By contrast, as shown in Figure 1(b), *Validation* strategy only inserts the new entry { $s1 \rightarrow p2$ } but does not maintain the consistency of obsolete entries in secondary indexes (e.g., DELI [50], and secondary indexing proposed by Luo et al. [40]). However, secondary index query operations need to validate all relevant entries by checking the primary table to filter out obsolete mappings. Though previous work proposed some approaches to reduce the validation overhead, their benefits are limited. For example, DELI [50] lazily repairs the secondary index along with compaction of the primary table. Luo et al. [40] propose to store an extra timestamp for each entry in the secondary index and use a *primary key index* that only stores primary keys and their latest timestamp for validation. The primary key index is validated instead of the primary table. However, since the primary key index is also an LSM-tree, though it filters out unnecessary point lookups on the primary table, it still requires point lookups on itself.

Index type. As a secondary key can have multiple associated primary keys, LSM-based secondary indexes have two types surrounding this issue, including *composite index* and *posting list* [47]. The key in a *composite index* (i.e., *composite key*) is a concatenation of a secondary key and a primary key. The composite index is easy to implement and adopted by many applications [16, 44, 47]. However, it turns a secondary lookup operation into a prefix range search operation.

The *posting list* stores multiple associated primary keys in the value of a KV pair. When a new record is inserted, there are two update strategies. *Eager* update strategy conducts read-modify-write, fetching the old posting list and merging the new primary key to the posting list. *Lazy* update strategy blindly insert a new posting list which only includes the new primary key. It leaves posting lists merging to compaction. However, a secondary lookup needs to search all levels to fetch all relevant entries.

Limitations. Even though there are multiple strategies, types, and optimizations, LSM-based secondary indexes have to sacrifice either the write performance of storage systems or the secondary index query performance, which results from the incompatibility of inherent attributes of LSM-trees and characteristics of secondary indexes.

2.3 Persistent Memory

Persistent Memory (PM), also called Non-Volatile Memory (NVM) or Storage Class Memory (SCM), provides several attractive benefits for storage systems, such as byte-addressability, DRAM-comparable access latency, and data persistency. CPUs can access data on PM directly with load and store instructions. Compared to DRAM, PM has a much larger capacity and lower cost and power consumption. In addition to DDR bus-connected PM (e.g., Intel Optane DCPMM), the recent high-bandwidth and low-latency IO interconnection, Compute Express Link (CXL) [3, 29], brings a new form of SCM, CXL device-attached memory (e.g., Samsung's Memory-semantic SSD [8]).

However, PM also has some performance idiosyncrasies.

For example, the current commercial PM hardware (i.e., Intel Optane DCPMM) has physical media access granularity of 256 bytes, leading to high random access latency (about 3× of DRAM) and write amplification for small random writes, which needs to be considered when designing PM systems [14, 51, 53, 55, 57, 60]. These idiosyncrasies should be more obvious on CXL device-attached memory due to the physical media characteristics (e.g., flash page in CXL-SSD).

3 Motivation

Though recent work introduces some techniques to optimize secondary indexing in LSM-based systems, we find that *the performance of LSM-based secondary indexing is still unsatisfactory due to the incompatibility of inherent attributes of LSM-trees and characteristics of secondary indexing*. On the one hand, LSM-tree is not a competent data structure for secondary indexes, since the characteristics of secondary indexes exacerbate the deficiency of LSM-tree's read operations: (1) KV pairs are usually small in secondary indexes, to which LSM-tree's cumbersome lookup operations are unfriendly; (2) Secondary keys are not unique and can have multiple values, which LSM-tree's out-of-place update will exacerbate the query inefficiency. On the other hand, the blind-write attribute of LSM-based primary tables makes the consistency of secondary indexes troublesome.

Therefore, this motivates us to find a better solution for secondary indexes in LSM-based storage systems. As PM provides attractive features such as byte-addressability, DRAM-comparable access latency, and data persistency, we argue that it is promising to provide secondary indexing with PM.

Though there are many state-of-the-art PM-based index structures, they are not specifically designed for secondary indexes. To adopt them as secondary indexes (e.g., support the multi-value feature), naive approaches include the composite index or using a conventional allocator to organize posting lists (§2.2). However, *simply adopting these naive approaches to use existing PM-based indexes as secondary indexes will overshadow their superior advantages*.

Why not use a PM-based composite index? Though this method is straightforward and easy to implement in LSM-based systems, it is not ideal for tree-based persistent indexes. First, when adding or removing a primary key for a secondary key, a value update operation turns into a new composite key insert or delete operation for composite indexes. Insert and delete operations are more expensive than update operations in a PM-based tree index because they may cause shift operations or structural modification operations (SMO). Second, composite indexes store every pair of mappings as an individual KV pair, expanding the number of KV pairs, which increases the height of the tree index and thus degrades its query performance. Third, storing the same secondary keys repeatedly in multiple composite keys wastes PM space, which can be a dominant overhead for some real-world databases [59].

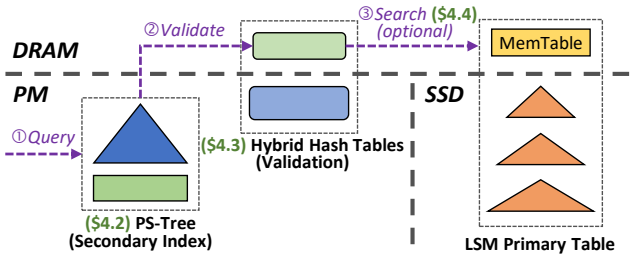

Figure 2: The overall architecture with Perseid.

Why not use a conventional allocator? One may use a conventional allocator, such as a log-structured approach or a slab-based allocator, to allocate space for values out of the indexes. Nevertheless, they are not suitable for values of secondary keys. The log-structured approach is friendly to PM for its sequential-write pattern. One may use the log-structured approach to append new values in the log and use pointers to link associated values belonging to the same secondary key. However, it will scatter values (primary keys) associated with the same secondary key and thus reduce the query performance due to poor data locality. Slab-based allocators are widely used for volatile memory, but they are not suitable for PM and secondary indexes. First, these general-purpose allocators usually have high overheads on PM since they conduct expensive mechanisms for crash consistency (e.g., logging) and perform many small writes on their metadata which is necessary for recovery [6]. Second, slab-based allocators have low memory utilization due to the memory fragmentation issue [49], which cannot be eliminated by restarting on PM [18]. These issues are more severe for secondary indexes. In secondary indexes, the value of a secondary key is changed by inserting or removing primary keys, which means the value size (the total size of associated primary keys) changes constantly. This characteristic not only needs frequent reallocation but also exacerbates the fragmentation issue.

Our experiments (§5.2) show that these naive approaches on PM-based indexes lead to several times performance degradation. It thus motivates us to explore a new PM-based secondary indexing mechanism for LSM-based KV stores. In addition, an efficient validation approach is required to retain the blind-write attribute of LSM-based KV stores.

4 Perseid Design

4.1 Overview

Motivated by the analysis above, we propose PERSEID, a PM-based secondary indexing mechanism for LSM-based storage systems, which overcomes traditional LSM-based secondary indexes' deficiencies. Figure 2 shows the overall architecture of an LSM-based storage system with PERSEID.

- PERSEID contains a PM-based secondary index, `PS-Tree`, which is both PM and secondary index friendly: by adopting

log-structured insertion, PS-Tree achieves fast insertion on PM; by storing primary keys which associate to the same secondary key closer and further rearranging them adjacent, PS-Tree supports efficient query operations (§4.2).

- PERSEID retains the blind-write attribute of the LSM primary table for write performance without sacrificing query performance by introducing a lightweight hybrid PM-DRAM and hash-based validation approach. The validation approach contains a persistent hash table to record version information of primary keys, and a volatile and lite hash table to absorb random accesses to PM. (§4.3).
- To accelerate non-index-only queries, PERSEID adapts two optimizations on primary table searching issued from secondary indexes. PERSEID filters out irrelevant component searching with sequence numbers and parallelizes primary table searching in an efficient way (§4.4).

4.2 PS-Tree Design

PERSEID introduces PS-Tree, a PM-based secondary index, which is designed considering the multi-value feature and PM characteristics. We first present PS-Tree's structure (§4.2.1), and then describe its operations (§4.2.2).

4.2.1 Structure

The overall structure of PS-Tree is shown in Figure 3. PS-Tree consists of two layers, *SKey Layer* for indexing secondary keys and *PKey Layer* for storing values. Specifically, the SKey Layer resembles a normal in-memory index and can leverage an existing high-performance PM-based index (e.g., P-Masstree [33, 43] and FAST&FAIR [25]). The PKey Layer stores variable-number values (i.e., primary keys and other user-specified values) of secondary keys in a manner of blended B$^+$-Tree leaf nodes and log-structured approaches, which combines the advantages of the two approaches. The value of a secondary key in the SKey Layer is a pointer, which points to corresponding primary keys in the PKey Layer. Each pointer is a combination of the address of the PKey Page and an offset within the page.

In the PKey Layer, primary key entries (*PKey Entries*) are stored in *PKey Pages*. Each PKey entry has an 8-byte metadata header and a primary key. The header consists of a 2-byte size, a 1-bit obsolete flag, and a 47-bit sequence number (SQN) of the primary key. The SQN is internally used for multi-version concurrency control (MVCC) in LSM-based KV stores [22, 24]. Each new record (including updates and deletes) in the primary table gets a monotonically increased SQN. PERSEID leverages the SQN mechanism to guarantee data consistency among the primary table and secondary indexes, and also for validation which will be described in §4.3. PKey Pages are aligned to PM physical media access granularity (e.g., 256 bytes of Intel Optane DCPMM [57]). PS-Tree inserts PKey Entries into PKey Pages in a log-structured manner to reduce the write overhead and ease crash consistency on PM.

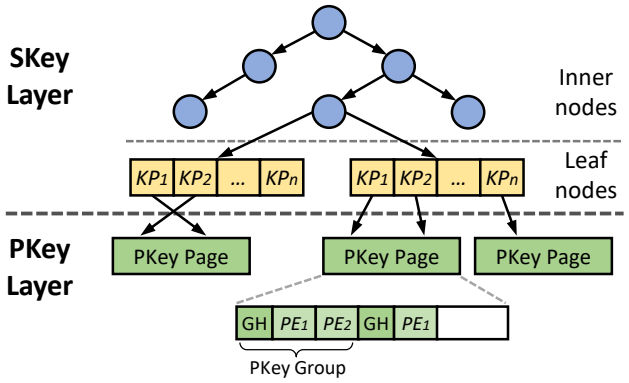

Figure 3: The structure of PS-Tree. *KP: Key Pointer pair, GH: Group Header, and PE: PKey Entry.*

Nevertheless, traditional log-structured approaches scatter different values of the same secondary key in the log, resulting in poor data locality and degraded query performance. To improve data locality, PS-Tree stores PKey Entries of contiguous SKeys in the same PKey Page, similar to the leaf node in a B$^+$-Tree. Furthermore, during the PKey Page split, PS-Tree rearranges PKey Entries that belong to the same secondary keys to store continuously as a *PKey Group*. Each PKey Group has an 8-byte *Group Header* and one or multiple PKey Entries. The lower 48 bits of a group header are the address of the previous PKey Group of the same secondary key or null if the current group is the last one. Thus all PKey Groups belonging to one secondary key are linked as a list. The remaining 16 bits store the number of total entries and the number of obsolete entries in the group.

4.2.2 Basic Operations

PS-Tree considers features of both secondary indexing and persistent memory. Compared with DRAM, PM has limited write bandwidth and the write amplification issue. Therefore, PS-Tree adopts log-structured insertion and copy-on-write split for efficient writes and lightweight crash consistency mechanisms. To avoid high latencies of multiple random accesses of multiple values on PM during query operations, PS-Tree reorganizes values of the secondary index and conducts lazy garbage collection during the PKey Page split.

Log-structured Insert. Algorithm 1 describes the process of the insert operation. First, PS-Tree searches for the SKey and its pointer in the SKey Layer. From the pointer, PS-Tree locates the previous PKey Group and the corresponding PKey Page (Line 1-3). If the SKey is not found, then the PKey Page is located from the pointer of the previous SKey which is just smaller than this new SKey (Line 5).

Second, PS-Tree appends a new PKey Group in that PKey Page (Line 11-12). The new PKey Group contains one entry with the new PKey and other values if specified, and the header points to the previous PKey Group if exists.

Third, the new pointer of the SKey (i.e., the address of

Algorithm 1: Insert(SKey sk, PKey pk, Slice val, SeqNumber seq)

```
1  search for the leaf_node and pointer ptr of sk in SKey Layer;
2  if ptr ≠ NULL then // found sk
3  |   pkey_page = pointer.pkey_page;
4  else
5  |   pkey_page = leaf_node→get_prev_pkey_page(sk);
6  end
7  if pkey_page is full then
8  |   pkey_page split;
9  |   goto Line 1;
10 end
11 construct a PKeyGroup pg with pk, val, seq, and ptr;
12 new_ptr = pkey_page→append(pg);
13 leaf_node→upsert(sk, new_ptr);
```

the new PKey Group) is updated or inserted in the SKey Layer (Line 13). Thus, the insert request usually performs an update operation in the SKey Layer. PKey Entries of a secondary key are always linked in the order of recency to facilitate query operations which usually require the most latest entries [11, 47].

Search. The search operation in PS-Tree starts with searching for the secondary key and its pointer in the SKey Layer. Then, from the latest PKey Group indicated by the pointer, primary keys and other user-specified values can be retrieved in the order of recency. PERSEID adopts the *Validation* strategy (§2.2) for its high ingestion performance. Therefore, all primary keys are first validated before returning. Obsolete PKey Entries are marked as obsolete by setting their obsolete flags, which will be removed physically when the PKey Page splits. The LSM-based primary table supports MVCC by attaching one snapshot and using reference counters to protect components from being deleted [22, 24]. In PS-Tree, we adopt an epoch-based approach: readers publish their snapshot numbers during query operations, and obsolete entries whose sequence number is larger than any reader's snapshot number are guaranteed not to be removed physically.

Update and Delete. PS-Tree has no update or delete operations (from the point of view of secondary indexes rather than the data structure). Since updating the primary key of a record in the primary table is commonly not supported in database systems, there is no need to update values (primary keys) in secondary indexes. With the Validation strategy, PS-Tree does not delete the obsolete entries synchronously with the primary table. PS-Tree leaves obsolete entry cleaning to garbage collection.

Locality-aware PKey Page Split with Garbage Collection. When a PKey Page does not have enough space for a new entry, it splits into two new PKey Page in a copy-on-write manner. Since insertions are performed in a log-structured manner, the PKey Entries which belong to one SKey may

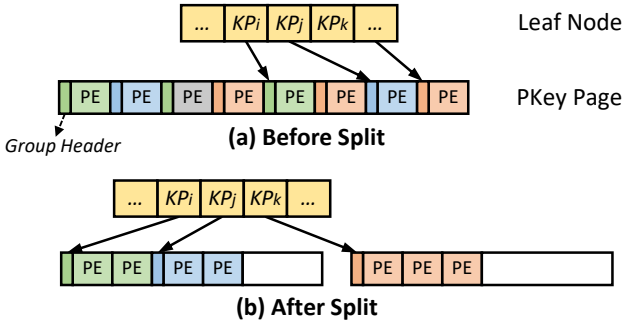

Figure 4: An example of PKey Page split. *PEs (PKey Entries) with the same color belong to the same secondary key; PE in gray are obsolete.*

scatter discontinuously. Querying these entries may need multiple random accesses on PM. As PM has non-negligible read latencies compared to DRAM (e.g., about 300 ns with Intel Optane DCPMM [57]), query operations can have high overheads. Therefore, as shown in Figure 4, to improve locality, PS-Tree reorganizes PKey Entries when the PKey Page splits. PS-Tree rearranges PKey Entries belonging to the same SKey in one PKey Group, so these entries are stored continuously, and the storage overhead of the Group Header is reduced since multiple PKey Entries share one Group Header.

Besides, entries not marked as obsolete in the current PKey Page are validated by a lightweight approach (described in §4.3) and obsolete entries are physically removed during reorganization to reduce space overhead. Since a secondary key may have many primary keys which occupy more than one PKey Page, for those PKey Entries not in the current PKey Page, PS-Tree lazily garbage collects them only when the number of obsolete entries exceeds half of the number of total entries in that PKey Group. To support MVCC, PS-Tree retains obsolete entries whose sequence number is larger than the minimum snapshot number of concurrent readers. Obsolete entries may retain long if there exists a long-running queries. PERSEID can be enhanced with similar techniques in recent work [30, 35] to handle long-lived snapshots. After rearranging valid entries to the new PKey Pages, pointers of related SKeys are updated and the old PKey Page is freed.

Crash Consistency. PERSEID relies on the existing write-ahead-log (WAL) of the LSM-based primary table to guarantee atomic durability among the primary table and secondary indexes. During recovery with WAL, PERSEID redoes uncompleted operation to the PS-Tree.

PS-Tree also handles its own crash consistency issues. Insert operations are committed only when the pointers in SKey Layer are updated. If the system crashes before updating pointers but after allocating a new PKey Page, then the PKey Page is unreachable. After restart, a background thread will scan the allocated pages and PS-Tree to find and reclaim unreachable pages. Besides, PS-Tree allows concur-

rent insertion in one PKey Page. A thread obtains the space to write by compare-and-swap the tail pointer of the PKey Page. Thus, the space may leak if any thread obtains it but does not update the pointer in SKey Layer when the system crashes. `PS-Tree` tolerates this situation and leaves these leakages to page splitting which naturally reclaims these leaked spaces.

4.3 Hybrid PM-DRAM Validation

PERSEID adopts the Validation strategy (see §2.2) for high write performance, which necessitates a lightweight validation approach. Since update-intensive workloads are quite common nowadays [11, 12], if the validation approach is heavy, validating a large number of obsolete entries brings no outcomes but generates huge overhead.

PERSEID introduces a lightweight validation approach based on the requirement of validation. PERSEID adopts a hash table on PM storing version information for primary keys. The hash table is indexed by the primary key and stores its latest sequence number (§4.2.1). Nevertheless, even though point lookups on a PM-based hash table are much faster than on a tree, the validation time is comparable to the query time of `PS-Tree`. This is because one secondary key has multiple primary keys to validate, and PM has non-negligible random access latency. Simply placing the hash table on DRAM will occupy a large memory footprint. However, as validation only needs to validate whether a version of a primary key is valid, but not obtaining the specific latest version number, PERSEID builds another volatile hash table on DRAM which only stores versions for primary keys that have been updated or deleted. In this way, PERSEID only needs to query the small volatile hash table and thus the validation overhead is further reduced.

Figure 5 illustrates the hybrid PM-DRAM validation approach. The values in the hash tables consist of the sequence number of the record (6-byte) and a 2-byte counter. The counter is used to determine whether a primary key has obsolete versions. There is a slight difference in the counters of the two hash tables. In the volatile hash table, each counter indicates the number of *logically* existing entries related to a primary key in the secondary index. By contrast, each counter in the persistent hash table indicates the number of *physically* existing entries in the secondary index. Next, we describe the validation approach in detail according to operations.

Insert. When a new record (including update and delete) is inserted into the primary table, the primary key is inserted or updated with its sequence number into the persistent hash table. If the persistent hash table does not contain this primary key before, its counter is set to one, which means this primary key has only one version and no obsolete entries of this primary key exist in the secondary index. For example in Figure 5, at *t2*, key *c* is inserted for the first time, and it is inserted into the persistent hash table. Otherwise, the primary key's counter in the persistent hash table is increased by one; besides, the primary key is inserted or updated with its sequence number into the volatile hash table, and the counter

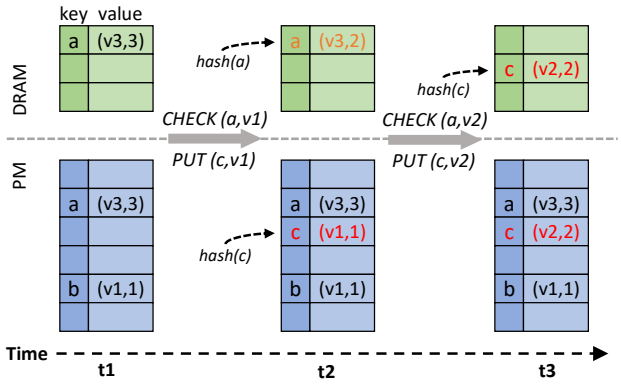

Figure 5: Hybrid PM-DRAM hash-based validation.

in the volatile hash table is set to two if it's an insertion or increased by one if it's an update. For example, when key *c* is updated with a new version *v2* at *t3* in Figure 5, the entry in the persistent hash table is updated and a new entry is inserted into the volatile hash table.

Validate. The secondary index validates an entry by querying the volatile hash table. Specifically, the entry is valid if the sequence number of this entry matches the latest sequence number stored in the hash table, or the hash table does not contain the primary key which means there are no obsolete entries of this primary key. Otherwise, the entry is not valid and PERSEID marks the entry as obsolete and decreases the counter of the entry in the volatile hash table by one. For example, when key *a* is checked with an obsolete version *v1* at *t2* in Figure 5, the result is false, and then the counter is decreased from 3 to 2. If the counter is decreased to 1, which means all obsolete entries have been marked, the entry is removed from the volatile hash table to restrict the hash table size. For example, when key *a* is checked with an obsolete version *v2* at *t3* in Figure 5, the counter is decreased to one, the validation return false and the entry is removed. A rare case is that the volatile hash table reports a new sequence number larger than the current reader's snapshot number, which means a concurrent writer has updated this primary key. In this case, we cannot directly confirm whether this entry is valid in this snapshot, so we have to validate it by the primary table. During validation for secondary index queries, PERSEID only operate with the volatile validation hash table. Thus, the validation overhead is quite small.

Garbage Collection. During the PKey Page split, entries that are not marked as obsolete are also validated to remove obsolete entries (§4.2.2). Since this step physically removes obsolete entries, PERSEID decreases the corresponding counters in the persistent hash table. If a counter is decreased to one, PERSEID removes the corresponding hash pairs from the volatile hash table.

Recovery. When the system restarts from a crash or a normal shutdown, the volatile hash table needs to be recovered. PERSEID iterates the whole persistent hash table and

inserts primary keys whose counter is greater than one into the volatile hash table. Now the counters in the volatile hash table are numbers of physically existing entries, which may be larger than the actual numbers of logically existing entries. Therefore, some false positive primary keys may exist in the volatile hash table. However, this does not affect the validation accuracy and these primary keys can be removed by garbage collection.

4.4 Non-Index-Only Query Optimizations

Though the PERSEID significantly reduces the overhead of secondary indexing, the overhead of non-index-only queries (require full records) is still dominated by the LSM-based primary table. Thus, PERSEID further introduces two optimizations for non-index-only queries.

4.4.1 Locating Components with Sequence Number

A secondary index query operation may need to search the primary LSM table multiple times for all its associated records. LSM-trees have mediocre read performance due to the multi-level structure. Besides device I/Os, if data is cached in memory or using fast storage devices, LSM-trees have non-negligible overheads on probing components (i.e., indexing and checking Bloom filters) [17, 20, 60]. Moreover, the read performance gets worse with the tiering compaction strategy since more components (SSTables) need to check and read.

