are developed on top of the relational model (RM) [7], where data is organized as a collection of tables. Each table is essentially a relation storing the records inserted by the developers, which is a multi-set of tuples from a mathematical perspective. Finally, a database in the DBMS consists of one or more tables, storing the data in a relational manner. In this paper, we use the DBMSs to indicate the relational DBMSs without introducing ambiguity.

There have been an increasing number of DBMSs released by the industry and academia, including MySQL, MariaDB, TiDB, and OceanBase [9, 22, 26, 29]. To interact with DBMSs, SQL [3], which is the most commonly used domain-specific language to store and operate data, was proposed. When retrieving data, developers write SQL queries and send them to DBMSs to get querying results. Each querying result is a multi-set of tuples indicating specific attributes of queried records in the tables. Overall, DBMSs provide an intuitive and flexible way to store and retrieve information, promoting the prosperity of database-backed applications in the real world.

```
--create a table
CREATE TABLE t ( c1 FLOAT );
INSERT INTO t VALUES (-1);

-- queries
(SELECT 1 FROM t WHERE COT(0.2)=0)
UNION ALL (SELECT (BINARY c1 | 0) FROM t);
--result: {0}

(SELECT 1 FROM t WHERE TRUE)
UNION ALL (SELECT (BINARY c1 | 0) FROM t);
--result: {18446744074709551615, 1}

(SELECT 1 FROM t WHERE FALSE)
UNION ALL (SELECT (BINARY c1 | 0) FROM t);
--result: {18446744074709551615}
```

Figure 1: An example of a logical bug in OceanBase.

2.2 Logical Bugs in DBMSs

With the prevalent usage of DBMSs in real-world industrial scenarios, their reliability and correctness have recently been paid increasingly more attention. As complex software systems, DBMSs can have bugs that cause crashes and other unexpected behaviors. Remarkably, the logical bugs are one of the most tricky bugs underlying the DBMSs. When a developer writes a SQL query and executes it upon a database, the returned result may be erroneous, which means that the semantics of the query is not correctly evaluated.

Figure 1 shows a logical bug in OceanBase [25]. We simplify the creation of the table for better demonstration. Specifically, the first query selects the constant value 1 from the table *t* if the cotangent of 0.2 is equal to 0, while the second and the third queries replace the predicates in the where clauses with 1 and 0, respectively. Obviously, the querying result of the first query should be a subset of the one of the second query, and meanwhile, it subsumes the querying result of the third one. However, the actual querying results do not conform to such inclusion relations. As confirmed by the developers of OceanBase, the querying result of the first query is incorrect, which is caused by the simultaneous usage of the set operator **UNION ALL** and the functions **COT** and **BINARY**.

As shown by the above example, logical bugs are more mysterious than system crashes, which have apparent manifestations. In contrast, people are often unaware of logical bugs in DBMSs. Typically, the developers of database-backed applications may realize the abnormal data retrieved from the database, while they are still uncertain whether their application is wrongly implemented or a logical bug of the DBMS is triggered. Therefore, detecting a logical bug in the DBMS has been typically recognized as a problem with both high impact and significant technical challenges.

2.3 Metamorphic Testing

Recent years have witnessed tremendous efforts in resolving the test oracle for logical bug detection in the DBMSs. Notably, the metamorphic testing based approach has been recognized to be state-of-the-art in DBMS testing for logical bug detection [35, 37]. Generally, the metamorphic testing based techniques attempt to construct multiple SQL queries of which the querying results have a specific relation, namely a metamorphic relation. If the querying results violate the metamorphic relation, we can have the confidence that at least one of the queries triggers a logical bug in the tested DBMS. For example, NoREC [34] transforms a query into a form in which the DBMS does not apply optimizations, which yields the test oracle that the two queries should make the tested DBMS return the same result. Besides, TLP [35] gets the equivalent query result by splitting the input query into several sub-queries and merging the results of sub-queries into one. When adapting the metamorphic testing, they take randomly-generated queries as the seed queries and then transform them into other queries to ensure the metamorphic relations, which automates the testing process for logical bug detection.

Unfortunately, the existing effort has not resolved the test oracle problem perfectly. To the best of our knowledge, previous studies only leverage the equivalent transformations, which are supported by the tested DBMS or conducted by their approaches, leaving the functions and operators in the query unchanged. This greatly limits their approaches to exploring the code of the tested DBMSs and thus reduces the chance of finding logical bugs. For example, the logical bug shown in Figure 1 can not be revealed by NoREC [34] and TLP [35], as the transformations preserve all the operators and the functions, still triggering the buggy evaluation process. To improve the capability of the metamorphic testing in finding logical bugs in the DBMSs, we propose a new DBMS testing approach in this work, which relaxes the equivalence relation with a less restrictive metamorphic relation, finally supporting finding more insightful logical bugs.

3 Approximate Query Synthesis

We propose the approximate query synthesis technique PINOLO[1] for detecting logical bugs in the DBMSs. Basically, our insight comes from the intuition that the mutation of specific grammatical constructs can induce the approximation relation between the original query and the mutated one, which can be adopted as the oracle of DBMS testing. Specifically, we start from a randomly generated seed query and mutate several constructs, such as predicates in where clauses, comparison operators, and set operators. Based on the mutation upon any seed query, we can successfully synthesize

[1] Pinolo is the English name of a cartoon character named Pinocchio. Once he tells a lie, his nose will become longer. The relative change in its length is the evidence to verify whether he is lying.

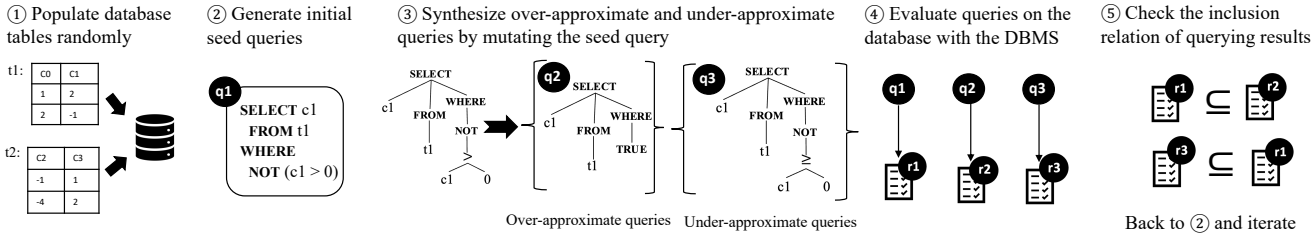

Figure 2: The workflow of PINOLO

a series of queries, of which the return results are the superset or the subset of the result of the seed query. If the seed query and a synthesized query do not produce the results with the expected inclusion relation, we safely conclude the existence of a bug underlying the DBMS. This section presents the system design of PINOLO to show how it resolves the oracle problem in detecting logical bugs in the DBMS and demonstrates the details of mutation-based query synthesis.

3.1 Approach Overview

We demonstrate the overall workflow of PINOLO in Figure 2. In the pre-processing phase, we populate several tables in a database by generating table records randomly, which leverages the existing DBMS random testing technique [27]. After preparing the database, PINOLO first generates a syntactically valid SQL query as the seed query. Then it parses the seed query and traverses its AST to determine whether each grammatical construct can be mutated. The mutations can make PINOLO synthesize several new queries of which the querying results have the inclusion relation with the one of the seed query, achieving the over or under-approximation for the seed query. Based on the synthesized queries and their approximation relation with the seed query, we further evaluate them on the populated database. Any violation of the approximation relation reveals a potential logical bug of the DBMS as at least one of the querying results of the seed query and the synthesized one is incorrect.

The critical component of PINOLO is to automatically generate the pairs of SQL queries with known approximation relations. To show more technical details, we first propose the approximation relation for SQL queries (§ 3.2), and then demonstrate how to synthesize the queries with approximation relations based on mutations (§ 3.3 and § 3.4). We summarize our design and highlight the advantage of PINOLO (§ 3.5).

3.2 SQL Query Approximation

In this work, we concentrate on the syntax of SQL queries shown in Figure 3. Basically, a SQL query can be a select-from-where query or the result of the set operation upon subqueries. The logical connectives and arithmetic operators make the query support depicting sophisticated predicates and

$$
\begin{aligned}

\textit{Table } T &:= t \qquad \textit{Attr } C := c
\end{aligned}
$$

Figure 3: The syntax of SQL queries

quantities. Without the loss of generality, we only instantiate an arithmetic expression with an integer literal, an attribute, the result of an arithmetic operator, and the result of a SQL built-in function. Notably, we can also utilize the keywords **ALL** and **ANY** to support advanced comparison between an arithmetic expression and the numeric attributes.

To resolve the test oracle problem in the DBMS testing, we follow the spirit of metamorphic testing and propose the approximation relations among the SQL queries. In what follows, we first formulate the concept of the approximation relation and then characterize the form of the SQL queries that can have approximation relations with other queries.

Definition 3.1. (Approximation Relation) Given a database D, a SQL query q_1 is the over-approximation of q_2 over D, denoted by $q_2 \trianglelefteq_D q_1$, if and only if $R(q_2, D) \subseteq R(q_1, D)$. Here, $R(q, D)$ is the return result set of q upon the database D, which is essentially a multi-set. $\subseteq$ is the inclusion relation between two multi-sets. We say q_2 is the under-approximation of q_1 over D, denoted by $q_1 \trianglerighteq_D q_2$, if and only if $q_2 \trianglelefteq_D q_1$.

Intuitively, the approximation relation between two SQL queries indicates the inclusion relation of their querying results. If we construct a pair of SQL queries (q_1, q_2) such that

$q_1 \trianglelefteq_D q_2$ or $q_1 \trianglerighteq_D q_2$, we can utilize the approximation relation as an instantiation of the metamorphic relation, which serves as the test oracle for DBMS testing.

Example 3.1. Assume that we have a database $D = \{\text{t1}\}$, where the schema of t1 is (c1) and $\text{t1} = \{(-1),(0),(1)\}$. Consider the following three queries.

q_1 : **SELECT** c1 **FROM** t1 **WHERE NOT** $(\text{c1} > 0)$

q_2 : **SELECT** $c1$ **FROM** t1 **WHERE TRUE**

q_3 : **SELECT** c1 **FROM** t1 **WHERE NOT** $(\text{c1} \geq 0)$

The first query q_1 selects all the non-positive values of the attribute c1 of the table named t1. The second query q_2 selects all the values of the attribute c1. The third query q_3 selects all the values of the attribute c1 that are not large than or equal to 0. Obviously, their querying results, denoted by $R(q_1,D)$, $R(q_2,D)$, and $R(q_3,D)$, respectively, have the relation that $R(q_3,D) \subseteq R(q_1,D) \subseteq R(q_2,D)$, implying $q_3 \trianglelefteq_D q_1 \trianglelefteq_D q_2$, i.e., $q_2 \trianglerighteq_D q_1 \trianglerighteq_D q_3$.

To sum up, the syntax shown in Figure 3 characterizes the search space of constructing a pair of queries with an approximation relation. Given a seed query in the syntax, we can always obtain a query upon a smaller/larger relation or with a stronger/weaker where clause, which induces a subset/superset of the return result of the seed query, achieving the under/over-approximation of the given seed query. Therefore, it is feasible to automatically generate the queries that have the approximation relation with a specific query q by mutating the query q, which trims/enlarges the relation or strengthens/weakens the predicate in the seed query. In this way, we can resolve the test oracle problem by synthesizing queries with approximation relations.

3.3 Approximate Mutators

Based on the key insight in § 3.2, we propose to resolve the test oracle problem by constructing SQL queries with the approximation relation. Specifically, we can always obtain the approximation relation if we transform a query to another one preserving the set inclusion relation of the relations and the implication relation of the predicates. According to high-level intuition, we propose the concept of the approximate mutator as follows, which is the fundamental ingredient of the approximate query synthesis in § 3.4.

Definition 3.2. (Approximate Mutator) An approximate mutator is a mapping from a SQL query q_1 to a query q_2 such that $q_1 \trianglelefteq_D q_2$ or $q_1 \trianglerighteq_D q_2$.

Essentially, an approximate mutator transforms a SQL query into another such that they have the over or under-approximation relation. We notice that a relation can be derived from other relations, e.g., the results of a select-from-where query and set operations, while compound and atomic logical expressions pose restrictions over relations. Therefore, we propose three categories of approximate mutators, which are shown in Table 1.

Table 1: Some representative approximate mutators. Transforming the construct **C1** into **C2** achieves the under-approximation, while transforming the construct **C2** into **C1** achieves the over-approximation.

Type	C1	C2
Relation	**SELECT** a **FROM** r	**SELECT DISTINCT** a **FROM** r
	r_1 **UNION ALL** r_2	r_1 **UNION** r_2
	r_1 **UNION** r_2	r_1
	r_1 **UNION** r_2	r_1 **INTERSECT** r_2
	r_1	r_1 **MINUS** r_2
Predicate	p	**FALSE**
	p **IS** ℓ_b	**FALSE**
	p **IS NOT** ℓ_b	**FALSE**
	TRUE	p
	TRUE	p **IS** ℓ_b
	TRUE	p **IS NOT** ℓ_b
Comparison expression	$e_{a1} \leq e_{a2}$	$e_{a1} = e_{a2}$
	$e_{a1} \geq e_{a2}$	$e_{a1} = e_{a2}$
	$e_{a1} \leq e_{a2}$	$e_{a1} < e_{a2}$
	$e_{a1} \geq e_{a2}$	$e_{a1} > e_{a2}$
	$e_{a1} \neq e_{a2}$	$e_{a1} < e_{a2}$
	$e_{a1} \neq e_{a2}$	$e_{a1} > e_{a2}$
	$e \odot$ **ANY**(r)	$e \odot$ **ALL**(r)

Concretely, the mutators alter the relations and predicates in a SQL query, and meanwhile, mutate the comparison expressions, which are often atomic constraints in a predicate, achieving the approximation relation between the queries before and after the mutation. For each row, if we replace the SQL grammatical construct in the second column with the one in the third column, we can obtain a query that under-approximates the original one; if we replace the one in the third column with the one in the second column, we can obtain a new query that over-approximates the original query. Now we provide more explanations on the approximate mutators.

- **Mutating relations.** Using **DISTINCT** in a select-from-where query removes the duplicate values in the querying result, which under-approximates the original query. The set operator **UNION ALL** preserves the duplicate values and the operator **UNION** does not, so replacing the former with the latter ensures the under-approximation relation between the new query and the original one. Other mutators altering relations are fairly simple.
- **Mutating predicates.** For an arbitrary predicate p, we can strengthen it by mutating it to **FALSE** and weaken it by mutating it to **TRUE**. The logical implication would pose more or less restrictive constrain upon the tuples in the relations, which finally achieve the under-approximation or over-approximation, respectively.
- **Mutating comparison expressions.** For each comparison expression as an atomic constraint, we can alter its comparison operator to strengthen or weaken the constraint induced by the expression. For example, replacing

$\geq$ with $=$ makes the new expression more restrictive than the original one. Also, mutating the keyword **ANY** with **ALL** also induces a stronger predicate in the query.

Example 3.2. For the simpler SQL query q_1 in Example 3.1, we can mutate it by replacing the negation with **TRUE** and altering $>$ to $\geq$, which yield two queries q_2 and q_3 that over-approximate q_1, respectively. We can further consider a more complex SQL query as follows.

$\widetilde{q}$: **SELECT** 1 **FROM** t1 **WHERE**
(**NOT** (**FROM_DAYS**(1) = **ALL**(**SELECT** c1 **FROM** t1)))

We can mutate the predicate in the where clause of $\widetilde{q}$ to **TRUE** to over-approximate the query $\widetilde{q}$. Also, mutating **ALL** to **ANY** weakens the comparison expression in the negation, and thus, strengthens the predicate in the where clause, yielding an under-approximation of the query $\widetilde{q}$.

Notably, the approximate mutator proposed in this section is a general concept. The mutators shown in Table 1 are just several instances of the mutators, while we can further define more mutators to enable us to obtain the queries with approximation relations more flexibly. Actually, we provide a systematic framework to instantiate such mutators in these categories. The complete list of the instantiated mutators, including REGEXP and IN operators, has been published online [31].

3.4 Mutation-based Query Synthesis

Leveraging the approximate mutators in § 3.3, we can finally propose the approximate query synthesis algorithm by applying the mutators upon a seed query. This section demonstrates the technical details of the synthesis algorithm on how to generate two sets of SQL queries that over-approximate and under-approximate a seed query, respectively. We also formulate our test oracle with a theorem as the theoretical guarantee for the approximation relations among the seed query and the synthesized ones.

Algorithm 1 shows the mutation-based query synthesis algorithm. Initially, it takes a seed query as the input, parses the query, and generates an AST of the query to facilitate further mutations (Line 2). Basically, it traverses the AST in a top-down manner, during which it identifies the potential SQL constructs for the mutation (Line 3–Line 4). Consider synthesizing the queries that under-approximate the seed query as an example, where *kind* is set to be *UNDER* (Line 4). Specifically, it processes each SQL construct in two ways.

- When encountering the SQL construct (r_1 **MINUS** r_2), it attempts to trim the relation r_1 and enlarge the relation r_2 so that the difference of the two relations can be trimmed (Line 12–Line 15). Similarly, it strengthens the predicate p for (**NOT** p) and (p **IS NOT TRUE**), and also enlarges the relation r for the comparison expression $e \odot$ **ALL**(r) (Line 16–Line 24).

Algorithm 1: Mutation-based query synthesis

```
1  Procedure synthesizeApproximateQueries(q):
2      τ ← parseQuery(q) ;
3      Q_over ← mutate(q, τ, OVER) ;
4      Q_under ← mutate(q, τ, UNDER) ;
5      return (q, Q_over, Q_under);
6  Procedure mutate(u, τ, kind):
7      if kind == OVER then
8          negKind ← UNDER;
9      else
10         negKind ← OVER;
11     S ← applyApproxMutator(q, τ, kind) ∪ {q};
12     if u : (r1 MINUS r2) then
13         S'1 ← mutate(r1, getAST(r1), kind);
14         S'2 ← mutate(r2, getAST(r2), negKind);
15         S ← S ∪ {r'1 MINUS r'2 | r'1 ∈ S'1, r'2 ∈ S'2} ;
16     else if u : (NOT p) then
17         S' ← mutate(p, getAST(p), negKind);
18         S ← S ∪ {NOT p' | p' ∈ S'};
19     else if u : (p IS NOT TRUE) then
20         S' ← mutate(p, getAST(p), negKind);
21         S ← S ∪ {p' IS NOT TRUE | p' ∈ S'};
22     else if u : e ⊙ ALL(r) then
23         S' ← mutate(r, getAST(r), negKind);
24         S ← S ∪ {e ⊙ ALL(r') | r' ∈ S'} ;
25     else
26         Γ ← getSubASTs(u) ;
27         Π ← ⊥;
28         foreach (v, τ_v) in Γ
29             Π[(v, τ_v)] ← mutate(v, τ_v, kind);
30         S ← S ∪ concat(q, Γ, Π) ;
31     return S;
```

- For other SQL constructs, it trims each relation and strengthens each predicate and comparison expression appearing in the constructs. Lastly, it composes each mutated constructs together by the function *concat* to obtain the ASTs of the synthesized queries under-approximating the seed query (Line 26–Line 30).

By applying the approximate mutators during the AST traversal, Algorithm 1 finally synthesizes two sets of queries on the fly, which are syntactically valid and have the approximation relation with the seed query q.

Example 3.3. Consider the query $\widetilde{q}$ in Example 3.2 as the seed query. We show how to synthesize the queries that under-approximate $\widetilde{q}$. After generating its AST, which is shown by the leftmost tree in Figure 4, Algorithm 1 examines each SQL construct in a top-down manner. When encountering the predicate in the where clause, we can mutate the predicate, which is a logical negation, to **FALSE**, or strengthen the predicate in the logical negation. For the latter case, we can further mutate the comparison expression in the negation to **TRUE**, mutate the comparison operator with $\geq$, or replace **ALL** with **ANY**, which finally weakens the logical negation. Finally, we can

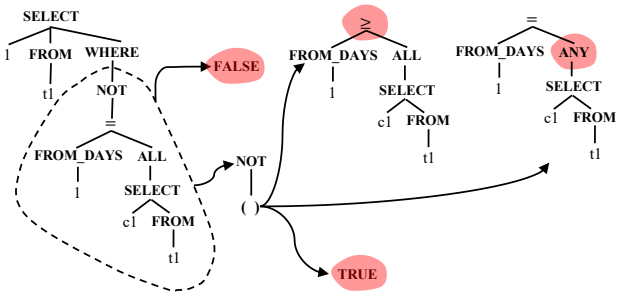

Figure 4: An example of synthesizing queries under-approximating the query $\widetilde{q}$

obtain four queries that under-approximate $\widehat{q}$. Particularly, one of the synthesized queries is as follows:

$\widetilde{q}'$: **SELECT** 1 **FROM** t1 **WHERE**
(**NOT** (**FROM_DAYS**(1) $\geq$ **ALL**(**SELECT** c1 **FROM** t1)))

Fortunately, we find that $R(\widetilde{q}', D)$ is not subsumed by $R(\widetilde{q}, D)$, indicating that the querying result of $\widetilde{q}$ or $\widetilde{q}'$ is incorrect, which is confirmed by the developers of MySQL [21].

It is worth mentioning that we have to restrict the values in the database tables not to be null. Any comparison between a non-null value and a null value can introduce an unknown value of the comparison expression, denoted by **NULL** without the ambiguity, which is smaller than **TRUE** but larger than **FALSE** in the logical order. However, we can notice that the predicate (p **IS NULL**) evaluates to **FALSE**, **TRUE**, or **FALSE**, if p is **TRUE**, **NULL**, or **FALSE**, respectively, which indicates that strengthening or weakening the predicate p does not always strengthen or weaken the predicate p **IS NULL**. In this case, we cannot ensure the expected approximation relation between the seed query and the synthesized queries in Q_{over} and Q_{under}. Formally, we state the following theorem to formulate our test oracle.

Theorem 3.1. (Test Oracle) Assume that the database D does not contain any table storing null values. Taking the query q as a seed query, Algorithm 1 can always synthesize two sets of queries Q_{over} and Q_{under} such that:

- For any $q' \in Q_{over}$, we have $q \trianglelefteq_D q'$, i.e., $q' \trianglerighteq_D q$.
- For any $q' \in Q_{under}$, we have $q' \trianglelefteq_D q$, i.e., $q \trianglerighteq_D q'$.

To solidify the theoretical foundation of our test oracle, we sketch the proof of the theorem briefly. First, the fact that the database tables do not contain null values implies that the evaluation results of any expressions, including comparison expressions and predicates, are not evaluated to unknown values, and the intermediate relations, such as the results of the join and the union operator, do not contain null values. Second, it is trivial to prove that the approximate mutators applied to different constructs finally yield a weaker predicate or larger relation when *kind* is *OVER* in the absence of null values. A similar argument also holds when *kind* is *UNDER*. Therefore, we can prove the approximation relation between each synthesized query and the seed query based on the principle of structural induction.

3.5 Summary

PINOLO automates the DBMS testing via the approximate query synthesis, which discovers underlying logical bugs in the DBMSs. The syntax in Figure 3 ensures the syntactical validity of the seed queries, and furthermore, guarantees that the synthesized queries have valid SQL syntax. Meanwhile, our approximate mutators enable us to obtain the approximation relation between the seed query and the synthesized ones, which perfectly resolves the test oracle problem. Compared with the existing techniques [34–36], PINOLO considers more SQL features, such as set operators, arithmetic expressions, sub-queries, etc. The expressive syntax permits us to test the DBMS more thoroughly and discover more logical bugs reported in previous studies, which will be evidenced by our experiments. Besides, the approximate operators can aggressively mutate the seed query, which may remove the buggy operators and functions, revealing the logical bugs more thoroughly than existing techniques. Lastly, it is worth noting that PINOLO provides a general framework for discovering the logical bugs in the DBMS. We can further extend the syntax of SQL queries and instantiate more approximate mutators, which can promote the capability of discovering the logical bugs triggered by sophisticated SQL queries.

4 Implementation

We implemented our approach PINOLO as a DBMS testing system, which was written in GO with 8,055 lines of code. The source code of our tool is hosted in the github repository [2]. Next, we present more details of our implementation decisions that are important for the outcome of our experiments.

Database population. We randomly generate the database tables by leveraging an existing tool, GO-RANDGEN [27]. Following the best practice summarized in the prior study [36], we restrict the number of table records to be no more than 30. Besides, we randomly generate the tables with the same attributes, which makes the join operator yield a non-trivial result. Particularly, we avoid null values in any table, as the test oracle requires non-null values as a prerequisite, which is stated in Theorem 3.1.

Seed query generation and parsing. To generate seed queries as the input of our synthesis algorithm, we utilize GO-RANDGEN [27] to automatically produce seed SQL queries. Specifically, we use the general-purpose parser generator BISON [13] to write a context-free grammar file describing the SQL syntax with a series of production rules. We provide

[2] https://github.com/qaqcatz/impomysql.git

this grammar file to GO-RANDGEN, so that it can generate the queries by searching each production rule randomly. It then heuristically selects the terminal or non-terminal symbols to avoid exceeding the limitation of recursion. Moreover, we permit users to write embedded LUA code blocks in the grammar file to further restrict the form of seed queries, which can ensure the successful query execution, e.g., the number of columns in the two queries of **UNION** should be equal. To apply the approximate mutators to seed queries, we utilize another tool PINGCAP PARSER [28], which accepts the same context-free grammar as the one for the seed query generation, to generate ASTs of seed queries for the mutation.

Approximate mutator instantiation. As mentioned at the end of § 3.3, we instantiate a series of approximate mutators for the relations, predicates, and comparison expressions in a given query. Each approximate mutator consists of two SQL grammatical constructs, which indicate the construct after the over and under-approximation, respectively. To cover most features of DBMSs, we instantiate 25 approximate mutators in total, including the approximate mutators demonstrated in Table 1. Among them, 5, 6, and 14 approximate mutators correspond to the mutations of the relations, predicates, and comparison expressions, respectively. Apart from the approxmiate mutator in Table 1, we also include 7 mutators supporting **LIKE**, **REGEXP**, **IN**, and **BETWEEN**.