Nevertheless, we find that many components are unnecessary to probe in searching processes issued from the secondary index. Previous work uses zone maps, which store the minimum and maximum values of an attribute, to skip irrelevant data blocks or components during searching [9, 10, 47]. We found that this technique can also be used by secondary indexes to search the primary table. Since we have already recorded the sequence numbers of primary keys in the secondary index, the sequence number can be used as an additional attribute to skip irrelevant components. PERSEID builds a zone map that records a sequence number range (i.e., the minimum and maximum sequence numbers of records) for each component (including MemTables).

Moreover, since tiering compaction does not rewrite SSTables in the higher level (except for the last level), for a range partition, the sequence number ranges of different levels and even different sorted runs are strictly divided. For primary tables adopting the tiering strategy, with the primary key to search SSTables horizontally and the additional sequence number to search sorted runs vertically, PERSEID can locate the exact component that contains the record directly. Besides, since PERSEID already validates the version so it must exist in the component, PERSEID can further skip the Bloom filter checking. Thus, the overheads on indexing and checking Bloom filters are almost eliminated.

This optimization does not fit with leveling strategy perfectly. The sequence number ranges in different levels have overlaps because compaction rewrites SSTables in the higher level and generates new SSTables with blended sequence numbers from multiple levels. However, since most LSM-base KV stores adopt the tiering strategy on L_0 at least [22, 24], this optimization is still effective to some extent.

4.4.2 Parallel Primary Table Searching

A single secondary key usually has multiple associated primary keys, and queries on these primary keys are independent. Therefore, using multiple threads to accelerate primary table searching is a natural optimization method. One naive approach is to assign primary keys to each thread in a round-robin fashion. However, point lookups on LSM-trees may have a large latency gap, since some KV pairs can be fetched from MemTable or block cache directly and others may reside at a relatively high level and need several disk I/Os due to Bloom filter false positives. The naive approach will result in a load imbalance among parallel threads where some threads have finished their tasks and become idle while others are still stuck and there may still exist some unfinished tasks.

To avoid this situation, we apply a *worker-active* fashion. PERSEID publishes primary keys into a shared queue as tasks, and each parallel thread fetches one task from the queue. In this way, though each thread may complete a different number of tasks, parallel threads are fully utilized.

5 Evaluation

In this section, we evaluate PERSEID against existing PM-based indexes with naive approaches and state-of-the-art LSM-based secondary indexing techniques [40, 47]. After describing the experimental setup (§5.1), we evaluate these secondary indexing mechanisms with micro benchmarks to show their performance on basic operations (§5.2). Then, we evaluate these systems' overall performance with mixed workloads (§5.3) and recovery time (§5.4).

5.1 Experimental Setup

Platform. Our experiments are conducted on a server with an 18-core Intel Xeon Gold 5220 CPU, which runs Ubuntu 20.04 LTS with Linux 5.4. The system is equipped with 64 GB DRAM, two 128 GB Intel Optane DC Persistent Memory in AppDirect mode, and a 480 GB Intel Optane 905P SSD.

Compared Systems. We implement `PS-Tree` of PERSEID based on two typical PM-based indexes, a B$^+$-Tree FAST&FAIR [25] and a trie-like P-Masstree [33, 43]. We compare PERSEID against the two original PM-based indexes, and LSM-based secondary index (denoted as `LSMSI`) approaches of *LevelDB++* [47]. The compared PM-based indexes are implemented as secondary indexes via the composite index approach and the log-structured approach (denoted as `FAST&FAIR-composite`, `FAST&FAIR-log`, `P-Masstree-composite`, `P-Masstree-log`, respectively). For the log-structured approach, we provide enough space

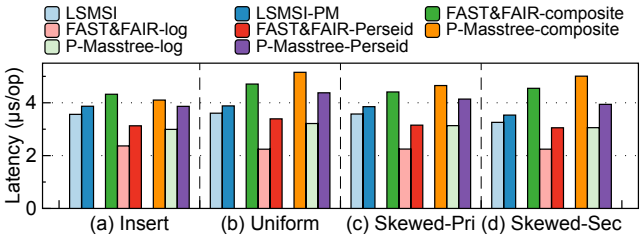

Figure 6: Insert and upsert performance.

and disable garbage collection to avoid its influence and present the ideal performance [51]. We enhance other PM-based indexes with PERSEID's hybrid PM-DRAM validation approach (§4.3) and `LSMSI` with the primary key index [40] (§2.2) for validation. For a fair comparison, we also implement LSM-based secondary indexing approaches on PM. We use *PebblesDB* [48], a state-of-the-art tiering-based KV store, as the primary table.

Workloads. Since common benchmarks for key-value stores such as YCSB [15] don't have operations on secondary indexes, as in previous work [36, 40, 47], we implemented a secondary index workload generator based on an open-source twitter-like workload generator [2] for evaluation. With this generator, we generate several microbenchmark workloads and mixed workloads. The primary key (e.g., ID) and secondary key (e.g., UserID) are randomly generated 64-bit integers. The key space of primary keys and secondary keys is 100 million and 4 million, respectively. Thus the average number of records per secondary key is about 25. The size of each record is 1KB.

KV Store Configurations. For the primary table, according to configuration tuning guide [23], MemTable size is set to 64 MB and the Bloom filters are set to 10 bits per key. As our workloads will generate a primary table larger than 100 GB, we set a 16-GB block cache for the primary table and a 1-GB block cache for the LSM-based secondary index. Compression is turned off to reduce other influencing factors.

5.2 Microbenchmarks

In this section, we evaluate the basic single-threaded performance and scalability of compared secondary indexing mechanisms.

5.2.1 Insert and Update

The *Insert* workload (i.e., no updates) has 100 million unique records. Figure 6(a) shows the average latency of insert operations of each secondary index. PERSEID performs about 10-38% faster than the corresponding composite indexes, but 25% slower than the *ideal* log-structured approach without garbage collection due to the page split overhead in `PS-Tree`. The composite index approach results in inferior performance as we analyzed in §3. Other approaches have higher performance due to the sequential-write pattern.

The upsert workloads contain 100 million insert operations and 100 million update operations. Operations are shuffled to avoid all newer entries being valid in secondary indexes. In the *Uniform* workload, both primary keys and secondary keys follow a uniform distribution. In the *Skewed-Pri* workload, primary keys follow a Zipfian distribution with the skewness parameter 0.99, and secondary keys are selected randomly. In the *Skewed-Sec* workload, secondary keys follow a Zipfian distribution (parameter 0.99), and primary keys are uniform. Thus, hot secondary keys have lots of associated primary keys, which represent low-cardinality columns.

Compared with other secondary indexes, composite indexes perform even worse in upsert workloads. This is because, with additional upsert operations, composite indexes have more KV pairs and larger tree heights. By contrast, `PS-Tree` and the log-structured approach do not increase the number of KV pairs in the index part.

5.2.2 Query

In this experiment, we evaluate the performance of index-only queries of each system after loading the insert workload or upsert workloads. Index-only query reflects the performance of a secondary index itself and is a common query technique (i.e., covering index [5, 7]) to avoid looking up the primary table. We show two different selectivities by specifying limit N (10 and 200) on return results. The most recent and valid N entries are returned. For limit of 200, the actual average number of returned entries per query is 25 and 142 for the *Skewed-Pri* and *Skewed-Sec*, respectively.

Figure 7 shows the results of index-only query performance. From the results, we have the following observations.

First, PM-based indexes have significantly lower latencies than LSM-based secondary indexes. Putting `LSMSI` on PM (`LSMSI-PM`) has very limited improvement, which is because `LSMSI` already benefits from block cache and OS page cache. Even so, `LSMSI` is still inefficient due to the high overhead of indexing and Bloom filter checking. Besides, `LSMSI` has a high overhead on validating the primary key index.

Second, PERSEID outperforms existing PM-based indexes with the composite index and the log-structured approach by up to 4.5× and 4.3×, respectively. The log-structured approach has poor locality since relevant values are scattered across the whole log and require multiple random accesses to fetch them all. Composite indexes are inferior due to the larger number of KV pairs in the indexes and range-scan operations as we analyzed in §3. They are especially inefficient under the *Skewed-Sec* workload with a large limit (e.g., 200), where they fetch a large number of entries and fail to enjoy the cache effect. By contrast, the performance of PERSEID is much more stable across different workloads, owing to the locality-aware design of `PS-Tree`. For a limit of 10, PM-based secondary indexes benefit from higher cache hit ratios under the *Skewed-Sec* workload, thus achieving better performance than other upsert workloads. Composite indexes also occupy about 4×

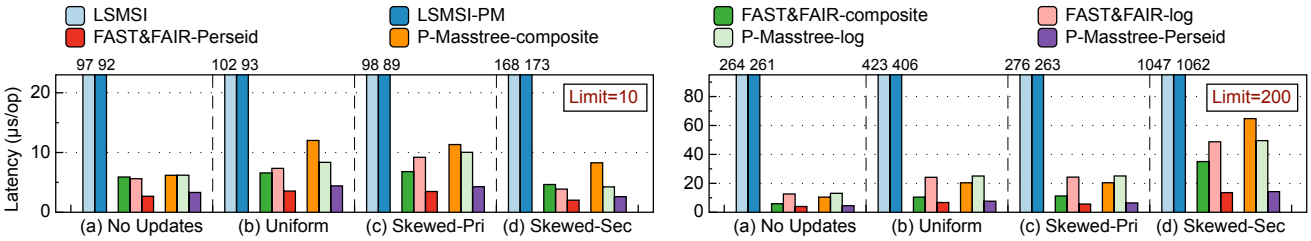

Figure 7: Index-only query performance.

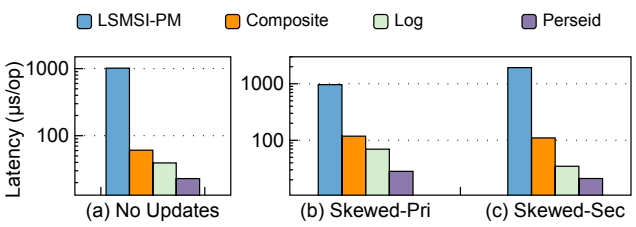

Figure 8: Index-only range query performance.

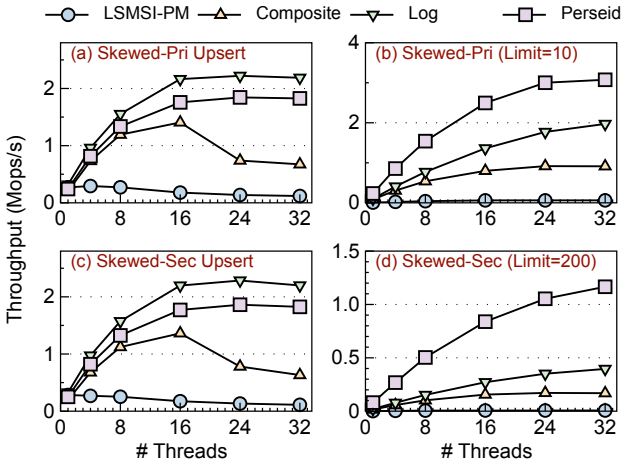

Figure 9: Multi-threaded performance.

more PM space than `PS-Tree`, which is because they repeatedly store secondary keys and have more index nodes. In addition, `P-Masstree-composite` has higher latencies than `FAST&FAIR-composite`, because trie-based indexes are less efficient than B$^+$-Trees in range search since their leaf nodes do not have sibling pointers pointing to neighbor nodes.

Third, under upsert workloads, all systems need to validate more primary keys to exclude obsolete entries, which also contributes to the higher overheads than under insert workloads. For `LSMSI`, since the primary key index needs multiple heavy point lookups on LSM-trees, validating the primary key index accounts for the lion's share of the total cost of an index-only query. `LSMSI` has lower latencies under the *Skewed-Pri* workload than other upsert workloads since the primary key index enjoys the data locality on primary keys. By contrast, PERSEID (and other PM-based indexes) validates on a volatile hash table, which takes up less than half of the total cost. The overhead on PERSEID increased little due to the locality-aware design of `PS-Tree` and the lightweight validation approach.

5.2.3 Range Query

In the following experiments, we show results of the LSM-based secondary index on PM (`LSMSI-PM`), and PM-based secondary indexes based on P-Masstree as representatives. We evaluate the range queries of these secondary indexes. Each range query searches for 20 secondary keys and retrieves 5 latest associated primary keys of each secondary key.

The results are shown in Figure 8. Range queries need to search more KV pairs from ten different secondary keys, showing a more pronounced difference between these secondary indexes than low-limit query operations. PERSEID outperforms `LSMSI-PM`, the Composite P-Masstree, and the log-structured approach by up to 92×, 5.2×, and 1.6×, respectively under the *Skewed-Sec* workload. Though `LSMSI-PM` benefits from PM access latency and DRAM caching, it still has a fairly high latency. This is because the range operation in LSM needs to merge-sort multiple iterators of components. The composite index needs to perform more range search than PERSEID in the index since PERSEID groups primary keys outside of the index.

5.2.4 Multi-threaded Performance

Figure 9 shows the multi-threaded performance of compared secondary indexes. We take the results of *Skewed-Pri* and *Skewed-Sec* workloads as representatives. For *Skewed-Sec*, we show the result with the limit of 200, and the result with the limit of 10 is similar to that of *Skewed-Pri*. For upsert operations, PERSEID scales up to 24 threads, achieving 2.8× and 16× the upsert throughput of the composite P-Masstree and `LSMSI-PM`, and slightly slower than the ideal log-structured approach. For query operations, PERSEID scales well and achieves 7× and 3× query throughput of `P-Masstree-composite` and `P-Masstree-log` under the *Skewed-Sec* workload due to the locality-aware design of `PS-Tree`. `LSMSI` has poor scalability due to its coarse-granularity lock and non-concurrent logging mechanism. Though using the same index structure (P-Masstree), because

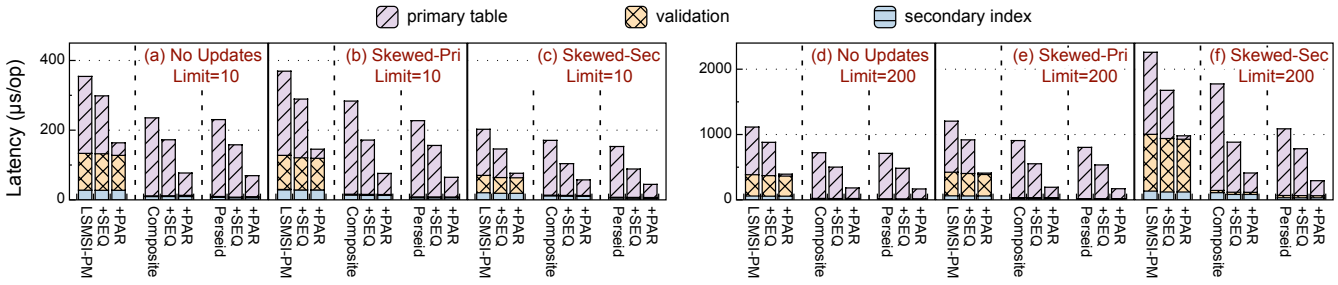

Figure 10: Non-index-only query performance. *The primary table time on +PAR only shows the time not covered by other parts.*

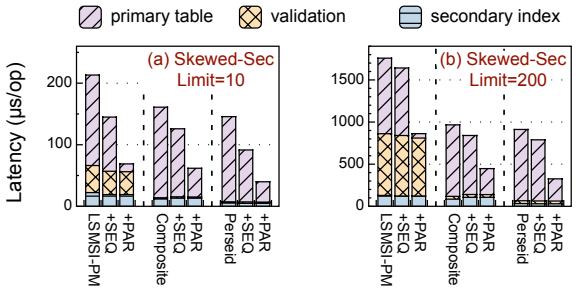

Figure 11: Non-index-only query performance on Leveling-based LSM table.

the composite index turns update operations into insert operations, the index operations limit its write scalability; and because it expands the number of KV pairs and thus has a bigger tree height, the increased index overhead limits its query scalability. As for the log-structured approach, the poor data locality restricts its query performance, especially for large-range queries.

5.2.5 Non-Index-Only Query

We next evaluate the non-index-only query operations. Besides the basic compared secondary indexes, we also enhance them by applying the two optimizations (§4.4), sequence number zone map (*+SEQ*) and parallel primary table searching (*+PAR*) sequentially. In this experiment, we use 4 threads for parallel primary table searching. Figure 10 shows the performance and time breakdown of non-index-only query operations. Note that the breakdown of primary table time on *+PAR* only shows the time not covered by the secondary index and validation. PERSEID brings considerable improvements against the `LSMSI-PM`, even if it has the two optimizations applied. PERSEID outperforms `LSMSI-PM` by up to 62% and 2.3×, when without and with optimizations on primary table lookups (the sequence number zone map and parallel primary table searching), respectively.

Though the primary key index indeed reduces unnecessary point lookup operations on the primary table for `LSMSI-PM`, with advanced low-latency storage devices and sufficient DRAM caching, it also has significant overhead. On the contrary, the hybrid PM-DRAM validation of PERSEID reduces the primary table lookups with subtle extra overhead.

PERSEID's optimizations on primary table searching can also boost other compared secondary indexing. The zone map improves the overall query performance of the KV store with PERSEID by about 50%, and the parallel primary table searching further improves by up to 3.1×. However, the numbers are only 20-36% and up to 2.4× for `LSMSI-PM`, respectively. This is because these optimizations only accelerate the primary table lookups, but the `LSMSI-PM` still has huge overheads. In addition, `LSMSI-PM` has to conduct the heavy validation first then it can pass the lookup tasks to parallel worker threads. Therefore, parallel threads cannot work adequately for `LSMSI-PM`.

We also implement secondary indexes and conduct the experiments on a leveling-based LSM primary table (LevelDB [24]). Figure 11 shows the results of *Skewed-Sec* as an example. The main difference is that the sequence number zone map is less effective on leveling-based LSM primary tables. However, the zone map is still effective when the limit is small, since the latest few records stay in MemTables or SSTables in lower levels like L_0, and these components can be filtered by sequence number with a high probability.

5.3 Mixed Workloads

Workload	Operation Ratios			
	Upsert	Get	Index-Only Query	Non-Index-Only Query
Write-Heavy	70%	10%	10%	10%
Balanced	45%	10%	25%	20%
Read-Heavy	20%	20%	40%	20%

Table 1: Mixed workloads description.

In this section, we evaluate PERSEID, the composite P-Masstree, and `LSMSI-PM` under mixed workloads. The mixed workloads consist of interleaved and various types of operations, which are more representative of real-world workloads. Each workload has 40 million operations, containing both *Skewed-Pri* and *Skewed-Sec* operations. Table 1 describes these workloads' traits. Each system is prefilled with 80 million records before performing the workloads. We also enable PERSEID's optimizations on primary table searching (i.e.,

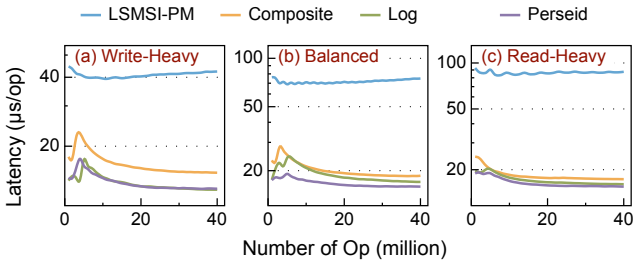

Figure 12: Performance of mixed workloads.

the sequence number zone map and parallel primary table searching) for all systems.

Figure 12 reports the average operation latencies every million operations. At the beginning of the Write-Heavy workload and the Balanced workload, PM-based secondary indexes have a spike in latency, which is mainly caused by seek-driven compaction in the LSM primary table. PERSEID outperforms `LSMSI-PM` significantly under different mixed workloads. Even though the overhead of the primary table dominates the whole operations, PERSEID still has visible advantages against the other PM-based indexes. Note that `PS-Tree` has much less capacity overhead than the composite index. As we set the limit on return results to 10 for query operations, the log-structured approach is not affected too much by its poor data locality.

5.4 Recovery Time

We evaluate the recovery time of PERSEID and `LSMSI-PM` after the Zipfian upsert workload that contains 200 million upsert operations with a single thread. Since we only need to recover the volatile validation hash table in PERSEID, it takes 2.7 seconds to scan the persistent hash table and rebuild the volatile hash table. By contrast, it takes 2.3 seconds and 1.4 seconds to recover the LSM-based secondary index and the primary key index, respectively. Their recovery time is mainly spent on rebuilding MemTables from logs and varies with the size of MemTables.

6 Related Work

Secondary Indexing in LSM-based KV stores. Qader et al. [47] conduct a comparative study on secondary indexing techniques in LSM-based systems. They conclude and evaluate several common secondary indexing techniques, including filter-based embedded index, composite index, and posting list. DELI [50] proposes an index maintenance approach that defers expensive index repair to compaction of the primary table. Luo et al. [40] propose several techniques for LSM-based secondary indexes, improving data ingestion and query performance. However, their techniques are mainly saving random device I/Os for traditional disk devices which reduce random reads at the cost of more sequential reads. Based on key-value separation [39], SineKV [36] keeps both the primary index and secondary indexes pointing to the record values. Thus, secondary index queries can get records directly without searching the primary index. However, SineKV has to discard the blind-write attribute and maintain index consistency synchronously. Cuckoo Index [32] enhances the filter-based indexing with a cuckoo filter. However, as a filter-based index, Cuckoo Index does not support range queries.

Though there are many proposed optimizations, LSM-based secondary indexing is not efficient enough due to the nature of LSM-trees. In this work, we revisit the design of the secondary index with persistent memory.

PM-based indexes. There has been plenty of research on high-performance PM indexes [13, 25, 31, 33, 42, 45, 46, 52, 56, 61]. These general-purpose indexing are not directly competent for efficient secondary indexing.

Improving LSM-based KV stores with PM. There is a lot of work optimizing LSM-based KV stores with PM. NoveLSM [27] introduces a large mutable MemTable on PM to lower compaction frequency and avoid logging. SLM-DB [26] utilizes a B$^+$-Tree on PM to index KV pairs on disks; SSTables on disks are organized in a single level, which reduces the compaction requirements. MatrixKV [58] places level L_0 on PM and adopts fine-granularity and parallel column compaction to reduce write stalls in LSM-trees. Facebook redesigns the block cache on PM to reduce the DRAM usage and thus reduce the total cost of ownership (TCO) [21, 28]. Different from these efforts, this work revisits the secondary indexing for LSM-based KV stores with PM.

7 Conclusion

In this paper, we revisit secondary indexing in LSM-based storage systems with PM. We propose PERSEID, an efficient PM-based secondary indexing mechanism for LSM-based storage systems. PERSEID overcomes the deficiencies of traditional LSM-based secondary indexing and existing PM-based indexes with naive approaches. `PS-Tree` achieves much higher query performance than state-of-the-art LSM-based secondary indexing techniques and existing PM-based indexes without sacrificing the write performance of LSM-based storage systems. The prototype of PERSEID is open-source at https://github.com/thustorage/perseid.

Abstract

Persistent memory (PMEM) allows direct access to fast storage at byte granularity. Previously, processor caches backed by persistent memory were not persistent, complicating the design of persistent applications and reducing their performance. A new generation of systems with flush-on-fail semantics effectively offer persistent caches, offering the potential for much simpler, faster PMEM programming models.

This work proposes Whole Process Persistence (WPP), a new programming model for systems with persistent caches. In the WPP model, all process state is made persistent. On restart after power failure, this state is reloaded and execution resumes in an application-defined interrupt handler.

We also describe the Zhuque runtime, which transparently provides WPP by interposing on the C bindings for system calls in userspace. It requires little or no programmer effort to run applications on Zhuque.

Our measurements show that Zhuque outperforms state of the art PMEM libraries, demonstrating mean speedups across all benchmarks of 5.24× over PMDK, 3.01× over Mnemosyne, 5.43× over Atlas, and 4.11× over Clobber-NVM. More important, unlike existing systems, Zhuque places no restrictions on how applications implement concurrency, allowing us to run a newer version of Memcached on Zhuque and gain more than 7.5× throughput over the fastest existing persistent implementations.

1 Introduction

Persistent memory (PMEM) exposes fast storage devices as byte-addressable main memory, allowing the processor to access persistent data via load and store instructions. The durability of PMEM enables an application's in-memory data to survive across system reboots and unexpected power failures. It promises to realize a vision of high performance, data persistence, a simple programming interface, and low storage overhead at the same time.

*The first two authors contributed equally to this work

However, building a system that realizes the promise of persistent programming is not simple. The contents of CPU caches do not survive power loss, and, since caches may delay evicting a modified cache line, writes may not reach PMEM in program order. This makes reasoning about the state of memory after a crash extremely challenging.

Programming systems (e.g., libraries, programming models, language support, and compilers) to help address the challenges of persistent memory programming have proliferated over the last decade. Broadly, three families of systems have emerged: each takes a different approach to consistency, and each faces significant challenges which bar widespread adoption.

The first and largest family [50, 63, 68, 71] requires programmers to access persistent state only through well-defined atomic operations (often called transactions). This provides a clean notion of consistency: after recovery from crash, each atomic section has either executed entirely or not at all. However, like all transactional memory models, this approach suffers from serious weaknesses: it is fundamentally incompatible with non-transactional synchronization, and has never gained significant traction in real systems.

The second family of systems [6, 26, 30, 42] uses FASEs, regions of code protected by locks, as atomic regions for PMEM updates. Legacy code can run with minimal changes, but these systems suffer from fundamental weaknesses arising from complex locking schemes and external IO. As we will show, addressing these weaknesses either cripples the system or essentially reduces it to a transaction-based system.

The final family of systems takes the more dramatic step of making *everything* in the system persistent via whole-system persistence (WSP) [47]. WSP provides the conceptually simplest programming model: Nothing much changes and, from the program's perspective, crashes never occur. WSP faces two major challenges: First, making all of memory persistent has until recently been infeasible, because regularly flushing volatile caches to PMEM creates enormous performance overheads. Second, making *everything* persistent would require a far-reaching redesign of many system components, for an

unclear benefit.

We think that WSP-style persistence is due for a renaissance: The advent of PMEM devices and platforms supporting *flush-on-fail* semantics (e.g. eADR for NVDIMMs or GPF for CXL devices) allows developers to treat caches as effectively persistent [14, 29], removing the main performance argument against WSP. Further, we believe that limiting the scope of persistence to a process – yielding *Whole Process Persistence (WPP)* – and providing well-defined, application-level semantics for system failures combine to produce a programming model that is fast, flexible enough to support legacy programs and complex locking schemes, and easy for programmers to use and understand.

WPP provides a simple abstraction to the process: its entire memory is persistent and will survive a power outage. If a power outage occurs, the process receives an OS signal after restart notifying it of the crash. The process can install a normal error handler for this signal which cleans up and exits, or performs more complex application-specific recovery; by default, program execution simply continues at the point of failure.

This work makes the following contributions:

- We identify a fundamental limitation of FASE-based PMEM systems.
- We introduce the WPP programming model, which treats power failure as a recoverable exception.
- We build the Zhuque runtime which provides WPP and describe its design and implementation.
- We provide experiments demonstrating the viability of the WPP system and its performance improvements over existing alternatives.

Zhuque is faster than existing PMEM programming systems. It is between 4.7× and 10.14× faster than PMDK [50], Mnemosyne [63], Atlas [6] and Clobber-NVM [68] on STAMP applications. Zhuque is also more flexible than these systems: Since Zhuque is agnostic about the application's locking scheme, it can run the most recent version of memcached, while those systems cannot. As a result, our Zhuque-based persistent memcached is more than 7.5× faster than any similar system. We also demonstrate Zhuque's flexibility by running unmodified Python benchmarks with minimal performance loss.

The rest of this paper is organized as follows. Section 2 provides some background on PMEM and associated software systems. Section 3 describes fundamental limitations of prior art necessitating the WPP model. We discuss the WPP design and musl-based system implementation in Section 4 and Section 5, respectively. Section 6 showcases the performance of WPP. We discuss related work in Section 7 and conclude the paper in Section 8.

2 Background

PMEM has introduced new possibilities for designing storage systems: programs can have byte-addressable access to terabytes of persistent data at near-DRAM latencies. However, utilizing PMEM in a both performant and programmer-friendly manner remains a challenging problem.

This section begins by describing our machine model, and then reviews existing general-purpose persistent memory programming models and their limitations to motivate WPP.

2.1 Machine Model

WPP is designed for a multi-core, cache-coherent machine equipped with PMEM (e.g. Intel DC Persistent Memory [28] or persistent CXL.mem devices [53]), and supporting *flush-on-fail* semantics, meaning that they provide a hardware guarantee that all in-flight and cached writes will reach PMEM in the event of an external power failure (as opposed to a fault in the machine or its onboard power supply). Such guarantees are provided by eADR-compliant platforms and NVDIMMs, and CXL platforms and devices supporting Global Persistent Flush (GPF). eADR and GPF are similar solutions targeting different device interfaces: the primary hardware requirement for both is that the platform must store sufficient energy to allow caches and internal device buffers to be drained to persistence after a power failure [1, 53].

On x86 systems, both eADR and GPF require system firmware to initiate and oversee the drain to persistence in response to a System Management Interrupt (SMI) [1, 13, 14]. Upon receiving this interrupt, the processor retires all in-flight instructions, drains all stores to the cache, and saves architectural state (register file etc.) to a designated per-core memory region before beginning execution of the SMI handler [16]. In both GPF and eADR, this handler first flushes the processor caches (and, for CXL, the caches of any CXL.cache device), and then proceeds to flush the buffers on the PMEM devices (NVDIMMs for eADR, CXL.mem devices for GPF) [1, 14].

2.2 Persistent Programming Models

Most existing persistent programming libraries rely on marking regions as *failure-atomic*, that is, all of the code region's effects will survive a failure or none will. Models differ in whether regions are explicitly marked (*transactional*) or inferred from locks (*FASE-based*). In addition, one work has proposed making the whole system persistent.

2.2.1 Transactional Libraries

Transactional PMEM libraries expect the programmer to explicitly mark failure atomic sections. For concurrency, these libraries either rely on off-the-shelf transactional memory systems or require the use of their own locks. For example,

NV-Heaps [9], Mnemosyne [63], and DudeTM [41] are built on existing transactional memory (TM) systems, and implement their failure-atomicity techniques (e.g. redo or undo logging) on top of those systems.

Meanwhile, transactional libraries that rely on locks generally expect transactions to acquire and release locks in a conservative, strong strict two-phase locking pattern [51, 64], that is: transactions acquire all locks at transaction begin, transactions release all locks at transaction commit, and locks are released in the order they are acquired. For example, PMDK [50], Pangolin [71] and Clobber-NVM [68] require applications to follow this lock pattern.

2.2.2 FASE-based libraries

Atlas [6] proposed the concept of failure-atomic sections (FASEs) as an alternative to transactions. A FASE is a failure-atomic operation which begins when a thread acquires its first lock and ends when it holds none — importantly, the final lock held may be different from the first lock. Because this locking scheme allows updates to be visible to other FASEs before a FASE commits, FASE-based libraries are required to track dependencies between threads, and roll back dependent FASEs in case of failure. Because FASEs are dynamically formed at runtime, user annotation is not required for existing lock-based code. NVThreads [26], JUSTDO [30], and iDO [42] follow this model.

2.2.3 Whole System Persistence

Instead of basing persistence on bounded sections of code, whole-system persistence (WSP) [47] focuses on the persistence of the entire system. WSP describes a system substantially similar to eADR and GPF, where an interrupt at power failure triggers the draining of volatile caches/buffers to persistence. This model requires no annotation and avoids the extra work done by transactional or FASE-based systems, but requires that large amounts of state be made persistent at the instant of failure, which until the advent of flush-on-fail systems was not possible.

3 Limitations of Prior Art

In this section, we argue that the existing programming models for persistent memory, namely transactional or FASE-based, necessitate an alternative path, especially when working with legacy code.

Fortunately, the emergence of persistent caches has enabled our efforts to develop a revitalize a model that does not fit either of these directions, namely, whole process persistence, in which all process state is preserved at a power failure.

3.1 Limitations of Transactions

The fact that many failure atomicity libraries leverage transactional memory is not surprising — transactions are commonly leveraged for durability within databases and file systems. When applied to (volatile) multi-threaded code, the transactional memory programming model simplifies concurrency by exporting to the programmer "single global lock" semantics, that is, the programmer should simply protect groups of accesses to shared data as "transactions," each of which are mutually exclusive. The transactional programming model is in theory appealing as programmers need not worry about data races on shared data, multiple locks, or parallel performance. To this transactional programming model, many failure atomicity libraries add persistence: transactions become both visible to other threads, and persistent, upon transaction completion.

In practice, however, despite decades of research and dedicated hardware support, (volatile) transactional memory has failed to become a common programming paradigm for general purpose multi-threaded code. Transactions generally mix poorly with both other synchronization methods (locks, barriers, condition variables, etc.) [4, 70] and IO [45, 52], tend to incur significant performance overhead when compared to fine grained locking [4, 19], and are incompatible with legacy multi-threaded code [52], whose locking discipline is rarely compatible without significant rewriting. Support for transactional memory in C++, for example, remains experimental [45]. There is no indication that persistent transactional memory systems will solve these problems, indeed, they appear to perpetuate them.

Generally, the transactional programming model is exported to the programmer using a scoped transaction, (e.g. `transaction{}`) and the library guarantees transactions will execute mutually exclusively (e.g. PMDK's C++ interface). However, for PMEM, transactional libraries may syntactically decouple mutual exclusion from failure atomicity due to language limitations (e.g. PMDK's C interface). In such an API, the library expects the programmer to first explicitly acquire the necessary locks to gain mutual exclusion before, subsequently, executing the transaction's failure atomic contents.

Despite this apparent separation, a transactional PMEM library's programming model imposes hard limits on the locking discipline - it expects that all transactional updates are mutually exclusive and isolated by the locking discipline. This restriction effectively forces the application to use a limited locking scheme such as single-global-lock or strong strict conservative two phase locking to protect any failure-atomic update. The programming model *explicitly disallows* releasing or acquiring a lock while executing a failure-atomic update.

For more complex locking schemes in which failure-atomic writes are visible to other threads before they are committed, the use of a FASE-based programming model is required,

and is often necessary for legacy programs as, in general, their existing synchronization fails to follow the restrictive transactional requirements.

3.2 Limitations of FASEs

Despite being, at first appearances, more compatible with legacy code, we argue the FASE-based model is also fundamentally flawed, or, at the very least, excessively permissive. The FASE model defines a failure-atomic code region as a "contiguous critical section," that is, it defines a failure-atomic code region as stretching from a thread's first lock acquire until the point where it holds no locks. While flexible with respect to locking scheme, this model requires tracking runtime dependencies between concurrently running failure-atomic code regions, which may not be isolated from each other. This permissiveness results in complicated and degenerate scenarios for recovery.

As a contribution of this work, we demonstrate that, for certain adversarial application patterns, any FASE-based system will either fail to recover or collapse into a degenerate case in which literally all program state must be logged for recovery, including volatile data never accessed within failure atomic regions — effectively, the FASE programming model requires whole process persistence for correctness.

Theorem 3.1 (FASE Limitation) *There exist applications for which, in order to consistently recover from a crash, a reasonably permissive FASE-based failure atomicity system requires all volatile program state be available at recovery.*

We prove this theorem by counterexample. This counterexample (Figure 1) can emerge naturally where two threads communicate via shared variables and one executes IO, a common pattern in event-based servers. In these servers, some threads handle the IO socket (thread 2 in example), some threads are application workers (thread 1), and they communicate via shared flags to manage outstanding requests. Detecting this pattern requires detailed reasoning about synchronization, and therefore prevents the blind use of FASEs on applications.

In the remainder of this section, we describe the counterexample and a brief sketch of our proof's reasoning. A full proof by contradiction, formal definitions, and additional discussion incorporating related work can be found in Appendix A.

Figure 1 gives our adversarial application that breaks FASE-based systems. In this example, two threads compute a fixed series of four values for nonvolatile variable x. Thread 1 computes the first value, Thread 2 the second and third, and Thread 1 the final, fourth value.

The two "tricks" of the code are that (1) the long FASE executed by thread 1 (lines 6 through 22) spans the entire example and (2) the third value of x, computed, but not assigned, outside of a FASE (line 39), is dependent on an access to a large volatile array Q.

```
1  lock_t lock0, lock1, lock2;
2  bool cond1 = false, cond2 = false;
3  int Q[] = rand(); // large random volatile array
4  nvm<int> x = 0; // x resides in nvm
```

```
5  void thread1{
6    lock0.lock();
7      x = (int s1=f1(x));
8
9      lock1.lock();
10       cond1 = true;
11     lock1.unlock();
12
13     bool w = true;
14     while(w){
15       lock2.lock();
16         if(cond2)
17           {w = false;}
18       lock2.unlock();
19     }
20
21     x = (int s4=f4(x));
22   lock0.unlock();
23 }
```

```
24 void thread2{
25   bool w = true;
26   while(w){
27     lock1.lock();
28       if(cond1){
29         w = false;
30         x =(int s2=f2(x));
31       }
32     lock1.unlock();
33   }
34
35   int in;
36   printf("x=%d", s2);
37   scanf("%d",&in);
38   /*****/
39   int s3 = f3(s2,in,Q);
40
41   lock2.lock();
42     x = s3;
43     cond2 = true;
44   lock2.unlock();
45 }
```

Figure 1: FASE counterexample

Recovery of this example presents an unsolvable problem. First, we note that Thread 1's long FASE, due to failure-atomicity semantics, forces recovery to recover either to the very beginning of the program or the very end. However, both options are impossible for a crash at line 38, just before x's third value is computed. At this point, thread 2 has already issued IO, so rolling back program state at recovery is inconsistent with the external world. However, rolling forward from this point requires the computation of the third value of x, which is dependent on an arbitrarily sized volatile array (Q). Since Q can be of any size, it can be replaced, without loss of generality, with any or all of the program's volatile state, effectively requiring whole process persistence.

Our proof requires failure atomicity systems to be "reasonably permissive," by which we mean that this counter example can be expressed as valid input for the system. Systems that restrict locking to two-phase-locking (e.g. [50,68]) or a single, semantic, global lock (i.e. transactional memory [63]) avoid this counterexample by prohibiting the locking pattern. Of course, by the same token, this restriction hampers their utility for legacy code, which rarely follows such a strict locking discipline.

The FASE programming model may be fixable by prohibiting situations like the counter-example. Simple (but undesirable) solutions include prohibiting all volatile accesses or all IO in the program. Alternatively, we could try to prohibit the precise counter-example problem by targeting the interplay

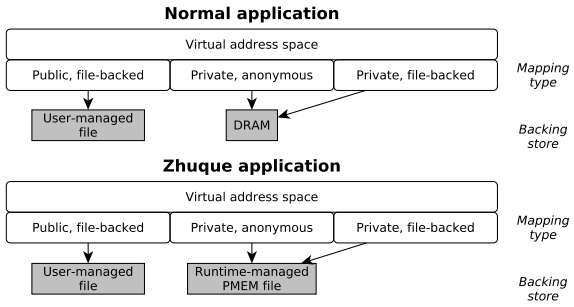

Figure 2: **Virtual memory in Zhuque.** The runtime modifies the backing store based on the mapping type, but the interface presented to the userspace application does not change.

between FASE dependencies, volatile accesses, and IO. One potential approach to achieve this involves a specification that disallows volatile accesses concurrently with a FASE execution. However, formally defining this specification is tricky, and formally verifying the proper use of FASEs is almost certainly undecidable through the halting problem. Notably, the requirement of a transactional locking scheme (e.g. strict, strong conservative 2PL) would also prevent the counterexample by explicitly disallowing its locking discipline.

To our knowledge, all existing FASE-based systems (e.g. [6, 26,30,42]) are "reasonably permissive" and would both accept this code as valid input and fail to recover correctly on it.

4 Design

Whole process persistence (WPP) is our answer to the limitations of transaction- and FASE-based programming models. In WPP, the in-memory state of an individual process is made persistent with, in simple cases, no modification to the application, primarily by interposing on the creation of virtual memory mappings (see Figure 2). WPP is designed for systems with flush-on-fail support, so we expect the contents of the process's PMEM-backed cache lines to survive a power failure. When the process is restarted after a power failure, it receives an OS signal, which it can ignore or handle with a signal handler. If no signal handler is installed, or if the installed signal handler does not exit the program, each thread continues execution at the point where it was interrupted by the failure.

There are several benefits to this model over transactions and FASEs. First and most importantly, WPP solves the problem described in Section 3 by discarding the concept of a failure-atomic section. The visible effects of an instruction on process state (that is, not including effects on OS state or peripherals) are guaranteed to survive a failure at least from the point at which they are visible to other threads. Second, restarting at the point of failure removes the need to "redo" or "undo" any writes at recovery, and with it the need to keep a persistent log and incur the cost of extra writes to PMEM. Third, no longer needing to define failure-atomic sections either reduces the programmer's burden directly, compared to manually-annotated failure-atomicity systems, or allows them to design concurrency schemes orthogonal to persistency without incurring overhead, unlike FASE-based systems.

There are two requirements that must be satisfied in order for an application to use WPP. The first is that its threading and virtual memory must be managed using a well-defined API for those purposes (i.e., on POSIX: `mmap()`, `pthread_create()`, etc). Any modern application targeting a POSIX system would have to go out of its way in order to violate this requirement.

The second is that applications must check error returns from system calls and other mechanisms that access non-process-private state, to detect failure-related errors beyond the process boundary, such as an application using a file on a filesystem that was not remounted after system restart. This requirement is more onerous than the first, but in our experience a wide range of applications can be correctly restarted without modification or special handling.

The principal challenge in implementing WPP is preserving process state across a power failure. Continuing execution after failure requires that the process's virtual address space, volatile architectural state, and relevant kernel-resident state (e.g., the file descriptor table) are a) persistent or b) can be resurrected along with the application.

The remainder of this section introduces Zhuque, our runtime implementing WPP, and describes how it makes process state persistent and restores that state after failure.

4.1 Overview

Zhuque provides WPP functionality by interposing on system calls which allocate resources (memory, file descriptors, threads), and by modifying the application startup process. In order to do this, we modified `libc`, which provides C bindings for system calls and implements the application startup process. Zhuque also requires small changes to the kernel to protect userspace context when failures occur in kernel mode (see Section 5.3 for details).

Interposing on system calls allows Zhuque to ensure that all application state which is normally volatile is instead stored in PMEM, as shown in Figure 2. It also allows Zhuque to track memory mappings and system calls so it can reconstruct the program's address space and re-create its kernel-resident state after a failure. Remaining volatile architectural state (e.g., the register file) is preserved by writing it to PMEM at failure.

When the application is resurrected after failure, Zhuque restores the application's address space, respawns its threads, and each thread reloads its architectural state. Execution resumes by calling the program's power failure signal handler, if it exists, and then resuming execution of each thread at the point interrupted by power failure.

4.2 Ensuring State Persistence

The first requirement that Zhuque must fulfill is ensuring that all state required for continuing correct execution of a program is preserved across power failures. This state can be divided into three categories based on its storage location: architectural state, memory state, and file state.

If a system supports flush-on-fail, it would be possible to modify its firmware to write per-thread architectural state (register file, floating-point configuration, etc.) to PMEM in response to power failure. However, we do not have the ability to modify that firmware, so we emulate it using userspace signals (see heading Power Failure in Section 5.1). We also save architectural state to PMEM on every kernel entry, in case a failure occurs in kernel mode (see Section 5.3).

File state is either inherently persistent, if the file was opened read-only or if changes have been written to disk, or is buffered awaiting being written to disk, in which case it is actually memory state and is handled as described below.

Automatically ensuring memory state is persistent is more complex, and is one of the main innovations of this design. Memory state itself can be divided into dynamic and static memory.

Dynamic memory Programs conjure dynamically allocated (heap) memory and thread stacks by calling anonymous `mmap()` (often via `malloc()`). Zhuque interposes on `mmap()` so that requests for anonymous memory return DAX-mapped persistent memory backed by a runtime-managed PMEM file, making heap and stack memory persistent.

Static memory Before an application binary is executed, the loader uses `mmap()` to create memory regions to hold code and static data (globals) from the application binary and linked dynamic libraries. Zhuque treats these regions differently based on whether they are un/zero-initialized, or initialized to non-zero values. The loader creates un/zero-initialized regions with anonymous `mmap()`, so they are treated as dynamic memory.

Initialized static memory, however, actually takes up space in the binary, and is loaded by mapping that region of the binary into memory as a private mapping. Thus, Zhuque transforms any writable, private mapping backed by a file to a writable, shared mapping that is backed by a PMEM file (see Figure 2), which is populated with the initialization values from the binary.

This mechanism also cleanly handles other outputs of dynamic loading, like relocations of position-independent code and cross-binary symbol resolutions, since they also are stored in writable, file-backed, private mappings.

4.3 Ensuring Correct Restoration

Having persisted the application's state, we also have to ensure it can be restored correctly. Recovery must restore the application address space, restore kernel-resident state, and restore architectural state.

Application address space All of the PMEM-backed memory mappings managed by Zhuque, as well as any other mappings the application created with `mmap()`. Zhuque stores the mapping table in a persistent memory file, and updates it to match any changes to the address space as they occur, so no action is required at failure to ensure this metadata is persistent.

At recovery, restoring the virtual memory map to its previous state must be done first, because all other state to be restored is stored in virtually mapped persistent memory. Restoration consists of re-mapping each virtual memory region with the correct backing store and access permissions. This restoration also replaces dynamic loading.

Kernel-resident state Any data required for continuing execution that resides outside the address space (and architectural state) of the process. The specific data varies depending on operating system and implementation decisions: for instance, Zhuque tracks the state of open Linux file descriptors in PMEM and restores them at restart using system calls. We discuss Zhuque's handling of kernel-resident state in Section 5.

Architectural state Any state stored in the processor itself and directly accessible from software. This state is per-thread, and since it includes the program counter and stack pointer registers, restoring it is equivalent to restarting execution of the thread (so it must be done last).

Zhuque manipulates the saved PC and stack so that the thread resumes as if it had just called the application-defined failure handler (if it exists), and then that handler returns to the point interrupted by execution when it executes a `RET` instruction. To avoid references to a thread which has not yet been recreated, threads wait to restart execution after they are created until all threads have been created.

5 Implementation

Zhuque is based on the musl implementation of the C standard library runtime [46], plus a minor modification to the Linux kernel (Section 5.3). Figure 3 depicts Zhuque's place in the runtime environment, and Figure 4 shows the changes to control flow at initialization and termination. This section describes the life cycle of a Zhuque process, describes how Zhuque handles the userspace-kernel boundary, and finally discusses some limitations of our prototype implementation.