Bug report post-processing. After synthesizing queries, PINOLO obtains the querying results by evaluating queries on the populated database in the tested DBMSs. It is noted that inconsistent querying results frequently occur in our testing process. For example, during a 24-hour testing period, 46,772 inconsistent query pairs are generated for MySQL. The large number of such query pairs makes the process of confirming and fixing bugs quite verbose. To make the testing results easier to understand, we borrow the idea of *delta debugging* [56] to localize the root cause of the inconsistent returned results of each query pair. Specifically, we associate each problematic query pair with a release version of the under-test DBMS's code base, the earliest one where inconsistent query results appear. We denote such release version with respect to a given query pair as the bug-inducing version. Further, two bugs are considered the same if their bug-inducing versions are the same. Based on our interactions with DBMS developers, our bug reports and the release version's change lists can help developers pinpoint culprit updates easily.

5 Evaluation

To evaluate the performance of our approach PINOLO in detecting logical bugs in the popular real-world DBMSs, we design the following research questions:

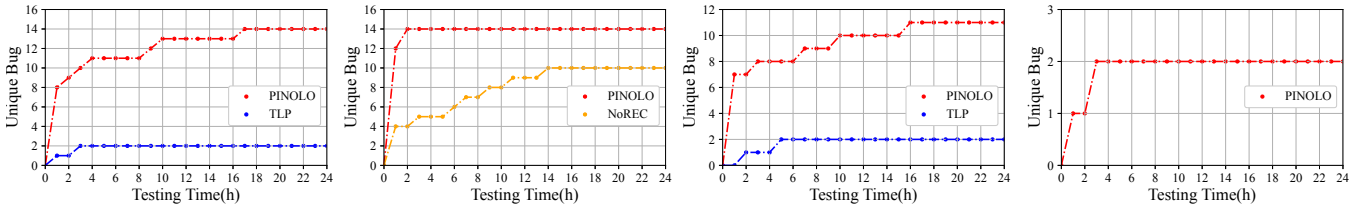
- **RQ1:** How many logical bugs in real-world DBMSs can be detected by PINOLO?
- **RQ2:** Can PINOLO outperform the state-of-the-art logical bug detection techniques?
- **RQ3:** How does the randomness introduced by the seed query generation affect the performance of PINOLO?

5.1 Experiment Setup

Environment. We conducted the experiments on one server with 104-cores Intel(R) Xeon(R) Gold 6230R CPU @ 2.10GHz and 500 GB memory. The server runs Ubuntu 18.04 system that uses Linux kernel version: 5.4.0-135-generic. To ensure fair comparisons, we allocated four threads for each DBMS testing in our following experiments.

Tested DBMS. Our focus was on testing four widely-used and large-scale open-source DBMSs: MySQL, MariaDB, TiDB, and OceanBase. There are two main reasons for the subject selection. First, these selected DBMSs are representative DBMSs from phenomenal open-source and/or commercial products: MySQL and MariaDB are the two most well-known open-source DBMSs; OceanBase is a mature commercial database product from Ant Group; TiDB is developed by PingCap Inc. They are also commonly used in the evaluation of previous studies [34–36]. Moreover, we admit and discuss potential limitations introduced by our selection of DBMS systems in § 6. Second, we chose a DBMS whose SQL syntax is compatible with MySQL as an evaluation subject to reduce the implementation effort. This is because, although our approach can be generalized to other DBMSs, the implementation of the seed query generation and parsing (See § 4) requires a grammar file that describes the SQL syntax of a tested DBMS. To obtain timely feedback from developers, we tested the latest release versions of the selected DBMSs: MySQL 8.0.31, MariaDB 10.11.1, TiDB 6.4.0, and OceanBase 4.0.0.

Baseline. We compared PINOLO with the three state-of-the-art logical bug detection techniques, namely PQS [36], NOREC [34], and TLP [35], respectively, which correspond to three kinds of test oracles. Similar to our approach, these baselines also require knowledge about the SQL syntax of different DBMSs for seed query generation and parsing. Unfortunately, their implementations cannot support all the selected DBMSs. We also sought help from their authors, but they still could not fix the problems before the paper submission. Therefore, we skipped the evaluation of the baselines on the unsupported DBMSs. Moreover, we tried to use the same random seed as the baselines. However, we found that they can neither export their random seeds nor import the random seeds provided by users. Therefore, we generated the random seeds by ourselves for PINOLO. To understand the impacts of the random seed query generation, we investigated how PINOLO is robust to such randomness in § 5.4.



(a) MySQL (b) MariaDB (c) TiDB (d) OceanBase

Figure 5: Comparison between PINOLO and the baselines. (a)-(d) show the number of unique logical bugs over time (24 hours) on each DBMS. We ignore the results of the baselines on the unsupported DBMSs and the baselines finding no bugs.

Table 2: The demographics of the DBMSs under the test

DBMS	Version	GitHub Stars	LOC	First Release
MySQL	8.0.31	8.6K	4,766,086	1995
MariaDB	10.11.1	4.6K	3,727,410	2009
TiDB	6.4.0	33.1K	985,518	2017
OceanBase	4.0.0	5.1K	2,722,881	2021

Table 3: Applicability of existing logical detection techniques and PINOLO for the selected DBMSs

DBMS	PQS	NOREC	TLP	PINOLO
MySQL	✓	×	✓	✓
MariaDB	×	✓	×	✓
TiDB	×	×	✓	✓
OceanBase	✓	✓	✓	✓

5.2 Effectiveness of PINOLO

We used PINOLO to test the latest version of MySQL, MariaDB, TiDB, and OceanBase for 24 hours. Table 4 summarizes the results of PINOLO. The column **All** shows the number of problematic query pairs that induce unexpected results, which indicate the existence of logical bugs. As we can see, PINOLO discovered a large number of problematic query pairs, ranging from 4,675 to 46,772 for the tested DBMSs. However, we found that most of these pairs can be attributed to the same bug. To relieve the developers from the heavy burden of checking the duplicate bugs, we leverage the bug-inducing version to deduplicate the bugs (See § 4). The column **Unique** shows the number of bug reports after deduplication, which is significantly smaller than the value in column **All**, ranging from 2 to 14. We submitted the deduplicated bugs to the developers for confirmation. The column **Verified** shows the number of bug reports that have been verified by developers, ranging from 2 to 14.

Table 4: The number of logical bugs found by PINOLO.

DBMS	All	Unique	Verified
MySQL	46,772	14	14
MariaDB	42,208	14	12
TiDB	5,268	11	11
OceanBase	4,675	2	2

In total, PINOLO found 41 unique logical bugs in these DBMSs, 39 of which have been confirmed by developers. For MySQL, TiDB, and OceanBase, all of the detected bugs have been confirmed by developers. For MariaDB, twelve out of fourteen bugs have been confirmed, while the rest are still waiting for the investigation. We sampled several bug reports of MariaDB submitted by others and found that developers typically take a much longer time to handle the bugs. To keep track of the status of our reported bugs, we release the bug list in a public GitHub repository[3].

Answer to RQ1: PINOLO discovers 41 unique bugs on MySQL, MariaDB, TiDB, and OceanBase, 39 of which have been confirmed by DBMS developers.

5.3 Comparisons on Detecting Logical Bugs

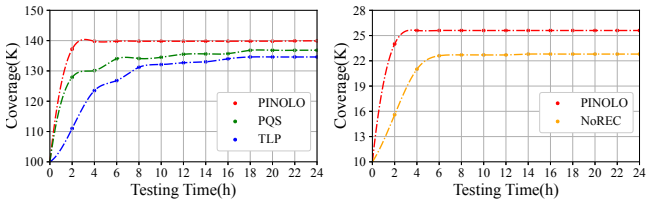
Logical bug detection. We compared PINOLO with the three state-of-the-art baselines, i.e., PQS, NOREC, and TLP. We ran all methods with a time budget of 24 hours. The comparison results are shown in Figure 5. Note that the baselines do not support all the DBMSs, and thus we only concentrated on the comparison between PINOLO and the runnable baselines with respect to each DBMS.

For MySQL, PINOLO detected 14 logical bugs, while TLP only discovered 2 bugs. For MariaDB, PINOLO detected 14 bugs, while NOREC discovered 10 bugs. For TiDB, PINOLO detected 11 bugs, while TLP only discovered 2 bugs. For OceanBase, PINOLO can detect 2 bugs, while the baselines cannot find any. We also manually verified the overlap in the bugs detected by PINOLO and the baselines. For MariaDB, 4 out of 10 bugs detected by NOREC can also be found by PINOLO. For TiDB, 1 out of 2 bugs detected by TLP can also be found by PINOLO. There are no bugs detected by PQS.

Figure 5 shows the logical bug detection progress over time for PINOLO and the baselines. We found that PINOLO is more efficient in finding logical bugs compared to all of the baselines. Within one hour, PINOLO was able to detect 57.1% (8/14) of bugs on MySQL, 85.7% (12/14) on MariaDB, 63.6% (7/11) on TiDB and 50% (1/2) on OceanBase.

Code coverage. To understand why PINOLO can find more

[3]https://github.com/qaqcatz/impomysql_bugreports



(a) MySQL (b) MariaDB

Figure 6: Code coverage comparison between PINOLO and the three baselines over 24 hours

logical bugs than all other methods, we used GCOV [30] to compute the line coverage achieved by PINOLO and all others. Note that we are unable to provide code coverage results for TiDB and OceanBase. As TiDB is developed in GO, we cannot find any feasible tool to support the program instrumentation or the code coverage profile for system test [4]. For OceanBase, the instrumented binary has to be deployed by the specific tool OBDEPLOY [24], which breaks the functionality of code coverage profiling.

Figure 6 shows the code coverage over time for MySQL and MariaDB. The results show that PINOLO achieves a higher line coverage than the three baselines. For MySQL, the improvement of PINOLO over PQS and TLP is 2.2% (3,008 lines) and 4.0% (5,316 lines), respectively. For MariaDB, the improvement of PINOLO over NOREC is 12.4% (2,835 lines).

Code coverage is well recognized as an approximation of testing capability, because a bug cannot be detected if its buggy code is not executed. However, larger code coverage does not mean more bugs. To better understand the impact of larger code coverage achieved by PINOLO, we further investigated whether there were some bugs whose buggy code is uniquely covered by PINOLO. TiDB#40015 [42] is a typical example. The root cause of this bug is the improper exception handling in the function *vecGetDateFromString*, which has been covered by PINOLO but missed by other baselines during the 24-hour running.

Answer to RQ2: Compared with the state-of-the-art techniques, PINOLO can find more unique logical bugs and achieve higher line coverage.

5.4 Impacts of The Seed Query Generation

PINOLO uses GO-RANDGEN, which takes a random seed to generate a set of seed queries. To understand whether the randomness affects the efficiency and effectiveness of PINOLO, we conducted the experiments which used GO-RANDGEN with five different random seeds to generate five sets of seed queries. We then ran PINOLO under each set and compared their performance on detecting logical bugs.

[4] Go 1.20 plans to cover the features of program instrumentation and code coverage profile, but will be available after Feb 2023 [15].

Table 5: The numbers of the discovered logical bugs when feeding different seed queries to PINOLO

DBMS	Seed1	Seed2	Seed3	Seed4	Seed5	Common
MySQL	14	18	16	16	17	11
MariaDB	14	16	13	13	13	10
TiDB	11	9	11	11	13	9
OceanBase	2	2	2	2	2	2

Table 6: Importance of the logical bugs found by PINOLO

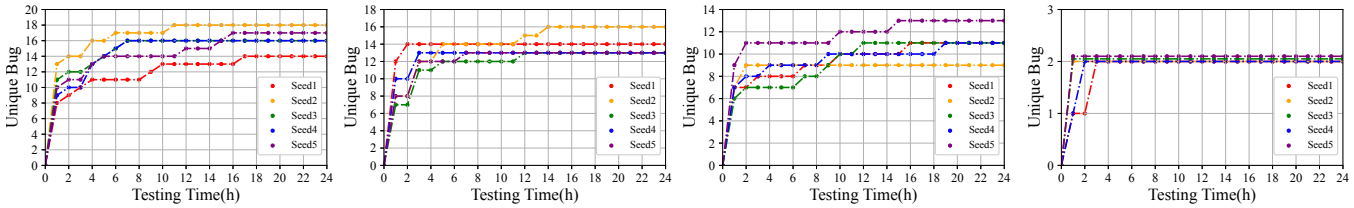
DBMS	Severity		Bug impact duration		
	S2	S3	<1 year	1∼5 years	5∼10 years
MySQL	6	8	1	7	6
MariaDB	9	3	1	7	4
TiDB	8	3	5	6	0
OceanBase	-	-	1	1	0

Figure 7 shows the progress of detecting unique logical bugs over time for the five sets of seed queries. We found that the growth trend of the number of unique bugs over time is similar under different sets. Table 5 shows more details about these detected logical bugs. Among the five sets of random seed queries, the common bugs, of which the numbers are shown in the column **Common**, account for an average of 68.4%, 72.9%, 82.9%, and 100% of the total bugs on MySQL, MariaDB, TiDB, and OceanBase respectively. This result shows that PINOLO can find different unique logical bugs via different sets of random seed queries.

Answer to RQ3: The randomness introduced by the seed query generation does not have a significant impact on the overall bug detection performance of PINOLO. Meanwhile, the different random seed queries can benefit PINOLO in detecting different bugs.

5.5 Discussion

Bug Importance. To understand the importance of the bugs found by PINOLO, we investigated their severity and the impact duration. The results are shown in Table 6. The column **Severity** indicates the severity of the bugs labeled by developers. Our reported bugs were classified as the levels of S2 and S3, which represent the second and third highest severity levels, respectively. Typically, the S2 level indicates a severe loss of service or missing significant functionality, while the S3 level indicates a minor loss of service or inconvenient usage. Note that there is no severity level in the bug tracking system of OceanBase, so we skipped the discussion for OceanBase. We discovered 6, 9, and 8 bugs in the S2 level in MySQL, MariaDB, and TiDB, respectively, which account for 62.2% of the bugs in the three DBMSs. The bugs in the S3 level are less severe, but developers still considered them to be fixed



(a) MySQL (b) MariaDB (c) TiDB (d) OceanBase

Figure 7: The number of unique logical bugs over time for each group of the random seed queries on the tested DBMSs

necessarily. For example, we received an appreciation from the MySQL developers in one of the bug reports with the S3 level: "*Thank you for your contribution. It is our standpoint that all bugs should be fixed, whether major or minor.*"

Table 6 also shows the **bug impact duration**, which is computed as the interval between the time of the bug-inducing version and the bug reporting time. Surprisingly, we found that 10 (25.6%) and 21 (53.8%) of bugs have lasted for 5-10 and 1-5 years, respectively. Specifically, the two earliest bugs of MySQL [20] and MariaDB [17] can be traced back to 2014. This result indicates that the logical bugs are typically difficult and slow to be found, which is also consistent with the findings of the prior study [35].

False Positive and False Negative. According to Theorem 3.1, PINOLO will not produce false positives in theory. However, we observe two bugs that have not been confirmed by developers for more than five months, and thus suspect that they are false positives. We manually inspected the two cases. In one bug report, a query returns "0", while the approximated query returns "-0". In the other one, a query returns "0", while the approximated query returns "-0.001". Although PINOLO considers the above inconsistency results as bugs, developers may have a higher tolerance for such inconsistencies. These reports allowed us to refine our implementation to reduce false positives in the future.

In terms of false negatives, we observed 9 cases that are detected by the baseline approaches but cannot be detected by PINOLO. This is mainly due to the DBMS features that are currently not supported by PINOLO. Specifically, there are six, two and one bugs that are related to aggregate functions, left/right join, and three-valued logic, respectively.

Limitations and Future Work. We currently do not support all features of DBMSs, such as aggregate functions, window functions, and left/right join. This is because, these features may break the approximation relation (Definition 3.1). For example, aggregate functions typically map a set of values into a single value (e.g., sum, average, maximum, minimum, and so on), and the mapped value will not preserve the inclusion relation of the original sets, thus breaking the approximation relation. In our future work, we will design new approximation relations to support more features. In addition, we intend to explore the application of metamorphic testing in other system software domains (such as networking and distributed systems [1, 32, 43, 44]).

As shown in § 5.4, different random seed queries can benefit PINOLO in detecting different bugs. This indicates that adjusting seeds dynamically is helpful to make PINOLO find more bugs. Therefore, in the future, we will consider to integrate PINOLO into the fuzzing framework to better prioritize the seed selection and enhance the bug detection capability.

Another possible direction for the future exploration is bug deduplication. In this work, we determine whether two bugs are duplicated by checking their bug-inducing versions. However, the bug-inducing version is an approximation of root causes, which would misclassify the bugs. This is because a release version of DBMS would introduce numerous bugs, which lead to multiple problematic query pairs. In the future, we will consider leveraging the spectrum-based fault localization techniques or mutation testing to improve the precision of discovering the root cause of the bugs, so as to improve the precision of bug deduplication.

6 Threats to Validity

The threat to internal validity is primarily associated with the implementation of our approach. To mitigate this concern, we have employed several DBMSs to cross-check whether the mutants generated by PINOLO accurately represented over-approximations or under-approximations of the seed query.

The threat to external validity lies in the representative of the evaluation subjects. Our proposed approach was evaluated on a restricted set of DBMSs, as explained in the evaluation section. As a result, the conclusion drawn in this paper may be limited. However, we believe that it is non-trivial to detect new bugs in these selected DBMSs, as they have been thoroughly tested by SQLancer [33]. In the future, we will extend the implementation of PINOLO to support the evaluation of additional open-source and commercial DBMSs.

7 Related Work

PINOLO is an unique DBMS testing system for finding logical bugs in DBMSs, but draws inspiration from several areas in the literature, including DBMS testing, metamorphic testing, differential testing, and grammar fuzzing.

DBMS testing. Recent efforts on DBMS testing focus on various aspects of DBMSs. Most of them target discovering logical bugs in the relational DBMS [34–36]. They use specific metamorphic relations or multiple implementations as the oracles and generate syntactically valid SQL queries for metamorphic testing [5] or differential testing [18]. Some also attempt to improve the coverage of the DBMSs and leverage fuzzing techniques to enumerate the queries in various forms [10, 46, 49, 57]. PINOLO uses a new design, termed approximate query synthesis, and does not use other DBMS implementations as the oracle.

Metamorphic testing. Metamorphic testing [5] has become more and more popular over the past decade. It has been used in testing many software systems, such as compilers [16, 50], SMT solvers [48, 54], DBMSs [35, 36], and AI systems [2, 47, 55]. Metamorphic testing uses one type of metamorphic relations to compare outputs produced by a seed input and a mutated one. As long as the two outputs violate the specific metamorphic relation, then at least one of the two inputs yields a wrong result [4]. PINOLO utilizes an instantiation of a metamorphic relation, i.e., the approximation relation, as an effective testing oracle for discovering logical bugs in the DBMSs. Similar to the skeleton approximation enumeration in the SMT solver testing [54], PINOLO performs the over-/under-approximation of the seed queries. However, PINOLO has to deal with more sophisticated syntax and supports more flexible mutations so that more buggy operators and functions can be removed. Therefore, it is able to detect insightful logical bugs that existing approaches, such as NOREC [34] and TLP [35], fail to discover.

Differential testing. Apart from metamorphic testing, differential testing provides another testing paradigm for resolving the oracle problem in software testing [6, 40, 52, 53]. Utilizing another software system with the same functionality as an oracle implementation, differential testing techniques compare the system's outputs under testing and the oracle implementation and reveal potential functional bugs with the divergent outputs. Although the techniques can generate the inputs of the systems flexibly, they can only be applied to software systems that have other implementations supporting the same functionality, such as JVM [6], ORM frameworks [40], and SMT solvers [53]. We believe PINOLO and other metamorphic testing approaches are orthogonal to differential testing techniques, which can be applied and strengthened to each other in testing DBMSs.

Grammar fuzzing. Grammar fuzzing is used to generate inputs that satisfy a specific language syntax [8, 11, 19, 19]. It has been widely used in testing many real-world software systems, such as browsers [45], compilers [51], and DBMSs [36, 57]. The generated inputs can always pass the syntax checking of software systems, which avoids the unnecessary enumeration of the inputs in an ill form, improving the effectiveness of generated inputs. Instead of relying on a specific grammar, PINOLO mutates an existing seed query to synthesize an approximate query. Our synthesis process rewrites specific grammatical constructs in the seed query, which ensures the syntactical validity of the synthesized one. We do think it is also promising to utilize existing grammar fuzzing techniques to enumerate initial seed queries automatically [36, 57], which can provide more opportunities for improving the coverage in the DBMS testing.

8 Conclusion

This paper presents PINOLO, an automatic query synthesizer for discovering logical bugs in DBMSs. Given a seed query, PINOLO mutates specific SQL constructs and generates a query that over-approximates or under-approximates the seed query. We posit that the approximation relation provides effective guidance for discovering logical bugs underlying DBMSs. Our experimental results demonstrate the effectiveness of PINOLO. Benefiting from our approximate query synthesis, PINOLO discovers 41 logical bugs in four mature DBMSs. At the time of the submission, 39 bugs have been confirmed by the developers. We hope that the promising results will put forward the study of DBMS testing, further promoting the reliability of database-backed systems.

Abstract

Labelling incident postmortems with the root causes is essential for aggregate analysis, which can reveal common problem areas, trends, patterns, and risks that may cause future incidents. A common practice is to manually label postmortems with a single root cause based on an ad hoc taxonomy of root cause tags. However, this manual process is error-prone, a single root cause is inadequate to capture all contributing factors behind an incident, and ad hoc taxonomies do not reflect the diverse categories of root causes.

In this paper, we address this problem with a three-pronged approach. First, we conduct an extensive multi-year analysis of over 2000 incidents from more than 450 services in Microsoft Azure to understand *all* the factors that contributed to the incidents. Second, based on the empirical study, we propose a novel hierarchical and comprehensive taxonomy of potential contributing factors for production incidents. Lastly, we develop an automated tool that can assist humans in the labelling process. We present empirical evaluation and a user study that show the effectiveness of our approach. To the best of our knowledge, this is the largest and most comprehensive study of production incident postmortem reports yet. We also make our taxonomy publicly available.

1 Introduction

Cloud platforms and services, despite the best efforts of cloud providers, still suffer from production incidents and outages [13,15]. To improve reliability, cloud providers must first discover and resolve existing reliability risks [14]. Aggregating root causes of past incidents based on their post-incident reports (PIRs) is one effective approach to uncover common problem areas, trends, patterns, and risks (e.g., the most common root causes in the last year). Likewise, bucketing past incidents by their root causes can help on-call engineers (OCEs) to quickly retrieve and learn common mitigation strategies for a given root cause category. Such tasks are crucial for large-scale cloud platforms like Microsoft Azure that continuously strive to improve reliability by learning from past incidents caused by diverse factors.

PIRs are commonly written in natural language, with little structure. This makes the tasks of aggregating or bucketing past reports challenging, especially at a large-scale. One common practice to address this is to label each PIR with a *root cause tag* representing the category of its root cause. For example, a PIR for an incident caused by a code bug in the network driver can be tagged as "*Network.Driver.Code.Bug*". This enables quick and accurate aggregation of and retrieval from a large collection of PIRs simply based on their root cause tags instead of expensive and potentially inaccurate natural language processing of the PIR contents. For example, the tags can enable quickly answering questions such as: "how frequently did network driver code bugs cause incidents in the past year?" and "how were such bugs mitigated?"

Challenges and limitations. There are two key challenges in effectively labelling PIRs with root cause tags (more in §2).

The first challenge is to decide *what root cause tags to use to label the PIRs*. A well-defined taxonomy of root cause tags is essential for labelling PIRs consistently, otherwise different teams may tag the same root cause differently, hindering the cross-team aggregation analysis. A well-designed taxonomy for a large-scale cloud system such as Microsoft Azure should balance two competing objectives: it should be *comprehensive* enough to cover the myriad of potential root causes, yet *compact* enough for the OCEs to navigate and use easily. Moreover, it should be *fine-grained* enough to surface actionable insights from across many services.

Designing such a taxonomy is nontrivial. Several recent works analyzed production incidents and proposed taxonomies to capture their root causes. However, most of these works focus on specific root cause categories, such as software bugs [4,5,11,19,21,40], and thus their taxonomies are not comprehensive enough to cover other types of failures (e.g., hardware failures). Some other works consider multiple types of root causes, but they target specific services or

[*]Work done during internship at Microsoft

[†]Except for the first author, all authors are in order by their last names.

systems, such as big-data systems [38], a business data processing platform [9], or a particular cloud service [13, 14], rather than a large-scale cloud system. Moreover, existing taxonomies are not fine-grained enough to represent all the root causes we observe in Azure incidents.

Prior to our work, individual service teams in Microsoft designed their own root cause taxonomies based on domain knowledge. However, due to the lack of a comprehensive root cause labelling, many potential root causes were not anticipated when the taxonomies were designed. Consequently, a large portion of PIRs, whose root causes were not covered by existing taxonomies, were labelled with "Other" instead of more informative root cause tags (see §2 for more details).

The second challenge concerns *how to select root cause tags for incidents*. Currently, this is done manually—an individual (OCE) reads *lengthy* incident and post-incident reports, identifies the root cause, and chooses a suitable tag from a taxonomy that is often a long flat list of tags. This manual process is error-prone and can result in inconsistent tags across incidents—at Microsoft, tens of thousands of OCEs with varying levels of expertise and different interpretations of root cause tags conduct root cause analysis. We manually examined a small sample of 1241 PIRs and found that 29% of the OCE-assigned tags are incorrect. This problem might be mitigated if root cause tagging is done by a small group of experts through a stringent procedure, but this is infeasible at large scale systems like Microsoft Azure.

Contributions. In this work, we make the following three contributions that address the challenges described above.