5.1 Process Life Cycle

When Zhuque starts a process, it checks an environment variable for a path to a directory which holds or will hold the persistent state for that process. One file in the directory holds the process's global "process context", a memory map of a C

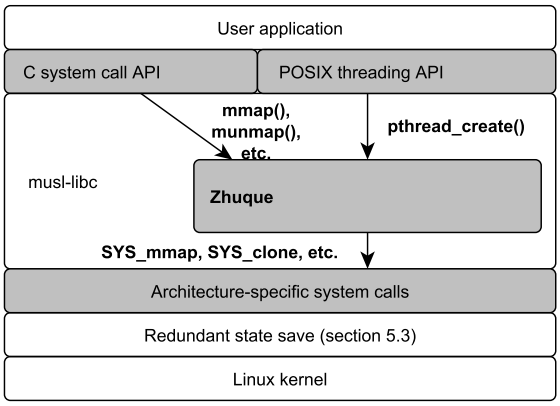

Figure 3: **Zhuque architecture.** User applications link to the C APIs provided by musl libc, and we modify the implementation of the APIs and the arguments passed to the underlying system calls. To protect against failures in kernel mode, we save userspace context to PMEM on entry to the kernel.

structure. The directory also holds all other persistent memory files allocated during the process's life.

Zhuque takes control of the process after the dynamic loader loads its own metadata using information provided by the kernel ("loader bootstrapping"). If the context file is present, then Zhuque takes steps to *restart* the process. If the context file is missing, but the environment variable is set, then it is a newly created Zhuque process (i.e., a *clean start*).

Clean start In the clean start case, Zhuque creates and initializes the process context file. Then, it records the locations of the dynamic loader and the main binary in the mapping table and remaps their static memory sections to memory backed by a persistent file. This retroactive process is necessary because our userspace runtime cannot interpose on mappings created by the kernel.

Next, control returns to the loader and it loads the application's dynamically-linked dependencies. Our code intercepts the loader's calls to `mmap()` and `mprotect()` during this process in order to record the mapping metadata and transform any writable, private mappings into persistent memory regions.

After loading is complete, control returns to Zhuque just before `main()` executes. Zhuque copies `main()`'s arguments into PMEM and runs it in a new thread with a persistent stack.

Power failure To save volatile architectural state (e.g. the register file) to PMEM at failure, we propose repurposing existing functionality. NVDIMM eADR and CXL GPF both rely on a System Management Interrupt (SMI) to implement the flush-on-fail process on x86 systems (see Section 2.1). SMI handling saves volatile architectural state to a designated per-core region (the *SMRAM*) before beginning execution of the handler, and x86 allows the SMRAM to be PMEM-backed [16]. However, the location of the SMRAM is controlled by system firmware. Unfortunately, updates to firmware must be signed by the manufacturer — the firmware uses encryption to prevent modification by the end user [15], so we were unable to make this change for our prototype.

Instead, to test Zhuque's application support, we emulate the SMI's state save using userspace signals. If SIGPWR is delivered while the process is executing, the volatile thread receives it and sends a second signal to each thread. When the kernel interrupts a thread to run the signal handler, it first pushes the register file and other state needed to resume execution onto the persistent thread stack. The handler body saves the current stack pointer and some context not saved by handler entry in PMEM, and then exits the thread directly, preserving the contents of the stack. Thus, at recovery, we have access to a persistent memory region containing a snapshot of volatile architectural state at failure, as if it had been saved by an SMI.

Restart after failure On restart, the runtime opens the context file, re-creates PMEM mappings, re-opens file descriptors, and finally re-maps file-backed memory. If a file descriptor was closed after being used to create a mapping, it is temporarily re-opened while the mapping is restored.

After the virtual memory map and file set are re-established, Zhuque restarts the execution of each thread from the point of failure. Zhuque does this by starting each thread with the same start routine, and the same initial stack pointer, so that the bottom frames of the stack are overwritten with new frames of the same size, and the contents of application frames are preserved. From this entry routine, we use assembly to restore architectural state, including setting the stack pointer and PC to the addresses saved at failure. Execution resumes within the runtime's failure handler, which calls the user-defined failure handler if present. If there is no user-defined handler, or the handler does not exit the program, execution continues at the point interrupted by the signal at failure.

5.2 Kernel-resident State

In order to preserve correctness in a userspace-only implementation, our runtime tracks and restores two pieces of kernel state tied to the process: the file descriptor set and the thread set.

To track the **thread set**, our runtime interposes on calls to `pthread_create()`, wrapping the passed thread entry point and arguments in our own entry point function (which itself is wrapped in the musl entry point function). It also saves both the Linux and pthreads identifiers for the thread; the Linux ID is used at failure to signal each thread individually with `tgkill()`, while the pthreads ID is the address of the thread metadata, and is used at restoration to continue execution at the point of failure. The Linux ID of a thread changes when the process is restarted, while the pthreads ID does not, because we restart threads at recovery with a modified version of `pthread_create()` which uses an existing thread metadata object rather than creating a new one.

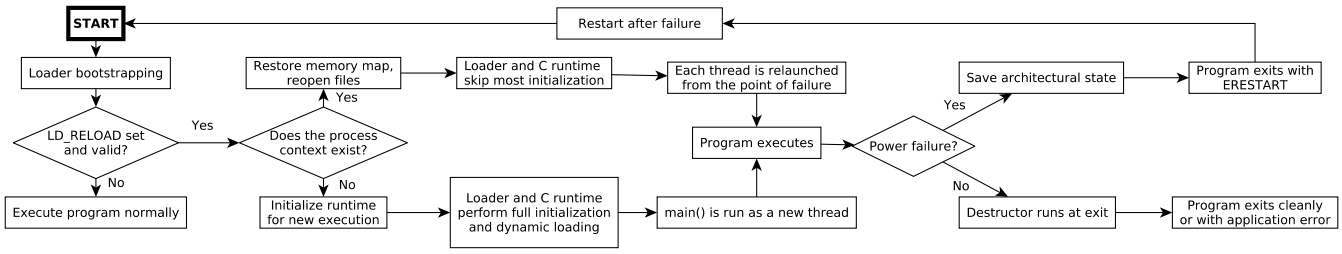

Figure 4: **Zhuque runtime control flow.** Zhuque modifies runtime startup and termination; application code is not modified.

To track the **file descriptor set**, Zhuque interposes on calls which assign (e.g. `open()`, `socket()`), modify (e.g. `fcntl()`, `bind()`), or release (i.e. `close()`) file descriptors and replays them at restart, using `dup()` to patch any discrepancy in assigned descriptors. This approach is sufficient for sockets with stateless protocols, `epoll` file descriptors, and simple file accesses.

However, pipes and files require special handling: for regular files, we ensure that they will not be deleted between failure and restoration by creating separate hardlinks to the files and using those to reference the file, deleting them when the program exits cleanly; we also open them without kernel buffering (i.e. with O_SYNC) due to the limits of a userspace implementation. And for pipes, we use the `splice()` family of system calls to save and restore unconsumed contents at failure/restoration. Support for restoring network sockets is best-effort, and a more systematic approach to network support under WPP is an interesting future extension of this work.

5.3 Failures in kernel mode

When an application makes a system call, or is suspended by an interrupt, the kernel will save the application's volatile architectural state on the suspended thread's kernel stack and restore it when application execution resumes. In our implementation the kernel stack is volatile, so we must save this state in persistent memory to allow recovery if power failure interrupts the kernel-mode operation.

To enable this, we added a `prctl()` operation to designate a page as a redundant state save area. We added code on all entries from user- to kernel-mode which checks whether such a page has been provided, and if so saves the state there as well as to the kernel stack. Accesses to the page must not fault: since a page fault is itself an interrupt, a fault in interrupt entry deadlocks the kernel. We found that there is no way (in our test kernel version) to reliably prevent access to a filesystem DAX page from faulting, so we use device DAX to provide the save memory.

5.4 Limitations

There are two notable limitations of our implementation, neither of which is fundamental to the design.

Multi-process applications are not supported. Zhuque currently has no support for persisting multiple processes in the same process tree; if an application under our runtime forks a new process while leaving the `LD_RELOAD` environment variable unchanged, the child process will crash when it attempts to use the same context object as its parent. By the same token, we make no attempt to preserve OS process IDs across failures, so applications that save and retrieve their PID after failure may find it invalid. Our runtime supports unrestricted concurrency schemes, so we believe it would be possible to extend it to support multi-process operation by interposing on the creation and termination of processes, similar to our approach to threads.

Some ASLR is not supported. Address space layout randomization (ASLR) is a security technique which randomizes the address of virtual memory mappings. Random addresses returned by `mmap()` to userspace are not an obstacle, since the randomization only occurs once under Zhuque. However, Zhuque cannot prevent the kernel from mapping libc and the application binary at a random location at restart, which means that their static memory cannot be recreated at the same locations when ASLR is enabled. It would be possible to move those mappings after they are created, but since it does not otherwise affect correctness or performance, and it would add significant complexity to the startup process, we chose not to implement this feature.

6 Evaluation

In this section, we evaluate Zhuque's performance to provide answers to the following questions:

- How much performance improvement does Zhuque provide for persistent applications compared to existing libraries?
- How much performance overhead does Zhuque incur compared to native, volatile execution?
- What benefits does Zhuque provide by enabling zero-

effort persistence?

Our experimental workloads include a set of microbenchmarks, a set of Python benchmarks, and three recoverable applications.

6.1 Evaluation Setup

We compare against native application performance based on musl and the performance of four popular PMEM libraries.

Musl [46] stands for the default (volatile) implementation based on musl libc.

PMDK [50] is Intel's failure atomicity library. It uses hybrid undo-redo log for both failure-atomicity [27] and memory allocation [55]. **Atlas** [6] also uses an undo logging-based mechanism for failure-atomicity. It can automatically infer failure-atomic region boundaries by analyzing lock behaviors in application code. **Clobber-NVM** [68] is a state-of-the-art PMEM library. It records clobber_log and v_log during runtime, and recovers an application by re-executing any interrupted transactions. **Mnemosyne** [63] is a redo-log based system. Instead of relying on locks in user applications, Mnemosyne uses the C++ transactional memory model to parallelize code.

To measure their performance with flush-on-fail semantics, we removed the flushes and fences from all three comparison libraries. These *flush-on-fail (FoF)* versions are used for all experiments described below, unless otherwise noted.

We run the benchmarks on a platform with one 20-core Intel Xeon Gold 6230 processor, running at 2.1 GHz. The platform has a total of 96 GB of DRAM and 768 GB (6 ×128 GB) of Intel Optane DC Persistent Memory directly attached to the processor [28]. We configured our test machine such that Optane DCPMM is in 100% App Direct mode [2]. In this mode, software has direct, byte-granularity access to the Optane DCPMM. Zhuque uses DAX-mapped [40] `Ext4` files for all PMEM allocations except the kernel state save area, which uses device DAX for the reasons described in Section 5.3. Unless otherwise noted, all Zhuque experiments are run on the modified kernel with the state save area activated, while all comparison software is run on an unmodified kernel of the same version (Ubuntu kernel 4.15.0-169). Each data point reported is the average over five runs.

We observed variations in memory usage across different benchmarks, ranging from 20 MB to 1 GB. For all but two of the Python benchmarks, the memory usage exceeds the Last Level Cache (LLC) capacity of 30.25 MB.

As discussed in Section 5.1, we were unable to modify platform firmware to direct the SMI state save to PMEM, because firmware updates must be signed by the manufacturer [15]. However, since it only affects events at failure, we expect that making this change would produce no measurable changes in the steady-state performance results we report below.

We verified that, with Zhuque enabled, all benchmark applications restarted and ran to completion correctly after randomly-timed simulated power failures.

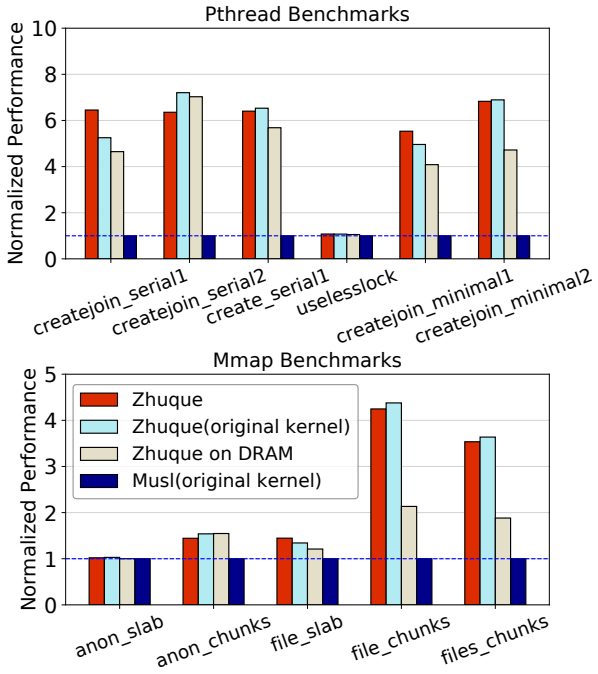

Figure 5: **Measuring the overhead of Zhuque on basic operations.** Performance values are normalized to the Musl(original kernel) value.

6.2 Microbenchmarks

In our first experiment, we compare Zhuque's performance with the default (volatile) musl libc on a set of microbenchmarks from the libc-bench [37] benchmark suite which tests the operations modified by Zhuque: thread creation and virtual memory mapping. We implemented the latter within the libc-bench test harness. Descriptions of the `pthread_create()` benchmarks can be found in the libc-bench documentation [37]. The `mmap()` benchmarks are described below.

anon_slab creates a 16 MB anonymous mapping, writes to every page, and then removes the mapping. **anon_chunks** creates, writes to every page, and then removes 128 128 kB anonymous mappings. **file_slab** creates a 16 MB file-backed mapping, writes to every page, and then removes the mapping. **file_chunks** creates, writes to every page, and then removes 128 128 kB mappings backed by a 16 MB file.
files_chunks creates, writes to every page, and then removes 128 128 kB mappings each backed by a separate 128 kB file.

We ran these benchmarks on four implementations: **Zhuque** is Zhuque using DAX-mapped PMEM as the backing store, running on modified kernel. **Zhuque(original kernel)** is Zhuque without kernel modification. **Zhuque on DRAM** uses non-PMEM files (loads and stores access the DRAM page cache) as a backing store, but also saves kernel

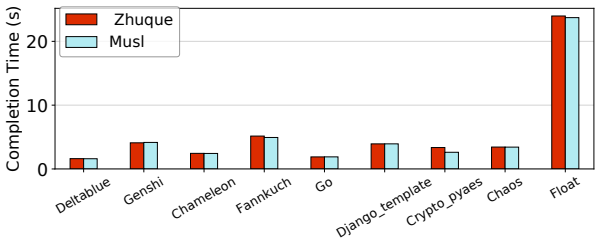

Figure 6: **Measuring the overhead of different Python benchmarks**: Zhuque matches native performance on some benchmarks

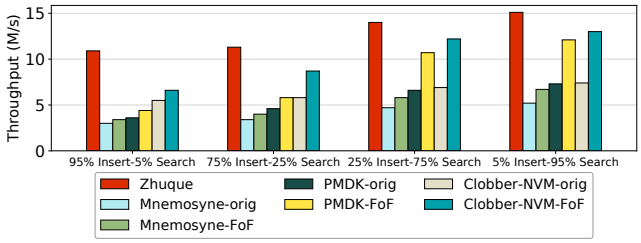

Figure 7: **Porting Existing PMEM Libraries to Flush-on-Fail Machines Provides up to 1.76× Improvement**

states. **Musl(original kernel)** is unmodified musl libc with unmodified kernel. We report the results in Figure 5.

We observe that Zhuque introduces significant overheads to modified operations, especially `mmap()` and `munmap()` – the bottleneck for all of the poorly-performing microbenchmarks is the allocation of new anonymous memory. The overhead is per-operation, and does not depend on the size of the mapping. This is not surprising: our modified versions still perform the original operations, and are also required to modify userspace data structures maintained by Zhuque in persistent memory, often including a search whose time is linear in the number of created mappings. As demonstrated by the results below, these overheads do not translate to a significant slowdown on macrobenchmarks, because modifications of the virtual memory map are rarely on an application's critical path. In addition, these overheads are a result of implementation choices, not the fundamental design. We anticipate they would decrease substantially in a kernel-based implementation of WPP.

6.3 Python Benchmarks

In this experiment, we ran nine Python benchmarks on the musl and Zhuque configurations using the CPython interpreter. It demonstrates that Zhuque can run a wide range of unmodified Python applications. We chose the first nine benchmarks (out of 42), in alphabetical order, from version 1.0.0 of the Pyperformance benchmark [21] suite. Descriptions of the benchmarks can be found in the Pyperformance documentation [21]. We ran them in our own benchmark framework, but did not modify the benchmarks themselves. We also added dynamic thread stack support, not present in vanilla musl, in order to support the large stack sizes required by the interpreter. We report the results in Figure 6.

Most of the Python benchmarks perform competitively with the musl versions. Those that perform worse generally incur overhead from frequent random-access reads and writes to data structures too large to fit in the cache, causing thrashing and exposing the higher access latency of persistent memory compared to DRAM.

6.4 Memcached

Memcached [44] is a widely-deployed key-value store. Early versions (1.2.*) have been ported to Mnemosyne, PMDK, and Clobber-NVM. We ran memcached-1.2.5 on Zhuque unmodified.

We evaluate memcached performance with four types of workloads: insertion-intensive (95% insertion / 5% search), insertion-mostly (75% insertion / 25% search), search-mostly (25% insertion / 75% search), and search-intensive (5% insertion / 95% search). We use memslap [39] to generate a stream of uniformly distributed memcached requests with 16-byte keys and 64-byte values. As shown in Figure 7, Mnemosyne, PMDK and Clobber-NVM can perform up to 1.76× faster with flushes and fences removed. This result indicates that the flush-on-fail semantics can benefit existing PMEM libraries.

Figure 8 presents the results of these experiments, using Musl-based memcached-1.2.5 performance on DRAM as baseline. We find Zhuque can always provide nearly 80% of musl memcached performance. Across different thread configurations, Zhuque provides up to 3.58× Mnemnosyne's throughput, 1.81× of PMDK's throughput and 1.71× of Clobber-NVM's throughput.

Poor scalability is a well-known problem with early versions of memcached [20, 42]. Memcached went through a rewrite of the synchronization framework to use fine-grained locking across seven years of development and over thirty versions [31]. Many current (transactional) PMEM libraries have strict requirements for applications' concurrency schemes. These requirements make converting recent versions of memcached to run on PMEM a complicated and difficult process. Zhuque places no restrictions on the locking scheme, so the newest version (1.6.17) can run unmodified on Zhuque. By simply running the newest version on Zhuque, we can provide more than 7.5× performance of the best performant older version of persistent memcached on the same workload, with the same thread count.

6.5 Vacation and Yada

Furthermore, we evaluated the performance of the Vacation and Yada applications from the STAMP benchmark suite [8],

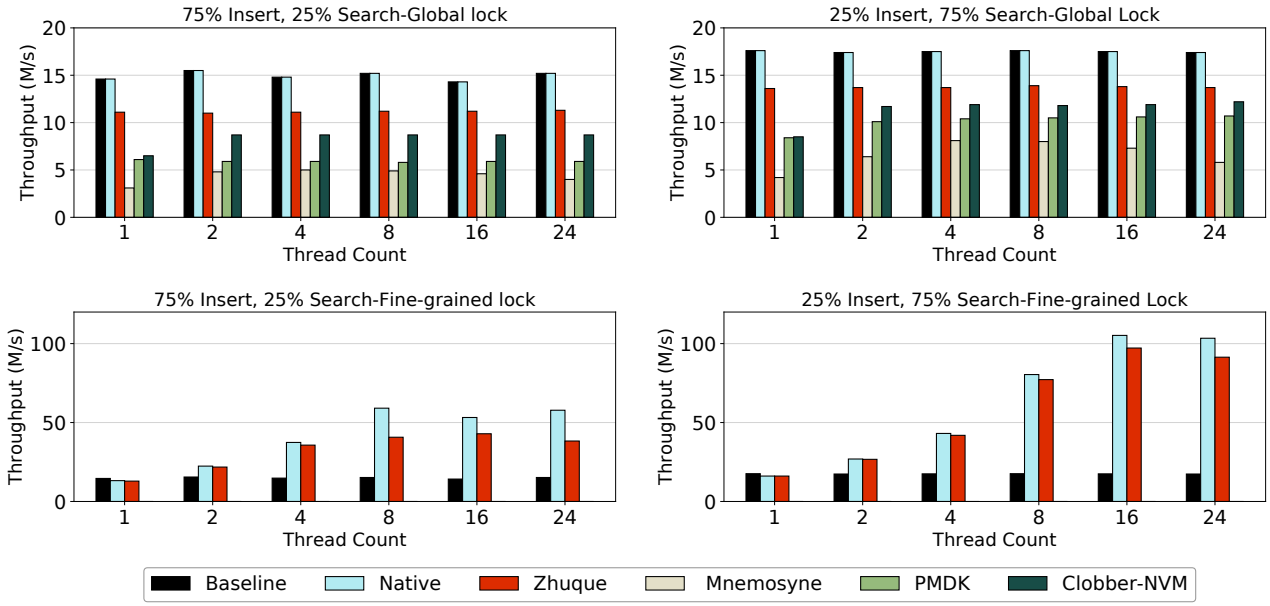

Figure 8: **Zhuque Enables Newest Version of Memcached to Run on PMEM, Provides Significantly Better Performance**

each targeting common PMEM applications such as, respectively, KV-stores and graph workloads. Prior works [25,63,68] provide readily available implementations of these applications built on top of existing PMEM libraries, with the exception of Yada - Mnemosyne.

We compare Zhuque with Musl, Mnemosyne, PMDK, Atlas and Clobber-NVM Vacation performance. Vacation is a travel reservation system, consisting of tables updated concurrently using transactions that span multiple tables.

Prior implementations [25, 63, 68] persist the tables in PMEM, and leave the client side in volatile memory. Zhuque persists the entire vacation application, including both the server tables and the client threads.

Figure 9 shows that Zhuque performs 10.8×, 4.8×, 3.7× and 3.6× faster on Vacation than Mnemosyne, PMDK, Atlas and Clobber-NVM, respectively. The performance gain comes from fewer logging writes and more efficient memory management: Zhuque uses vanilla `malloc()`, while the other libraries use either PMDK's transactional allocator (PMDK, Clobber-NVM) or a hand-written allocator (Mnemosyne, Atlas). The memory management efficiency problem is more prominent on Yada, which implements Ruppert's algorithm for Delaunay mesh refinement [54].

7 Related Work

PMEM Software & Hardware. In the past decade, researchers have designed many highly-optimized PMEM data structures [7, 10, 22, 48, 62, 69]. They are designed to reduce the cost of persistent updates while ensuring failure-atomicity. Because they are carefully designed by experts to cope with PMEM characteristics, they usually provide good performance. However, using and developing these data structures takes significant programming effort.

Because PMEM's bandwidth is significantly higher than traditional secondary storage, PMEM file systems [11, 33, 65, 67] aim to expose raw PMEM performance as much as possible. It is easy for existing applications to use files on these PMEM file systems, but they are not designed to solve the same problem that Zhuque targets (failure-resilience of the application's in-memory data).

The architecture community has also sought better hardware support for PMEM, often by allowing more permissive (and thus performant) store ordering at the memory controller [3,18,24,32,34–36,59]. Many of these systems demonstrate dramatic performance gains in simulation, but none that we are aware of are available in production.

General-purpose PMEM libraries. General-purpose PMEM libraries aim to ensure failure-atomicity for applications which directly access PMEM, with low overhead and minimal code changes.

Traditional undo-log systems [6, 9, 50] and redo-log systems [23, 63] write to a log alongside every visible update, at least doubling each write. On non-flush-on-fail PMEM machines, undo-logging usually requires expensive memory fences at the end of each log write, while redo-logging needs to redirect loads even if the machine supports flush-on-fail.

To avoid expensive synchronization between threads, some undo/redo systems buffer writes in "shadow" copies of PMEM data [5,17,41,43,66], at least doubling the amount of PMEM required by the application. These systems still incur the write amplification and read redirection costs of conventional log-

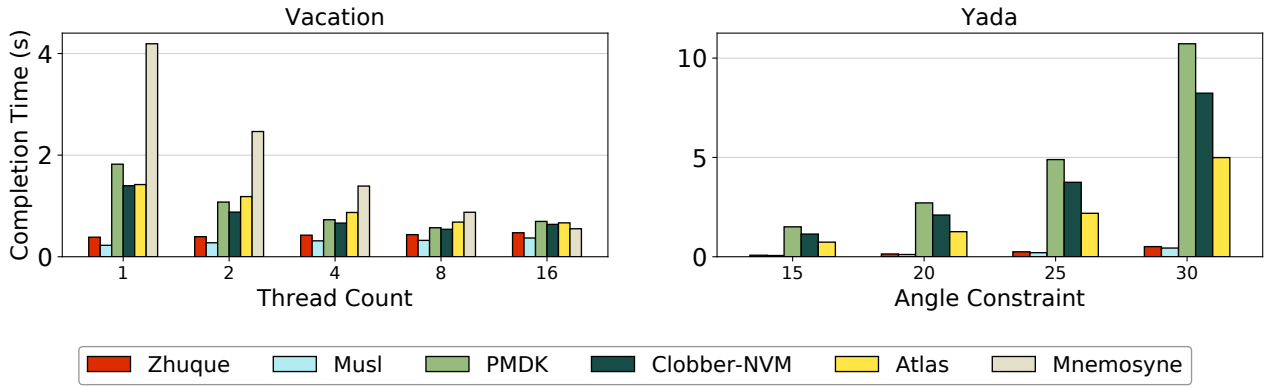

Figure 9: **Vacation and Yada performance on different PMEM libraries and Zhuque**

ging, and with flush-on-fail semantics the synchronization they are designed to reduce is no longer required at all. Compared to these systems, Zhuque does not amplify or redirect memory accesses, nor increase the size of the working set.

All these systems rely on either lock-inferred failure atomic sections (FASEs) [6, 26, 30, 42, 66], classical transactions [5, 41, 43, 63], or programmer delineated transaction boundaries with a restricted lock scheme [23, 50, 68] to identify failure-atomic operations. In contrast, Zhuque is not concerned with synchronization: it uses the same concurrency model as the original application.

JUSTDO [30], iDO [42], and Clobber-NVM [68] recover by resuming execution of the interrupted failure-atomic section or re-executing interrupted transactions. These systems are similar to Zhuque in that they also resume execution at the point of failure, but they all restrict concurrency and require manual annotation of atomic sections.

Single Level Stores. WPP transparently makes processes persistent by providing continuous checkpointing, durability guarantees for external observers of application IO (known as *external synchrony* [49]), and POSIX compatibility. Single level stores (SLS) [12, 38, 56–58, 60, 61] also provide persistent address spaces to applications, but they suffer from high overhead, rarely support external synchrony, and are often hard to use due to custom APIs [57, 60].

The high overhead arises from checkpointing and, for some systems, the enforcement of external synchrony. Checkpointing overhead is high because traditional storage devices are far slower than DRAM, and SLSes usually amplify writes by tracking memory modification at page granularity. To achieve external synchrony, SLS systems must delay IO until data is safely persisted. If checkpoints are too frequent, the communication delay can cause high overheads.

Because of the performance penalty of providing external synchrony, most SLSes choose not to enforce it. The state-of-the-art SLS system Aurora [61] points out the value of external synchrony, but does not support it. Zhuque shows that flush-on-fail semantics allow continuous checkpointing, making external synchrony feasible and performant.

8 Conclusion

This paper has described Whole Process Persistence (WPP), a programming model that treats power failure as a recoverable exception. Zhuque, implementing WPP, transparently makes applications failure-resilient by interposing on the POSIX-specified APIs. Zhuque ensures process state survives power failures, and allows for resumption of execution.

Compared with existing solutions, Zhuque greatly simplifies the programming model. Our evaluation shows that Zhuque significantly improves performance compared to state-of-the-art, and tends to match original volatile application performance on certain workloads.

A Proof

In this appendix, we provide a proof of theorem 3.1:

Theorem 3.1 (FASE Limitation) *There exist applications for which, in order to consistently recover from a crash, a*

reasonably permissive FASE-based failure atomicity system requires all volatile program state be available at recovery.

A.1 Definitions

We begin by defining terms. By *application* we mean a multi-threaded program, executed as a *process*. The process's *internal state* consists of all its data, including heap, globals, and stack. Some memory locations are designated *nonvolatile*, their contents (the *nonvolatile state*) survive a power outage; the remainder are *volatile*, and their contents (the *volatile state*) are lost. The process may perform IO operations — we term the set of IO operations performed by an executing process its *external state*. The process, being multi-threaded, contains code regions that execute while a lock is held, these are termed *critical sections*.

If power is lost during process execution, its volatile state is lost. The purpose of a *failure atomicity system* is to provide *consistent recovery* from a power outage. For consistent recovery, the system selects a point in execution, termed the *recovery point*. The recovery point is *consistent* with the external state; process execution from initialization through the recovery point would generate the observed IO. For failure atomicity, the recovery point also lies outside all critical sections. Consistent recovery of a process consists of selecting a valid recovery point and restoring the persistent state's contents to its values as of this point. If the power failure interrupts a critical section, consistent recovery will involve, for failure atomicity, chosing a recovery point outside the critical section and undoing or redoing changes made within the section.

We assume a powerful failure atomicity system which is free, during pre-crash execution, to intercept the process at any point and log data in nonvolatile memory. After a crash, the system has access both to these logs and the process's nonvolatile state — its task is to ensure that the nonvolatile state is restored to a recovery point; consistent with IO operations and outside any critical section. The failure atomicity system must be *reasonably permissive* with respect to its programming model — we require the system's programming model to support our adversarial example. To all our knowledge, all existing FASE-based systems are "reasonably permissive".

Figure 1 gives our counterexample. The "trick" is that the long FASE executed by thread 1 (lines 6 through 22) is dependent on non-FASE code executed by thread 2 that contains both IO and accesses to large volatile data (lines 36 through 39).

A.2 Proof Sketch

We prove Theorem 3.1 by contradiction. We consider a process executing the code sample in Figure 1 and suffering a power failure on line 38. Suppose, for contradiction, there exists a FASE system for which, given this situation, could restore the program's nonvolatile state to a recovery point consistent with the external state and outside any critical section. As thread 1, by construction, executes a critical section (FASE) for its duration, our recovery point for thread 1 must lie at line 6 or line 22 — all other points violate failure atomicity. We consider both options.

Suppose the recovery point lies at line 6 (i.e. recover `x` to 0), it is inconsistent with the external process state due to the IO executed before the failure on lines 36 and lines 37, which indicate that thread 2 (and therefore thread 1) have progressed beyond this recovery point, leading to a contradiction.

Suppose the recovery point lies at line 22 (i.e. recover `x` to `s4`). First we note that the value `s4` has a true dependence (read-after-write) on `s3`, and `s3` has a true dependence on both the inputed seed `in` and large volatile array `Q`. Since `s3` cannot be computed before `in` is known, `s3` must be computed after the `scanf` on line 37 is executed. Since the failure can interrupt the computation of `s3` after the `scanf`, all inputs to `f3` must be preserved in nonvolatile storage for recovery. However, since `Q` is an arbitrarily sized volatile array, Q can be of any size and can be replaced, without loss of generality, with any or all of the program's volatile state, requiring the failure atomicity system to preserve all volatile process state and leading to a contradiction.

B Artifact Appendix

B.1 Abstract

This appendix describes the artifact submitted with this paper. The artifact contains files to build a Docker image with Zhuque installed as the system `libc`, and containing all benchmarks and comparison PMEM systems evaluated in Section 6. It also contains our patch against the Linux kernel necessary for correct resumption, described in Section 5.3.

B.2 Scope

The artifact allows verification of the following claims:

- All performance results from Section 6, for both Zhuque and comparison systems.
- Zhuque can successfully restart programs after an simulated asynchronous failure, as described in Section 5.1.
- The kernel modification correctly saves userspace architectural state to the redundant state save area, as described in Section 5.3.

The artifact does not verify the following claims:

- The kernel modification is sufficient to protect against a failure in kernel mode (we cannot simulate this type of failure).
- The formal claims made in Section 3 about FASE-based systems.

B.3 Contents

The artifact is organized into these key directories (see README for detailed listing):

- `musl-src`: Source code of Zhuque-musl.
- `musl-src/src/psys`: Zhuque core implementation.
- `clobber-pmdk`: Source code for comparison PMEM systems and their versions of application benchmarks.
- `apps`: Zhuque/native implementations of application benchmarks.
- `pigframe`: Materials to build and test our kernel modification.

B.4 Hosting

This artifact is hosted in a Github repository at https://github.com/georgehodgkins/Zhuque_artifact. The commit ID for the current version is `ffc033972bb36adc23b7a4b8c8b2cc6d736bff53`. See README for build instructions.

B.5 Requirements

The only software required for the artifact is Docker on a Linux kernel; the build process bootstraps all other dependencies. Zhuque and most comparison applications can be run on a system without PMEM, but only a system with PMEM can fully reproduce the reported results. Zhuque was mostly developed against a rather old kernel version (4.15.18), and we have sometimes observed unexpected behavior when running on newer kernels.

We built and tested the artifact on the evaluation machine described in Section 6. Our kernel modification targets the Ubuntu kernel fork at version 4.15.0-169. The Docker image is based on Alpine Linux 3.14.

ENVPIPE: Performance-preserving DNN Training Framework for Saving Energy

Sangjin Choi *KAIST*
Inhoe Koo *KAIST*
Jeongseob Ahn *Ajou University*
Myeongjae Jeon *UNIST*
Youngjin Kwon *KAIST*

Energy saving is a crucial mission for data center providers. Among many services, DNN training and inference are significant contributors to energy consumption. This work focuses on saving energy in multi-GPU DNN training. Typically, energy savings come at the cost of some degree of performance degradation. However, determining the acceptable level of performance degradation for a long-running training job can be difficult.

This work proposes ENVPIPE, an energy-saving DNN training framework. ENVPIPE aims to maximize energy saving while maintaining negligible performance slowdown. ENVPIPE takes advantage of slack time created by bubbles in pipeline parallelism. It schedules pipeline units to place bubbles after pipeline units as frequently as possible and then stretches the execution time of pipeline units by lowering the SM frequency. During this process, ENVPIPE does not modify hyperparameters or pipeline dependencies, preserving the original accuracy of the training task. It selectively lowers the SM frequency of pipeline units to avoid performance degradation. We implement ENVPIPE as a library using PyTorch and demonstrate that it can save up to 25.2% energy in single-node training with 4 GPUs and 28.4% in multi-node training with 16 GPUs, while keeping performance degradation to less than 1%.

1 Introduction

Reducing carbon footprint is a worldwide mission. Experts estimate data centers take up 3% of the global carbon emission, which is roughly equal to the worldwide airline industry [2]. To mitigate carbon emissions, data center providers should actively explore energy-saving strategies for their operations. One significant area to address is the energy consumption associated with machine learning (ML) workloads, which constitutes a significant portion of overall energy usage. According to recent work, Google constantly spends 15% of its total energy running ML workloads for the past three years [22]. This study primarily focuses on energy saving in the context of multi-GPU deep neural network (DNN) training, which is a prevalent method employed in modern ML workloads.

There have been several approaches to save energy of GPU workloads. Common methods use GPU *Dynamic Voltage and Frequency Scaling* (DVFS), which seeks to identify the optimal frequency for the Streaming Multiprocessor (SM) clock or memory clock by balancing the tradeoff between performance and energy consumption [3, 7, 9, 12, 17, 27–29]. Recently, Zeus [29], considers the batch size and power limit to navigate the tradeoff between performance and energy consumption. It automatically finds the optimal configuration in recurring DNN training jobs based on the user-provided energy-efficiency importance. Although effective, these approaches leave several limitations.

First, they may have side effects by modifying user-provided hyperparameters. For example, Zeus adjusts the batch size of a training job which can potentially compromise statistical efficiency, even with optimally-tuned learning rates [24]. This issue becomes particularly challenging in non-recurring DNN training jobs where finding the batch size and learning rate pairs that maintain statistical efficiency is difficult. Second, it is difficult to determine how much performance degradation is acceptable at the cost of saving energy. Typically, the completion time of a training job varies and is unpredictable. Therefore, ML practitioners may not know how much delay they can accept. Furthermore, in a long-running training task, even a small performance degradation implies a significant delay. For instance, 10% degradation of a month-running task translates to three days. Third, these approaches primarily focus on individual GPU training jobs and do not adequately address the energy consumption associated with large-model training. Large model training utilizes multiple GPUs across multiple nodes with various parallelism techniques.

This work proposes ENVPIPE[1], a new energy-saving DNN training framework. ENVPIPE focuses on large model training using multiple GPUs with pipeline parallelism. ENVPIPE addresses the limitation of previous approaches with the design goals: *No accuracy and performance degradation*. With the goals, users can run any DNN training jobs as if they run them without ENVPIPE while saving energy under the hood. To preserve the original accuracy, ENVPIPE does not modify any user-provided hyperparameters such as batch size and does not change data dependency while executing pipeline units. ENVPIPE leverages the side-effect-free control knob only, SM frequency, to save energy. To avoid performance degradation, ENVPIPE utilizes pipeline bubbles inevitably occurring when training large models with pipeline parallelism. ENVPIPE selectively lowers SM frequency to reduce the energy consumption of pipeline units. This control stretches the execution time of pipeline units, but ENVPIPE confines the degree of each stretch up to the available slack time of the bubbles, avoiding end-to-end performance degradation.

[1] **Env**elope + **Pipe**line Parallelism.

This design idea is generally applicable to any DNN training job where layer-wise partitioning is feasible, enabling training with pipeline parallelism across a large number of GPUs. However, realizing the design idea is challenging due to the following problems. **i)** To decide the value of SM frequency, EnvPipe needs to know the trend of clock speed and training performance. The trend varies according to GPU hardware, batch size, and the number of layers in a pipeline stage. Offline profiling to obtain this information is impractical. Instead, EnvPipe performs online profiling by sweeping SM frequencies to obtain the energy-saving curve under the given hyperparameters and GPU hardware. **ii)** How to schedule pipeline units decides the amount of bubbles that can be exploited. It is essential to ensure that a bubble exists after a pipeline unit of which execution time is stretched while ensuring that the next unit, which has data dependency, is sufficiently distant to avoid overall performance degradation.

EnvPipe is implemented as a library using the existing ML framework. The EnvPipe policy and mechanism are clearly separated, so developers can easily add required APIs to support a new ML framework. The current prototype of EnvPipe is implemented on the DeepSpeed [25] library and uses the existing GPU device driver to control SM frequency. We evaluate EnvPipe in real-world workloads: BERT, GPT, Megatron, and ResNet, and demonstrate the performance and energy saving on two GPU hardware: V100 and RTX3090. We perform evaluations of the workload in a single node (4 GPUs) and in multiple nodes (16 GPUs) and show that EnvPipe saves energy up to 25.2% and 28.4% in single-node and multi-node setups respectively while keeping performance degradation to less than 1%.

This paper makes the following contributions:

- We present the design of EnvPipe, a performance-preserving energy-saving DNN training framework that supports distributed training across multiple GPUs.
- EnvPipe preserves the original statistical efficiency by not modifying any user-provided hyperparameters and controls only the side-effect-free control knob.
- We demonstrate EnvPipe saves up to 25.2% and 28.4% energy saving in single- and multi-node GPU servers with less than 1% performance degradation.

The source code of EnvPipe is available on https://github.com/casys-kaist/EnvPipe.

2 Background

2.1 Large Model Training with Parallelism

Recent advancements in language models have focused on increasing the number of parameters, achieving impressive results on various challenging tasks such as language understanding, generation, and reasoning. Google's Pathways Language Model (PaLM), a 540 billion parameter model stacked up with numerous transformer decoder layers, has shown breakthrough results outperforming finetuned state-of-the-art models on various natural language tasks [8]. However, scaling up the model size comes with a cost of increased memory footprint, making it challenging to fit on a single GPU memory, even with the latest GPU like the NVIDIA H100 with 80GB. To efficiently train extremely large models, there have been several efforts to combine various parallelism techniques such as *data*, *tensor*, and *pipeline* parallelism [1, 11, 15, 16, 18–20, 30]

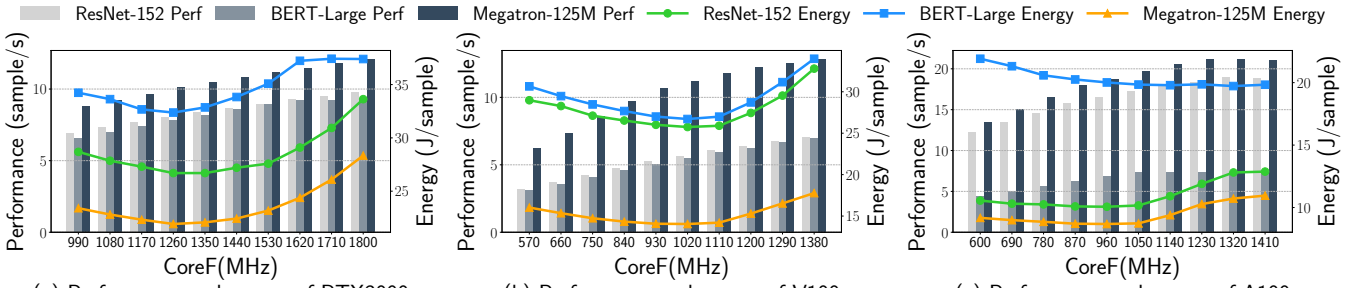
In this study, we focus on the pipeline parallelism [11, 15, 16, 18–20] which is a commonly used technique in training large DNNs whose models cannot fit on a single GPU. With pipeline parallelism, a model is vertically partitioned as evenly as possible to each worker (e.g., GPU) as pipeline stages. For transformer-based models such as GPT, each pipeline stage can have the same number of transformer decoder layers, balancing the execution time across the pipeline stages. To increase pipeline efficiency, the input batch is partitioned into multiple microbatches, and each worker handles the microbatches in a pipelined manner. There are two different approaches to synchronizing model parameters: synchronous and asynchronous. Synchronous pipeline parallelism (S-PP) ensures strict weight update semantics by periodic pipeline flushes. S-PP does not compromise the model's convergence but inevitably incurs pipeline bubbles which lower the training throughput [2]. Asynchronous pipeline parallelism (A-PP) relaxes weight update semantics and fully utilizes the pipeline throughput in a steady state by continuously pipelining microbatches without any pipeline flushes. A-PP hurts the statistical efficiency of the model and can fail to converge to the target accuracy [5].

In this work, we target S-PP which preserves the original statistical efficiency with strict weight update semantics. Due to pipeline flushes after every training iteration, pipeline bubbles are inevitable which lowers the pipeline throughput. Previous studies [15, 16, 20] focused on reducing the bubbles in S-PP. Rather than perceiving bubbles as an obstacle that slows down training, we consider pipeline bubbles as an opportunity to save energy in large model training.

2.2 Energy Scaling Valley Trend in GPUs

As it is convenient for ML practitioners to make use of GPUs rather than NPU-like accelerators for DNN workloads, modern cloud and data centers are operating a huge number of GPUs. However, when training DNN workloads, GPUs incur a significant fraction (e.g. about 70% according to [10]) of total power consumption in the whole system including other components such as CPU and DRAM. This high power consumption of GPUs during DNN training underscores the importance of optimizing their energy efficiency to reduce the overall energy consumption of cloud and data centers. To save energy in GPUs, previous studies [3, 7, 9, 12, 17, 27–29] have utilized *Dynamic Voltage and Frequency Scaling*

[2] GPU remains idle in pipeline bubbles



(a) Performance and energy of RTX3090 (b) Performance and energy of V100 (c) Performance and energy of A100

Figure 1: Energy scaling valley trend in modern GPUs

(DVFS) and focused on balancing performance and energy efficiency. DVFS is a widely studied technique in traditional CPUs to balance performance and energy consumption by scaling voltage/frequency in CPU cores. Generally, scaling down voltage/frequency saves energy but inevitably degrades performance, and GPUs tend to show a more complex energy scaling trend. Tang *et al.* [27] studied the energy scaling trend of various DNN training on modern datacenter GPUs and showed that energy saving is maximized on the middle-level core frequency and the energy consumption curve shows a valley trend when scaling core frequency.

We measure the training throughput and energy consumption by scaling the SM frequency in three different GPUs with various up-to-date DNN models in a single GPU training scenario. We use NVML [21], a library provided by NVIDIA, to adjust the SM frequency of GPUs. NVML can set the maximum limit of SM frequency and monitor the current energy consumption. Figure 1 exhibits that energy consumption decreases when lowering the frequency, but from the middle (e.g., 1350MHz and 1020MHz in RTX3090 and V100), this trend changes oppositely. This is because the training time is prolonged with lower SM frequency. Since energy consumption is related to both current power usage and overall execution time, if the end-to-end execution time increases at a faster rate than the rate of decrease in current power usage, the overall energy consumption increases. Thus, it is crucial to find the optimal point of SM frequency to achieve energy saving since the frequency cannot be lowered below the optimal point.

3 Energy-efficient DNN Training

This section describes the energy-saving problem of DNN training and discusses key insights that motivate the design of our system.

3.1 Objective and Constraints

DNN training is a complex and time-consuming process that places a significant emphasis on achieving statistical efficiency. Consequently, developing energy-efficient strategies for DNN training is a challenging task that can potentially lead to unintended side effects. In this section, we highlight several constraints that are crucial for ensuring the robustness of an energy-saving approach and mitigating any undesirable side effects.

No accuracy degradation. Given that training jobs are often already hyperparameter-searched, we do not modify any user-provided hyperparameters to ensure that the final accuracy after finishing the training is not compromised. Therefore, the way to achieve energy saving in this work is in sharp contrast to prior work that reduces energy consumption by changing hyperparameters, which can affect the final converged accuracy. For example, Zeus [29] studies how different batch sizes affect energy consumption when combined with a wide variety of GPU power scaling levels. The optimal combination chosen in Zeus thus alters depending on hardware and energy efficiency, which is the immediate consequence of the batch size in use. Optimizing energy consumption in this way is advantageous when users issue recurring DNN training jobs or can provide a set of batch sizes and corresponding hyperparameters that promise model convergence regardless of choice. Our target scenarios do not have that expectation from users. So, we decide to use control knobs that preserve the training's original statistical efficiency, such as controlling GPU SM frequency and dependency-aware pipeline scheduling.