First, we manually analyze over 2000 high-impact production incidents from 468 services in Microsoft Azure to identify a comprehensive set of root cause categories behind incidents in a large-scale cloud system. We carefully read the incident and post-incident reports and, if needed, consult the engineers from the affected service teams. Unlike previous empirical analyses of production incidents [4,5,9–11,14,21,38,40], we aim to identify not only a single root cause, but *all* factors contributing to the incidents. This analysis took more than four person-years and identifies 346 distinct root cause categories spanning all aspects of a production service, such as hardware and software, infrastructure and application, code and configuration, and so on. To the best of our knowledge, this is the most comprehensive empirical analysis of production incidents in cloud systems, considering the scale of incidents and affected services, the depth of analysis, and the diversity of root causes.

Our empirical analysis (§3) reveals several novel and interesting findings. For example, we show that most production incidents in real-world cloud systems involve multiple contributing factors; hence, preventing such incidents does not always require addressing all the causal factors, but only one (or a small subset) of them. This contrasts with existing research that focuses on a single root cause of an incident [10, 13, 21]. This finding implies that tagging a PIR with a single root cause does not capture the full picture of what caused the incident. Our analysis also shows that incidents result from many diverse factors spanning hardware and software, infrastructure and application, code and configuration, and so on. This, again, contrasts with existing research that focuses on a limited set of factors [4, 5, 9–11, 14, 19, 21, 38, 40]. We also show that the set of root causes evolves over time: new root causes emerge as new services or hardware are deployed, suggesting the need for a continuous root cause labelling effort. While our findings stem from analysis of incidents at Microsoft Azure, we believe that they generalize to similar large-scale systems and impact root cause analysis procedures at large.

Second, we propose a comprehensive taxonomy, the Azure Reliability Tagging System (ARTS), that organizes the root cause categories derived from our analysis. For ease-of-use, our taxonomy is organized hierarchically, with each leaf node representing a *root cause tag* describing a factor contributing to an incident. We expect that the root causes generalize to other cloud services and we open-source our taxonomy for the use of other researchers and practitioners.[1]

Finally, to reduce manual errors and inconsistencies in tagging PIRs, we developed AutoARTS, a tool that leverages machine-learning-based algorithms to assist humans. AutoARTS performs two key tasks: (1) it applies a multi-label classification technique to automatically analyze a PIR (written in natural language) and to extract multiple contributing factors and their corresponding tags from our proposed taxonomy; and (2) it generates a concise text snippet (from the PIR) that summarizes the relevant context for the factors. The snippet allows a human to quickly review the suggested tags without reading lengthy incident reports or PIRs. We describe how we adapt existing ML techniques for this purpose. Our empirical evaluation with real PIRs and a user study demonstrates the effectiveness of our approach. Specifically, our multi-label classification achieves an F1 score of 0.89. In the user study, our text snippets (contexts) received a score of 4.6 out of 5 (5 being 'very useful'), contained *no* unnecessary details, and helped an expert identify two additional contributing factors (in a set of ten incidents) that they had originally missed.

Deployment status. Most of the 468 services whose production incidents we analyze have been deployed as part of Microsoft Azure for several years. High-impact incidents in these services have been analyzed and labelled with ARTS tags since November 2020. The labels, available to all services in Azure, are regularly aggregated to identify key problem areas and to devise actionable insights (examples in §4).

2 Background and motivation

2.1 Background

Incident Reports. Incidents are unplanned outages that impact production services and their users. The severity of an in-

[1] ARTS Taxonomy: https://autoarts-rca-taxonomy.github.io

cident may vary based on aspects such as the criticality of the affected services and the number of impacted users. As described in [31], an incident's life-cycle is a complex process involving several steps such as detection, triaging, diagnosis, root cause analysis, mitigation, and resolution. An *incident report* documents important information related to these various steps. At Microsoft, an incident report can be created by impacted users as well as by automated monitors and it usually contains the following: (1) a concise title, (2) a summary of the incident, highlighting some events in the timeline from detection to mitigation, (3) engineers' discussion thread to share relevant information corresponding to the incident's resolution, and (4) several other fields such as severity, owning team, time to mitigation, mitigation steps, etc.

Post-Incident Reports (PIR). After an incident is resolved, a best practice is to conduct a retrospective or postmortem analysis of the incident to produce a *post-incident report* (PIR). In a PIR, the service team reflects on what went wrong, why it went wrong, what they learned from it, and how to avoid similar incidents in the future. At Microsoft, a PIR is a natural language document and it contains sections such as (1) root cause summary that describes all root causes, (2) five-whys [34] that iteratively drills-down the cause-and-effect relationships of various contributing factors, (3) preventive measures for similar future incidents, and so on. Generating a PIR requires significant effort, and hence, only the incidents with high severity are required to have them at Microsoft.

Root cause labelling. A critical component of a PIR is its *root cause tag* that represents the root cause categories of the incident as determined by a postmortem analysis. For example, a root cause tag *"Authoring.Code.Bug.RaceCondition"* indicates that the incident is caused by a race condition in software code. Such concise labelling allows one to efficiently and accurately aggregate and summarize a large number of historical PIRs solely based on their tags, without expensive and potentially error-prone natural language processing of the PIR contents. These aggregate results are regularly reviewed by the engineering leadership to find global trends (e.g., frequent root cause categories), which guide business decisions such as prioritizing engineering investments. These tags also simplify information retrieval and knowledge sharing: an engineer seeking to actively mitigate an ongoing incident caused by a network driver can quickly retrieve and consult past PIRs with root cause tag *Network.Driver*. For effectiveness of aggregation and retrieval, it is important that the root cause analysis and labelling process is accurate.

At Microsoft, authors of incident reports or PIRs can label their reports with root cause tags selected from taxonomies of root cause categories that are predefined by domain experts.

2.2 Challenges in root cause labelling

We analyze a sample of $\approx 1.7M$ root cause analyses in Microsoft, across all its services, to understand the challenges in root cause labelling. We now summarize the key findings.

Finding 1. *Existing taxonomies, although designed by domain experts, are not comprehensive enough.*

This is due to the lack of a comprehensive study of root causes, many potential root cause categories are missed or not anticipated when a taxonomy is designed. As an implication, a PIR author may not find a suitable predefined root cause tag to describe the current incident. In our sample of root cause analyses, $\approx 20\%$ incidents are labelled as 'Other' and $\approx 58\%$ are labelled with categories containing 'Other' (e.g., 'Network - Other'), implying that their root causes are not covered or only partially covered by the existing taxonomies. Such 'Other' tags are not useful in the aforementioned root cause aggregation and retrieval tasks.

Finding 2. *Existing manual root cause labelling process is expensive and error-prone.*

Root cause label of an incident is often determined based on its PIR and incident report. These documents are usually *long* (4542 words per incident in our sample) and *complex* (on average, ≈ 9 engineers engaged in discussion exchanging 20 comments). Thoroughly understanding these long documents to identify all contributing factors behind an incident, and then selecting from predefined root cause labels that represent the factors, is a nontrivial task.

Even when the root cause is understood, PIR authors may make mistakes in choosing the correct tag. This can happen due to multiple factors. Existing taxonomies at Microsoft are flat long lists, making it difficult to navigate through them and to pick the right tags. Moreover, many individuals are involved in the rootcausing efforts. For example, we observe $34K$ distinct individuals involved in a sample of $600K$ PIRs in Microsoft. This large number of individuals are likely to have varying degrees of expertise and different interpretations of root cause tags. This is further exacerbated by ambiguous or confusing tags in the taxonomy (e.g., 'Network' and 'Datacenter - Network'). All these factors can contribute to inconsistent and/or inaccurate labels. We manually examined a small sample of 1241 PIRs and found that 29% of the assigned tags are incorrect.

Our goals. In this paper we address the challenges above with a three-pronged approach. First, to address the first challenge above, we conduct an extensive multi-year analysis to identify a wide variety of fine-grained root causes of 2000+ production incidents from across 450+ services in Microsoft Azure. Second, based on this analysis, we propose a novel hierarchical and comprehensive taxonomy of potential contributing factors behind the incidents (§4). Third, to address the second challenge above, we develop an automated tool that can assist a human by presenting necessary context from PIRs that identify contributing factors to reduce cognitive load and improving accuracy in the root cause labelling process by suggesting tags from the taxonomy (§5).

3 Empirical Analysis of Production Incidents

3.1 Goals and Methodology

There exists several empirical studies of production incidents in large-scale cloud systems [4, 5, 9–11, 14, 21, 38, 40]. We have two goals that differentiate our study from them. First, we do not restrict our analysis to a limited set of root cause categories (e.g., software bugs [4, 5, 11, 19, 21, 40]) or specific services/platforms (e.g., big-data systems [38]). Second, for each incident, we try to identify not a single root cause, but *all* factors contributing to the incidents. These two goals enable us to identify a wide-range of contributing factors behind incidents happening in large number of services/platforms.

We analyze 2051 high-impact incidents in 468 Microsoft Azure services. We carefully analyze each incident by carefully reading and understanding its incident report and PIR, the discussion comments, and even the work items (e.g., bug fix, system upgrade) that are created due to the incident. When something is not clear, we reach out to the incident owners to clarify. As a part of the analysis, we not only identify the *contributing factors* causing the incident but also extract text snippets or *context* from the incident and PIR which helps explain and justify the identified root cause tag for future reference and validation. Every week, we peer review a randomly selected subset of incidents to help us refine our collective understanding of tag usage, promote learning and improve accuracy. If we identify a new category of root causes, which is not covered by existing tags, we then propose new tags which are internally reviewed before getting introduced to the taxonomy. For any tag in the taxonomy, we also provide it's description in natural language for future reference. This data lives in an internal database which can be easily joined with incident databases and visualization reports are created for easy data analysis based on various pivots such as contributing factors, services, incident impact, etc. We also meet with the engineering teams on a weekly basis, and review our data both for accuracy and to share insights that result in reliability improvements.

Our root cause analysis effort is guided by several principles: (1) Our analysis is intellectually honest so that individual teams that conduct their own postmortem analysis (to identify a single root cause) feel psychologically safe, valued, and included; (2) Our analyses have meaningful depth because we start by capturing customer pain and go down to "work as done" by our engineers; (3) We focus on both depth and breadth of incident analysis enabling us to highlight thematic learning that broadly improves Azure services and the underlying cloud platform; (4) Our findings are turned into new standards or updates to existing standards and are actionable and useful because they address customer pain; and (5) While learning is important; continuous learning is necessary and crucial.

The above process is required to ensure high quality of root cause analysis. However, it needs significant manual effort. Since 2020, we have analyzed 2051 incidents in 468 Azure services with a team of 2-4 members.

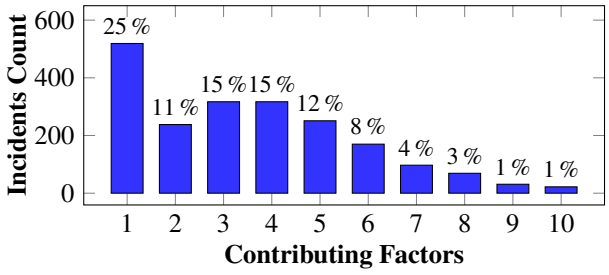

Figure 1: **Distribution of incidents across number of distinct contributing factors (shown until 10 factors).**

3.2 Analysis Results

We here present several interesting findings from our analysis.

Finding 3. *Incidents are often caused by multiple contributing factors working together instead of an isolated root cause.*

This is contrary to prior work [13, 15, 16, 21] that focus on identifying a single root cause per incident. Consider, for example, a real incident where a service became unavailable after a single customer continuously pushed a load that was 60x greater than what the service was scaled to handle. The original PIR author chose the root cause label "*Service – Load Threshold*." This itself is not an inaccurate root cause when forced to pick only one cause. However, there are many more factors involved in this incident: (1) there was an inrush of load from a single customer, (2) there was a lack of throttling on the customer end as well as the service end, (3) increased load significantly increased CPU and heap usage and thread count at the server, which lead to failed requests with exceptions, (4) the exception handling didn't release some resources that were allocated by the failed requests, leading to resource leaks, (5) there were no automated watchdogs to detect early symptoms of the outage (or resource leaks), and (6) the team was unable to access their own metrics during the outage since the metrics were collocated with the service. In contrast, our analysis of the incident identifies all these factors and the corresponding tags in our taxonomy.

Figure 1 shows the distribution of the number of contributing factors behind each incident. As shown, over 75% of incidents have been caused by more than one contributing factors. And, more than 50% of the incidents have 4 or more contributing factors. On average, each incident has ≈ 3.6 factors. This reaffirms the need for holistically analyzing the incidents to understand all the contributing factors.

The presence of multiple contributing factors per incident has important implications. On one hand, identifying the possibility of such incidents before deployment to production with integration and end-to-end tests is challenging since test-

Category	Description	Frequency	TTM (Hrs)
Detection	Issues related to detecting problems before they affect production	**61%**	50
Authoring	Issues in authoring artifacts like code, config, troubleshooting guides, etc.	**50%**	**58**
Dependency	Issues in a dependency the service has, most typically another service but can also be some things where a boundary between teams is present	**37%**	16
Architecture	Issues in how the service is architected and likely where any work to fix would require changes to the architecture of the service	20%	33
Deployment	Issues related to deployment of code or config	20%	27
Process	Any issue caused by human errors, a flawed process or the lack of a process	18%	**123**
Load	Any issue caused by the service not being able to handle changes in load	14%	13
Auth	An authentication or authorization related issue	7%	21
Performance	An issue that caused excess latency	6%	16
Datacenter	Events (hardware, installations, power interruption, etc.) in the datacenter	4%	**70**

Table 1: **High-level root cause categories from ARTS taxonomy with their descriptions, frequency of occurrence in our analysis and mean Time-To-Mitigate (TTM) for incidents caused by their sub-categories.**

ing needs to be performed in the presence of multiple potential contributing factors (e.g., high load *and* no throttling *and* no monitoring of early symptoms). On the other hand, *preventing such an incident does not always require addressing all the causal factors, but only one (or a small subset) of them.* For example, the aforementioned incident could have been prevented by using proper throttling mechanism, *or* by fixing the resource leak bug, *or* by having monitors that can restart the service on early symptoms of resource leaks. This insight presents a unique opportunity to fix the incidents (by addressing the easiest causal factor); but it requires identification of all the causal factors (as we do) instead of identifying a single root cause.

Finding 4. *A wide-variety of factors contribute to production incidents.*

Our analysis identified a wide range of factors, including hardware, software, code bugs, underlying infrastructure to external dependency issues, configuration errors, deployment issues, and so on. Specifically, we have identified 346 root cause categories (i.e., contributing factors) for the 2051 incidents we analyzed. Table 1 shows the high-level root cause categories, each of which contains many finer-grained sub-categories. The full list of categories and their respective frequencies observed in our analysis can be found in https://autoarts-rca-taxonomy.github.io. This contrasts our study with prior works that focus on a small set of root causes such as code bugs [4, 5, 11, 19, 21, 40].

Finding 5. *New root-cause categories keep appearing over time.*

As software and hardware systems evolve, novel root causes appear to contribute to their incidents. For example, when a service migrates to a containerized environment, its incidents may be caused by container-related factors. Similarly, when a service takes a new external dependency, it may start experiencing incidents caused by factors related to the failures of the new dependency. We analyze incidents in the same timeline as they appear and we create root cause categories incrementally—we create a new category only if none of the existing ones can precisely represent a new root cause. We observe that even though many common root cause categories (e.g., code bugs) appear in early incidents that we analyze, a few categories appear only in much later incidents (e.g., those happening two years after the first incident we analyzed). Figure 2 shows how often such new categories appear in our analysis. As shown, even after 1.5 years, new root cause categories appear, albeit with a smaller rate (i.e., we can tag higher number of incidents successfully before we need to introduce a new root cause category). The fact that novel root cause categories keep appearing implies that root cause labelling needs to be a continuous process to identify (and take actions on) emerging root cause categories. This calls for an automated solution.

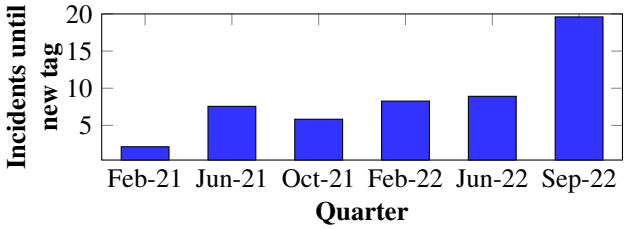

Figure 2: **Average number of incidents successfully tagged until a new root cause tag is introduced across quarters.**

Finding 6. *Lack of monitoring (i.e., observability) is the most common factor behind incidents.*

Table 1 shows the distribution of various contributing factors behind the incidents we analyzed (only high-level factors are shown). As shown, Detection is the most common contributing factor leading to outages. Detection related issues represent missing observability signals that prevent us from detecting early symptoms of problems, many of which could have been avoided, e.g., by rebooting the service, if their early

Contributing Factor	Frequency
Detection.Monitoring.MissingAlert	34%
Authoring.Code.Bug.Change	25%
Detection.Monitoring.InsufficientTelemetry	18%
Detection.Validation.MissingTestCoverage	17%
Detection.Monitoring.CodeDeployment. InsufficientHealthSignal	9%
Authoring.Documentation. NoOrInsufficientTSG	9%
Architecture.SinglePointOfFailure	8%
Authoring.Code.Bug.Latent	7%
Detection.Monitoring.Synthetic	6%
Deployment.Mitigation.ManualTouch	5%

Table 2: **Distribution of top 10 most frequent contributing factors in our analysis from the ARTS taxonomy.**

symptoms were detected. We also analyzed finer-grained contributing factors from ARTS taxonomy. Table 2 shows distributions of the top ten contributing factors (a contributing factor X.Y.Z means factor Z is a specific case of factor Y, which is a specific case of factor X). As shown, Missing Alerts, which is a specific case of Monitoring, which is a specific case of Detection, is the most common contributing factor. Insufficient telemetry captured from services is also a major contributing factor which also prevents from deploying automated alerts. An organizational policy on collecting key telemetry and defining automated watchdogs informed by this aggregate analysis can mitigate incidents (or severity) in the future.

We also analyze the most frequently *co-occurring* root causes to identify the pairs that jointly cause incidents. The two most frequent pairs are "*Authoring.Code.Bug.Change*" & "*Detection.Monitoring.MissingAlert*" (15%) and "*Authoring.Code.Bug.Change*" & "*Detection.Validation.MissingTestCoverage*" (11%). This aligns with our experience that many production incidents are caused by buggy code changes that are deployed without proper monitoring and testing.

Finding 7. *Incidents caused by deployment and datacenter related issues are the most time consuming to mitigate.*

In incident management, TTM is defined as the time elapsed between the start of the incident and when its customer impact was completely resolved. The higher the TTM, the more the customer impact and dissatisfaction. From Table 1, we can see that incidents caused by Process and Datacenter related root causes have the highest mean TTM. Process related incidents have a high TTM because these incidents are caused by human errors and lack of standard operating procedures which result in non-trivial hard-to-resolve issues (e.g., accidental deletion of a database). Datacenter related incidents are caused primarily due to hardware failures which are quite complex given that there are multiple layers of capacity buffers all of which need to fail before an incident is caused by hardware issues.

4 Root Cause Taxonomy

We organize the root cause categories identified in our empirical study as a taxonomy of reliability tags that can be used to label PIRs of incidents.

Design goals. We have the following design goals in designing the taxonomy. First, the taxonomy should be *comprehensive* enough to capture not only the primary root causes of past incidents in Azure, but also other (secondary) contributing factors. Second, in order to avoid having a taxonomy too large to be easily used in practice, the taxonomy should be *sufficient* and it should include only the root causes found in past incidents. This implies that the taxonomy is continuously and organically grown to include new categories as they are discovered. Third, the tags should be *unambiguous*, to enable high-quality annotations. Finally, the taxonomy is organized *hierarchically*, for ease of labelling and updates.

The ARTS taxonomy. We achieve the goals with a novel taxonomy called ARTS (Azure Reliability Tagging System) taxonomy. The taxonomy is built on top of the root cause categories identified by our empirical analysis described before. We start with a small number of tags representing orthogonal categories of themes (such as datacenter issues and authentication issues) and grow it horizontally to include new themes and vertically to include more specific sub-themes as new incidents are analyzed and existing themes/sub-themes deem inadequate. We have established a continuous feedback loop based process for building the ARTS taxonomy and tagging of new incidents on an ongoing basis.

For ease-of-use, we organize the ARTS taxonomy hierarchically, by grouping related sub-themes under one common theme. Currently it consists of four levels and contains 346 root cause categories identified from our empirical analysis. The top level consists of ten broad themes (shown in Table 1), each of which consists of multiple sub-themes. There are 346 leaf nodes, each representing a root cause tag with the name obtained by concatenating the names of the path from the root to the leaf node. For example, the root cause of "a gap in preproduction detection due to missing integration tests" is represented with the tag "*Detection.IntegrationTest.Missing*" in which "*Missing*" is the most precise leaf-level tag. The hierarchical taxonomy naturally distinguishes between problem spaces at different granularities. In this example, if the root cause is that the integration tests existed but were skipped somehow, that representative tag would have the leaf-level tag "*NotRun*" instead of "*Missing*".

As mentioned, the taxonomy is grown as new root causes are identified in newly analyzed incidents. Figure 2 shows how the taxonomy has been growing over time, with the y-axis showing the average number of incidents analyzed until a new tag needed to be introduced in ARTS. A larger value indicates better stability of the taxonomy: many incidents can be analyzed with existing tags. As shown, over time, the taxonomy can be seen becoming stable. Specifically, in the

most recent quarter, only one new tag needed to be introduced after analyzing ≈ 20 incidents (i.e., after using ≈ 70 existing tags) on average. We hope to see significantly more stability in coming months.

For lack of space, we omit further discussion about 346 leaf nodes in the taxonomy. However, we open source the taxonomy, with all tags and their descriptions, at https://autoarts-rca-taxonomy.github.io. We believe our open-source effort will foster future research and allow practitioners use our taxonomy. Even though the ARTS taxonomy is developed based on incidents in Azure, we believe that its categories are general enough to be used in any large-scale cloud system.

Deployment Status. The ARTS taxonomy and PIRs labelled with ARTS tags have been available to Microsoft engineers since when we started building it (November 2020). It enables various service teams within Microsoft Azure to systematically look at past incidents. The learnings have been valuable, especially for service teams without the required expertise or resources to dig deep into their service reliability. They have enabled engineering teams prioritize work items and often times this also results in creation of new engineering standards and tools. For example, lack of unit testing was a common factor contributing to many incidents in a large organization in Azure—incidents were caused by bugs in code that was not tested (or poorly tested). This caused the organization to enforce the policy that all checked-in code must have sufficient tests to achieve a certain code coverage. Lack of throttling was another factor highlighted by aggregating ARTS labels; this started a new engineering group with the goal of building a common throttling service that all Azure services can easily use. Last but not the least, engineering teams emphasize on using more extensive monitoring/observability tools, since as ARTS labelling showed, adequate monitoring could prevent many incidents.

Overall, Microsoft engineers found the ARTS labels in their PIRs useful. Here we show samples of the verbatim feedback from the service owners at Microsoft: *"Tracking incidents against a known set of root causes is extremely useful. Your effort has enabled us to make data-driven decisions, and already produced several benefits in a short time." "Your data established clearly that services that have high maturity in certificate management had fewer outages. This validated that our investment across Azure is in the right direction." "The ARTS report is an important resource for us for data driven planning related to Azure Quality."*

5 AutoARTS for Automated Labelling

As mentioned before, identifying and labelling PIRs with their root causes is expensive and error-prone. To reduce the cost and errors, we have developed an automated tool called AutoARTS that can assist a human in the labelling process with two important tasks. First, it uses a multi-label classification technique to automatically analyze an incident's PIR (written in natural language) and to identify multiple contributing factors and their representative ARTS tags. Second, it can produce a short text snippet (from the PIR) that captures important context explaining the factors. The snippet enables a human to easily review the selected tags without reading lengthy incident reports or PIRs. We now describe how AutoARTS performs these two tasks by using ML techniques. Figure 3 shows the architecture and components of AutoARTS.

5.1 Automatic identification of ARTS tags

AutoARTS uses multi-label text classification to classify a PIR into a set of ARTS tags. One key challenge we face is that conventional multi-label text classification algorithms that treat each class as opaque and independent, require sufficient labelled data for each class to achieve good accuracy. However, even though we have a reasonable collection of labelled data, many of the fine-grained classes (i.e., ARTS contributing factors) contain very few labelled samples (i.e., PIRs). Specifically, 68% classes have fewer than 10 labelled samples in our dataset, which can adversely affect classification accuracy.

To address this, we leverage the hierarchical relationship between root cause labels by encoding the taxonomy structure using Graph Convolutional Networks [18]. Exploiting the structure of the taxonomy enables transfer of knowledge from the categories with adequate labels to categories with few labels (§6.2). In particular, we apply a hierarchical text classification model called HiAGM [42]. Contrary to the conventional multi-label text classification methods that disregards the holistic label structure for label correlation features, this model attempts to fully utilize the mutual interactions between the text feature space and label space, as well as label dependencies. As an illustration, consider the root cause taxonomy in Figure 3. The "*Authoring.Code.Change*" category only contains 13 samples, making training difficult owing to the small amount of labelled samples. However, by modeling the root cause taxonomy as a graph, we can transfer knowledge from "*Authoring.Code.Bug*", which has 733 labels, to "*Authoring.Code.Change*" since they share the features of their same parent root cause category, "*Authoring.Code*".

Given a Post-Incident report $x = (w_1, w_2, \ldots, w_n)$ with n tokens, the sequence of token embedding is initially fed into a bidirectional GRU neural network [6] to extract text contextual features. Following the GRU model, multiple CNN layers are employed to generate the n-gram features. The top-k max pooling layer is then applied to obtain the overall text representation $S \in \mathbb{R}^{n \times d_c}$ that highlights the key information, where n is the top-k output dimension of CNN layers and d_c represents the embedding dimension.

To model the ARTS taxonomy, we formulate the taxonomic hierarchy as a directed acyclic graph $G = \{V, E_t, E_b\}$, where V refers to the set of label nodes. E_t and E_b represent the top-

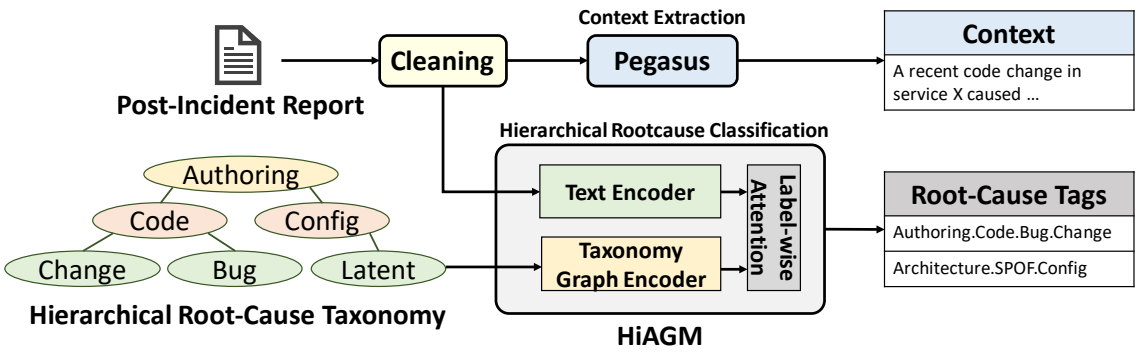

Figure 3: **Overview of our Context Extraction and Hierarchical root cause Classification using Post-Incident reports.**

down and bottom-up hierarchy paths respectively. To encode the hierarchy graph, a GCN-based hierarchy encoder [18], Hierarchy-GCN, is used to aggregate data flows within the top-down, bottom-up and self-loop edges based on the associated neighborhood of each node. The GCN-based graph encoder adapts the convolution concept from images to graphs, in which the graph convolutional operator can effectively convolve the multi-order neighborhood information by forming multiple propagation steps during the forward pass. For each node, the feature information is aggregated by the node feature from all the neighbors, including the node itself, to leverage the graph structure of label taxonomy.

Next, we aggregate the features of texts and labels together using a label-wise attention mechanism [37]. Specifically, the attention α_{kj}, which indicates how informative the j-th text feature is for the k-th label, is calculated as follows:

$$\alpha_{kj} = \frac{e^{\mathbf{s}_j \mathbf{h}_k^T}}{\sum_{j=1}^{n} e^{\mathbf{s}_j \mathbf{h}_k^T}}, \tag{1}$$

where $\mathbf{s}_j$ is the j-th text feature of the root cause input and $\mathbf{h}_k$ represents the k-th node in the label hierarchy. The label-aligned text feature $\mathbf{v}_k = \sum_{i=1}^{n} \alpha_{ki} \mathbf{s}_i$ for the k-th label is then obtained and fed into a classifier for hierarchical label prediction.

Finally, we flatten the label hierarchy by treating all nodes as leaf nodes for multi-label classification, regardless of whether a node is a leaf or an internal node. A binary cross-entropy loss function is employed to train the model using the ground truth and predicted sigmoid score for each label. In additional, a recursive regularization for the parameters of the final fully connected layer is used to encourage classes nearby in the hierarchy to share similar model parameters.

$$L_r = \sum_{i \in C} \sum_{j \in child(i)} \frac{1}{2} \|\mathbf{w}_i - \mathbf{w}_j\|^2, \tag{2}$$

where the node j is the child of node i in the label hierarchy.

5.2 Context Extraction from PIR

The objective of context extraction is to extract key text snippets from a given Post-Incident Report (PIR) for on-call engineers to comprehend the contributing factors of an incident without reading the complete lengthy report. Many text summarization techniques exist. *Abstractive summarization*, where summaries may contain generated sentences, is not a good fit for us since our goal is to select and highlight existing texts in the PIR, as is done by *extractive summarization*. However, existing language models such as BERT [8] and XLNet [36] are trained on large corpuses such as Wikipedia articles, etc., where the syntax and semantics of the language used is quite different from what is observed in PIRs due to domain-specific usage of words (e.g., 'Fabric' in networking terminology vs clothing) and different vocabulary. Moreover, existing extractive summarization models are trained on and their traditional usage in *summarizing* text documents, which is different from context extraction from PIRs. Our experimental evaluation in §6.3 shows that they perform poorly. We therefore finetune an existing model called Pegasus [39] with our labelled data (from our empirical study described before).

In Pegasus, important sentences are removed or masked from an input text and are generated together as one output sequence from the other remaining sentences, similar to an extractive summary. Hence, Pegasus is amenable for context extraction from PIRs, because we can mask the key sentences identified in our analysis (§3.1) to finetune the model parameters. Using the standard Transformer encoder-decoder, Pegasus model is pre-trained on two enormous text corpora: 1) Colossal and Cleaned version of Common Crawl (C4) [27], which comprises of text from 350 million web pages with a size of 750 gigabytes; 2) HugeNews [39], a dataset of 1.5 billion news articles gathered from 2013 to 2019. Similar to MLM tasks for predicting masked tokens, a new pre-training task called Gap Sentences Generation (GSG), is applied to fill the masked sentences. Three different strategies are applied for selecting m gap sentences without replacement from a document. The first method is to uniformly select m sentences at random, whereas the second strategy is to simply select the first m sentences. The aforementioned two strategies are combined with the Principal strategy, in which top-m scored sentences are chosen based on their significance as measured by rouge score [20] without the selected sentence. Formally, the

The root cause of this monitor alert was that a lot of subscriptions could not deploy VMs on indiacentral region.
... ... *(omit 132 words)*
This problem occurred because the traffic that was re routed to AZSM could not be handled. This problem occurred on indiacentral prod b and indiacentral prod b. As part of increasing inventory we have introduced news sets of AMD clusters. The AZSM services on these clusters still needed some configuration and build out related processed to be completed. Hence these clusters stamps could not handled the traffic re routed to them. The traffic was routed as part of default behavior. We are going to change this. The Fabricator clusters started taking tenant traffic even though their corresponding Az SM clusters weren't ready. This was done as part of flighting on Broad clusters. India Central was one of the region for this flighting. We did not anticipate a case where new build out clusters would not be able to take the new traffic. This was detected as part of the API failure monitor. We will be working on adding more robust feature specific monitoring and more strict rollout to not encounter this failure again.

Figure 4: **Context extraction from a redacted PIR. Green sentences are extracted by both our model and human expert, red are extracted by model only and blue are extracted by human only.**

score s_i of the i-th sentence x_i can be expressed as follows:

$$s_i = \text{rouge}\big(\text{x}_\text{i}, \text{D} \setminus \{\text{x}_\text{i}\}\big), \tag{3}$$

where the D is the set of all the sentences in the document and rouge function is a commonly employed metric for evaluating how good an automatically produced summary against a reference summary.

Even though Pegasus has been pre-trained on massive datasets, it is not trained to generate context from root cause descriptions in software engineering domain. To completely comprehend the context extraction task in our domain, we utilize the human-labeled context to further fine-tune the Pegasus model as a sequence-to-sequence task.

Based on the empirical results in §6.3, we found the Pegasus model can outperform the state-of-the-art abstractive summarization technique on our dataset for the reasons listed below. The human-labeled contexts are chosen straight from the original root cause details with no alteration to the phrase structure. Pegasus, an abstractive summarization model that pre-trained on the Gap Sentences Generation task, may immediately replicate the important sentences from the input, resulting in a higher overall rouge score than the traditional abstractive technique.

Figure 4 illustrates an example of context extraction from a PIR report consisting of 328 words. The human-labeled context is shown in blue and green, whereas the context extracted from Pegasus is shown in the green and red. This example shows that ≈50% tokens can be filtered, which can considerably enhance the efficiency with which on-call engineers read the PIR report. Also, we discover that the extracted context from Pegasus has a high recall compared to the human labels, allowing engineers to seldom overlook vital information.

Section	Micro-F1	Weighted-F1
Whole PIR	**0.55**	**0.40**
Title	0.53	0.45
Summary	0.47	0.46
RC-Details	0.52	0.45
5-Whys	0.54	0.40
Discussion	0.53	0.40
Mitigation	0.47	0.40
RC-Details + 5-Whys	**0.56**	**0.42**

Table 3: **Study on the utility of different PIR sections in top-level root cause classification using Random Forests.**

6 Evaluation

We now empirically evaluate the performance of AutoARTS.

Dataset. Our dataset consists of 1120 PIRs that are expert-annotated with ARTS root cause tags and contextual sentences to justify them. We use stratified sampling to divide this dataset into train(72%) and validation(8%) splits to train and tune the hyperparameters of different models and test(20%) split to report the results with the trained models.

Data Pre-processing. We found that engineers often included various types of data such as debugging queries issued on logs, error messages, stack traces, screenshots, etc., in PIRs (also identified in [31]). These add significant noise to the vocabulary of the language processed by NLP models, without contributing to performance. We carefully remove such noise with regular-expression based filters and only select alphabetic text for our evaluation. For experiments in §6.1, we also use the NLTK [3] library to remove stop-words and extract stems of words to construct vocabulary.

Evaluation Metrics. For root cause classification, we use micro-F1 score to analyze performance across different incidents with multiple labels. We also use weighted-F1 score to analyze performance across different classes since our dataset is imbalanced as shown in Table 1. For context extraction, we use ROUGE (Recall-Oriented Understudy of Gisting Evaluation) [20] and BLEU (Bi-Lingual Evaluation Understudy) [25] scores to evaluate the similarity of extracted context against the ground truth. Rouge-N score is based on the percentage (higher the better) of N-grams from the ground truth that are present in the extracted context. BLEU-N score indicates the percentage of N-grams from the extracted context that are present in the ground truth. Rouge-L F1-score is based on the longest common subsequence (not necessarily consecutive) between the extracted context and target context.

6.1 Featurization and Feature Selection

R1: Given the input text sequence length limitations of DL models, what information should be used from PIRs?

Sophisticated DL language models impose constraints on input sequence length (e.g., 512 tokens for BERT [8]). The

Model	ROUGE			BLEU			
	Rouge-1	Rouge-2	Rouge-L	BLEU	BLEU-1	BLEU-2	BLEU-3
Pegasus - Pretrained	32.55	18.72	24.30	9.61	18.03	10.31	8.93
Pegasus - Finetuned	**45.46**	**35.65**	**38.43**	**24.60**	**32.19**	**24.98**	**23.41**
T5 - Pretrained	34.38	23.31	28.03	10.06	15.68	10.83	9.43
T5 - Finetuned	41.63	33.86	35.76	23.81	29.81	24.10	22.70
BERT-cased - Pretrained	40.05	27.03	31.01	18.62	28.43	18.95	16.83
BERT-cased - Finetuned	40.08	27.35	31.20	18.80	28.32	19.03	16.95
BERT-uncased - Pretrained	39.52	26.58	30.74	17.63	27.47	17.98	15.89
BERT-uncased - Finetuned	39.92	27.44	31.57	18.64	28.08	18.91	16.90

Table 4: **Performance of Pegasus and T5 models with their corresponding pre-trained versions and fine-tuned versions. We also present performance of unsupervised clustering based approach for extractive summarization using BERT.**

Model	Micro-F1	Weighted-F1
HiAGM	83.16	89.63
HiAGM_Flat	45.40	68.66
BERT_MLC	42.29	46.85

Table 5: **Performance of HiAGM compared to using flattened root cause taxonomy (HiAGM_Flat) and a finetuned-BERT based multilabel classifier (BERT_MLC).**

Model	Test Perplexity	Test Accuracy
BERT-uncased	7.57	34.83%
BERT-cased	6.69	35.26%

Table 6: **Performance of MLM based pre-finetuning and OCE-assigned root cause based finetuning of BERT.**

limit is much smaller than our preprocessed PIRs (avg. length of $\approx$ 1900 words). However, a PIR is organized into multiple sections and we conduct an ablation study by featurizing each section in the PIR into Bag-of-Words encodings and classify them to top-level root cause categories using a Random Forest classifier. Table 3 highlights that "root cause details" and "5-Whys" sections achieve better micro-F1(1.8% higher) and weighted-F1 (5% higher) scores compared to using the whole PIR. These sections capture information relevant to root cause classification and by only using them, we minimize sequence length to meet constraints imposed by DL models.

6.2 Hierarchical Classification

R2: Is the hierarchical nature of our taxonomy beneficial in leveraging relationships between root causes to classify incidents?

Table 5 compares the level-3 root cause classification performance of our trained HiAGM model against a flattened version of our hierarchical taxonomy (HiAGM_Flat), where we remove parent-child relationships between different root causes in the taxonomy and consider all the root causes tags to be opaque and independent of each other. We also compare HiAGM against a multi-label classifier (BERT_MLC) with the flattened version of the taxonomy using finetuned BERT [8] model (details in §6.4) to encode the PIR text. We observe that HiAGM performs significantly better (31% higher weighted-F1 measure) than HiAGM_Flat indicating the utility of GCN to leverage neighboring relationships between root causes and the need for root cause taxonomies to be hierarchical. HiAGM performs significantly better (91% higher weighted-F1 measure) than BERT_MLC along with HiAGM_Flat (47% higher weighted-F1 measure), demonstrating no utility in finetuning existing language models on PIRs.

6.3 Context Extraction

R3: How do supervised (abstractive and extractive) or unsupervised (extractive) summarization approaches fare for context extraction? Is finetuning necessary for context extraction and does it work with limited data?

Using the train and validation splits of the dataset, we finetune Pegasus for 15 epochs and T5 (3 Billion parameters) [27] for 7 epochs and report the results on the test set. Table 4 compares the performance of finetuned Pegasus model against baseline approaches using T5 and clustering-based extractive summarization [23] using BERT. We can clearly see that our finetuned Pegasus model achieves the highest performance across various ROUGE and BLEU metrics. We observe a significant (58.15%) improvement in Rouge-L score as a result of finetuning Pegasus, because pre-trained version of Pegasus is trained on significantly different domains of language such as news articles, etc., and is trained to summarize them, which is different from context extraction. We also observe a 7.6% increase in ROUGE-L score compared to the finetuned-T5 model, because Pegasus extracts sequences of text from the PIR as opposed to T5 which generates new sequences of words, which might not represent the content present in the PIR which is where engineers derive their context from. Finetuned-Pegasus performs significantly higher (21.73%) than unsupervised clustering based summarization approaches using finetuned-BERT, because summary of the PIR doesn't represent the context.

Metric	Response	Description
(Q1) Usefulness of generated context to identify contributing factors	4.6/5	1 - Not useful at all, 5 - Very useful
(Q2) # Contexts generated with unnecessary details	0/10	No unnecessary details in generated contexts
(Q3) # New Rootcauses from generated contexts	2	False negatives identified by AutoARTS
(Q4) # Examples with a crucial Rootcause tag missing in classification	7/10	Crucial contributing factor missing from predictions

Table 7: **Quantitative user feedback from an expert over the effectiveness of AutoARTS across context generation and root cause classification tasks over a randomly chosen set of 10 incidents.**

6.4 Fine-tuning Language Models

R4: Can existing language models like BERT be finetuned to model software incident reports?

We conducted Masked Language Modeling(MLM) based pre-finetuning of BERT to fit our domain-specific language model, using 110K PIRs (un-tagged due to scale) from several Microsoft services. We then finetuned the models by leveraging the OCE-assigned "root cause Category" tag (which are chosen from the predefined taxonomies in Microsoft) of each of the PIRs. As mentioned in §2, OCE-assigned root cause category tags are not accurate; however, they are available at a large scale and this classification task is semantically the closest to our target classification task using the ARTS taxonomy. Table 6 shows the results for both pre-finetuning and finetuning tasks, highlighting a high perplexity of 7.57 for BERT-uncased (perplexed between choosing 8 candidate words for a blank in a given sentence) and poor classification accuracy ($\approx 35\%$) on the finetuning task. Errors in tagging of PIRs (by OCEs) coupled with lack of sufficient training data makes finetuning language models infeasible. Due to space constraints, we omit the results from other variations of BERT, but we had similar experience with them.

7 User Study

To evaluate the utility of AutoARTS, we randomly sampled 10 example incidents and the tool's generated contexts, the corresponding root cause categories and presented them to one of the leads that developed the ARTS taxonomy (by studying PIRs). These were examples that were tagged by them in the past that are not used for training any of our models. The goal of this study is to understand, for each example: (Q1) How useful the generated context is in identifying all the contributing factors that they identified, (Q2) If the generated context has extra details that are not useful for identifying contributing factors (to evaluate the succinctness of our generated contexts), (Q3) Whether the generated context can help them identify any new contributing factor that they have not identified previously (to evaluate the generalization of the model's outputs beyond accidental False Negatives in ground-truth) and (Q4) Whether the tool missed the most important contributing factors (to evaluate the importance of False Negatives).

Although we quantitatively evaluated the syntactic similarity of generated contexts to the ground truth, the developer study helps us understand if they are semantically similar and ultimately usable by a human (OCE). Similarly for Root cause classification task, the relative severity of each individual contributing factor is not identifiable from ground truth (no ranking). Q4 helps us understand if the predicted contributing factors miss any crucial tag from the ARTS taxonomy.

We quantify response to Q1 on a Likert scale of 1 to 5, where 1 meant 'not useful at all' and 5 meant 'Very useful'. Q2-Q4 were answered as a binary Yes/No, by providing clarifying responses wherever necessary for sanity check. Table 7 shows the utility of the tool based on the subject's responses to Q1-Q4. We find from the study that the contexts generated by the tool are extremely useful in identifying all the contributing factors and they are succinct enough without presenting additional information that is not useful in identifying contributing factors. In addition to this, we also found that our tool helped the subject find 2 new root cause tags that should have been assigned to these incidents in the past, highlighting the difficulty in manually sifting through postmortem reports to identify contributing factors.

At the end of the experiment, the subject was asked to answer on a scale of 1-5 (5 being very useful, 1 being not useful at all), indicating the overall usefulness of our tool to assist them in their task based on the 10 examples. The subject rated our tool 'above 4.5'. In addition to this, the subject's verbatim feedback on our tool — **'This tool is very useful from context generator perspective for the root cause classification task. From the Tags perspective, if we had 4th level for just code change related tags this is very useful for change management standards team. Need to fix the dependency tags related logic as it's defaulting to "Data Bricks". Over all I am very happy with this tool'** — highlights the utility of our context generation and the lapses in automated root cause classification. The imbalance in tag distribution over our training set resulted in misclassifying incidents with tags that do not have sufficient supporting training samples. Overall, the feedback indicates the promise for deploying the tool for practical use in assisting engineers by providing enough context from PIRs to assign root cause tags from ARTS taxonomy.

8 Related Work

Rootcause analysis of past incidents. Rootcause analysis of incidents and outages and defining taxonomies to capture their root causes has been a popular topic of study in the software engineering and systems community. We find that prior work can be categorized into two major buckets. The first category of prior work focuses on specific type of production issues such as software bugs [4, 5, 11, 19, 21, 40] or network issues [14]. The other category focuses on specific services or systems such as big-data systems [38], business data processing platform [9], high performance computing [17, 29] and a specific cloud service [13]. In contrast, we consider a large-scale cloud system consisting of many hundreds of services and *all* types of failures including hardware and software, infrastructure and application, software code and configuration, and so on. The scale of our study also differentiates us from existing studies (e.g., 152 incidents from 1 service considered in [13], 100 incidents from networking service in [14]). To the best of our knowledge, this is the most comprehensive effort of analyzing production incidents and building a fine-grained taxonomy. Prior work that propose solutions to simplify the task of actively identifying the root cause of a failure [10, 32] are orthogonal to our focus.

Text Summarization & Root cause classification. Text summarization [33] is the task of rewriting a long document into a condensed form while retaining its essential meaning, hence reducing the burden to read through lengthy documents. The most prevalent paradigms for summarization are extractive and abstractive based approaches. When generating summaries, abstractive summarization approaches [35] are typically considered as a sequence-to-sequence learning problem [24, 26, 30], whereas extractive summarization methods [12, 41] extract key sentences as summary directly from the text. In our context extraction task, we utilize the gap sentence based summarization technique not to condense the PIR context, but to extract essential text snippets describing different contributing factors. Saha et al. [28] construct a causal knowledge graph from postmortem reports but do not generate consistent root-cause tags for incidents. This can lead to ambiguous and non-uniform tagging of similar incidents, as we observed from manual tagging using different taxonomies (in Finding 2).

Prior work focused on diagnosing different kinds of incidents such as, Rex [22] suggests changes in potential misconfigurations using syntax trees, DeepAnalyze [32] identifies culprit frame in Windows Error Reporting (WER) crash stack traces, Orca [2] identifies buggy commits using differential code analysis and provenance tracking, Revelio [10] generates debugging queries for root cause analysis using logs and user reports, SoftNER [31] analyzes postmortem reports to extract entities. To the best of our knowledge we are the first to classify incident postmortems into an extensive high-granularity taxonomy.

9 Discussion

Generality of AutoARTS. Postmortems are routinely conducted in large scale production cloud systems to document learnings from incidents, similar to PIRs in Microsoft Azure (e.g., Google [14], AWS [1], and Cloudfare [7]). These postmortem reports may have different structures and content across different clous systems, but they all contain natural language descriptions of root cause diagnosis of incidents. Since the ARTS taxonomy is based on a diverse and large set of services and incidents, and AutoARTS is trained on postmortems, we believe that they can benefit other cloud systems.

Evolution of Taxonomy. Our open-sourced ARTS taxonomy captures a wide range of contributing factors, but new factors may emerge and the taxonomy may evolve. Therefore, we deliberately separate context generation and classification in AutoARTS so that new categories can be detected from the generated contexts (Table 7). When a new category is identified, the HiAGM model of AutoARTS can be finetuned for the new tags only (which takes a few minutes). We also hope others can contribute to the growth of ARTS taxonomy.

10 Conclusion

Incident postmortems are treasure troves of rich insights and retrospective analyses of them reveals actionable insights to improve reliability and availability of large-scale production systems. Unfortunately, it's not done at scale today because of the manual effort required in analyzing them. We developed a novel hierarchical and comprehensive taxonomy based on a painstaking extensive multi-year analysis of 2000+ severe incidents across 450+ Microsoft Azure services. To make this taxonomy accessible and assist engineers in analyzing postmortem reports, we proposed techniques to extract key context from postmortems and automatic classification to identify all the contributing factors for an incident and presented our findings. To the best of our knowledge, this is the largest study of production incident postmortem reports yet.

We envision that this paper enhances the audiences' understanding of contributing factors for production incidents and fosters future research by leveraging the open-sourced taxonomy for root cause labelling. Our experimental findings show promise in assisting engineers with classifying postmortem reports and we intend to fully automate this task incorporating engineers' feedback and leverage larger training datasets in future work.

Abstract

It is common for performance studies of computer systems to make the assumption—either explicitly or implicitly—that results from each trial are independent. One place this assumption manifests is in experiment design, specifically in the order in which trials are run: if trials do not affect each other, the order in which they are run is unimportant. If, however, the execution of one trial *does* affect system state in ways that alter the results of future trials, this assumption does not hold, and *ordering must be taken into account* in experiment design. In the simplest example, if all trials with system setting *A* are run before all trials with setting *B*, this can systematically bias experiment results leading to the *incorrect* conclusion that "*A* is better than *B*" or vice versa.

In this paper, we: (a) explore, via a literature and artifact survey, whether experiment ordering is taken in to consideration at top computer systems conferences; (b) devise a methodology for studying the effects of ordering on performance experiments, including statistical tests for order dependence; and (c) conduct the largest-scale empirical study to date on experiment ordering, using a dataset we collected over 9 months comprising nearly 2.3M measurements from over 1,700 servers. Our analysis shows that ordering effects are a hidden but dangerous trap that published performance experiments are not typically designed to avoid. We describe OrderSage, a tool that we have built to help detect and mitigate these effects, and use it on a number of case studies, including finding previously unknown ordering effects in an artifact from a published paper.

1 Introduction

Systems performance analysis typically involves running a series of trials and then calculating statistical measures (such as mean or median) from the performance data collected. These measures are used to conclude that one system is, on average *X*% faster than another, that the addition of a new feature does not have a statistically-significant impact on performance [12, 16], or that software scales well to large problem sizes. One of the most fundamental assumptions of this kind of analysis [36] is that trials are *independent*; in particular, that each trial is unaffected by prior trials in the series. If this assumption does not hold, it can systematically bias results and alter or even invalidate conclusions drawn from them.

Typical systems research work does not take ordering into consideration as part of experiment design. This can lead to violations of the independence assumption.

The problem is especially pernicious because there is not one, or even a few, root causes behind performance-affecting state that carries over between trials. In the highly complex environment of a modern computer system, there are a large number of hardware and software components whose state can be carried over from one trial to another [26]. These include caches [8], data layout in RAM and on disk [22], application and operating system tuning parameters [20, 41], and even temperature (with consequences such as thermal throttling [3, 13]). The systems under test themselves can, intentionally or unintentionally, make changes that persist between trials, such as changes to software packages, global system configuration, environment variables [26], or files.

Thus, while the question of *why* order matters is important, it is highly specific to the software being tested, the hardware it is run on, and the design of the experiment. Before "*why*" can be considered, there is the more fundamental question of *whether* the order matters for a specific experiment. In many cases, knowing that order-dependent performance *exists* can itself be an interesting result because it indicates some unexpected property of the software or system under test. Therefore, eliminating it entirely through experiment design is not always even desirable.

In this paper, we formulate a systematic approach to analyzing whether the order of trials within an experiment affects results. We use this method to collect and analyze a large new performance dataset that we collected on over 1,700 servers over a period of 9 months and show that experiment order is a factor that cannot be neglected. We find that for the selected benchmarks the order can bias performance by 50% or more and potentially alters conclusions in 72% of cases.

Order is acknowledged to have some level of impact in the literature [1, 26]. However, we show this acknowledgment has not translated into experiment design *in practice*. We conducted a survey of three major systems conferences and found that it is exceedingly uncommon to discuss experiment ordering in these papers. Furthermore, we examined the artifacts for the papers and find that they are not designed to detect or avoid ordering effects. To help relieve this situation, we contribute OrderSage, a tool that helps experimenters with both

the orchestration and analysis aspects of experiment ordering.