No performance degradation. Given that curbing SM frequency to save energy affects DNN training speed, e.g., time taken to execute a single pipeline unit, we do not want to slow down the end-to-end training performance in exchange for energy savings for several reasons. First, from an ML practitioner's standpoint, it is difficult to determine how much performance degradation is acceptable across a wide range of training jobs. The completion time of a training job typically varies and remains unpredictable until the training is completed. Additionally, even a minor performance degradation in a long-running training task can result in a significant delay. For instance, a 10% slowdown in training time might seem small, but it can translate to a three-day increase in the duration of a month-long training job. Second, from a system administrator's standpoint, it is difficult to estimate an abrupt increase in GPU requests caused by prolonged DNN training jobs, which are already computationally expensive. Because GPU resources are highly contended and shared, prolonged DNN training jobs that occupy GPUs for extended periods contribute to increased GPU contention, necessitating the allocation of additional GPUs to alleviate resource bottlenecks.

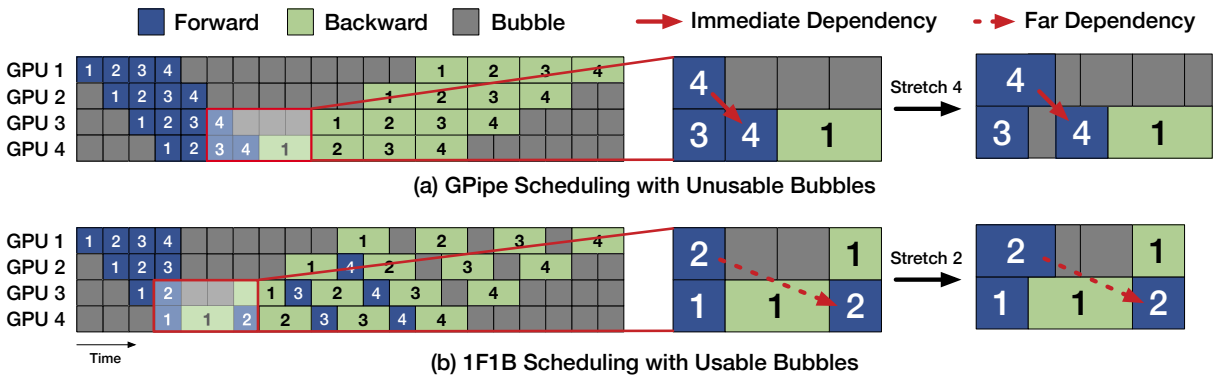


Figure 2: Comparison of two representative pipeline scheduling

Prior systems have centered on navigating the energy-performance tradeoff while keeping energy and time minimum, i.e., Pareto optimality. Unlike these approaches, our work primarily targets saving energy without sacrificing training time when training large models across multiple GPUs with pipeline parallelism, one of the most commonly used techniques in training large DNN models.

3.2 Insights

Our baseline model for distributed training, synchronous pipeline parallelism (S-PP), inevitably incurs bubbles, as shown in Figure 2. We selectively leverage these bubbles only when the pipeline units preceding them do not have immediate data dependencies. By reducing the SM frequency in these units, we can extend their execution time without necessarily delaying the start-up time of the subsequent units that rely on their outputs. This approach enables us to achieve energy savings while preserving performance. However, it is important to constrain the extent of stretching in each unit to a certain limit. This constraint ensures that no adverse performance delays occur as a result of elongated pipeline units.

Usable and unusable bubbles. Several S-PP designs have been proposed to schedule pipeline units during forward-backward computations of a single training iteration. Figure 2 shows the execution details of two representative S-PP designs, `GPIPE` and `1F1B`. The examples take four microbatches on four GPUs. In both cases, each microbatch execution goes through GPUs in order (GPU1 $\rightarrow$ GPU4) during the forward pass (FP) and then in reverse order (GPU4 $\rightarrow$ GPU1) during the backward pass (BP).

We observe that the performance-preserving energy-saving opportunity differs significantly in these two S-PP examples. To better understand this, we classify bubbles into two types: `Unusable` and `Usable`. A bubble is considered unusable when a stretched pipeline unit delays the overall training time. In Figure 2(a), stretching the forward pipeline unit of microbatch 4 (denoted as FP4) in GPU3 delays the start-up time of FP4 in GPU4 because of the `immediate dependency` caused by sending activation. This control delays the overall execution of the total pipeline. Even though plenty of bubbles are available after FP4 in GPU3, these bubbles are considered unusable, and exploiting unusable bubbles to save energy slows down training throughput, violating the constraints defined in § 3.1.

On the contrary, a bubble is considered usable when a stretched pipeline unit does not postpone the overall training time. For example, in Figure 2(b), stretching the forward pipeline unit of FP2 in GPU3 does not affect the execution of the backward pipeline unit of microbatch 1 (denoted as BP1) in GPU4 as these two units do not exhibit data dependency. FP2 in GPU4 exhibits the data dependency for activation communication, but it begins execution much later. We refer to this type of dependency as `far dependency`. Consequently, when utilizing the bubbles after FP2 in GPU3 for energy saving, none of the pipeline units in GPU4 gets penalized.

Based on this observation, we seek to exploit as many usable bubbles as possible for maximizing energy saving without performance degradation.

4 Design

4.1 Design Overview

This section presents the overview of our proposed system called EnvPipe. For a given DNN model and its hyperparameters, EnvPipe automatically tunes the order of pipeline units and generates an energy-saving plan controlling the SM frequency without any manual efforts from users. First, EnvPipe profiles the energy consumption of the DNN training job for each pipeline stage to understand performance and energy tradeoffs. Second, to increase the energy-saving opportunities, EnvPipe reschedules the pipeline units elaborately, increasing the amount of usable bubbles without breaking any data dependencies between the pipeline units. Last, EnvPipe finds an optimal SM frequency for pipeline units on the non-critical path to maximize energy savings without sacrificing training throughput.

Figure 3 depicts the overview of EnvPipe. EnvPipe consists of `online profiler` (§ 4.2), `scheduler` (§ 4.3), `frequency planner` (§ 4.4), and `execution engine`. At its

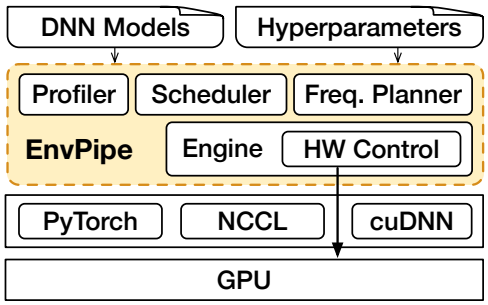

Figure 3: EnvPipe Overview

core, EnvPipe design clearly separates policy from mechanism. EnvPipe generates a performance-preserving energy-saving plan by executing in the workflow of online profiler → scheduler → frequency planner (policy). The execution engine runs the energy-saving plan (mechanism).

Policy: Building the energy-saving plan. At first, EnvPipe runs the `online profiler` to construct the energy valley curves for each pipeline stage when training the given DNN model. Based on the online profiling result, EnvPipe `scheduler` decides the best schedule of forward and backward execution units, which creates plenty of usable bubbles. Using the scheduling decision, EnvPipe runs the `frequency planner`. It lowers the SM frequency of all pipeline units inside the outermost path of the total pipeline (we call it *envelope*) to the optimal value identified from the energy valley curve. At this point, it is likely to degrade the training performance because execution units inside the envelope are stretched. To avoid performance degradation, EnvPipe identifies the performance-critical path and reconfigures the SM frequency (i.e., undo lowering SM frequency) of all units in the performance-critical path to avoid performance slowdown.

After these steps are completed, EnvPipe obtains the energy-saving plan that specifies I) a schedule (placement) of forward and backward pipeline units, and II) SM frequency value of each pipeline unit, which achieves energy saving without degrading performance.

Mechanism: Executing the energy-saving plan. The execution engine provides APIs for the `online profiler` and the `frequency planner`. Internal APIs used in the EnvPipe's execution engine are translated to ML platform-specific APIs (e.g., PyTorch API calls). The engine includes HW control APIs communicating GPU device driver to control SM frequency.

EnvPipe is implemented as a user-level library to invoke APIs of underlying ML platforms, providing an easy-to-use, platform-independent way to control multi-GPU pipeline scheduling and energy consumption. In addition, due to this clean separation of policy and mechanism, EnvPipe can be applicable to any ML platform by implementing required APIs in the execution engine to support the ML platform [3].

[3]The current implementation supports PyTorch only

4.2 Fine-grained Online Profiling

As shown in Figure 1, energy consumption shows the valley trend according to SM frequency. The form of valley curves depends on GPU hardware, batch size, model architecture, and the method of splitting the model for pipelining. Therefore, EnvPipe runs the *online* profiler to obtain the energy valley curve from given DNN models, GPU hardware, and hyperparameters. For each pipeline stage, the online profiler sweeps available ranges of SM frequency and measures energy consumption to find the optimal SM frequency that maximizes energy saving. The profiling steps are seamlessly integrated into the training procedure, allowing EnvPipe to continue training with the weight version obtained from the profiling steps. The energy valley curves for each pipeline stage are generated within 100 steps and just 5 steps per frequency are enough to detect the optimal point where the energy-saving trend changes oppositely. Since training a model usually requires thousands to millions of steps, the overhead of the online profiler can be considered negligible. Note that the SM frequency of a pipeline unit cannot be lowered below the optimal energy-saving point which stretches the execution time of the pipeline unit to about 20 - 25% in our GPU settings. In addition, the online profiler measures the execution time at maximum and optimal SM frequency's forward and backward pass, and available GPU memory, which is used in the scheduling phase.

4.3 Scheduler: Utilizing Bubble

Design problems. As discussed in § 3.2, the scheduling of forward and backward pipeline units determines the amount of usable bubbles. When making scheduling decisions, it is important to consider two key questions: 1) how to effectively identify usable and unusable bubbles, and 2) how to optimize the utilization of usable bubbles by scheduling pipeline units.

Identifying usable bubbles. To answer the first question, we first need to identify pipeline units in the performance-critical and non-critical paths. Figure 4(a) shows bubbles and the performance-critical path (red boxes). It is important to note that usable bubbles are placed after pipeline units of the non-performance-critical paths. On the contrary, bubbles after the pipeline units of performance-critical paths are unusable. For example, if we stretch BP8 in GPU3 (★) which is on the performance-critical path to use the following bubbles, it will delay the start of BP8 in GPU2 (♠) causing performance degradation in the overall pipeline execution.

Optimizing utilization of usable bubbles. To answer the second question, we should consider the stretch limit of the pipeline units. Recall that there is a limit for the pipeline unit to get stretched because EnvPipe does not set SM frequency below the optimal point, which is usually about 20 – 25% (§ 4.2). To optimize the utilization of usable bubbles, EnvPipe should distribute the usable bubbles since a certain group of bubbles at the front of the pipeline with a long idle

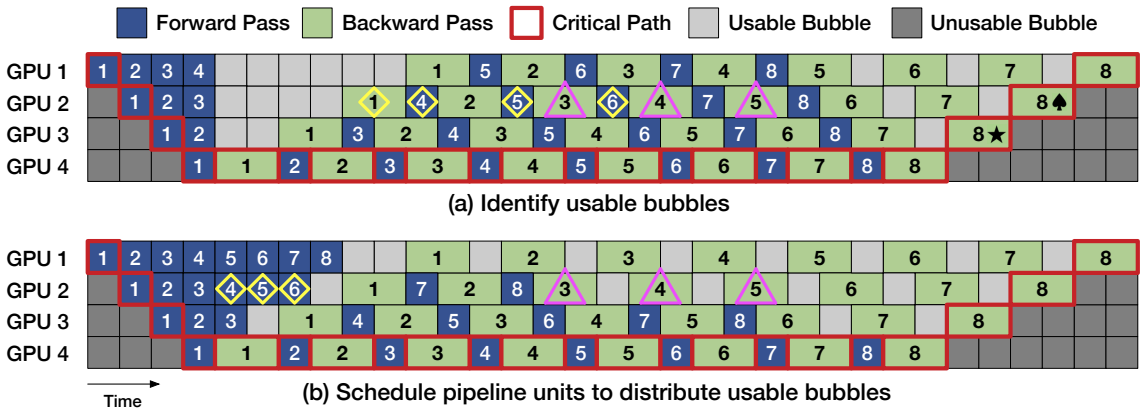

Figure 4: EnvPipe scheduling

time can be underutilized. For pipeline units to utilize the usable bubbles at their best, the usable bubble must be evenly distributed throughout the pipeline execution.

The EnvPipe scheduler operates in two phases: initialization and rescheduling. During initialization, EnvPipe employs a proven method for scheduling pipeline execution, which has been successfully deployed in a wide range of environments. Next, in order to enhance the utilization of usable bubbles, EnvPipe scheduler reschedules pipeline units in a manner that evenly distributes these bubbles while preserving the original data dependency between pipeline units.

Initialization. Among various existing approaches, we select one of the known methods that have the fewest units on the performance-critical path because it contains more usable bubbles. As observed in § 3.2, for the 1F1B schedule, pipeline units only along the outermost path (denoted as *envelope*) are on the performance-critical path. Therefore, we select the 1F1B schedule, which has the minimum number of pipeline units on the performance-critical path, as a starting point and further reschedules the pipeline units based on this initialization.

Rescheduling pipeline units. After initialization, EnvPipe reschedules pipeline units in order to reserve usable bubbles right behind pipeline units and to distribute usable bubbles among pipeline units. To save energy consumption, EnvPipe can stretch pipeline units up to the slack time made by the following bubble. Figure 4(b) shows the result of scheduling Figure 4(a). EnvPipe moves FP units to upfront usable bubbles (e.g., FP4, FP5, and FP6 in GPU2 ◇), generating usable bubbles after backward units (e.g., BP3, BP4, and BP5 in GPU2 △).

EnvPipe can compute how many FPs can be rescheduled and stretched by computing the available slack time of bubbles. When rescheduling the FP units, EnvPipe considers the following conditions. I) EnvPipe never breaks the data dependency for sending and receiving activations and gradients. For instance, FP3 in GPU3 starts only after the activation is sent from FP3 in GPU2. This is essential for preserving the original data dependency of the pipeline execution. II) Because EnvPipe moves forward units upfront, it needs to hold additional activation generated by each forward unit, which uses extra GPU memory. The memory used by activation is freed after the corresponding backward unit consumes it. The size of memory used by each activation is obtained by the online profiler. Therefore, EnvPipe computes available memory to hold the activations and only reschedules a certain number of forward units that can fit in the available memory to avoid an out-of-memory error.

Algorithm 1 Frequency Planner

```
while True do
    ExecutePipelineStep()
    criticalPath ← FindCriticalPath()
    if criticalPath ≠ outer envelope of total pipeline then
        ReconfigureCriticalPath(criticalPath)
    else
        break
    end if
end while
```

Figure 5: Frequency Planner Algorithm

4.4 Frequency Planner: Minimizing Performance Impact

Design problems. According to the scheduling decision, the goal of the frequency planner is maximizing energy saving while minimizing performance impact (less than 1%) by controlling SM frequency. To achieve this, the system leaves the SM frequency at its maximum for units on the performance-critical path and lowers the frequency to its energy-optimal value (obtained from the online profiler) for units not on this path using the available slack time of usable bubbles. However, this does not guarantee minimal performance degradation, since not all bubbles can accommodate the stretched pipeline units inside the envelope. So the question is how to selectively reconfigure the SM frequency to minimize performance impact. In addition, when reconfiguring the frequency of units on the performance-critical path, it is possible that the path may change. To prevent performance slowdowns, the system must be able to efficiently identify the new performance-

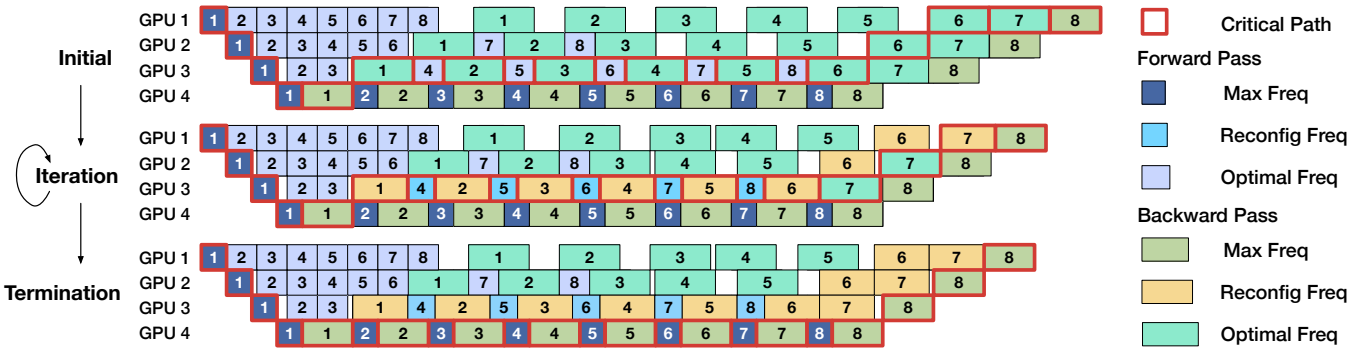

Figure 6: ENVPIPE frequency planning

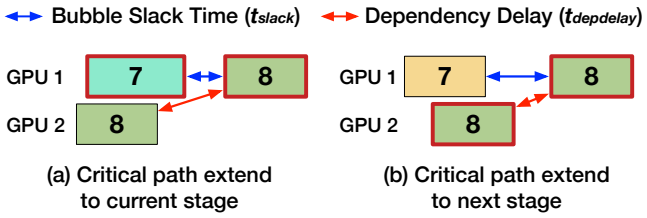
critical path. This leads to the second design question: how can the performance-critical path be identified quickly and effectively?

Our strategy. Initially, ENVPIPE sets the energy-optimal SM frequency to pipeline units on non-critical paths which is all pipeline units inside the outer envelope of the total pipeline. To achieve the design goal, ENVPIPE runs an iterative algorithm as shown in Figure 5. Figure 6 illustrate the steps. After executing a single pipeline step, at Line 3, the algorithm finds the critical path of the executed pipeline (**Initial** of Figure 6). Then, at Line 5, it reconfigures SM frequency of pipeline units on the detected performance-critical path to avoid performance slowdown (**Iteration** of Figure 6). It repeats the *find and reconfigure* steps until the performance-critical path becomes the outer envelope of the pipeline. The algorithm stops when the critical path is identical to the outer envelope (**Termination** of Figure 6). The termination condition of the iterative algorithm ensures that the performance-critical path is the same as that of running pipeline parallelism without using ENVPIPE while our frequency planner stretched as many pipeline units as possible on the non-critical path.

Algorithm for finding the critical path. Figure 7 shows the algorithm to identify the performance-critical path. The algorithm incrementally builds the critical path backward. *current* in Figure 7 is a cursor, pointing to pipeline units, and moves backward. Initially, the cursor starts with the last unit (BP8) in GPU1. The algorithm repeatedly updates the cursor to point to the next pipeline unit to insert into the critical path until the cursor reaches the starting unit (FP1) in GPU1. At line 9, the algorithm decides the next pipeline unit to extend the critical path backward. Figure 7(a) and (b) illustrates the idea. Recall that the critical path consists of pipeline units that delay the overall execution time when stretched. Thus, we should find the pipeline unit that is affecting the start time of the pipeline unit that the cursor is currently pointing at. Let's assume the current cursor points to BP8 in GPU1. The algorithm finds the pipeline unit that is affecting the start time of BP8 in GPU1 by comparing the slack time — the bubble between BP7 and BP8 in GPU1 (t_{slack} of *current*) — and the dependency delay — spare time between the end of BP8 in GPU2 and the start of BP8 in GPU1 ($t_{depdelay}$). If t_{slack} of



Algorithm 2 Finding critical path

1: *GPUID*: e.g., GPU 1 - GPU 4
2: t_{slack}: Slack time of the precedent bubble
3: $t_{depdelay}$: Delay between *pipelineUnits* with data dependency
4: *current* ← last backward *pipelineUnit* in GPU 1
5: *criticalPath*.insert(*current*)
6: **while** *current* ≠ first forward *pipelineUnit* in GPU 1 **do**
7: $n \leftarrow$ *GPUID* of *current*
8: $k \leftarrow$ *microbatchID* of *current*
9: **if** t_{slack} of *current* $< t_{depdelay}$ **then**
10: *current* ← the previous *pipelineUnit* in GPU n
11: **else**
12: **if** *current is* forward *pipelineUnit* **then**
13: *current* ← *pipelineUnit* k in GPU $(n-1)$
14: **else**
15: *current* ← *pipelineUnit* k in GPU $(n+1)$
16: **end if**
17: **end if**
18: *criticalPath*.insert(*current*)
19: **end while**

Figure 7: Finding critical path

current $< t_{depdelay}$ (Figure 7(a)), the precedent pipeline unit of the same GPU is affecting the start time of BP8. So the algorithm updates the cursor to BP7 in GPU1 to add to the critical path. Otherwise, the pipeline unit that has the data dependency from the next GPU is affecting the start of BP8. Thus, the cursor is updated to BP8 in GPU2 and is added to the critical path. After that, the algorithm repeats the same step iteratively. The algorithm ends when the cursor reaches the first forward unit in GPU1, which is the first pipeline unit on the critical path that decides the starting time of the overall pipeline execution step.

Algorithm for reconfiguring critical path. EnvPipe reconfigures the pipeline units on the critical path by increasing a small amount of SM frequency. The reconfiguration should be done in small steps in an iterative way for two reasons. First, by increasing the frequency in small increments, the stretched execution time can be gradually shortened, likely finding the point of fully utilizing the slack time of the usable bubbles. Second, due to the complex data dependencies between pipeline units, the critical path may change after reconfiguring pipeline units on the critical path. By reconfiguring in small steps, it will be less likely to unnecessarily increase the frequency of pipeline units on the non-critical path, since the critical path may have changed during the reconfiguration process.

The key question in the algorithm is identifying which pipeline units on the critical path should be reconfigured. To determine this, we use the observation of the trend in the energy-scaling valley curve shown in Figure 1. From the optimal point (minimum energy), as the SM frequency increases, the energy consumption and performance increase at different rates. Therefore, EnvPipe defines the *performance-energy utility* as the ratio of performance increase to energy increase for a frequency increase. In general, the performance-energy utility diminishes as it is further from the optimal point. Thus, to maximize the utility, the system should prioritize reconfiguration of SM frequency close to the optimal point.

Using this observation, EnvPipe takes a `balanced` approach. After finding the critical path, EnvPipe finds the pipeline units with the minimum SM frequency (i.e., closest one to the optimal value) and increases their SM frequency. This allows for the SM frequencies of all pipeline units on the critical path to be balanced as much as possible. For comparison, the system also implemented a simple approach called `greedy`. This approach selects pipeline units backwards from the end of the critical path and reconfigures them until their frequency is the maximum default frequency of a GPU. This approach also achieves the performance goal by increasing the SM frequency of pipeline units on the performance-critical path, but not in a balanced way.