In this paper, we make the following contributions:

- We perform a literature survey of top-tier systems conferences (Section 2), showing that experiment order is reported as part of experiment design in fewer than 10% of papers. We also analyze these paper's artifacts, and show that this neglect extends to the way experiments are run in practice: more than 94% of artifacts run experiments in either a single fixed order or do not specify an order.
- We develop a methodology (Section 3), using established statistical tests, for determining whether results are order-dependent and narrowing down specific experimental tests that are particularly affected.
- We collect and publicly release a large, first-of-its-kind dataset for studying the impact of ordering on performance experiment results (Section 4). This dataset contains the results of over 2.3M trials run in a variety of different orders.
- We analyze this dataset using our methodology (Section 5) and show that ordering can make a significant difference, even to the level of potentially changing conclusions. This provides strong evidence for the claim that systems researchers should consider order in their experiment design.
- We developed and release OrderSage, a tool that easily applies our methodology to performance experiments (Section 6). OrderSage embodies both a mechanism for randomizing experiment order and analyzing its effects. To demonstrate its use, we present case studies (Section 7) applying it to the performance test-suite for `memcached` [2, 7, 21], and to NPBench [43]. We also use OrderSage on one of the artifacts from our literature survey and find a previously-unknown ordering effect in it.

We cover related work in Section 8 and conclude in Section 9.

2 Literature and Artifact Survey

To evaluate the extent to which ordering effects are taken into account in practice in the systems research literature, we conducted a survey involving the OSDI '21, SOSP '21, and EuroSys '22 conferences. We selected these three conferences because they ran *Artifact Evaluation Committees* (AECs), meaning that we were able to look at both what *papers say* about ordering and what the artifacts (code, scripts, etc.) *actually do*.

We had two inclusion criteria for our survey. First, the papers need to have received all three AEC badges (Available, Functional, and Reproduced)—this lets us know that not only did the paper have an artifact submitted, but that the artifact is complete. Second, the papers need to base their main claims

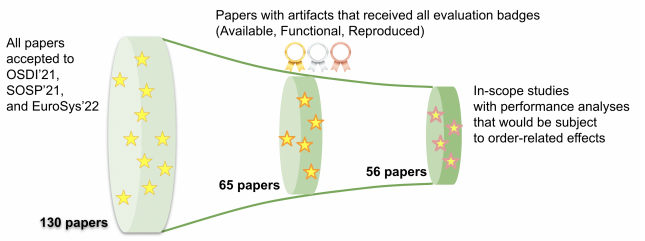

Figure 1: Paper selection for our literature and artifact survey.

on a set of performance metrics (e.g., runtime, latency, bandwidth, etc.) executed on real (not simulated) systems. Under these criteria, we ended up with 56 papers out of the three conferences' 130 papers, as seen in Figure 1.

Following the selection and filtering phase, we performed the survey in two passes; each paper/artifact was reviewed by a different reviewer in each pass, with the goal of countering individual reviewers' biases. Table 1 presents the results from both passes as well as the agreement between the two passes. It is worth noting that the spread is larger for the artifact analyses because they required more investigation than reading the evaluation sections of the surveyed papers. Regardless, we consider all observed relative agreement numbers to be high enough to serve as a convincing basis for our conclusions. As detailed below, our artifact review provided much more insight into how the studies were run compared to the information in the papers alone.

Do papers specify the ordering of their experiment design? Only 4 out of 56 papers (7%) clearly stated the order in which the corresponding performance experiments were run. This percentage is not surprising, because space constraints lead authors to focus on describing the factors that are key to their work instead of latent factors such as the order of execution. Of special note is that EuroSys '22 allowed artifact description appendices, which we considered as part of the paper rather than part of the artifact. This is where we found most of the ordering-related information; these appendices allowed authors to detail steps in their evaluation workflows, leaving no ambiguity about the orderings.

Do papers describe their inter-experiment reset procedures? Between 4 and 10 papers, or 7–18%, described reset procedures for ensuring that subsequent trials are not potentially impacted by the preceding tests. Such procedures included clearing caches, running warmup tests, rebooting hardware, and launching new cloud instances, among others. Similar to our conclusion about the order information, the reset specification was scarce in the studied papers.

What order do artifacts execute experiments in? Because papers do not tell us much about what order is used for experiments, we examined the artifacts themselves. 36 to 37 artifacts (64–66%) use a fixed-order experiment design. This was typically implemented by providing a "run all" script

Table 1: Results of studying 56 papers and the corresponding artifacts.

Attribute being tested	1st pass	2nd pass	Match b/w passes
Paper explicitly describes an order of experiment execution	4 (7%)	4 (7%)	93%
Paper describes a reset procedure to be run between experiments	4 (7%)	10 (18%)	82%
Artifact's primary experiment execution order:			63%
fixed	36 (64%)	37 (66%)	
undefined	17 (30%)	17 (30%)	
parallel	3 (5%)	2 (4%)	
Artifact runs a reset procedure between experiments	27 (48%)	16 (29%)	73%

that iterates through the studied algorithms or configuration options in sequence with no randomization. In other cases, a specific order was documented in the repository's README files. Many other artifacts (17, or 30%) provided instructions on how to run individual groups of tests (e.g., for specific figures and sections in the papers) but did not specify any sequence between them—we categorized their orderings as undefined. Another small class of studies (2–3 artifacts) used parallel execution, where tests were run concurrently on multiple worker machines or cloud instances and therefore can be considered to run each test in its own clean environment. We have not identified any artifacts that implemented a randomized ordering, or which clearly showed explicit attention to ordering concerns. To summarize, 53–54 artifacts out of 56 (94–96%) used undefined or fixed orderings, both of which can be questioned from the presentation and experiment design perspectives. Expanding on the latter case, we show in this study that fixed-order experiment designs have potential to introduce adverse bias in performance analysis.

Do artifacts use inter-experiment reset procedures? Between 16 and 27 artifacts (29–48%) ran identifiable procedures to reset the system to a known state between experiments. Finding these procedures in the code is a non-trivial and time-consuming process, which explains the spread between the results in the two survey passes. While we did find reset procedures in up to half of the artifacts, it is concerning that the other half of the artifacts did not manifest any reset procedures. While it may not matter for some of the studies because of the nature of their performance analysis, there is a chance that for a subset of them it may be an oversight causing undesirable effects on their conclusions.

From the survey, we learn that the literature does not make order an explicit part of experiment design, and we do not see evidence that ordering issues are explicitly addressed. In the remainder of this paper, we show how this can constitute a trap for experimenters and discuss how to avoid this trap.

3 Analyzing Order Dependence

In this section, we detail the procedure we have designed to find order dependence in performance experiments. There are two primary outputs from this procedure: first, it reports whether the statistical distribution of performance results differs when run using *fixed-order* and *random-order* experiment designs—that is, whether the order has an effect on the experiment results. Second, it reports whether these differences are potentially large enough to *change inferences*—that is, whether it is possible for ordering effects to be large enough that the conclusions drawn from an experiment could change based on the execution order.

For consistency, we use the following terminology in this section and throughout the remainder of the paper:

Test: A test is an individual unit of the system under evaluation. A test typically represents an individual benchmark or an application with a specific configuration or input.

Trial: A trial is an execution of a test. The outcome of a trial is a single-metric performance assessment, such as runtime, throughput, latency, etc. Multiple trials of the same test typically exhibit variations in performance stemming from the nondeterminism intrinsic to the test itself or the system used for benchmarking.

Run: A run is a set of trials, in a particular order, of *all* tests in series. Conceptually, one could (and often does) report the results from a single run in a single order.

Experiment: An experiment is a collection of one or more runs done for the purpose of reaching a conclusion about the system(s) under evaluation; typically, such a conclusion will be reached by comparing results of the trials associated with different tests. The order of trials within the runs of an experiment is part of the *experiment design* and is referred to as the *experiment order*.

An outline of the method is shown in Algorithm 1; below, we go through each step in detail.

❶ Select a "Baseline" Order Select an ordering of trials that will be used for "fixed order" runs. The order itself is not important; the order in which trials have been run in the past, or a "natural" order (such as by increasing parameter value) is sufficient. This does not need to be a "correct" order: it will act as the control against which we test random orderings.

❷ Define a "Reset to Clean State" Procedure Each run (series of trials) should start from a clean state, such that

Algorithm 1 Order-Dependence Test

Input T: List of trials in baseline order ▷ ❶
Input R: Reset procedure ▷ ❷
Input N: Number of repetitions
Input α: Desired family-wise error rate (commonly 0.05)
1: **for** $n = 1, \ldots, N$ **do** ▷ ❸
2: Execute R
3: **for all** $t \in T$ **do** ▷ Run trials in baseline order
4: fixedOrderResults$[t][n] \leftarrow$ Execute t
5: **end for**
6: Execute R
7: **for all** $t \in$ RandomlyPermute(T) **do** ▷ Run trials in random order
8: randomOrderResults$[t][n] \leftarrow$ Execute t
9: **end for**
10: **end for**
▷ ❹
11: **for all** $t \in T$ **do** ▷ Calculate p-values for distribution comparison
12: $p_{KW}[t] \leftarrow$ KruskalWallis(fixedOrderResults$[t]$, randomOrderResults$[t]$)
13: **end for**
14: $\alpha_{BC} \leftarrow \alpha / length|T|$ ▷ Use Bonferroni corr. for multiple comparisons
15: **if** $\exists t \in T \mid p_{KW}[t] < \alpha_{BC}$ **then**
16: **return** true ▷ Order matters for 1 test $\rightarrow$ it matters for the experiment
17: **else**
18: **return** false
19: **end if**

Algorithm 2 CI Overlap Test

Input fixedOrderResults, randomOrderResults from Algorithm 1
Input t: test to check
1: (fLow, fMedian, fHigh) $\leftarrow$ RankBasedCI(fixedOrderResults$[t]$) ▷ ❺
2: (rLow, rMedian, rHigh) $\leftarrow$ RankBasedCI(randomOrderResults$[t]$)
3: **if** (fLow $>$ rHigh) $\vee$ (fHigh $<$ rLow) **then**
4: **return** Case 1 ▷ Inference *does* change
5: **else if** (fLow $<$ rMedian $<$ fHigh) $\wedge$ (rLow $<$ fMedian $<$ rHigh) **then**
6: **return** Case 2 ▷ Inference likely does *not* change
7: **else**
8: **return** Case 3 ▷ Inference may or may not change
9: **end if**

state left over from earlier runs will not affect performance results of the next run. In many cases, this will be much more expensive than running the benchmarks themselves: for the purposes of the experiments in this paper, this procedure is a reboot of the server on which the benchmarks are executed. This might instead consist of restarting a server process, provisioning fresh VMs, clearing storage devices, etc.

❸ Run in Both Fixed and Random Orders We execute a series of runs. Each run consists of the same set of trials, and each trial may comprise of multiple invocations of the system under evaluation in order to increase statistical significance. For half of our runs, trials are run in the fixed baseline order; in the other half, the order is randomly permuted (separately for each run). Between runs, the environment is reset to a clean state using ❷. Since the evaluation might take long enough that time-varying effects (such as hardware degradation) could be observed, fixed (Lines 3–5) and random order (Lines 7–9) runs are interleaved to avoid bias. The outcome of each run is a set of performance results, one from each trial, with the units being the "natural" units for the tests, e.g., seconds for runtime, MB/s for bandwidth, etc. The experimenter should complete a sufficiently sized set of runs (Line 1) to provide the desired statistical significance in the subsequent steps.

❹ Compare Distributions The next step is to compare the samples obtained from the fixed- and random-order runs. The intuition behind this step is that if the two sets of samples come from the same statistical distribution, it can be said that the order does not change the distribution, and thus does not matter. If they come from different distributions, then the order does indeed matter.

To avoid assumptions of normality (which have been shown to rarely hold for computer systems performance results [22]), we use the non-parametric Kruskal-Wallis test (Lines 11–13). This distribution-comparison test produces a p-value indicating the likelihood of observation assuming the null hypothesis (i.e., that both samples come from the same distribution). This should be performed *for each test*, longitudinally across all runs: the two populations are (a) the outcomes for all trials (executions) of the test from fixed-order runs, and (b) the outcomes of all trials for the same test from random-order runs. Thus, we are looking at whether a particular test's performance differs based on where its trials occur in the runs that are differently ordered.

For each test, compare the p-value produced by Kruskal-Wallis with a threshold chosen to provide the confidence level desired; we aim for a family-wise error rate of $\alpha = 0.05$ (95% confidence) as is common in such tests. Because we perform a potentially large number of comparisons, the problem of multiple comparisons [25] arises; we apply the Bonferroni correction [9] (Line 14) to obtain the per-test thresholds (α_{BC}) required for multiple comparisons to reach the target family-wise confidence level. This correction scales the thresholds down (making them stricter) in proportion to the number of comparisons made.

If the p-value is above the threshold, we cannot reject the null hypothesis, and therefore conclude that both samples could have come from the same distribution—the order *likely does not matter*. If the p-value is below the threshold, we reject the null hypothesis and conclude that a single distribution would be highly unlikely to yield the observed samples—*the order of the tests **does** matter*.

We note that it is possible, and in our experience common, that different tests within an experiment produce different results at this step. This could indicate that some tests are affected by what runs before them and others are more robust in this respect. Overall, however, as long as *any* test shows order-dependence, this indicates that the experiment design as a whole needs to be aware of ordering (Lines 15–19).

❺ Compare Confidence Intervals A typical experiment setup in performance analysis is to ask whether there is a difference in performance between two systems. A situation

particularly important to avoid is one in which inferences from the experiment could *change* depending on the ordering, in turn leading to a change in the *conclusions drawn*. We look for such situations by comparing confidence intervals [12] (CIs) as shown in Algorithm 2. CIs can be compared *within* tests (e.g., comparing fixed and random orders, to determine whether order changes the median computed), or *across* tests (e.g., comparing two or more tests and checking whether different performance is observed.)

The outcome of this test tells us something related to, but distinct from, the Kruskal-Wallis test. Kruskal-Wallis tells us whether the distributions differ, but not directly whether they differ enough to change conclusions in a significant way. Looking at the effect size (detailed in Section 5.1.1) gives us a sense of the latter, but the CI test answers it directly. Recall that a CI is an estimated interval we expect to include the true value of a population measure [12]. For instance, for the 95% CI of the median (the interval we use), we expect that in a collection of many such intervals, 95% of our estimates would contain the true population median.

We use rank-based CIs estimating the population median [17] to avoid assumptions of normality. This comparison results in three possible cases (visualized in Figure 5):

Case 1: The CIs for the fixed- and random-order runs do not overlap. In this case, we can have high confidence that we would expect to compute different medians depending on the order. This is a **red flag**, and indicates that we could come to different conclusions based on the order.

Case 2: The median for at least one of the two samples lies within the CI for the other population. If this is the case, given one population, we could have potentially arrived at the *other* observed median, and we conclude that our conclusions likely would not change based on order.

Case 3: In the final case, the CIs overlap, but both medians are outside the other group's interval. This case is inconclusive, and requires more careful analysis to determine if it could change conclusions. Still, it is a potential sign that more careful experiment design is needed.

4 Dataset and Data Collection

To study performance effects at a large scale, we have collected a dataset covering nearly 2.3 million executions (*trials*) of 25 benchmarks on 1,700 machines over a period of nine months. Many benchmarks were run in multiple configurations, such as on different sockets or with different CPU frequency settings, resulting in multiple *tests* per benchmark application. This data was collected across more than 9,000 *runs*. We released this dataset as part of this paper's artifact: `https://github.com/ordersage/paper-artifact`. Collection of the dataset covers the first three steps of the method described in Section 3; we cover the rest of the steps in the this section.

This dataset focuses on *low-level measurements* of CPU and memory performance through the use of standard benchmarks, in particular STREAM [23], the NASA Parallel Benchmarks [27] (NPB), and Reece's memory benchmarks [30, 31]. We have additional benchmarks of disk and network performance, but leave analysis of them to future work. Our case studies in Section 7 have examples of our methodology applied to higher-level applications.

4.1 Environment

We collected our data by running experiments in CloudLab [5], a public testbed for research use. CloudLab has a variety of different types of server hardware [37], and we ran our experiment across 13 different server types. We considered each configuration of each benchmark on each node type as constituting its own test for the purposes of this analysis: thus, we have 1,880 different collections of corresponding trials to compare. CloudLab is an attractive platform for this work, as it has previously undergone study to quantify and calibrate the level of variability across different hardware in the platform [22].

Servers in CloudLab are allocated at a *bare-metal* level to one user at a time. Disks used are all local to the server, and for this paper, we do not consider the network or other shared resources. Thus, our benchmarks were not affected by any other simultaneous users of the servers in question or the CloudLab system as a whole, and did not have any artifacts due to virtualization. We believe our dataset to be robust with respect to time-varying, location-dependent (e.g., environmental/temperature), and micro-architectural factors: we gathered this data over a period of months; CloudLab nodes are in three different geographically distant data centers; and they encompass a variety of processor and memory technologies.

4.2 Baseline Order ❶

The baseline order that we use is a "natural" one that groups benchmarks from the same suite (e.g., NPB [27]) together, and reflects the order in which we added the suites to our experiment setup. This reflects the type of order that a systems experimenter would be likely to arrive at in the process of developing scripts to run their experiments.

4.3 Reset Procedure ❷

The reset procedure we use is a fresh load of the operating system and clean boot of the host on which the experiments are run. This means that each run sees, as much as possible, the "pristine" state of a just-booted machine, not affected by any software or configuration changes made by prior users.

It is important to note that we do not claim this clean state to be *correct*: we do not claim that the results of a trial gathered under these conditions are more "valid" than results after the machine has been running for some time. It is possible for boot-time effects to alter results, and for some tests, a scenario in which a machine has been booted and active for a long period of time may be more *realistic*. What we *do* claim about this procedure is that we can be confident that all runs *started* from the same state. Therefore, it can tell us if the order of trials within the run affected results.

4.4 Running in Fixed and Random Orders ❸

Our data collection framework allocates machines in CloudLab on which to perform runs. For each run, it randomly chooses—with equal probability—to execute trials in our *fixed baseline* order or a *random order*. This procedure ensures that we *interleave* baseline and random runs, running them in approximately equal proportion throughout the entire time period to avoid a systematic bias in one direction or the other due to potential changes in the facility over time. If the random order is chosen, the framework shuffles the list of all trials for that run. The framework records this order information for use in future analysis.

5 Analysis Applied to Our Dataset

We now describe how we analyze the order-dependence of the performance results gathered in Section 4. This section covers steps ❹ and ❺ from the method described in Section 3.

The nature of our data collection adds another dimension to our *tests*, and thus we adopt terminology used elsewhere in the literature [22] for clarity. Because CloudLab contains servers of many different types, each of the *tests* we define will be executed on 13 different hardware types—each different hardware type may have a different processor, different amount of RAM, etc. We refer to a combination of *{test, hardware type}* as a *configuration*, where the *test* itself is a combination of *{benchmark, settings}*. For example, the STREAM benchmark run in its `COPY` mode on a server of type `m400` represents one configuration; STREAM in `COPY` mode on a server of type `c6520` is another; and STREAM in `SCALE` mode on an `m400` would be a third. In total, we have 1,880 such configurations. Results from *trials* executed under a particular *configuration* across all *runs* are grouped together: our primary comparison of interest is whether the same configuration produces different results when run as part of differently-ordered runs. It is worth noting that we do not expect results from different configurations to be independent, and do not analyze them as such: there is strong likelihood, for example, that STREAM in `COPY` mode exhibits similar order-dependent performance effects to STREAM in `SCALE` mode. The value derived from running so many configurations is that it helps to make our results robust with respect to many different programs, settings for those programs, and types of hardware.

We analyze data from our memory and CPU benchmarks as separate experiments: this avoids mixing results from performance tests with very different goals, and offers interesting insight into how the effects of ordering can differ depending on the main resource being exercised.

5.1 Comparing Distributions ❹

The next step in our method is to compare the distributions of performance results for each configuration when run in fixed vs. random orders.

5.1.1 Memory Benchmarks

The left side of Figure 2 plots the p-values for all 1,198 configurations of memory benchmarks. For this test, the Bonferroni-corrected α_{BC} ($n = 1,198$) is 4.2×10^{-5}. Configurations are sorted on the x-axis according to the effect size (discussed below). As can be seen from the figure, most (1,042, or 87%) of the configurations fall well below the α_{BC} threshold, showing clear evidence of performance effects due to ordering.

To strengthen our analysis, we calculated the *effect size* for each pair of compared samples. This measure is not meant to replace the p-values but rather should complement them [40]. While the statistical tests indicate that the probability of the sampling error causing the observed performance difference may be low, measuring the effect size helps us understand the scale of the difference between the groups.

We calculate the effect size for each statistical test. The larger the effect size, the larger the estimated difference between the populations being compared; a small effect size can indicate that even when there is a statistically significant difference revealed by a p-value, it may be small enough not to be of *practical* importance. To align with the Kruskal-Wallis test, we use the non-parametric formulation of the effect size η^2 that is defined using the H-statistic [4]. In statistics terms, η^2, which yields values between 0 and 1, estimates the fraction of variance in the dependent variable that can explained by the independent variable. The review article [40] provides additional context and includes the formula for η^2 calculation.

η^2 values are plotted in the right side of Figure 2. Past the first few hundred configurations, η^2 becomes larger indicating that the difference between the fixed-order and random-order results becomes larger. This is also the exact region in which $p < \alpha_{BC}$, which indicates significance. It is worth noting that we do not compare η^2 with arbitrary thresholds but rather observe its growth across the range of the tested configurations for comparison purposes; from this standpoint, it is assessed similarly to how we interpret percentage differences in Section 5.1.3.

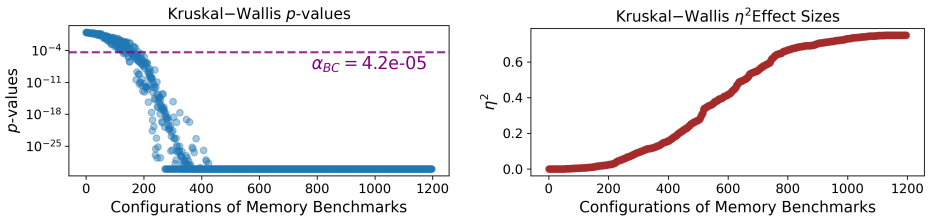

Figure 2: Kruskal-Wallis p-values and effect sizes for memory benchmarks, sorted in order of increasing Kruskal-Wallis η^2 effect size. The horizontal line at the bottom of the left plot comes from rounding small values up to 10^{-30} for display.

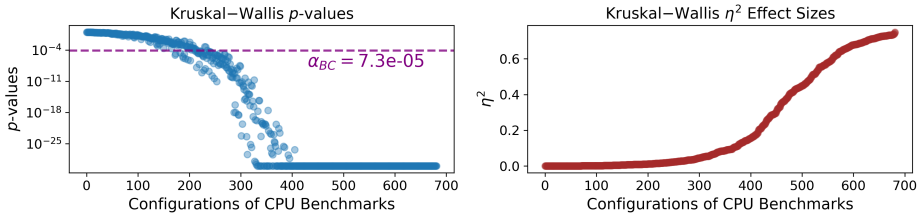

Figure 3: Kruskal-Wallis p-values and η^2 effect sizes for CPU data. The plotting is as described for Figure 2.

5.1.2 CPU Benchmarks

Figure 3 shows the Kruskal-Wallis p-values and effect sizes for our CPU benchmarks. For these comparisons, α_{BC} ($n = 682$) is calculated as 7.3×10^{-5}. As with the memory benchmarks, most configurations fall well below the α_{BC} threshold, indicating that the order in which they are run makes a difference. The most observable distinction between the CPU tests and the memory tests is the shape of the effect size curve: while there are still some configurations that have large effect sizes, there are fewer of them. There are a larger number of configurations that reach statistical significance in the p-value test but have an effect size small enough that it may not have a practical impact. This demonstrates the need to look at both significance tests *and* effect sizes.

Table 2 summarizes the observed Kruskal-Wallis p-values. From this table, we can clearly conclude that the order of experiments matters for the selected microbenchmarks. This effect appears to be more pronounced for memory benchmarks which have a higher ratio of configurations with $p < \alpha_{BC}$.

5.1.3 Relative Difference

Most computer systems studies report their results not in terms of effect sizes but in terms of absolute or relative differences between several alternatives. To align our analysis with our research community, we also looked at the order effects in terms of percentage differences (representing the difference between the mean fixed-order result and mean random-order result, divided by the mean-fixed order result):

$$\Delta_{\%} = \frac{\mu_{fixed} - \mu_{random}}{\mu_{fixed}} \times 100\%$$

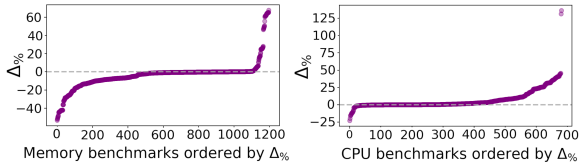

Figure 4: Percent Difference for Memory & CPU benchmarks.

Figure 4 shows the observed $\Delta_{\%}$ values for memory and CPU benchmarks. The configurations are sorted on the x-axis by $\Delta_{\%}$ values, and the y-axis is $\Delta_{\%}$ for a particular configuration. The range of $\Delta_{\%}$ values gives a sense of the magnitude of the studied order-related effects.

Our memory data is measured in throughput, so the higher the value, the better the performance—since we calculate $\Delta_{\%}$ as fixed order performance minus random order performance, a positive $\Delta_{\%}$ indicates that the *fixed* order had better performance than the randomized order. A negative $\Delta_{\%}$ means the *randomized* order performed better. Conversely, our CPU data is measured as execution times, so *lower* values mean better performance: for these, *positive* values mean that the *randomized* experiment design results in better performance.

From these figures, we can see that both memory and CPU benchmarks have some effects that would be considered large enough to affect results. Though they have similar absolute average $\Delta_{\%}$ values (8% for memory, and 7.3% for CPU), the details of their curves are quite different. Both have some configurations that are faster in random order and some that are slower, but the magnitudes and shapes of the curves differ.

Table 2: Configuration classification showing whether there is difference between fixed and random orders or not. The comparisons used Kruskal-Wallis test with Bonferroni-corrected $\alpha_{BC} = 4.17 \times 10^{-5}$ for memory and $\alpha_{BC} = 7.33 \times 10^{-5}$ for CPU comparisons.