4.5 Discussions

4.5.1 Size of Bubble and Energy Saving

The size of the bubble highly influences the achieved energy saving. The opportunity to leverage pipeline bubbles increases as the size of the bubble increases thus leading to higher energy savings. Since EnvPipe does not change the user-provided hyperparameters, achieved energy saving may differ according to the user-provided input or bubble-reducing methods that were studied in previous S-PP works [15, 16, 20].

Number of microbatches. The size of the bubble gets amortized over the number of micro-steps. Thus, as the number of microbatches increases, the fraction of the pipeline bubble decreases. For the portion of the bubble to be minimized, the number of microbatches should be larger than the number of pipeline stages. However, increasing the number of microbatches indefinitely is not possible because increasing the number of microbatches leads to an increase in global batch size. Even with a carefully tuned learning rate, there is a maximum limit in global batch size to preserve the statistical efficiency [24]. We show as a sensitivity study how the number of microbatches affects energy saving.

Partition method of pipeline stages. The partition method to split pipeline stages affects the size of pipeline bubbles. Pipeline bubbles are minimized when the execution time among pipeline stages is well-balanced, but it is not straightforward. Several partition methods are possible, but each of them has its own pros and cons. First, the model can be partitioned by balancing the execution time of layers per stage. By balancing the execution time of layers per stage, the size of the bubble is minimized. However, balancing the execution time of layers may lead to memory imbalance among pipeline stages. Second, stages can be partitioned by balancing the memory consumption of GPUs. Balancing the memory footprint across pipeline stages can provide advantages in memory-constrained environments. However, because of the imbalance of execution time among stages, the size of the bubble increases. We evaluate how the stage partition methods affect the energy saving in § 6.2.3 (Table 2).

Bubble-reducing methods. Our work stands apart from previous studies that aim to reduce bubbles in S-PP [15, 16, 20]. While these studies may reduce pipeline bubbles, the bubbles cannot be completely eliminated, so EnvPipe can still leverage the bubbles to save energy. Moreover, these bubble-reducing methods have inherent drawbacks. For instance, Merak [15] necessitates activation recomputation, leading to additional performance overhead by repeated computations. Chimera [16] proposes a bidirectional pipeline but with additional memory consumption from weight parameters and activations since a single stage needs to maintain weights and activations that were originally maintained by two stages. PTD-T [20] introduces an interleaved 1F1B pipeline schedule, which reduces bubbles but adds communication overhead to the scheduling process. In contrast, our approach in EnvPipe effectively utilizes bubbles without introducing these drawbacks, offering a clear advantage in saving energy in pipeline parallelism.

4.5.2 Energy Consumption of Bubbles

Readers may raise the following question, "Would a naïve approach that just reduces the power consumption of bubbles save more energy than EnvPipe?" Even if one hypothetically assumes that the power usage of bubbles is reduced to 0W, EnvPipe's approach still demonstrates superior energy savings. Figure 8 illustrates a simplified example comparing the naïve approach and EnvPipe. In the naïve approach, the total energy consumption is 8.75J, where the forward unit consumes 8.75J of energy while the bubble consumes 0J. On the

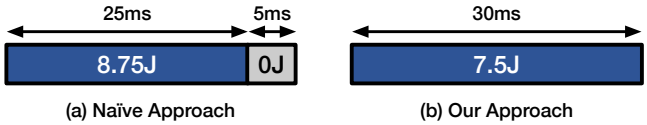


Figure 8: Energy consumption of bubbles

other hand, in EnvPipe's approach where the forward unit is stretched to exploit the bubbles, the total energy consumption becomes 7.5J. The energy consumption of the stretched forward unit is already lower than the naïve approach's forward unit since decreasing the SM frequency reduces the end-to-end energy consumption of the forward unit. As demonstrated in this example, even when the power usage of bubbles is reduced to 0W, EnvPipe's approach still has lower end-to-end energy consumption. Furthermore, in RTX3090, we measure that the power usage of bubbles is approximately 100W out of 350W at the lowest SM frequency with P2 P-State.

4.5.3 Scaling with Data Parallelism

The common practice for training large models that cannot fit in a single GPU is to combine pipeline parallelism with data parallelism or tensor parallelism, allowing for sharded models to fit within the constraints of a single GPU. We show in the evaluation section that our performance-preserving energy-saving approach with pipeline parallelism can easily scale with data parallelism in multi-node training.

5 Implementation

We implement our prototype, EnvPipe, on top of DeepSpeed [25]. EnvPipe's HW controller to lock SM frequency and DeepSpeed's basic mechanism such as executing forward/backward pass, send/receiving activations and gradients, and reducing computed gradients are used for executing EnvPipe's performance-preserving energy-saving plan. In this section, we introduce some important considerations when utilizing the underlying mechanisms of ML platforms since naïve usage of those mechanisms can lead to ineffective usage of bubbles or performance degradation.

5.1 Asynchronous Communication

Activations and gradients must be transferred between GPUs for the pipeline to be executed. When sending activations or gradients, communication needs to be asynchronous (i.e. non-blocking) for pipeline units to effectively use bubbles. If GPU communication is synchronous, idle time of bubbles is wasted since blocking communication calls prevents the next scheduled pipeline units to execute. When the source GPU sends data to the target GPU, the communication gets blocked until the target GPU receives the data and the next scheduled pipeline units cannot be executed, thereby wasting the opportunity to utilize pipeline bubbles. On the other hand, for non-blocking asynchronous communication, when the source GPU sends data to the target GPU, the source GPU does not have to wait until the target GPU receives the data and can execute the next pipeline unit, effectively utilizing pipeline bubbles.

NCCL's default blocking p2p communication can be easily changed to non-blocking communication by increasing the NCCL buffer size with NCCL_BUFFSIZE environment variable. NCCL buffer is used when communicating data between pairs of GPUs. P2p send operation fills up the target GPU's buffer and the target GPU fetches data from the buffer in FIFO for another send operation to fill the buffer. If the NCCL buffer is full, send operation should wait until the buffer of target GPU has free space. If the NCCL buffer has enough free space, p2p send operation can complete without waiting for p2p recv operation to be called from target GPU. EnvPipe makes sure that NCCL buffer size is enough to handle all activations and gradients to be communicated in a non-blocking way to effectively use bubbles.

Figure 9: Precise SM frequency control

5.2 Precise SM Frequency Control

Controlling SM frequency from user space needs an `ioctl` system call to the device driver which can induce overhead lowering the training throughput. Also because of the asynchronous CUDA programming model, `ioctl` calls on the CPU side should be executed with precise synchronization barriers between pipeline units for SM frequency to be controlled at exact timing.

Figure 9 shows how precise SM control with minimal overhead can be performed. In Figure 9(a), `lock_gpu_clock()` is called between two forward executions without any synchronization barrier. Because of the asynchronous CUDA programming model, `ioctl` call gets executed on the CPU side before the first forward execution completes, resulting in an unintended early frequency change. In Figure 9(b), the synchronization barrier is placed before `lock_gpu_clock()`,

	Model	Microbatch	Minibatch

	Megatron-350M	4	64
	Megatron-760M	4	64

Table 1: Model configuration for single-node training.

preventing unintended early frequency change. However, the `ioctl` call on the CPU side with the default synchronous programming model delays subsequent forward execution calls and GPU remains idle until the `ioctl` call returns. In Figure 9(c), by executing `lock_gpu_clock()` in another thread, subsequent forward execution on the GPU side can be concurrently executed with the `ioctl` call on the CPU side, performing precise frequency control with a minimal performance impact.

6 Evaluation

Our evaluations focus on confirming our energy-saving design choices that preserve DNN training performance. Specifically, we compare performance and energy consumption for various scheduling strategies when training different, up-to-date DNN models, including transformer-based language models and CNN models, on both single-node and multi-node training setups. To faithfully demonstrate the benefits of our approach in challenging scenarios, we have all models partitioned to balance execution time among pipeline stages, e.g., balancing the number of layers for transformer-based models. This pipeline-balanced parallel execution provides high training performance, making the energy savings on top of it more meaningful.

6.1 Methodology

Testbed setup. All experiments are performed on PyTorch 1.13. For single-node experiments, we use two different server setups: Single-V100 and Single-3090. **Single-V100** uses AWS `P3.8xLarge` instance which has four NVIDIA Tesla V100 GPUs with 16GB of memory each, Intel Xeon E5-2686 v4 CPU (32 vCPUs), and 244GB of main memory, while **Single-3090** has four NVIDIA Ampere RTX3090 GPUs with 24GB of memory each, Intel(R) Xeon(R) Gold 6326 CPU (64 vCPUs), and 256GB of main memory. For multi-node experiments, our setup **Multi-V100** uses two AWS `P3.16xLarge` instances each with 8 NVIDIA Tesla V100 GPUs, Intel Xeon E5-2686 v4 CPU (64 vCPUs), and 488GB of main memory. So, Multi-V100 is equipped with a total of 16 V100 GPUs. These cloud instances are connected to a 25Gbps Ethernet network.

Benchmarks. We compare EnvPipe with the following energy-saving methods:

- Baseline: run all GPUs with maximum SM frequency.
- Uniform: run all GPUs with optimal SM frequency that represents the minimum point in the energy valley curve.
- NoRecfg: EnvPipe without reconfiguring critical path to minimize performance impact.

Our single-node experiments are based on nine different models, as shown in Table 1. All models run with 16 microbatches, while for Megatron-125M, ResNet-152, and BERT-3.9B, the minibatch and microbatch size are reduced to fit in GPU memory. For multi-node experiments, we combine data parallelism (DP) and pipeline parallelism (PP) in several different ways across 16 GPUs. The number of microbatches for pipelining changes according to the DP and PP dimensions while the size of minibatch remains constant.

Metrics. Performance for all experiments is measured by averaging the throughput of 30 training iterations after warm-up and energy consumption is measured using the NVML library [4] during the 30 training iterations.

6.2 Experimental Results

6.2.1 Single-node Energy Saving

Main results. We first compare EnvPipe to Baseline, which consumes the most energy among competing methods, to highlight our ability to preserve performance. We measure the throughput and energy consumption for the benchmarks in Table 1 and present the results in Figure 10. The results show that EnvPipe consistently uses less energy than Baseline while retaining the original training performance for all models, confirming its effectiveness. Specifically, for Single-V100, EnvPipe saves energy consumption by an average of 18.6%, ranging from 12.1% to 25.2%. For Single-3090, EnvPipe saves energy consumption by an average of 12.8%, ranging from 8.1% to 19.4%. Performance is mostly preserved, with throughput only degrading less than 1% in all cases.

Analysis of energy saving. We next compare EnvPipe to other baselines by focusing on two models, BERT-1.3B and GPT-350M, trained on Single-3090. The results from Figure 11 show that other naïvely designed strategies, such as Uniform or NoRecfg, fail to meet our energy savings goal without sacrificing performance. Specifically, in Uniform, as all GPUs blindly scale SM frequency without considering performance effects, both throughput and energy consumption inevitably become the lowest. In NoRecfg, which does not reconfigure the SM frequency, all pipeline units inside the outer envelope are stretched to the largest extent. This strategy also inevitably degrades performance since not all bubbles can accommodate those stretched pipeline units inside the envelope. On the other hand, EnvPipe allows for more adaptive and effective use of pipeline bubbles, minimizing the impact on performance.

[4] Energy consumption of GPUs (not entire system).

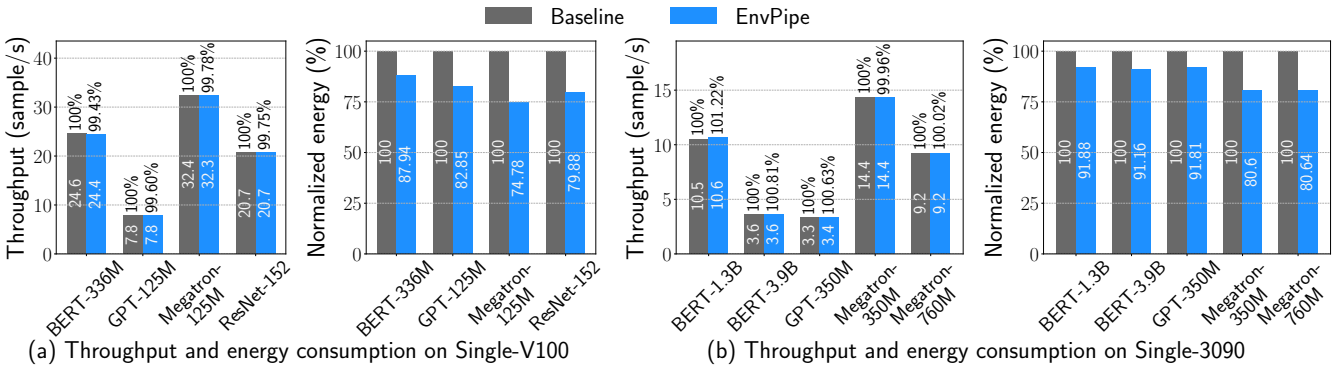

Figure 10: Throughput and energy consumption of various DNN models in single-node training

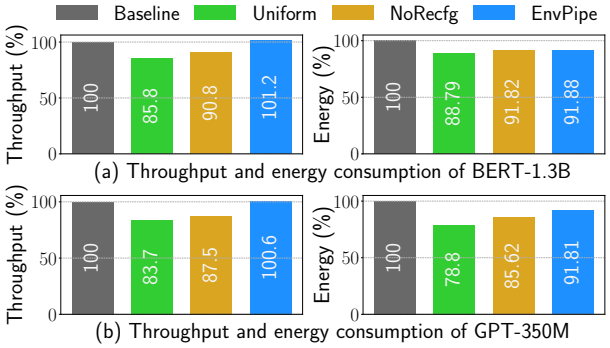

Figure 11: Normalized throughput and energy consumption breakdown

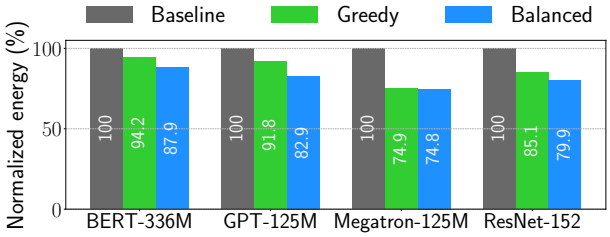

Figure 12: Comparison of reconfiguration policy

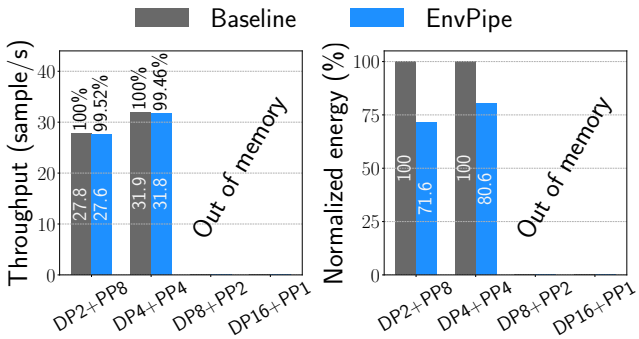
Comparison of reconfiguration policies. We now evaluate two different reconfiguration policies for the frequency planner of EnvPipe, balanced (our default) and greedy, using models trained on Single-V100. The results shown in Figure 12 demonstrate that for BERT-336M, GPT-125M, and ResNet-152, the balanced method saves more energy than the greedy method, with a range of 5.2 to 8.9%. However, the difference in energy savings is insignificant for Megatron-125M. This is because the portion of pipeline bubbles (a measure of how much time is spent by bubbles) is larger for Megatron models due to additional computation on the loss computation layer, which is insignificant in other models, leading to longer execution times in the last stage of the pipeline. This portion exists even though the model is evenly partitioned across GPUs w.r.t. the number of transformer-based layers placed on each GPU. In summary, the balanced method delivers more benefits than the greedy method but exhibits different relative effectiveness according to how bubbles are composed.



DP	PP	Microbatch	Minibatch	Num of Microbatch
2	8	2	512	128
4	4	2	512	64
8	2	2	512	32
16	1	2	512	X

Figure 13: Throughput and energy consumption of Megatron-1.3B on Multi-V100

6.2.2 Multi-node Energy Saving

To study the efficacy of EnvPipe under multi-node training, we examine the throughput and energy consumption of Megatron-1.3B trained on Multi-V100. Training sweeps different data parallel (DP) and pipeline parallel (PP) dimensions, as shown in Figure 13. Achieving efficient memory utilization in distributed training can be challenging when relying solely on data parallelism. Due to memory constraints, training could not be completed for DP8+PP2 and DP16+PP1. Also, we omit DP1+PP16, i.e., single-way DP combined with 16-way PP, since it is challenging to evenly split 24 transformer-based layers in Megatron-1.3B over 16 pipeline stages. We thus compare the throughput and energy consumption of Baseline and EnvPipe mainly for DP2+PP8 and DP4+PP4, and show the results in Figure 13. EnvPipe saves energy by 28.4% for DP2+PP8 and 19.4% for DP4+PP4 compared to Baseline. Similar to the single-node experiments, the throughput degradation for both cases is less than 1%, indicating that EnvPipe can maintain its benefits when scaling to two or potentially more GPU nodes.

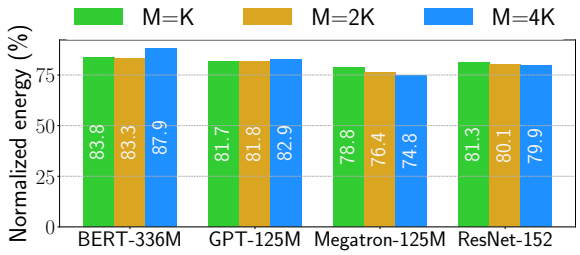


Figure 14: Sensitivity study of number of microbatches (M = number of microbatches, K = number of pipeline stages)

6.2.3 Sensitivity Study

Different number of microbatches. We examine how changing the number of microbatches affects the effectiveness of EnvPipe on Single-V100. The results, shown in Figure 14, reveal that the impact on energy savings differs between Megatron-125M and other models (BERT-336, GPT-125M, and ResNet-152). Megatron-125M model can save more energy when trained on a larger number of microbatches. This is largely due to an imbalance in pipeline stages and a larger portion of pipeline bubbles as compared to other models, which can be effectively harnessed over a long sequence of pipelined executions. However, for other models, increasing the number of microbatches does not result in further energy savings because it quickly leads to amortized bubble sizes.

Stage partition methods. Transformer-based models, which we have used for experiments thus far, are easy to partition in a balanced manner because of their regular structures. However, models like CNNs have non-regular structures, so different partitioning methods with EnvPipe can presumably offer different benefits. To investigate this, we evaluate two different partitioning methods, balancing execution time or memory footprint, using a popular CNN model, ResNet-152 on Single-3090. Both methods are considered beneficial from the perspective of system utilization, as they make training faster or more memory-efficient. The results from Table 2 show that balancing execution time leads to higher throughput, but the energy savings between the two methods are similar. This is because the stages at the front of the pipeline have more activations to store in memory, so shifting computation to the back of the pipeline stage can balance memory usage but cause an imbalance in computation between stages. Consequently, there is not much computation left to stretch in the pipeline stages at the front, limiting energy-saving opportunities.

7 Related Work

Pipeline parallelism. Bubbles in pipeline parallelism have been considered as an obstacle that slows down training throughput and previous studies focused on reducing the bubble with new scheduling methods [15, 16, 20]. On the other hand, EnvPipe considers bubbles as an opportunity and leverages bubbles to save energy.

Data center energy analysis. Recent studies focused on analyzing carbon emission and energy usage to measure the environmental impact when training large models in datacenters [14, 22, 23]. Treehouse [4] aims to reduce the carbon intensity of datacenters from a software perspective by providing suites of resources to application developers to better understand the trade-off between performance and carbon emissions. Strubell *et al.* [26] emphasizes the importance of quantifying the environmental cost of training neural network models for NLP.

Partition Method	GPU Memory (GB)	Perf. (sample/s)	Energy (%)
Execution Time	7.5 / 7.1 / 6.1 / 3.8	20.5	83.1
Memory	6.9 / 5.0 / 6.0 / 5.0	14.2	84.4

Table 2: Comparison of partition method of pipeline stages

Improving energy efficiency with GPU DVFS. Previous approaches to improve energy efficiency in GPUs have utilized GPU DVFS techniques by characterizing the relationship between performance and energy efficiency [6, 9, 13, 28]. Tang *et al.* [27] studied the energy scaling trend of various DNN training jobs on modern datacenter GPUs. Zeus [29] considers batch size as a new control knob for improving energy efficiency on DNN training, navigating the energy-performance tradeoff with Pareto optimality. Similarly, Batchsizer [17] considers batch size on DNN inference. Unlike previous approaches, EnvPipe saves energy by leveraging only the side-effect-free control knob in multi-GPU training.

8 Conclusion

In this study, we propose EnvPipe, a performance-preserving energy-saving DNN training framework. EnvPipe saves energy with no accuracy and performance degradation by leveraging bubbles in pipeline parallelism. EnvPipe profiles the optimal SM frequency of each pipeline stage, schedules pipeline units to make the best out of usable bubbles, and selectively reduces the SM frequency of pipeline units as much as possible with only a certain limit to avoid any adverse performance delay. EnvPipe can save energy up to 25.2% energy in single-node training with 4 GPUs and 28.4% in multi-node training with 16 GPUs with less than 1% of performance degradation.

Abstract

As more apps embrace AI, it is becoming increasingly common that multiple Deep Neural Networks (DNN)-powered apps may run at the same time on a mobile device. This paper explores scheduling in such multi-instance DNN scenarios, on general *open* mobile systems (e.g., common smartphones and tablets). Unlike *closed* systems (e.g., autonomous driving systems) where the set of co-run apps are known beforehand, the user of an *open* mobile system may install or uninstall arbitrary apps at any time, and a centralized solution is subject to adoption barriers. This work proposes the first-known decentralized application-level scheduling mechanism to address the problem. By leveraging the adaptivity of Deep Reinforcement Learning, the solution is shown to make the scheduling of co-run apps converge to a Nash equilibrium point, yielding a good balance of gains among the apps. The solution moreover automatically adapts to the running environment and the underlying OS and hardware. Experiments show that the solution consistently produces significant speedups and energy savings across DNN workloads, hardware configurations, and running scenarios.