Benchmark Type	Kruskal-Wallis $p < \alpha_{BC}$	Kruskal-Wallis $p > \alpha_{BC}$	Total
Memory	1042 (86.97%)	156 (13.02%)	1198
CPU	475 (69.65%)	207 (30.35%)	682

5.2 Comparing Confidence Intervals ❺

In Section 5.1, we showed that experiment order does impact performance using statistical tests and percentage difference. In this section, we look at whether the bias caused by experiment order can result in incorrect conclusions. Answering this question will allow us to establish whether a researcher should consider experiment order while analyzing performance.

Figure 5 shows each of the three cases from the confidence interval overlap test, using examples drawn from our memory benchmarks. The *x*-axis represents the experiment order. The *y*-axis is the rank-based 95% confidence interval of the median performance for each order, with the shaded region representing the interval and dashed lines extending the interval limits to the full width of each figure for comparison. The diamond represents the median value. Case 1 indicates that the conclusion *would* change based on order, Case 2 indicates that it is *unlikely* to do so, and Case 3 is *inconclusive*.

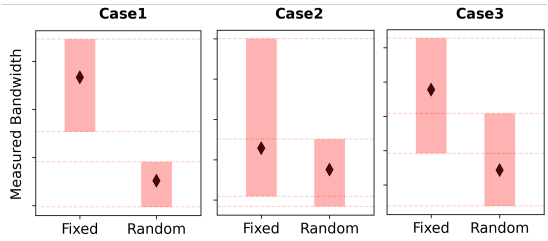

Figure 5: Examples of CI arrangements. The plots are created based on actual measurements for three memory tests; scales are different for them. Red vertical bars are rank-based non-parametric 95% CIs for medians, and ♦—median estimates.

For both memory and CPU benchmarks, we found that most configurations fell into Case 1, meaning that order could change conclusions. This can be seen in Figure 6. The effect is more pronounced for memory benchmarks, where 81% of the configurations fall into Case 1, than for CPU benchmarks, for which only 56% fall into Case 1. Overall, 72% of all configurations are in Case 1. From these results, it becomes amply clear that one can arrive at an incorrect conclusion by merely modifying the experiment order. A performance analysis needs to consider order to ensure accurate results.

6 Automating Experiment Order Testing

We have shown that order can be important in experiment designs. However, it can be difficult for experimenters to rethink their performance experiments to account for this factor. To this end, we have developed OrderSage, a tool that enables experimenters to follow the methodology from Section 3 in their experiments with minimal effort.

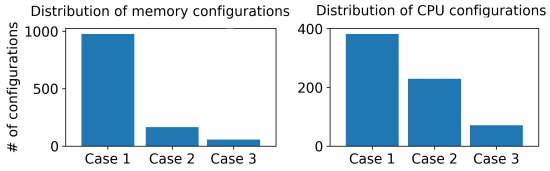

Figure 6: Three CI cases for memory and CPU tests.

6.1 Motivation

The data collection efforts described in Section 4 can be characterized as *long-term*, *extensive*, and *requiring robust infrastructure*. The first refers to the fact that we collected the studied measurements over the period of 9 months. The second indicates that we benchmarked a large pool of hardware types, used numerous tests, and studied many unique permutations of commonly tuned benchmark and system parameters. The third stresses that experimentation of this kind requires reliable computing resources and software for orchestrating test execution, gathering and storing results, etc. We met these requirements using CloudLab hardware, the testbed's programmatic interface built upon `geni-lib` Python package [38], and a set of custom scripts developed for orchestration [39].

This is in contrast to most studies, which describe *short-term* and *focused* analysis efforts, where experimenters thoroughly study subsets from many combinations of tunable parameters and gather the needed results in a limited timeframe. In such settings, the emphasis often is on demonstrating that one algorithm or hardware implementation is better than the alternatives and on characterizing its observed gains. To arrive at such conclusions, experimenters need to make sure that their measurements are not significantly impacted by the order-related effects. In the simplest cases, this means that if they were to run the same sets of tests in different orders, their conclusions would remain valid. We note that in many cases in which order-dependent performance is discovered, this may indicate unexpected behaviors in the system, and is itself an interesting finding.

Aiming to support such focused experimentation, we design OrderSage with the target user in mind who is an experimenter collecting performance data for publication (such

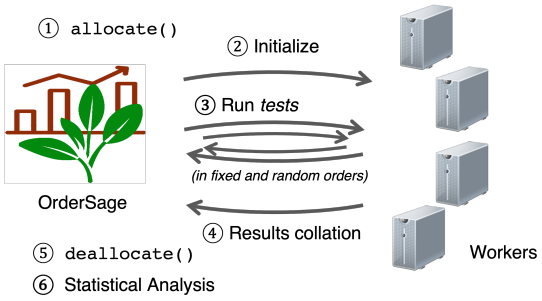

Figure 7: The main operation of OrderSage.

as in a research venue) or for decision-making (such as in a production computing environment.) We assume that such a user can script the execution of each test (e.g., in *shell* or *Python*), and thus OrderSage's primary responsibilities are to execute a number of runs with the scripted tests in different orders, collect and store test results, and analyze the results through the lens of possible order effects. Below, we describe the key components of OrderSage's experiment orchestration.

6.2 Implementation

OrderSage is implemented as a set of Python modules and is available at `https://github.com/ordersage/ordersage`. Its operation can be described using the following terms:

Controller: A machine that facilitates experimentation on a remote node or nodes and performs the statistical analyses. This is the primary place where OrderSage's code runs.

Worker: A machine that executes an experiment that consists of several fixed and random runs. Workers are accessed (through `ssh`) and controlled by a single controller node. One controller can make use of one or more workers.

Results: Each trial produces one performance result in the form of a floating-point number. Multiple performance metrics should be treated as separate results. OrderSage collects these results from the worker(s) and stores them on the controller for analysis.

Figure 7 shows a high-level system diagram that includes the key processes being orchestrated by OrderSage:

① **allocate():** Support is provided for use of worker nodes that are either pre-allocated by the user or reserved on CloudLab testbed. Outside of CloudLab, any node—local or remote—into which the user can `ssh`, run the tests (including installing software, if necessary), and execute the reset procedure can be used. Analogous `allocate()` routines can be implemented for commercial clouds using the APIs they provide.

② **Initialize:** Worker nodes are readied via an initialization script provided by the user. This typically includes installing and configuring the software under evaluation. During initialization, a baseline order is selected (Step ❶ from the method described in Section 3) by running a user-provided script that produces the commands for each test. OrderSage defaults to rebooting a worker node as the "clean state" reset procedure (Step ❷ from the method). However, this behavior can easily be redefined by the user.

③ **Run Tests:** After initialization, tests are run according to Step ❸ of the method. Each run consists of an execution of all trials in some order. Half of the runs are performed in the baseline order, and half in an order that is randomly shuffled (separately for each run); these orders are interleaved. The reset procedure is executed in between each run.

④ **Collect Results:** Performance measurements are collected as outlined in Step ❸ of our method and saved as raw data from each trial. Additionally, metadata such as random orderings, machine environment information, execution times, and `stdout` outputs are saved for each run.

⑤ **deallocate():** If the worker(s) were `allocated()`ed in ①, (such as with our CloudLab integration), OrderSage will handle the deallocation of nodes at the end of the experiment.

⑥ **Statistical Analysis:** Results are analyzed according to Steps ❹ and ❺ from the method described in Section 3. The results of all statistical analyses are saved on the controller node. If multiple worker nodes were used, the necessary result aggregation will take place. A final comparative step will provide a high-level overview of the combined vs. individual experiment analyses.

Running OrderSage is detailed in Appendix A.

7 Case Studies

We used OrderSage to facilitate the methodology proposed in Section 3 for three case studies. Our goals were to demonstrate its use on common benchmarks and application test suites and investigate the impact of test order on the results of these cases. All case studies were executed on CloudLab servers of the `xl170` hardware type [37]. For these experiments, which occurred over 24-48 hours, each experiment was run on a single worker. All data from these experiments are included in the released artifact: `https://github.com/ordersage/paper-artifact`.

7.1 `memcached` Benchmark Suite

This case study uses `memcached`'s own benchmark suite, which is designed to mimic the process of reporting perfor-

Table 3: Test results for the `memcached` experiment. We use Bonferroni correction with $n = 3$ and $\alpha_{BC} = 0.0167$ (providing a family-wise error rate of 0.05). The Kruskal-Wallis p-values are shown, as are their interpretation relative to α_{BC}: the column contains • if the null hypothesis can be dismissed or ○ if it cannot. $\Delta_{\%}$ is calculated as in Section 5.1.3 and the CI cases are as defined in Section 3.

Test	KW p-value	KW test	$\Delta_{\%}$	CI case
`cmd_set`	0.49	○	0.3	2
`cmd_get`	0.74	○	−0.2	2
`get_hits`	0.00009	•	5.3	3

mance numbers for this application. `memcached` [2] is an efficient and widely used in-memory key-value store, and its associated `mc-crusher` [24] benchmark suite includes a variety of scripts designed to exercise a server instance and measure its performance.

The `mc-crusher` documentation specifies "You should start a fresh `memcached`", and includes a series of three tests (`cmd_set`, `cmd_get`, and `get_hits`) in its included `sample` configuration file, executed serially in that order; accordingly, we start `memcached` after the reboot in our standard Step ❷ reset procedure, and perform those same three tests in each of our runs. We follow the same ordering of trials in the fixed case, with a single instance of `memcached` for all trials (following the `mc-crusher` distribution exactly). We increase the sample duration to 60 seconds per test (to reduce the influence of noise on each sample) and permute the order of the trials in our random runs to check our hypothesis that ordering affects the observed results, but otherwise do not modify the sample `mc-crusher` parameters. From inspection of the `mc-crusher` source, we expect the three benchmarks to operate on generally disjoint data, and therefore do not anticipate any direct connection between the execution of one and the output of the next. However, it is difficult to predict the presence or magnitude of *indirect* ordering artifacts, where the side effects of previous computation might influence the efficiency of subsequent operations, which is what our analysis aims to measure.

Table 3 presents the results we obtained by running OrderSage with `memcached` version 1.5.22, with 50 fixed and 50 random runs, each including the three tests described.

Overall, we conclude that the order of trials within a run *does* affect the measurements obtained for the `mc-crusher` environment under test, at the 95% significance level. This coincides with the `get_hits`'s median performance changing by over 5% based on whether a fixed-order or random-order experiment design is used.

7.2 NPBench & NPB

NPBench is a "a set of NumPy code samples representing a large variety of HPC applications" [43]. The authors use it to test a variety of Python HPC frameworks and compilers that aim to accelerate NumPy code; they also expect the results to be useful to end-users of such frameworks. NAS Parallel Benchmarks (NPB) is an open source benchmarking suite which includes "a small set of programs designed to help evaluate the performance of parallel supercomputers." [27] We select two tests from NPBench that exercise operations used in data analytics and machine learning: sparse matrix-vector multiplication (`SPMV`) and the normalized exponential function (`softmax`) used in neural networks. In addition, we select integer sort (`IS`) from NPB, which is used to benchmark random access memory. SPMV and softmax are generally CPU-bound, while IS generally has its performance limited by memory speed. Using OrderSage, we did 100 runs in each of fixed and random orders. We set problem sizes to large enough values to get meaningful results on CloudLab machines: flag L in NBbench is expected to take about 1000ms to run whereas class D in NPB is the largest test problem for IS, and the median runtime was 36 seconds.

Table 4: Test results for the NPBench & NPB experiment. Columns are as described for Table 3.

Test	KW p-value	KW test	$\Delta_{\%}$	CI case
`IS`	0.83	○	0.00	2
`SPMV`	0.69	○	−0.60	2
`softmax`	0.03	•	0.46	3

The results from these experiments are in Table 4. `IS` and `SPMV` show no order-dependence. While `softmax` does show a statistically-significant change in distribution when run in a random order, the effect size of 0.46% is small enough that it is unlikely to make a difference in practice: these three tests can be safely run in any order. This demonstrates the need to look at effect sizes as well as statistical significance: a positive result from the Kruskal-Wallis test does not, by itself, guarantee that the effect is large enough to matter.

7.3 uFS Paper Artifact Reproduction

Our final case study looks at the uFS filesystem presented at SOSP 2021 [19]. This paper submitted an artifact and was awarded the Available, Functional, and Reproduced badges; it was part of our survey in Section 2. uFS is a user-level filesystem "semi-microkernel" [19] that claims good base performance and better scalability than the ext4 filesystem in the Linux kernel. This is demonstrated with benchmarks at various scales and under various threading conditions. Using OrderSage, we find that some experiments run for this paper *are* order-dependent with large effects (up to 17%), though not large enough to change the conclusions of the paper.

The evaluation scripts supplied with the artifact run multiple benchmarks, of which we selected the Microbenchmarks with single-threaded uFS and ext4 (both without journaling.) Their scripts run all 32 workloads in sequence; we modified

Table 5: Test results for the uFS experiment. In the original paper, `ufs` results are compared with corresponding `ext4nj` experiments. Columns are as described for Table 3.

Test	KW p-value	KW test	$\Delta_{\%}$	CI case
`ufs.ADSS`	0.028	•	16.8%	2
`ext4nj.ADSS`	0.364	○	-4.0%	2
`ufs.ADPS`	0.013	•	6.7%	2
`ext4nj.ADPS`	0.406	○	4.7%	2
`ufs.RDSR`	0.112	○	0.2%	2
`ext4nj.RDSR`	0.406	○	-0.8%	2
`ufs.RMS`	0.940	○	0.8%	2
`ext4nj.RMS`	0.650	○	0.1%	2
`ufs.LsMS`	0.650	○	-0.6%	2
`ext4nj.LsMS`	0.940	○	0.0%	2
`ufs.RMP`	0.545	○	0.0%	2
`ext4nj.RMP`	0.545	○	0.3%	2
`ufs.CMP`	0.496	○	-0.2%	2
`ext4nj.CMP`	0.256	○	-0.1%	2
`ufs.LsMP`	0.151	○	3.6%	2
`ext4nj.LsMP`	0.406	○	0.1%	2
`ufs.CMS`	0.019	•	-1.3%	2
`ext4nj.CMS`	0.705	○	0.3%	2
`ufs.RDPR`	0.112	○	0.2%	2
`ext4nj.RDPR`	0.226	○	1.9%	2

them to run one workload at a time as individual tests. We use the leftmost data point for evaluation as described in the paper's Section 4.2 and Figure 5a—these are used to evaluate the claim that uFS performs as well as or better than ext4 under baseline, single-threaded conditions. We used OrderSage and a `c6525-100g` node in CloudLab (which has a dedicated NVMe drive as does the original authors' machine) to run these tests in fixed and random orders (10 times each).

Our results (Table 5) show that order does not matter to most tests, but it does matter to three: `ufs.ADSS`, `ext4nj.ADPS`, and `ufs.CMS`, with the `ufs.ADSS` test changing the most: in the fixed order, its median is 119K with a tight CI of $[117K, 120K]$. In random order, its median drops by 16.8% with a much wider CI of $[74K, 121K]$. The conclusion from the uFS paper still holds: the random-order `ufs.ADSS` median of $98K$ is still greater than the $41K$ random-order result for baseline system it is compared to, `ext4nj.ADSS`, and the CIs do not overlap. This effect may be due to hardware differences: the original uFS paper was evaluated on an NMVe drive using Intel Optane memory, while the drive we used on CloudLab has traditional flash memory. As a result, latencies and flush strategies differ between the environments. However, this demonstrates the necessity of avoiding the ordering trap, as such order-dependent results are probably "hidden" in many published results, and likely indicate system effects that the authors may not be fully aware of.

8 Related Work

There is much scientific literature focused on experimental design and analysis of computer systems performance experiments [12, 16, 18, 32, 34]. Among recent work in related areas are studies of presentation flaws specific to performance results [11] and analysis of performance variability in computer systems [22]. In a separate but relevant context, some research and development efforts are focused on *testbeds*, i.e. computer infrastructure, designed for reproducible experiments [28, 42], and how they can facilitate trustworthy experimental evaluations. Studies of computer benchmarking [10, 15] consider both the nuances of benchmark design and interpretation of results. However, the aforementioned sources do not help conclusively answer the question: "Does the order of tests matter, and if so, how much?" Our study aims to bridge this gap.

One recent study related to our work focuses on repeatable experiments in highly variable cloud environments [1]. The authors study the following designs: 1) Single Trial, 2) Multiple Consecutive Trials, 3) Multiple Interleaved Trials (MIT), and 4) Randomized Multiple Interleaved Trials (RMIT). Another study of the RMIT execution plan led to the development of WPBench, a web serving benchmark suite that bundles a set of micro and application benchmarks [35]. The fixed and random orders we study correspond to MIT and RMIT, respectively. While those studies argue for using RMIT, our investigation extends previous work with a large-scale evaluation of both approaches and shows where the differences between the two are most significant. We also consider environments without "background noise" from other tenants.

The idea of turning a proposed methodology into a reusable tool was inspired by the recent work on Lancet, a self-correcting tool for latency analysis [14]. TraceSplitter [33] applies an analogous statistical approach to traffic traces. Similarly, Hyperfine [29] facilitates many tasks involved in the benchmarking process and common subsequent analyses. In turn, experimenters can focus more on creating interesting experiments with increased confidence that their conclusions are unbiased by factors such as test ordering. We implement OrderSage with this vision in mind and describe in this paper the results it collects in several use cases.

Another related study considers performance change-points [6]. The data collection in our work is similar to the process described in that paper. However, rather than characterizing temporal patterns broadly, we focus on the order-related effects and the methodology for studying them.

9 Conclusion and Future Work

The order in which tests are run is a significant, but often neglected, part of experiment design—as shown in our survey, it is rarely mentioned in papers, and the artifacts that support them show little sign of being designed with ordering in mind. Our findings show that order can indeed make a difference: sometimes quite a large one. Systems experimenters should take this into account in their experiment designs, and test for order dependence when feasible. The response to discovered order-dependence will vary depending on the system, the experiment, and its goals. In some cases, there may be aspects

of the system under test, test environment, or test procedure that need to be "fixed" to make runs more consistent and less dependent on order. In other cases, some amount of variability is simply to be expected, and experiments should be run in several randomized orders to avoid systematically biasing results with a single order. Finally, in some cases, it may be that a "clean" environment is not the most realistic one in which to run the experiment, and more effort needs to be taken to get the environment into a suitably realistic state.

Our work thus far has left out of scope a deep analysis of *why* order matters. This would be an interesting subject for follow-up research, and we expect that the reasons will be as varied as the tests that are run and the environments they are run in. One way to do such an investigation would be to analyze which tests *cause* changes in the following trials, and which ones see the largest *effects*. We hope that our open dataset and tool will help to enable such explorations.

Appendix A Using OrderSage

Using OrderSage is straightforward, and requires little beyond that used in a typical experiment.

- **Experiment Environment:** Users must have a controller node and at least one worker node that has remote-access capabilities. The controller is separate from the worker so that the latter can be rebooted as part of the reset procedure.
- **Experiment Repository:** The tests to run and their associated scripts are stored in a `git` repository created by the user, which makes them natively version-controlled. In addition to the system(s) under evaluation, the repository contains the following:
  - **Test Configuration Script:** Called during the initialization phase by the controller, this script prints a list of commands to `stdout`. The commands will be executed in-order for the fixed runs and shuffled for the random runs. Each command represents a single test and all commands must be unique. It is up to users to implement this script as they wish as long as these requirements are met. In the simplest case, it can be a series of print statements of varying test commands or it can be more complex and include methods to iterate through complex sets of parameters, producing a command for each one.
  - **Initialization Script:** The controller calls an initialization script to ready all workers for experimentation as defined by the user. This script can install packages, set machine states, etc. Its only requirement is that it creates a "results" directory in a location on the worker.
- **Configuration File:** To run OrderSage, the user creates a configuration file. This configuration contains the URL of the experiment repository, the location of the configuration and initialization scripts within the repository, and other parameters. These parameters include paths to results files, the number of runs, etc. If the set of worker node(s) is pre-allocated, the `workers` parameter of this file must contain a list of all worker node hostnames.
- **Define Reset Protocol:** Our default implementation of OrderSage calls `reset()`, which is implemented to reboot the worker node(s) and reconnect between runs. However, if users prefer a different reset procedure, they can override this method.
- **Results:** Results are collected in a single text file on each worker node. Each test run (trial) must provide a single, floating-point number on a new line of the file. It is important that this results file is presented in-order (i.e., the first trial produces the first number and the n^{th} trial produces the n^{th} number). In total, the number of lines in the result file must equal the *number of tests* $\times$ *the number of runs* $\times$ 2 (for fixed and random runs).

Once the aforementioned configuration is complete, a user can run OrderSage by executing the following command:

```
# python controller.py
```

The artifact with the code and data we released, https://github.com/ordersage/paper-artifact, has more information on running OrderSage and reproducing the results presented in this paper.

AWARE: Automate Workload Autoscaling with Reinforcement Learning in Production Cloud Systems

Abstract

Workload autoscaling is widely used in public and private cloud systems to maintain stable service performance and save resources. However, it remains challenging to set the optimal resource limits and dynamically scale each workload at runtime. Reinforcement learning (RL) has recently been proposed and applied in various systems tasks, including resource management. In this paper, we first characterize the state-of-the-art RL approaches for workload autoscaling in a public cloud and point out that there is still a large gap in taking the RL advances to production systems. We then propose AWARE, an extensible framework for deploying and managing RL-based agents in production systems. AWARE leverages meta-learning and bootstrapping to (a) automatically and quickly adapt to different workloads, and (b) provide safe and robust RL exploration. AWARE provides a common OpenAI Gym-like RL interface to agent developers for easy integration with different systems tasks. We illustrate the use of AWARE in the case of workload autoscaling. Our experiments show that AWARE adapts a learned autoscaling policy to new workloads 5.5× faster than the existing transfer-learning-based approach and provides stable online policy-serving performance with less than 3.6% reward degradation. With bootstrapping, AWARE helps achieve 47.5% and 39.2% higher CPU and memory utilization while reducing SLO violations by a factor of 16.9× during policy training.

1 Introduction

Motivation. Reinforcement learning (RL) has become an active area in machine learning research and is widely used in various systems tasks (e.g., resource scaling [23,47–49,59,62], power management [58, 64], job scheduling [4, 5, 32, 33, 35, 63], video streaming [34, 60], and congestion control [22, 28, 31, 56, 60]). As a viable alternative to human-generated heuristics, RL automates the repetitive process of heuristics tuning and testing by enabling an *agent* to learn the optimal *policy* directly from interaction with the *environment*.

One example is workload resource autoscaling for meeting application service-level objectives (SLOs) while achieving high resource utilization efficiency [8, 30, 47, 49, 50, 59]. Traditional rule-based approaches [2, 3, 6, 25] configure static upper and lower thresholds offline for certain system metrics (e.g., CPU or memory utilization) or application metrics (e.g., request arrival rate, throughput, or end-to-end latency) so that resources can be scaled accordingly when the measured metrics go above or below the thresholds. Tuning and testing of fine-grained thresholds require significant application/system-specific domain knowledge from experts to achieve optimal resource allocation. Further, repeated parameter tuning for each workload can be labor-intensive, especially for microservice-like applications in large-scale production systems. As different types of services may use different amounts of resources (e.g., CPU and memory) and are sensitive to different kinds of interference and workload spikes, a customized threshold has to be set for a service differently.

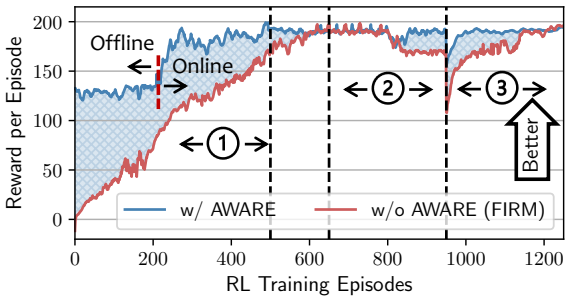

Figure 1: RL agent performance when managed by AWARE compared to the baseline (FIRM [47]). Stages ①, ②, and ③ demonstrate the benefit of RL bootstrapping, incremental retraining, and fast adaptation, respectively.

RL, on the other hand, is well-suited for learning optimal policies, as it models a systems task (e.g., workload autoscaling) as a sequential decision-making problem and provides a tight feedback loop for exploring the state-action space and generating optimal policies without relying on inaccurate assumptions (i.e., heuristics or rules) [32, 48]. Integrating RL with those complex systems management tasks in production systems can (a) make full use of the abundant monitoring data on applications and the infrastructure, and (b) automate the process of developing optimal policies while freeing operators from manual workload profiling and parameter tuning/testing. For example, FIRM [47]'s RL agent learns an optimal workload autoscaling policy that adapts to specific application workloads with online telemetry data that alleviates the need for handcrafted heuristics (see §2.2 for details).

Challenges. However, even as RL is starting to show its strength in the systems and networking domains [4, 5, 22, 23, 28, 31–35, 47–49, 56, 58–60, 62–64], there is still a large

gap in directly applying RL advances to real-world production systems due to a series of assumptions that are rarely satisfied in practice. First, a learned RL policy is workload-specific and infrastructure-specific. Retraining is needed to adapt to a new workload or underlying infrastructure in heterogeneous and dynamically evolving (possibly multi-cloud) datacenters [18,37,53,54,58]. For instance: (a) In SLO-driven resource management, application performance and utilization differ significantly among heterogeneous workloads [47]. Fig. 1 stage ③ shows that FIRM's trained RL policy suffers performance degradation and requires substantial retraining. (b) In power management, diverse power consumption and workload sensitivity to core/uncore frequency require separate training of RL policies [58]. (c) In video streaming and network congestion control, different sets of traces have diverse payload characteristics and network environments [60] (e.g., dynamic link bandwidth, delay, and loss rate). Even with transfer learning (TL) [47], nontrivial retraining is needed to adapt to new workloads and environment shifts in each problem domain, which is a critical problem in making RL practical in production. Further, TL requires fine-grained environment clustering to identify the most appropriate model to transfer from, and requires saving one model per cluster.

Second, for the same application and environment, there could be slight changes (e.g., patches and rolling updates), unusual workload patterns not seen before (e.g., due to migration rollout), or traffic jitters. Without timely retraining, the online policy-serving performance of the RL agent fluctuates and leads to undesired degradation (as shown in Fig. 1 Stage ②). It is crucial to ensure robust online performance in case of environment or model uncertainty [40,46].

Third, RL training is through trial and error [32,35,47], so worse-than-baseline or suboptimal decisions can be generated, especially at an early stage of training (as shown in Fig. 1 Stage ①). Direct training in the production system leads to suboptimal performance and undesired SLO violations, while training in a simulator and then transitioning to the production system face the problem of poor generalization [61].

A framework that can bring the RL advances to production systems is needed so that (a) the RL model can be trained in a safe and robust manner, (b) the learned RL policy can be adapted to new workloads and altered environments seamlessly without significant retraining, and (c) the online RL model policy-serving performance can be kept stable.

Our Work. We first performed a characterization study of RL in production systems in the task of workload autoscaling. The study focused on the impact of workload change and environment shift regarding (a) RL agent performance degradation or variation and (b) retraining cost. To facilitate the deployment and operation of RL agents in the systems management tasks of a production cloud environment, we introduce an RL model-serving and management framework. As a general framework to support a variety of RL agents for systems management tasks, it can be used by system operators to develop RL-based agents that can be quickly adapted to new environments and achieve stable online policy-serving performance with continuous monitoring and safe bootstrapping (as shown in Fig. 1). In the end, system operators can benefit from RL automation of systems management tasks.

- To achieve **fast model adaptation** in each domain or systems task, we leverage meta-learning [39] to model the RL agent as a *base-learner* and create a *meta-learner* for learning to generalize and adapt to new applications and environment shifts. The base-learner discovers policies that generalize across workload variations and intra-environment dynamicity for an <application, environment> pair, while the meta-learner generalizes across <application, environment> pairs to address inter-environment dynamicity and application heterogeneity. We designed a novel framework that allows the meta-learner to learn to generate an *embedding* [38, 39, 57] that projects the application- and system-specific data to a vector space. On this projected vector space, workloads with similar characteristics are projected to closer locations, while those with quite different characteristics are projected to locations far from each other. The embedding is generated by encoding a set of *episodes* from the RL agent's exploration of the environment. Since each episode records a step-by-step interaction of the RL agent with the environment, the time-series episodes naturally encode spatial and temporal characteristics. In the task of workload autoscaling, spatial characteristics correspond to the workload's performance sensitivity to different resource allocations, and temporal characteristics correspond to the time-varying load patterns. The generated embedding is then fed as input to the base-learner to adapt to the application and environment shift (from the environments with similar characteristics). With the embedding, fewer retraining iterations are needed for new, previously unseen workloads.
- To achieve **stable online RL policy-serving performance**, we leverage continuous monitoring, and designed a retraining detection and trigger mechanism. An RL agent observes a *state*, performs an *action*, and gets a *reward* at every step in an episode. The time series of states, actions, and rewards in an episode form a *trajectory*. RL trajectories are collected and stored in a time-series database. The most recent rewards are used to calculate the average reward and variation for comparison against user-specified targets. Continuous monitoring ensures that RL model retraining can be triggered or stopped timely so that the RL policy can seamlessly adapt to any environment jitters. We intercept the RL model update logic to enable the switch between RL policy serving and retraining.
- To achieve **safe RL exploration**, we designed an RL bootstrapping module that combines offline and online training. The agent starts with offline training, and a traditional heuristics-based controller (e.g., the Kubernetes Horizontal Pod Autoscaler (HPA) [25] and the Vertical Pod Autoscaler (VPA) [15] in the case of workload autoscaling), is used as the navigator for (online) exploration of the state and action space in the environment. After the RL model is trained to the

same level as the heuristics-based controller by comparing rewards, the agent continues to be trained online.

We have demonstrated the proposed framework in the task of workload autoscaling on Kubernetes by implementing AWARE (i.e., **A**utomate **W**orkload **A**utoscaling with **RE**inforcement learning). Each RL agent manages a Kubernetes Deployment and configures resources automatically, adjusting both the number of replicas (horizontal scaling) and the CPU/memory limits (vertical scaling) to maintain workload service-level objectives (SLOs) and achieve high resource utilization. To integrate RL agents with Kubernetes, we designed and implemented a multidimensional Pod autoscaler (MPA) system. MPA provides system support for RL-based controllers and translates RL outputs into multidimensional autoscaling actions in a holistic manner by (a) providing an API for RL agents to execute horizontal and vertical scaling decisions on Pod CPU and memory limits, (b) combining vertical and horizontal scaling actions in a single CRD object [24], and (c) providing a user interface for user-defined objective functions for multidimensional autoscaling.

Results. We present a detailed experimental evaluation of AWARE, demonstrating that AWARE significantly improves the practicality of applying RL in production cloud systems (for workload autoscaling). We first show that the adaptation process of a learned autoscaling policy to new workloads with meta-learning is 5.5× faster than the existing transfer-learning-based approach (§5.2), and then demonstrate that AWARE provides stable online policy-serving performance with less than 3.6% reward degradation (§5.3). AWARE's bootstrapping mechanism helps achieve 47.5% and 39.2% higher CPU and memory utilization while reducing SLO violations by a factor of 16.9× during training (§5.4).

Contributions. In summary, our main contributions are:

- A characterization of RL-based production workload autoscaling and the challenges involved in applying RL in production cloud systems (§2.3).
- The design of a novel meta-learning-based framework for fast RL model adaptation in workload autoscaling (§3.2).
- The design of an RL retraining management and bootstrapping mechanism for stable policy-serving performance (§3.3) and robust RL environment exploration (§3.4).
- An implementation of the proposed framework in the task of workload autoscaling with MPA, which enables integration of RL agents with Kubernetes (§4.1).
- A detailed evaluation of AWARE that demonstrates substantial improvements through meta-learning and RL lifecycle management while maintaining workload SLOs and resource utilization (§5).

2 Background & Characterization

2.1 Reinforcement Learning

In reinforcement learning (RL), an *agent* interacts with an *environment* modeled as a discrete-time Markov decision process (MDP) (as shown in Fig. 2). At time step t, the agent

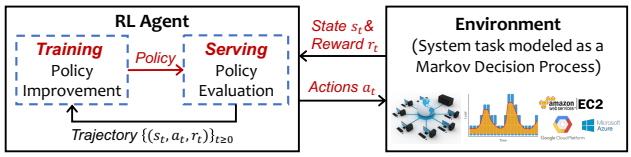

Figure 2: An RL agent interacting with an environment modeled as a systems task (e.g., workload autoscaling or congestion control) in the form of a Markov decision process (MDP).

perceives a *state* $s_t \in S$ of the environment and takes an *action* $a_t \in A$. The agent receives a *reward* $r_t \in \mathbb{R}$ as feedback on how good the decision is, and at the next time step $t+1$, the environment transitions to a new state s_{t+1}. The whole sequence of transitions $\{(s_t, a_t, r_t)\}_{0\leq t\leq T}$ is called a *trajectory* or *episode* of length T. The agent's goal is to learn a *policy* π_θ[1] that maximizes the expected cumulative rewards in the future, i.e., $\mathbb{E}[\sum_{t=0}^{T} \gamma^t \cdot r_t]$, where the discount factor $\gamma \in (0,1)$ progressively de-emphasizes future rewards. RL consists of a *policy-training* stage and a *policy-serving* stage [41]. At the policy-training stage, the agent (using an initialized policy) starts with no knowledge about the task and learns by reinforcement and directly interacting with the environment. At the policy-serving stage, the trained policy is used to generate an action based on the current state of the environment, and model parameters are no longer being updated.

2.2 Workload Autoscaling with RL

Because of the sequential nature of the decision-making process, RL is well-suited for learning resource management policies, as it provides a tight feedback loop for exploring the state-action space and generating optimal policies without relying on inaccurate assumptions (i.e., heuristics or rules) [32, 48]. In addition, since the decisions made for workloads are highly repetitive, an abundance of data is generated to train such RL algorithms even with deep neural networks[2]. By directly learning from the actual workload and operating conditions to understand how the allocation of resources affects application performance, the RL agent can optimize for a specific workload and adapt to varying conditions in the learning environment. RL [23, 47–49, 59, 62] has been shown to automate resource management and outperform heuristics-based approaches in terms of meeting workload SLOs and achieving higher resource utilization.

Specifically, we adopted the design and took the open-source implementation of an RL-based workload autoscaler from FIRM [47], which is the state-of-the-art RL-based autoscaling solution, to the best of our knowledge. FIRM uses an actor-critic RL algorithm called DDPG [29].

The RL agent monitors the system- and application-specific measurements and learns how to scale the allocated resources vertically and horizontally. Table 1 shows the model's state

[1] A policy π_θ maps the state space S to the action space A and is usually represented by neural networks (with parameters denoted by θ).

[2] Deep neural networks can express complex system-application environment dynamics and decision-making policies but are data-hungry.

Table 1: State-action space of the RL agent.

State Space (s_t)
Resource Limits (CPU, RAM), Resource Utilization (CPU, Memory, I/O, Network), SLO Preservation Ratio (Latency, Throughput), Observed Load Changes
Action Space (a_t)
Resource Limits (CPU, RAM), Number of Replicas

Table 2: RL training hyperparameters.

Parameter	Value
# Time Steps per Episode	100×64 mini-batches
Replay Buffer Size	10^6
Learning Rate	Actor (3×10^{-4}), Critic (3×10^{-3})
Discount Factor	0.99
Soft Update Coefficient	3×10^{-3}
Random Noise	μ (0), σ (0.2)
Exploration Factor	ε (1.0), ε-decay (10^{-6})

and action spaces. The goal is to achieve high resource utilization (RU) while maintaining application SLOs (if there are any). SLO preservation (SP) is defined as the ratio between the SLO metric and the measured metric. If no SLO is defined for the workload (e.g., best-effort jobs) or the measured metric is smaller than the SLO metric, $SP = 1$. An SLO metric can be either request serving latency (e.g., the 99th percentile of the requests are completed in 100ms) or throughput (e.g., request processing rate is no less than 100/s). The reward function is then defined the same as in FIRM [47], $r_t = \alpha \cdot SP_t \cdot |\mathcal{R}| + (1-\alpha) \cdot \sum_{i \in \mathcal{R}} RU_i$, where $\mathcal{R}$ is the set of resources. Table 2 lists the hyperparameters tuned for better performance in the experiments. The RL algorithm is trained in an episodic setting. In each episode, the agent manages the autoscaling of the application workload for a fixed period of time (100 RL time steps in our experiments).

2.3 Characterization of RL in Production

In the characterization study of FIRM for workload autoscaling, we selected 16 representative production cloud workloads based on a survey of 89 industry use cases of serverless computing applications [11], as serverless workloads are highly dynamic (and thus require autoscaling) and rely on the provider to manage the resources. The selected production workloads include CPU-intensive tasks (e.g., floating-point number computation), image manipulation, text processing, data compression, web serving, ML model serving, and I/O services (e.g., read, write, and streaming). Next, we deployed the selected workloads as Deployments in a five-node Kubernetes cluster in a public cloud and ran an RL-based multi-dimensional autoscaler (i.e., a FIRM agent) with each workload. All nodes run Ubuntu 18.04 with four cores, 16 GB memory, and a 200 GB disk. For RL agent training and inference, we used real-world datacenter traces [65] released by Microsoft Azure, collected over two weeks in 2021.

We next present the key insights from the characterization study in the order of adaptation, online policy-serving, and early-stage of RL training.

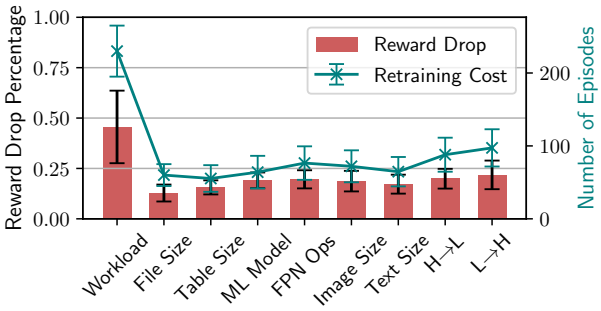

Figure 3: Retraining cost of RL models.

Insight 1: Adaptation Retraining Cost. To study the retraining cost of adapting a trained RL policy to new application workloads, we selected each application from the workload pool, trained an RL agent for the application until convergence, and retrained the learned RL policy to serve all the other different applications. We then measured the reward drop after the workload changed and the number of episodes each agent took to retrain to convergence. As shown in Fig. 3 (column 1), we observed a 45.6% average per-episode reward drop percentage when the workload had been changed, and retraining to convergence required around 230 episodes (with the model parameter transfer learning used in FIRM [47]).

Insight 2: Online Policy-serving Performance Jitters. We introduced seven scenarios to explore the performance instability of RL-based workload autoscaling agents when facing application or service payload size changes and load pattern changes. For I/O services to a backend file system (e.g., AWS S3) and the compression/decompression services, the size of files being read, written, or streaming was changed from [128 KB, 256 KB, 384 KB] to [512 KB, 768 KB, 1024 KB]. For database services, the size of the table being scanned was changed from 1024 items to 10240 items. For floating-point number calculation, the number of operations was changed from 10^8 to 20^8. For image manipulations, the dimension was changed from 40×40 to 160×160. For text processing, the JSON file size was changed from [250 B, 500 B, 1 KB] to [2 KB, 3 KB, 5 KB]. For ML model serving, we changed the matrix multiplication dimension from 50 to 150. For load pattern changes, we divided the Azure workload traces into two parts, one half with a higher daily load ($> 10^5$ per day) and the other half with a lower daily load ($\leq 10^5$ per day).

Fig. 3 (columns 2–9) shows the per-episode reward drop percentage and the retraining cost of each scenario. File size changes led to the lowest 12.8% reward drop and around 70 episodes of retraining. We attribute this to I/O-intensive workloads' relatively low sensitivity to CPU/memory allocation, compared to compute- or memory-intensive workloads. Other payload-related changes (i.e., table size, ML model, floating-point number operations, image dimension, and text size) resulted in a 15.6–19.9% reward drop. Load changes from high request arrival rates to low arrival rates (i.e., H→L

Table 3: Workload performance and utilization efficiency deficit (i.e., the relative difference compared to the rule-based approach) in early-stage RL model training.

RL Episodes	EP 1–100	EP 101–200	EP 201–300	EP 301–400
CPU Util	-32.3% ± 14%	-42.9% ± 15%	-22.1% ± 12%	-10.0% ± 6%
Memory Util	-28.8% ± 11%	-30.5% ± 10%	-26.5% ± 8%	-7.8% ± 2%
SLO Violations	56.1 ± 14 ×	22.2 ± 7 ×	12.7 ± 5 ×	10.1 ± 3 ×

in Fig. 3) and from low rates to high rates (i.e., L→H) resulted in 19.9% and 21.8% reward drops, which required around 98 and 107 episodes of model retraining, respectively.

Insight 3: Cost of Early-stage RL Training. As mentioned in §2.2, RL training proceeds in episodes. When the initialized RL agent starts to learn the optimal policy, especially at an early stage of policy training, the policy might be worse than the baseline heuristics-based approach or even produce undesired actions, such as an oscillating scaling up and down behavior. This is primarily due to the exploration of the state-action space and RL agent learning through trial and error. To study what is lost during policy training, we compared workloads managed by RL agents with the same workloads managed by the rule-based autoscaling approach (i.e., HPA and VPA). We define the early stage of RL training to be the training process from the beginning to the episode at which the RL agent starts to get better than the rule-based approach (which is around 400 episodes in our experiments) because we are interested in the loss due to RL training compared to non-RL-based approaches. We then divided the 400 episodes (in the early training stage) into four segments. For each segment, we calculated the accumulated utilization deficit and SLO violations of the application workloads controlled by the RL agents; the results are shown in Table 3. The relative difference in utilization or SLO performance is based on the comparison between the RL agent and the rule-based approach when used to control the same application workloads with the same set of traces.

Results show that RL policies necessarily lead to poor decisions in the early stages of training. In the first 100 episodes, the RL agents inevitably caused more SLO violations than in the other segments (56.1× more than the rule-based approach, which had five SLO violations per 100 episodes). We observe that most SLO violations were due to the under-provisioning of resources, so the CPU and memory utilization deficits (32.3% and 28.8% lower, respectively, than for the rule-based approach) were smaller than those in the later segments. In the last three segments, we observe a utilization deficit (i.e., 10–42.9% lower CPU utilization and 7.8–30.5% lower memory utilization) and more SLO violations (i.e., 10.1–22.7×) compared to the rule-based approach.

Summary and Implications. Workloads running in production cloud systems might be user-facing or high-stakes. *To enjoy the benefit of RL in systems management, the key challenge is to produce fast-adapting, effective, and robust RL-based solutions under the constraints of production cloud systems.* As of now, to the best of our knowledge, there are no systems that can help agent developers address this challenge.

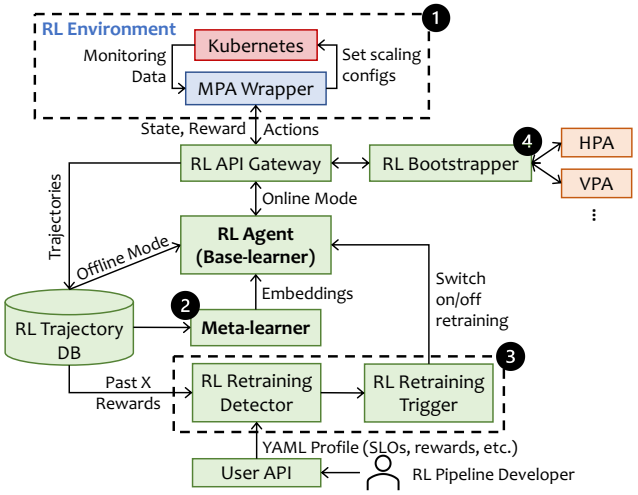

Figure 4: Overview of AWARE.

3 AWARE Design

3.1 Overview

Driven by the insights from §2.3, we describe the design of AWARE, a framework that supports RL agents for multidimensional Pod autoscaling (MPA) of workloads in production Kubernetes systems. AWARE manages the RL agent lifecycle to deliver stable and robust agent performance. Fig. 4 provides an overview of AWARE. We next present a brief summary of each component in this section.

RL Environment. The RL environment (denoted by ❶ in Fig. 4) of AWARE consists of a cluster deployment (e.g., Kubernetes) and an MPA wrapper. The MPA wrapper is designed and implemented as a shim layer that follows an "agent-centric" pattern of request-response interaction advocated by OpenAI Gym [44]. The purpose of the MPA wrapper is to translate measurements and scaling recommendations to and from RL abstractions (i.e., states/rewards and actions), respectively. The communication between the wrapper and the RL agent is through remote procedure calls (RPCs). When the agent steps the environment forward by sending an action to the MPA wrapper through the RPC request, the wrapper translates the received action to vertical and horizontal scaling configurations and applies it to the cluster deployments (e.g., by setting the VPA object [15] and calling the replica re-scaling API). The wrapper gets measurements from the monitoring service in the cluster (e.g., Prometheus [7] in Kubernetes), translates them to RL states and rewards, and sends them back to the agent through the RPC response. The wrapper then waits on the RPC server for the next action request. We describe implementation details in §4.1.

The framework can also be applied to other systems management tasks (e.g., job scheduling or network congestion control) by replacing the RL environment. Decoupling the RL environment (i.e., the environment wrapper) from the rest of the framework and using the standard OpenAI Gym interface

make environment replacement easy [33].

RL API Gateway. The RL API gateway connects the RL agent to the MPA wrapper by sending the RL action in an RPC request and unpacking the state and reward in the RPC response for the RL agent. Each RL trajectory consists of <state, action, reward> transitions in one episode where the RL environment defines the length or the terminating condition of an episode. The trajectories from each RL agent, along with the logical timestamp (i.e., the episode and time step index), are saved to the RL trajectory database.

RL Agent (Base-learner). The RL agent implements the DDPG RL algorithm (as described in FIRM [47]) and interacts with the RL environment to perform policy training or policy serving (i.e., inference). Since the interface between the RL agent and the MPA wrapper follows the OpenAI Gym standard, different advanced RL algorithms can be used to replace the original RL algorithm DDPG.

Meta-learner. To help adapt to new workloads or environment updates within the problem domain, the meta-learner (denoted by ❷) selects RL trajectories from the database and generates an embedding that accurately represents the workload running in the environment. RL trajectories are selected per application, and the criteria are based on the reward associated with each trajectory. The embedding is then fed to the base-learner (i.e., the RL agent) as part of the input. The RL agent leverages the embedding to adapt (fine-tune) its policy by differentiating heterogeneous workloads and environment updates. See §3.2 for more details.

RL Retraining Detector and Trigger. At the end of each episode, the RL retraining detector (denoted by ❸) pulls the recent episode rewards gained by the agent from the trajectory database. The mean and standard deviation of the per-episode rewards are calculated and compared to predefined thresholds for performance and variability assessment. If conditions are met, the RL retraining trigger will intercept the inference or training loop of the RL agent to switch retraining on or off, respectively. See §3.3 for more details.

RL Bootstrapper. The RL bootstrapper (denoted by ❹) determines whether the RL training is online or offline. In the online RL training mode, the RL agent interacts directly with the RL environment. However, offline RL training avoids worse-than-baseline performance or illegal actions in the early stages of RL training, which is desired by production systems. In the offline RL training mode, the RL policy training happens offline based on data collected using a fallback option (i.e., a heuristics-based method), while the RL policy is not used for interacting with the environment. The RL bootstrapper intercepts the request-response path between the RL agent and the RL API gateway and replaces the RL agent with the controller implemented as the fallback option. For instance, in the case of workload autoscaling, the default autoscalers widely used are the traditional rule-based approaches HPA (for horizontal scaling) and VPA (for vertical scaling). Given the states at each time step, corresponding autoscaling actions

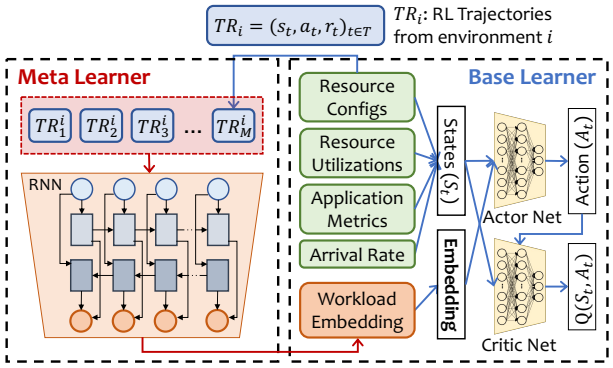

Figure 5: Architecture of meta-learning for RL.

are then generated based on the HPA and VPA algorithms and sent back to the RL API gateway for execution. The trajectories recorded in the RL trajectory database will be used for the offline RL policy training. See §3.4 for more details.

3.2 Meta-learner

Traditional RL-based resource management approaches [23, 47, 48, 59, 62] require the collection of large amounts of training data samples and retraining (even with transfer learning) to adapt to new environments for (a) updated or previously unseen application workloads or (b) constantly evolving cloud infrastructures [18, 37, 53, 58]. Pure RL-based approaches are no longer tenable in such dynamic cloud environments or even in the context of multi-cloud computing [54]. A novel approach that provides fast model adaptation is needed to make RL practical in production cloud systems.

In AWARE, we leverage meta-learning to reduce the retraining overhead and thus adapt quickly to new environments. In essence, the RL agent is treated as the *base-learner* for an individual environment, and a *meta-learner* is designed to generate representative *embeddings* that help differentiate environments. We next give a brief primer on meta-learning and the concept of embeddings before presenting AWARE's meta-learning model and an interpretation of embeddings from a systems perspective.

Meta-learning Primer. Meta-learning is known as learning to learn [26]. A good meta-learning model is capable of adapting well or generalizing to new environments that have never been encountered during training time. The adaptation process, essentially a mini-learning session (with limited exposure to the new environment), happens after the meta-learning model training stage. In the meta-learning model training stage, rather than training the learner on a single environment (with the goal of generalizing to unseen "intra-environment" samples from a similar data distribution), a meta-learner is trained on a distribution of environments, with the goal of learning a strategy that generalizes to unseen environments (i.e., "inter-environment"). Even without any explicit fine-tuning (i.e., with no gradient back-propagation on trainable variables), the meta-learning model autonomously adjusts internal hidden states to learn [12, 20, 39, 43].

Embedding Techniques. Embeddings map variables to low-dimensional vectors in a way that similar variables are close to each other [38, 57]. Embeddings have been widely used in the area of NLP and software engineering (e.g., word or code embeddings) and can also be applied to dense data to create a meaningful similarity metric. In AWARE, embeddings are used to explicitly represent and differentiate environments, and meta-learning enables learning to generate embeddings.

AWARE's Meta-learning Model Design. There are three key components in the design of the meta-learning model:

- A Distribution of MDPs (i.e., RL environments): Each MDP corresponds to one agent to which the base-learner will adapt. During the training of each agent, the meta-learner is exposed to a variety of environments and is trained to adapt to different MDPs. In our case of workload autoscaling, each environment represents a different application workload managed by the base-learner, where workloads can have heterogeneous SLOs, payloads, or architecture.
- A Model with Memory: We use a recurrent neural network (RNN) [17, 52, 55] that maintains a high-dimensional hidden state with nonlinear dynamics to acquire, process, and memorize knowledge about the current environment. In an RNN, hidden layers are recurrently used for computation. Compared to memoryless models such as autoregressive models and feed-forward neural networks, RNNs store information in the hidden states for a long time, so they are effective in capturing both spatial and temporal patterns. We did not explicitly use memory augmentation [51] for our RNN meta-learner because we found that the features of our application workloads are not as high-dimensional as those of computer vision tasks [51], and the RNN hidden states suffice to provide good representations.
- Meta-learning Algorithm: A meta-learning algorithm learns to update the base-learner to optimize for the purpose of adapting quickly to a previously unseen environment [20, 39]. Our novel approach uses an ordinary gradient descent update of RNN with a hidden state reset at a switch of MDPs. As training proceeds, the algorithm learns how to generate an embedding to best represent the environment and differentiate one environment from another.

Integration between Meta-learner and Base-learner. The base-learner discovers a rule that generalizes across data points for an <application, environment> pair, while the meta-learner generalizes across <application, environment> pairs. Fig. 5 illustrates the interaction between the meta-learner (❷ in Fig. 4) and the base-learner. Suppose that each data point used in the training and inference of the RL agent (i.e., a base-learner) with the <application, environment> pair i is $\{(s_t, a_t, r_t)\}_{0 \le t \le T}$, i.e., one RL trajectory TR_i from the environment i; then, each data point in the meta-learner is a bundle of M trajectories from the same environment, i.e., $[TR_1^i, TR_2^i, \ldots, TR_M^i]$. These episodes contain characteristics of the ongoing task that can be used to abstract some specific information about the environment (through <state, action, reward> transition sequences). The meta-learner uses a bidirectional RNN [52] to generate an embedding given a sequence of RL trajectories from the same environment (same base-learner). Unidirectional RNN has the limitation that it processes inputs in strict temporal order, so the current input has the context of previous inputs but not the future. Bidirectional RNN, on the other hand, duplicates the RNN processing chain so that the inputs are processed in both forward and backward orders to enable looking into future contexts as well.

The input trajectories (to the meta-learner) are selected from the RL trajectory database (that are generated by the RL agent interacting with the current RL environment) dynamically at runtime. We chose the top M trajectories that have resulted in the highest rewards so far because the experimental results show that the trajectories with lower rewards are unhelpful or even harmful. Intuitively, those lower-reward trajectories are generated with a random policy or a poorly trained policy, so they are not representative of the workloads.

The output from the bidirectional RNN of the meta-learner is an embedding that is used to fingerprint/represent the <application, environment> pair with which the base-learner is interacting. As shown in Fig. 5, the generated embedding based on past experience (i.e., the episodes previously explored by the base-learner) is fed to the base-learner as part of the input at each time step. Since we adopted as our base-learner the RL design from FIRM [47], which is an actor-critic RL algorithm, the embedding is taken by the actor network.

Interpreting Embeddings from Systems Perspective. The environment-specific embedding is able to differentiate one <application, environment> pair from another and thus guides the base-learner to adapt to the new environment. Fig. 6 visualizes the key idea of embedding. The spatial and temporal characteristics of the workloads are encoded and mapped onto a low-dimensional latent vector space by the embedding layer. Workloads with similar characteristics are projected to locations that are close to each other on that vector space. By calculating the cosine similarity between any two generated vectors (i.e., embeddings), we can get a monotonic similarity measure. To help understand how generated embeddings can represent spatial and temporal characteristics, we selected RL trajectories from <application, environment> pairs with human-detectable different performance sensitivities or load patterns, and then the plotted embedding projection shows that indeed similar workloads are closer to each other when comparing cosine similarities of their embeddings. In Fig. 6 (upper), the sensitivity of application performance to different resource allocations is shown in the heatmaps to illustrate the spatial characteristics, with the X-axis being CPU cores and the Y-axis being allocated RAM. Darker colors represent worse performance in terms of application request-serving latency. In Fig. 6 (lower), the application load-per-second time series are plotted to represent the temporal characteristics. Again, workloads with similar patterns are projected to adjacent locations in the output vector space.

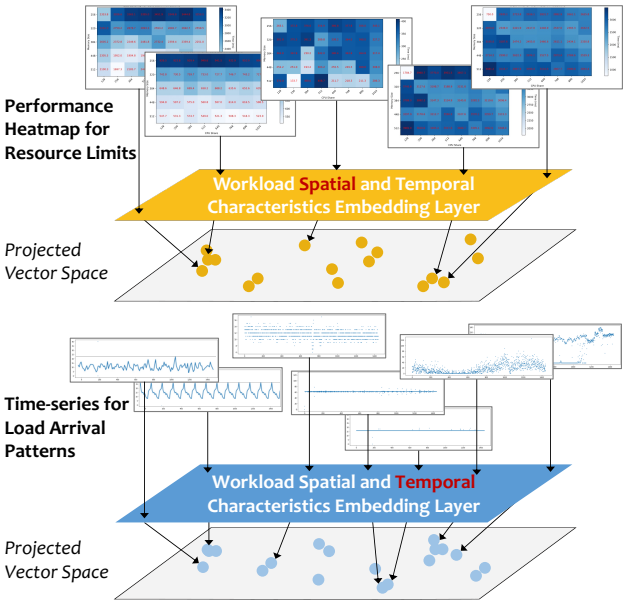

Figure 6: An example illustrating the idea of workload embedding for encoding spatial and temporal characteristics from a systems perspective. *The yellow points (upper figure) indicate that workloads with similar performance sensitivities (to resource allocations) are projected to locations near each other in the embedding vector space. The blue points (lower figure) show that workloads with similar load arrival patterns are projected to adjacent locations in the embedding vector space. The similarity metric used is cosine similarity.*

Meta-learner Training. During the training of the meta-learner, both the meta-learner and base-learner model parameters are updated. After each RL episode, the loss value is generated by the base-learner and is backward-propagated to update the model parameters in the base-learner. Since the meta-learner is trained across a distribution of environments, the total loss of all sampled environments in the training dataset is used to update the model parameters in the meta-learner. In the end, the trained meta-learner is capable of abstracting the individuality of each <application, environment> pair; the trained base-learner is a shared RL model that is able to generate optimal workload autoscaling policies conditioned on the workload embeddings provided by the meta-learner. The base-learner can be used as a starting point and as the basis for fine-tuning a specific novel <application, environment> pair in the inference stage.

Meta-learner Inference. After the meta-learner is trained, the meta-learning model is able to adapt the base-learner to a new <application, environment> pair that has never been encountered during training. Note that even though the new environment has never been encountered during training, it comes from the same distribution as, or shares similar patterns with, the encountered ones, so that transferring is still possible [12, 20, 39, 43]. The adaptation process only requires limited exposure to the new environment. Therefore, AWARE simply samples RL episodes and runs the meta-learner to generate the workload embedding. With the workload embedding, the base-learner can be continuously trained to learn the workload autoscaling policy for the new <application, environment> pair. The meta-learner model parameters are fixed during the inference stage.

Algorithm 1 RL agent lifecycle transition management for bootstrapping and triggering of online retraining. Four status codes `INITIALIZED`, `ONLINE`, `OFFLINE`, and `SERVING` stand for agent-initialized, online training, offline training, and online policy-serving, respectively.

3.3 Incremental Retraining

When deploying the RL agent in a production system, one needs to ensure that the policy behaves as expected and scales to the workload in production. AWARE leverages continuous monitoring to detect any anomalous behavior and trigger retraining when needed. Alg. 1 describes how AWARE's RL retraining module (❸ in Fig. 4) manages the lifecycle of the agent and enables incremental retraining at runtime (lines 14–21). The input to the retraining module includes (a) the user profile specifying the configuration, and (b) recent rewards pulled from the RL trajectory database. When the mean and the standard deviation of the recent rewards satisfy the threshold-based condition (i.e., agent performance is bounded to a target value), the agent enters the policy-serving stage; otherwise, the agent enters the policy-training stage. Retraining of the RL agent is by online interaction with the RL environment. As discussed in §3.4, non-RL-based approaches

(i.e., HPA and VPA) can be used as a fallback option for RL agents when high-stakes applications want to keep the RL agent in the offline mode during retraining.

3.4 Bootstrapping

The policy at the early RL training stages could be worse than the baseline approaches. For example, overprovisioning leads to low resource utilization, while under-provisioning results in SLO violations. For production workloads, especially high-stakes applications, such suboptimal actions are not acceptable. In AWARE, an RL bootstrapper (❹ in Fig. 4) has been designed to combine offline and online RL training. If the user specifies enabling bootstrapping (as shown in lines 4–9 Alg. 1), the offline mode will be turned on first. AWARE will then use Kubernetes HPA [25] (which is a threshold-based approach) for horizontal workload autoscaling, and use Kubernetes VPA [15] (which adjusts resource limits based on history profile) for vertical workload autoscaling. Note that HPA and VPA can also be used as a fallback option for RL when high-stakes applications want to keep the RL agent in the offline mode during retraining, as discussed in §3.3.

In the offline mode, the RL bootstrapper intercepts the request-response path between the agent and the RL API gateway and replaces the RL agent with the fallback controller to react to the received states and generate actions at each time step. The RL API gateway then takes the received action for execution, and the resulting behavior is the same as when workloads are managed by HPA and VPA. The RL agent samples trajectories from the trajectory database for offline policy training. To overcome extrapolation errors whereby previously unseen state-action pairs are erroneously estimated, we apply a state-conditioned generative model to combine with the critic network for producing previously seen actions [14]. In the online training mode, the agent will then directly interact with the RL environment through the API gateway.

4 Implementation

4.1 Kubernetes MPA

We propose our own design and implementation of multi-dimensional Pod autoscaling because the current HPA and VPA controllers are independent of each other and can lead to a large number of tiny Pods [16]. Google MPA [10] is a pre-GA beta version product that offers an integrated solution for HPA and VPA, but it is not open-sourced and does not support custom recommenders. In AWARE, the MPA framework combines the actions of vertical and horizontal autoscaling but separates the actuation from the controlling algorithms. As shown in Fig. 7, there are three controllers (i.e., a recommender, an updater, and an admission controller) and an MPA API (i.e., a CRD object [24]) that connects the autoscaling recommendations to actuation.

The multidimensional scaling algorithm is implemented in the recommender mostly by importing HPA and VPA libraries to serve as the fallback option for RL-based approaches. The

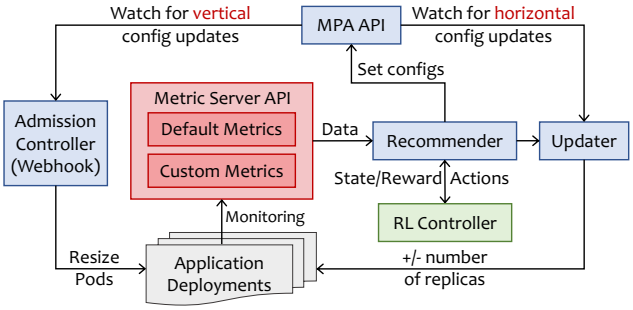

Figure 7: MPA design overview and integration with RL.

metrics required by the algorithm are collected from the Kubernetes Metrics Server, including default metrics such as container resource utilizations and custom metrics such as application throughput or latency. The scaling decisions derived from the recommender are stored in the MPA object as scaling configurations. The updater and the admission controller retrieve those updated configurations from the MPA object and then actuate them as vertical and horizontal actions on the application Deployments. The separation of action actuation from scaling decision generation allows developers to replace the default recommender with the alternative recommender, i.e., the RL controller. The implementation is in Go and at the stage of releasing to the Kubernetes upstream as well.

4.2 Integration with RL

The creation of MPA is through declarative YAML files. To integrate MPA with RL agents, one needs to specify a custom recommender to replace the default recommender (HPA+VPA). After an MPA is initialized for the application deployment, an MPA wrapper is created as a shim layer to communicate with the RL agent through RPCs. We follow the "agent-centric" pattern of request-response interaction advocated by OpenAI Gym [44]. The exposed interfaces include (a) `init()` (for initializing the RL environment), (b) `state = reset()` (for resetting the environment at the beginning of each RL episode), and (c) `state, reward = step(action)` (for RL agent stepping). When the MPA wrapper receives an action through the RPC request, it first translates the action to vertical and horizontal scaling configurations and writes to the MPA object. We deploy Prometheus [7], the standard monitoring service in Kubernetes, to export default and custom metrics from the application Deployment. The wrapper then queries the Prometheus service for real-time metrics and translates to RL states and rewards. Finally, the wrapper sends the metrics back to the agent through the RPC response. The MPA wrapper is implemented in Python.

4.3 Meta-learning-based RL-serving

AWARE's meta-learning-based RL agent management framework is implemented in Python. Both the base-learner (adopted from FIRM [47]) and the meta-learner are implemented using PyTorch [13]. The meta-learner is essentially a bidirectional two-layer RNN followed by two fully connected

layers with the ReLU activation function. We chose the trajectory bundle size to be 20 for the fastest adaptation with the fewest trajectories according to the sensitivity analysis. Each RNN hidden layer consists of 256 neurons, and the fully connected layers consist of 256 and 64 neurons. We chose two layers and an embedding size of 64 because adding more layers and hidden units does not increase performance in our experiments; instead, it slows down training speed significantly. We used the Adam optimizer for parameter updates.

RL trajectories are saved to InfluxDB [21], an open-source time-series database that is built to handle metrics with time-stamped data. Recent rewards, sampled RL trajectories for offline base-learner training, and the inputs for embedding generation are all pulled from the trajectory database by using the InfluxDB Python client library.

AWARE provides a simple and declarative user interface for RL pipeline developers, which is consistent with Kubernetes' way of creating and managing objects in the cluster. To specify the targets for the workloads, i.e., resource utilization targets and the application SLO (if there is one), users only need to provide a YAML file following the definition template. Both application latency and throughput SLOs are currently supported. In addition, users can also specify the thresholds for RL rewards and whether or not to enable bootstrapping in the YAML file, which constructs the profile used in Alg. 1.

5 Evaluation

Our experiments addressed the following research questions:

§5.2 Does AWARE provide fast model adaptation to new workloads? What is the value of meta-learning?

§5.3 How does AWARE perform in online policy-serving when workload updates or load changes occur?

§5.4 How does AWARE perform in the early stages of policy training, compared to RL agents without bootstrapping?

5.1 Experimental Setup

We implemented an application generator capable of generating a large number of synthetic applications by combining the 16 selected representative production application segments [11] (discussed in §2.3 as well) based on random sampling with replacement from the segment pool. Each segment represents the smallest granularity of common workloads in cloud datacenters. In addition, each segment has to be associated with its own inputs to simplify load generation (e.g., the image manipulation workloads come with random images). The generator also comes with setup and tear-down scripts for all external services each segment uses (e.g., databases or messaging queues). Overall, we generated 1000 unique applications, deployed them as Deployments in a Kubernetes cluster of 11 two-socket physical nodes, and ran an RL-based multidimensional autoscaler with each application. Each server consists of 56–192 CPU cores and RAM that vary from 500 GB to 1000 GB. Seven of the servers use Intel x86 Xeon E5 processors, and the remaining ones use IBM ppc64 Power8 and Power9 processors.

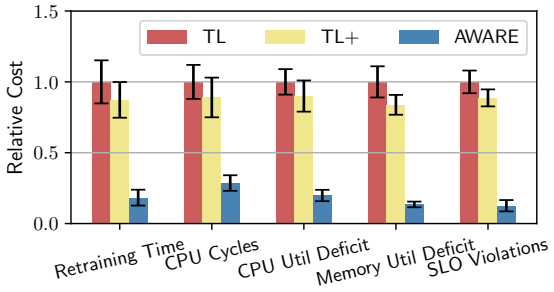

Figure 8: RL agent retraining cost and performance comparison of AWARE, transfer learning (TL), and transfer learning with augmented features (TL+).

While it would be impossible to cover all cloud workloads, the selected production workload segments should enable the generation of a large number of synthetic cloud workloads with varying resource consumption profiles. In the future, the number of implemented segments can easily be extended if specific workload profiles are missing. We refer to the open-source artifact for additional details on the generator implementation. With the same datacenter workload traces [65] discussed in §2.3 with respect to RL agent training and policy-serving, we divided the 1000 generated application pool with the 8:2 ratio. The 800 applications with varied workloads are used to train the meta-learner, while the remaining 200 applications are used to evaluate the adaptability. The total runtime is ∼60 days, and the meta-learner training time is ∼312 hours on an Intel(R) Xeon(R) E5-2695 processor.

The RL formulation and design (in the base-learner) are adopted from FIRM [47] (as mentioned in §2.3). As an end-to-end evaluation, Fig. 1 shows that, compared to AWARE, the RL-based autoscaler FIRM by itself suffered from poor performance during the initial training stage (i.e., Stage ①, which demonstrates the benefit of AWARE's bootstrapping mechanism), online policy-serving performance degradation (i.e., Stage ②, which demonstrates the benefit of the online retraining triggering mechanism), and slow adaptation with non-trivial retraining (i.e., Stage ③, which demonstrates the benefit of meta-learning). We then present the evaluation results related to each research question in §5.2–§5.4.

5.2 Fast Adaptation

To study adaptability to new workloads, we compared AWARE with the existing transfer learning approach. FIRM [47] leverages transfer learning to train an RL agent for a new service based on previous RL experience gained when training the RL agent for a known service. In the transfer-learning-based approach (TL), the model parameters (weights) are shared between the agents managing the known workload and the new workload. We also compared AWARE with a novel approach (TL+) based on transfer learning that includes additional spatial and temporal features in the RL states, since the meta-learner in AWARE is trained to output an embedding to represent the spatial and temporal characteristics of the <application, environment> pair. We

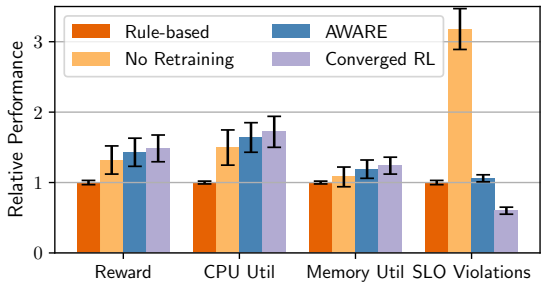

Figure 9: RL agent online policy-serving performance comparison of AWARE, no retraining, the rule-based method, and the agent with the converged RL policy. *In the comparison of reward and CPU/memory utilization, the higher, the better, while a lower number of SLO violations is better.*

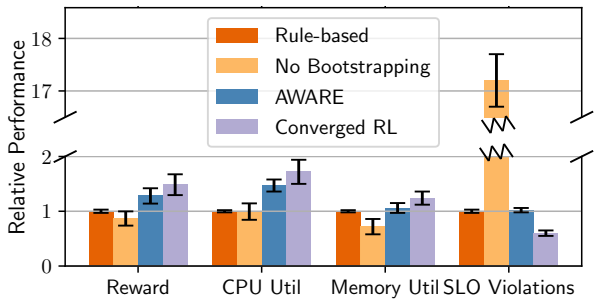

Figure 10: RL agent training performance comparison of AWARE, no bootstrapping, the rule-based method, and the agent with the converged RL policy. *In the comparison of reward and CPU/memory utilization, the higher, the better, while a lower number of SLO violations is better.*

used the widely used ARIMA model [19] to generate the predicted load for the next time step (i.e., temporal feature) and recorded a table mapping from resource allocation to performance (i.e., spatial feature). We performed A/B tests in which the workload traces were the same, but the recommender in MPA was replaced with TL, TL+, and AWARE, which drove the horizontal and vertical scaling of the workload. We repeated the A/B test 100 times. In each test, we randomly selected a workload from the pool and trained the RL agent to convergence. We then randomly selected 10 other different workloads from the pool for adaptivity evaluation. We measured the retraining time, CPU cycles involved in retraining, utilization deficit (compared to the converged RL policy), and SLO violations.

Fig. 8 shows that AWARE adapted 5.5× and 4.6× faster (saved 68–72% CPU cycles) than TL and TL+, respectively. During the adaptation period, TL+ had 4.6× and 6.2× higher CPU and memory utilization deficit compared to AWARE while AWARE reduced SLO violations by 7.1×. TL+ encodes additional spatial and temporal features, but each state is still a stateless snapshot of the running workload. Additional features (i.e., the table and the ARIMA output) greatly increase the state space. Meta-learning, on the other hand, offers a systematic and automated way of learning how to differentiate the workloads well and outputs a low-dimensional embedding to be used by the base-learner.

5.3 Online Policy-serving

To evaluate the online policy-serving performance when facing workload updates and load changes (described in §2.3), we compared AWARE with (a) a rule-based approach, (b) an RL agent without continuous monitoring and retraining, and (c) an RL agent with the converged policy. For the rule-based approach with manual scaling, we measured the maximum CPU utilization when the SLO was met, and set it as the threshold for HPA. We used the default Auto mode [15] for VPA. We performed the same style of A/B tests 100 times and replaced the MPA recommender with the four approaches. In each A/B test, we randomly selected a workload from the pool, trained the RL agent to convergence, and injected a series of the seven random instability scenarios introduced in §2.3. We then measured the average reward, CPU/memory utilization, and the number of SLO violations during the time until the agent managed by AWARE converged. Fig. 9 shows that AWARE had 9.6% and 14.8% higher CPU and memory utilization, and reduced SLO violations by 3.1× compared to the RL agent without retraining (the second-best approach), resulting in 8.6% higher per-episode reward. Compared to the converged RL policy, AWARE had a 3.6% lower average per-episode reward because we set the retraining threshold to be 5, corresponding to a 2.6% reward degradation. Sensitivity analysis showed that AWARE converged to the no-retraining baseline as the threshold increased while a smaller than 5 threshold led to constant retraining with no policy serving.

5.4 Bootstrapping

To study how much bootstrapping helps reduce the cost of early-stage RL training, we compared AWARE with (a) the rule-based approach (same as in Fig. 9), (b) an RL agent without bootstrapping, and (c) an RL agent with the converged policy. Since the per-episode reward achieved by the rule-based autoscaler is around 130 (translated from the measured utilization and performance), we set the bootstrapping threshold in AWARE to 130. In the sensitivity analysis, we observed that a higher threshold led to endless bootstrapping driven by the rule-based autoscaler (since the measured reward is always lower than the threshold), while the lower the threshold, the more performance degradation AWARE had during its early-stage training. A threshold of 0 basically converges to the learning curve without AWARE bootstrapping (i.e., no offline learning). We performed A/B tests 100 times and replaced the MPA recommender with the four approaches. In each A/B test, we randomly selected a workload from the pool and trained the RL agent to convergence (with or without bootstrapping). We then measured the average reward, CPU utilization, memory utilization, and the number of SLO violations during the time until the RL agent converged. Fig. 10 shows that AWARE had 47.5% and 39.2% higher CPU and memory utilization, respectively, and reduced SLO viola-

tions by a factor of 16.9× compared to the RL agent without bootstrapping (the second-best approach), resulting in 47.3% higher average per-episode reward before convergence.

6 Related Work

RL Training and Model-serving Frameworks. Ray [41] is an open-source distributed execution framework that facilitates RL model training and serving by making it easy to scale an RL application and schedule distributed runs to efficiently use all resources (i.e., CPU, memory, or GPU) available in a cluster. Amazon SageMaker [1] uses the Ray RLlib library that builds on the Ray framework to train RL policies. SageMaker also provides cloud services that help build and deploy ML models (e.g., data processing and model evaluation). RLzoo [9] is an RL library that aims to make the development of RL agents efficient by providing high-level yet flexible APIs for prototyping RL agents. RLzoo also allows users to import a wide range of RL agents and easily compare their performance. Park [33] provides 12 representative RL environments in the field of systems and networking (e.g., job scheduling) for developing and evaluating RL algorithms. Genet [60] is an RL training framework for learning better network adaptation policies. Genet leverages curriculum learning [42], which aims to sequence tasks to achieve the best performance on a specific final task instead of quickly adapting to a new task within a small number of gradient descent steps.

RL in Production. Panzer *et al.* [45] provide a survey of existing RL applications in production system domains, including resource scheduling. They summarize the implementation challenges and generalizability of simulation-trained RL models. SOL [58] is an extensible framework for developing ML/RL-based controllers for tasks such as core frequency scaling. SOL is complementary to AWARE, which can further guarantee that the RL agent operates safely under various realistic issues, including bad data and external interference like resource unavailability. SIMPPO [36, 48] provides a scalable framework based on the mean-field theory that enables multiple RL agents to coexist in a shared multi-tenant environment. Autopilot [50] is a workload autoscaler used at Google that leverages multi-armed bandits (i.e., the simplest version of RL) to choose a variant of the sliding window algorithms that historically would have resulted in the best performance for each job. In its essence, it is still a heuristic mechanism and has been shown [59] to suffer from poor system stability because of inaccurate estimation of horizontal concurrency; it can also result in a large number of tiny Pods [16] due to the independence between horizontal and vertical scaling.

7 Discussion and Future Challenges

Extension to Other System Domains. AWARE is a general and extensible framework that can be applied to other systems management tasks (e.g., congestion control or job scheduling). To apply it to a new domain, one needs to (a) replace the RL environment by implementing the provided environment wrapper interface; and (b) provide a default non-RL-based agent for the RL bootstrapper. We leave the study of the performance in other system domains to the future.

Out-of-distribution Workloads. AWARE provides the opportunity to quickly customize the model to specific workloads. However, out-of-distribution <application, environment> pairs still require training because meta-learning assumes that all pairs, including the unseen cases, are inherently within the learned distribution [20] (e.g., in terms of service request arrival patterns or sensitivity to resource allocation). Given the diversity of workloads in the cloud datacenter (used in the training dataset), the meta-learner and the shared base-learner can be continuously trained, and out-of-distribution cases are covered eventually. Meanwhile, with offline RL training, users can still benefit from the heuristics-based solution used as the fallback option. One limitation of our experiment was that the generated applications might not have covered all possible cloud workloads. However, application segments can easily be extended in the synthetic application generator if specific workload profiles are missing (§5.1).

On-policy RL Algorithms. When RL agents are being bootstrapped at the initial stage, off-policy RL agents (such as DDPG [29, 47] and DQN [59, 62]) can be trained directly using the collected RL trajectories. However, on-policy RL agents (such as PPO [48]) require trajectories generated from their own policy. One potential way to train on-policy RL agents offline would be to build a simulator based on the collected trajectories, which would essentially map resource allocation to workload performance and system metrics. A balanced experience replay scheme [27] could potentially be applied for locating near-on-policy samples from the simulator constructed based on the offline dataset. Instead of drawing trajectories from the trajectory database (as in §3.4), the RL base-learner can interact with the simulator for bootstrapping.

8 Conclusion

This paper explored the challenges of applying RL in workload autoscaling in production cloud platforms. We presented a general and extensible framework for deploying and managing RL agents in production systems. To demonstrate the framework, we implemented AWARE for automating RL-based workload autoscaling in Kubernetes and experimentally showed (a) the benefits of leveraging meta-learning for fast model adaptation, and (b) how the design of AWARE ensures the stable and robust online performance of RL models.