1 Introduction

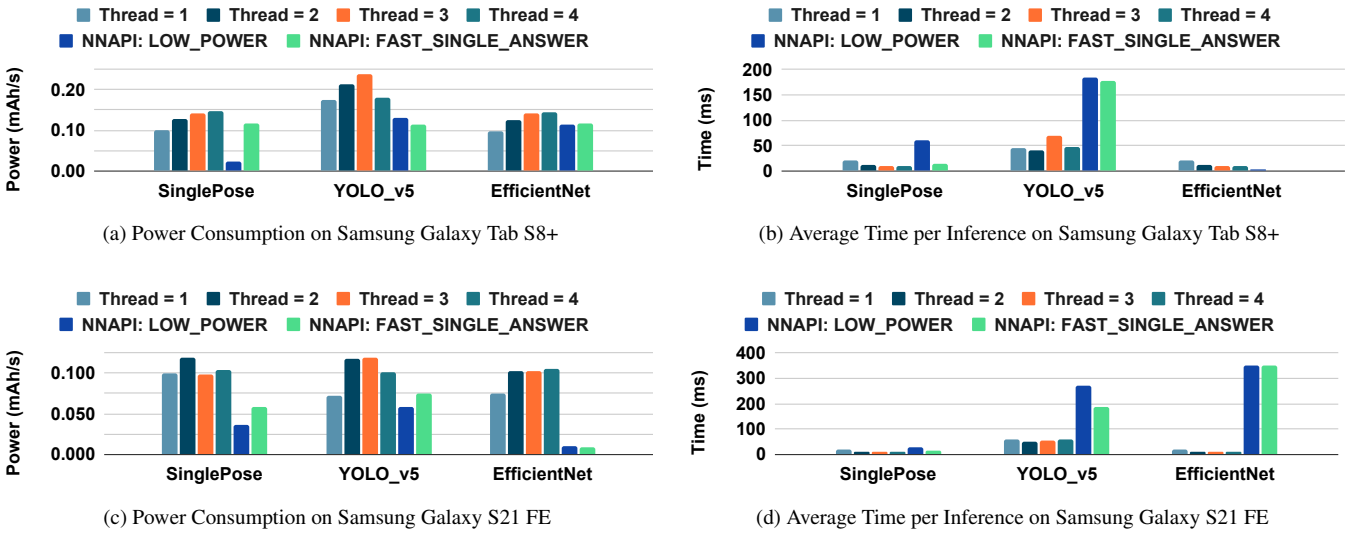
Deep Neural Networks (DNN) have attained remarkable success in various tasks. Recent years have witnessed increasing adoption of DNNs in mobile devices, thanks to the advancement in DNN compression [11, 18, 19], the increasing concerns on privacy, and the demands for real-time responses.

As more apps start to make use of AI, multiple DNN-equipped apps may run on a mobile device at the same time. For example, while a user is using her smartphone to examine some surveillance videos through a DNN-based object detection module, she may be speaking to the DNN-powered personal assistance app on her phone to take notes, while her social media app may be running some DNN-based recommendation algorithm in the background. We call such a co-run scenario *multi-instance DNN* executions.

Scheduling is important for multi-instance DNN executions, especially on resource-constrained systems. This paper particularly focuses on the *spatial* aspect of scheduling, which determines the placement of a DNN-based app on heterogeneous hardware units during each inference. It is critical for the computing efficiency of DNNs. On one hand, DNNs are computationally demanding, and their performance is heavily influenced by the type, configuration, and availability of the underlying computing resources. On the other hand, modern mobile devices (e.g., smartphones, tablets) are commonly equipped with heterogeneous computing units. On a Samsung Galaxy S21, for instance, there is one big "primary" CPU core (ARM Cortex-X1), three medium-sized "performance" CPU cores (Cortex-A78), four small "efficiency" CPU cores (Cortex-A55), one Adreno 660 GPU, and other accelerators. As a result, the speed and power consumption of a DNN running on the different computing units in a mobile device may differ as much as several times as illustrated in Figure 1. Multi-instance DNN executions further complicate the scheduling of DNNs to the best computing units, due to the contentions for computing resources by other co-running DNNs.

The objective of this work is to address such spatial scheduling problems on *open* mobile devices. Here, *open* mobile devices refer to mobile devices on which users can install or uninstall arbitrary apps anytime. In contrast, some devices (e.g., an autonomous driving system) are *closed*, where the applications to install and run are predetermined. The problem of multi-instance DNN scheduling also exists on *closed* devices, and has been explored in some previous studies [4, 9, 14, 28]. But those studies assume that the set of co-running apps are known beforehand and their schedules are fully controllable by a central agent (e.g., OS), which is not the case for *open* devices. Their solutions hence cannot apply to the *open* devices. To the best of our knowledge, no prior solutions have been proposed for multi-instance DNNs scheduling on open mobile systems.

This work proposes the first-known *decentralized* application-level adaptive spatial scheduler for multi-instance DNNs on open mobile devices. Being decentralized means



(a) Power Consumption on Samsung Galaxy Tab S8+

(b) Average Time per Inference on Samsung Galaxy Tab S8+

(c) Power Consumption on Samsung Galaxy S21 FE

(d) Average Time per Inference on Samsung Galaxy S21 FE

Figure 1: **Standalone Profiling of Three DNN Networks.** We profile the average power and inference time for different DNNs. They have their own best option for delegation. Thread = *i* means the model is executed on the CPU with *i* threads. NNAPI *low power* and *fast single answer* are two options that consider using GPU and accelerators.

that the spatial scheduling decisions are made by each application rather than by a centralized agent (e.g., OS). This distinctive design brings several benefits over centralized schemes: It is easy to adopt without the need for OS modifications; it requires no OS admin privileges; it preserves privacy and avoids inter-app communications or app-OS special communications and the associated overhead.

Specifically, the spatial scheduling considered in this work includes the decisions on running a DNN on GPU or on CPU and if on CPU how many CPU threads to use. We intentionally leave the temporal aspect of scheduling (i.e., at what time an app runs or gets evicted) and priority management as they are, because these tasks are what the OS is already taking care of. We meanwhile ensure that the spatial scheduling method can automatically adapt the scheduling decisions to the temporal scheduling by the underlying OS. This design makes the solution easy to adopt (as no OS modifications are necessary), applicable across systems, and workable regardless of what the other co-running apps are and what scheduling policies they follow. It also retains the fairness guarantees and starvation-avoidance provided by the underlying OS.

Our solution achieves these properties by leveraging the adaptivity of Deep Reinforcement Learning (DRL) [17,20,25]. We develop a DRL-based scheduling library. It is decentralized, working at the application level. Any app may call the library to dynamically determine, for the next DNN inference, whether CPU or accelerators is to be used, what modes (e.g., performance or power-efficiency modes) to use, and if CPU, what is the best number of threads to launch. It requires no direct knowledge about other apps. It gives recommendations based on the current state of the executing environment and the estimated rewards this application is expected to obtain for each of the possible schedules—produced by a model learned through the self semi-supervised approach of DRL.

By drawing on previous theoretical results on the Nash equilibrium of RL, we provide discussions on the convergence of the scheduling algorithm and the empirical evidences.

In a set of co-run scenarios formed by the subsets of nine DNNs, the proposed solution improves the average latency by as much as 4×, and saves the average energy consumption by as much as 3× compared to Android NNAPI, the official Android tool that automatically selects the computing units to use for running a DNN. Experiments on a smartphone (Samsung Galaxy S21) and a tablet (Samsung Tab S8+) show that the benefits are consistently significant. Further experiments show that the benefits remain even if those DNNs co-run with uncontrolled apps (i.e., apps that do not employ the proposed scheduling algorithm). The scheduling algorithm converges quickly (within seconds) and adapts to the running environments automatically, making it an immediately adoptable solution across mobile systems.

Overall this work makes the following main contributions:

- To our best knowledge, the solution in this work is the first decentralized application-level adaptive scheduling for multi-instance DNNs on open mobile devices.
- This work uncovers a set of novel insights: (i) It is possible for a scheduler to work effectively without direct knowledge of other apps in multi-instance DNN scheduling; (ii) the DRL-based scheduling is effective in adapting to the factors in the execution environment (OS, other apps, priorities, etc.); (iii) the decentralized scheduling

algorithm is quick in converging to a balance point.

- This work empirically evaluates the efficacy of the proposed solution, showing that it consistently gives significant speedups and energy savings across DNN workloads, hardware configurations, and running scenarios (with or without uncontrolled apps, various background/foreground combinations).

2 Background

Reinforcement Learning and Deep-Q-Network Reinforcement learning (RL) [20] is a machine learning approach in which an agent learns from environmental feedback and a series of decisions to maximize the total cumulative rewards to stimulate better decision-making. Q-learning [27] is a type of RL algorithm that seeks an offline policy to maximize the expected total rewards across all steps. "Q" refers to the policy function $Q(S,A)$ that inputs a state and action pair and outputs a Q-value. Two typical Q-learning schemes are Q-table and Deep-Q-network (DQN) [17]. DQN improves the limited representation of the Q-table.

Q-table stores the state and action pairs with the estimated Q-value. The Q-value of each step can be obtained by table lookup. However, this approach only works when states and actions are discrete values and the sets are small. In contrast, DQN replaces the Q-table with a neural network (NN) as a function approximator. Now, the sets of states and actions can be large, and the state space can be continuous. In the training phase, the loss function minimizes the squared error between the target Q-value and the predicted Q-value given by the NN. So the loss function of NN can thus be formulated as follows: $L = (Q(S,A) - (R + \gamma * \max(Q(S',A'))))^2$, where R is the immediate reward for taking action A in state S, γ is the discount factor (a value between 0 and 1 that determines the importance of future rewards), and S' and A' are the next state and the possible actions in that state, respectively.

Nash Equilibrium The Nash equilibrium is a concept in game theory that describes the optimal behavior of players in a game. It is a stable, self-enforcing, and Pareto optimal solution, where each player has chosen an optimal action, given the other players' actions. There are several methods for finding the Nash equilibrium of a game, including using best response functions and mixed strategies. The Nash equilibrium is a helpful tool for analyzing strategic interactions and predicting players' behavior in a game.

One way to find the Nash equilibrium is to use the best response function, which maps each player's action to the action that maximizes their reward, given the actions of the other players. The Nash equilibrium is then the set of actions where each player's action is the best response to the actions of the other players. Another approach is to use a mixed strategy, where players randomly choose their action with a certain probability. The Nash equilibrium is then the set of possibilities where each player's mixed strategy is the best response to the combined strategies of the other players.

3 Problem Statement and Research Questions

This section first provides a definition of the focused scheduling problem, and then lists the important research questions.

3.1 Problem Definition

Given: A set of apps A that may execute on a device V, and some of them may run at the same time. $A = A_c \cup A_u$, where, each app in A_c contains some DNNs and employs a policy P to decide the execution configuration of each of its DNNs, while the apps in A_u do not follow policy P. For each DNN, there are K possible configurations which affect the usage of CPUs and GPUs of the DNN differently.

Objective: Finding P such that the following is minimized:

$$\sum_{i \in A_c(DNN)} \sum_{j} L_{i,j} * W_{i,j}$$

where, $L_{i,j}$ and $W_{i,j}$ are respectively the latency and power consumption of the j^{th} inference of DNN_i, $A_c(DNN)$ is the DNNs in the apps in A_c. We use the product of latency and power to capture the common interest in both speed and energy usage on mobile devices.

Constraints: (1) The scheduling policy P in an app cannot access the information of another app (due to the isolation enforced by mobile systems); (2) each app's priority and temporal scheduling are controlled by the underlying OS.

3.2 Design Considerations and Principles

The main aspect of scheduling focused in this work is the execution configuration that affects the usage of computing units—which is essential for the performance and power consumption of DNN. The relevant factors include some that are controllable at the application level, and some at the OS level. For a DNN written in TFLite [3] (a popular development framework for mobile AI), for instance, the application can explicitly specify whether the DNN should run on CPU or accelerators (e.g., GPU), and the number of CPU threads to use. It may also call APIs in NNAPI [8] (the Android official library for running DNNs) with either a performance mode or an efficiency mode; the APIs will automatically determine the CPUs or accelerators to be used for the DNN. We uniformly regard such configurations as application-level controllable configurations, which specifically include the explicit specification of computing units and CPU thread number and the calls to other relevant libraries.

When a DNN runs with a certain configuration, the OS may exert further influence on the usage of the computing units.

For instance, if the application-level control sets the DNN to run on a CPU with 2 CPU threads, the OS will ultimately determine which two CPU cores the threads will run on. If they are small cores, the speed may be much lower than on medium cores.

We design our solution with the following principles:

(1) The scheduling should be decentralized, functioning inside each application. This is because most of the relevant factors are inside the app, and application-level solutions are easier to adopt as they do not need changes to the underlying OS.

(2) The scheduling should be able to adapt to the influence of the underlying OS and other environmental factors (e.g., priorities of apps, background/foreground differences).

(3) The scheduler should work efficiently and adapt to changes in the system agilely.

3.3 Research Questions

Creating a decentralized application-level scheduler on open mobile systems has many differences from centralized scheduling on closed systems and hence raises many new questions. We summarize them into the following six open research questions (RQ). They are gradually addressed in the rest of this paper.

RQ1: How can the scheduler work effectively without direct knowledge of other apps?

The apps on a smartphone may be developed by many different authors. For security and privacy, open mobile systems typically impose strong isolations among apps. One app cannot access the direct info of another app. How can the scheduler work well under such a constraint?

RQ2: How can the solution deal with the effects of the scheduler in the underlying OS?

OS influences the execution of the Apps: Ultimately, it is the OS that allocates computing units and other resources to each App and determines when an app runs and its priority level. The OS schedulers differ from one version of OS to another. We avoid demanding changes to the underlying OS for easy adoption of our solution. The user-level scheduling hence must be made adaptive to OS.

RQ3: Can decentralized scheduling converge to a good result?

On an open mobile system, apps come and go, and the workloads on the system may vary continuously. Without the knowledge of other co-running apps, can decentralized scheduling converge to good results?

RQ4: How fast can the decentralized scheduling learn and adapt?

Machine learning-based decision models usually take time to learn, but the dynamic nature of mobile systems demands fast responses. Can decentralized scheduling meet the speed needs?

RQ5: Can the solution work if there are uncontrollable apps?

In real mobile usage scenarios, not all Apps will adopt the same scheduling policy. The workload from uncontrollable apps can be unpredictable. Can the proposed solution still function well in the presence of such uncontrollable apps?

4 Decentralized DQN Scheduler

Algorithm 1: DQN Algorithm for each Apps

Input: Environment E; Replay Memory M; Exploration Ratio ε; The parameters of Policy Network θ and Target Network θ^-; Discount Factor γ; Batch Size B; Update Steps C; Huber loss function L

Output: $Q(s,a;\theta)$

Initialize: Take observation from E and generate current state s

```
while Inference start do
    if rand() < ε then
        Select action a randomly
    else
        Select action a ← argmax_a Q(s,a; θ)
    Run inference on a target defined by action a
    When Inference ends, Calculate reward r
    Observe from E and generate next state s'
    Store transition (s, a, s', r) to M
    if M.size() > B then
        Sample a mini-batch N from M
        for each transition (s_j, a_j, s'_j, r_j) in N do
            y_j = r_j + γ max_a' Q(s_j, a' : θ^-)
            Calculate Loss l_j = L(y_j, Q(s_j, a_j : θ))
        Batch Update θ using SGD algorithm by loss vector l
    s ← s'
    i ← i + 1
    if i mod C == 0 then
        θ ← θ^-
```

In this section, we introduce the design of the decentralized scheduler, which also answers RQ1 and RQ2.

The design is based on deep reinforcement learning (DQN). As Section 2 mentions, DQN is a deep reinforcement-learning method. As a semi-supervised method, it requires no manual labels, but actively explores the environment, learns the relations between actions and rewards automatically, and uses the learned model to predict the next suitable action. This nature makes it a good fit for the dynamic environment in our problem. In contrast, a DNN-based approach would require offline labels of many training cases and be slow in adapting to dynamic changes.

The DQN-based RL agent is also light-weighted and converges fast. For the storage overhead, the total extra mem-

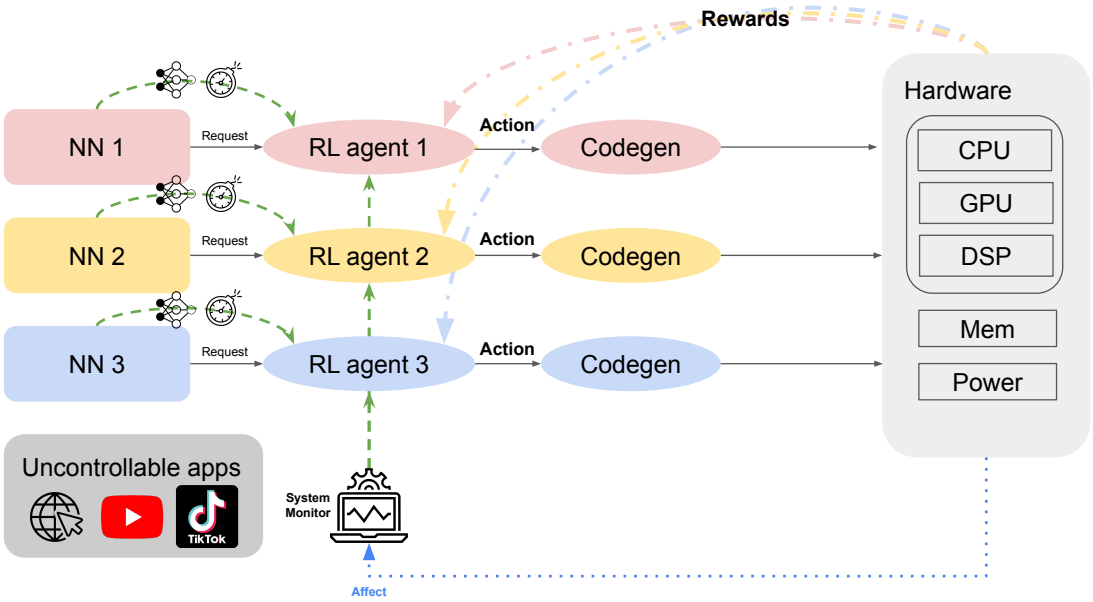


Figure 2: **The Structure of Decentralized DQN Scheduler.** The figure shows three controllable DNN applications that have their RL agent that selects actions (different code generation of the model). All of them collect system status as their RL agent input state. Also, we include the co-running uncontrollable apps that do not contain RL agents inside.

ory footprint needed less than 250KB. For the computation overhead, the inference time of the network only takes less than 1ms and one training process only takes about 1ms to 2ms when three DQN agents co-running. In general real-time constraints are 50ms for each inference, and those extra computations overhead in each model can be neglected.

Figure 2 illustrates the role of the scheduler in a multi-instance scenario. Other than the uncontrolled apps, each DNN-based app contains a DQN agent for configurations. They do not have access to other apps but can obtain the state of the resource utilization of the whole system.

We define the learning procedure of our DQN-based agents with *States*, *Rewards*, and *Actions* in the multi-DNN execution environment as follows:

States We use the following variable to capture the static and variance environment information. For static features, we use the number of convolution layers, the number of fully-connected layers, and the MAC operations of DNN models. For environment variance information, we use the CPU utilization, GPU utilization, and memory usage of co-run apps.

Rewards The reward function R is composed of three important metrics: latency, power consumption, and deadline. It is defined as follows:

$$R(L_i^{s,a}, W_i^a, d_i) = \begin{cases} -1000 & \text{, if } \quad L_i^{s,a} > d_i \\ -L_i^{s,a} \times Power_i^a & \text{, otherwise} \end{cases}$$

where, $L_i^{s,a}$ represents the latency of the inference of DNN_i with action a on state s, W_i^a is the average power of the inference of DNN_i with action a, and d_i is the deadline for the inference of DNN_i.

Because ($latency \times power$) can be regarded as the energy consumption estimation, we call it **Energy Factor** in our paper. Also, it is used as one of the metrics in our evaluation (Section 6). The multiplication of power and latency gives a linear relationship, with no skew towards either factor. For instance, if the latency doubles, the entire reward function doubles, and the same applies to power consumption. The simple production form of the reward function avoids additional hyper-parameters. A large negative reward is used when a deadline is passed to discourage missing deadlines.

Actions The action space involves the configurations that can affect the usage of computing resources on the hardware. In our study, we include six configurations as detailed in Section 6.1.

Neural Networks DQN includes a *policy neural network* and a *target neural network* inside, which learn about the relations between states, actions and rewards. We want to make the networks as simple as possible to control the runtime overhead. So we adopt a model that only maintains two fully-connected (FC) layers as our policy and target network. The first FC layer input channel is 8, and the output channel is 100. The second FC layer input channel is 100, and the output channel is 6. For the input, it is the vector of the state. Its dimension is 8, which contains four CPU and GPU usage pairs. The output is a vector that represents the q-values of six actions.

The DQN agents go through an exploration and learning

stage until they reach convergence. As listed in Algorithm 1, at the start of each episode, each agent selects the action with the maximum q-value generated by the policy network with parameters θ and current state s but has some exploration rate ε to select action randomly. Here, one episode is one inference of the DNN model. After making the inference with the selected action, the power consumption and latency are collected to compute the reward r. Then, the agent observes the environment and generates the updated state s'. One transition (s, a, s', r) is then pushed into the replay memory M. The training process starts when the replay memory M has enough data. It goes as follows. It first samples a mini-batch N from M. Then, it calls the *target network* to generate the expected q-value y for each transition. After that, it uses the Huber Loss function [10] to calculate the loss value between the expected q-value and the current q-value output by the *policy network*. The final step of the training process is to update the parameters θ based on the loss value. In every C episode, the parameters θ of the *policy network* are copied to the *target network* as its new parameters. In the targeted co-run scenario, each controllable App is equipped with a DQN agent that is trained for scheduling its DNN inferences.

5 Convergence Discussion

This section discusses the convergence of the DQN-based scheduling algorithm (RQ3). Prior works [6] generalize the multi-agent Q-learning method as a general-sum stochastic game and prove all reward functions in each agent are guaranteed to converge. Specifically, Hu and Wellman [13] present an algorithm to solve the general-sum stochastic games, and Bowling [6] strengthens the proof with further assumptions.

Their convergence theorem has four necessary assumptions, two of which are about exploration and the decay of the learning rate, and are similar to those used in the Deep-Q-Learning algorithm. It is assumed that they have been met. The remaining two assumptions [6, 13] are as follows:

Assumption .1 *A Nash equilibrium* $(\pi^1_*(s), \pi^2_*(s))$ *for any stochastic game* (Q^1_n, Q^2_n) *satisfies one of the following properties:*

1. The equilibrium is a global optimal.

2. The equilibrium receives a higher payoff if the other agent deviates from the equilibrium strategy.

Assumption .2 *The Nash equilibrium of all stochastic games* $Q_n(s)$*, as well as* $Q_*(s)$ *must satisfy property 1 in Assumption 1* ***or*** *the Nash equilibrium of all stochastic games,* $Q_n(s)$*, as well as* $Q_*(s)$ *must satisfy property 2 of Assumption 1*

Assumption 1 includes a property that states that there exists a set of strategies for the agents, where each agent individually obtains the highest possible payoff. This also guarantees that this set of strategies forms an equilibrium since no agents would gain from deviating from their chosen strategy. Assumption 2 includes another property in which the game's Nash equilibrium is a "saddle point." This implies that if an agent deviates from the equilibrium, the agent would not gain, but other agents would, which makes no agent want to deviate from the equilibrium.

Finding a globally optimal solution for the multi-agent problem is known to be NP-hard [7]. However, by reaching Nash equilibrium during convergence, RL can ensure that each agent adheres to a strategy that gives a good payoff to both itself and the other agents. Reflected in our scheduling context, it means that all controllable Apps may adhere to a strategy that helps meet their deadlines while minimizing energy consumption. The achievement of Nash equilibrium eliminates fairness concerns among controllable Apps, as they all reach a stable state where each maximizes its benefits within the given constraints.

Based on prior studies [6, 13], it has been demonstrated that a zero-sum stochastic game converges. Our scheduling problem for multi-DNN applications in this paper bears a resemblance to a zero-sum stochastic game. In our case, each agent corresponds to our DQN agent for each controllable DNN application. All DQN agents involved compete for limited resources, such as CPU and GPU, with a maximum utilization boundary. While our problem may not strictly adhere to all the definitions of a stochastic game, we empirically demonstrate its convergence under our circumstances in Section 6.

6 Evaluation

This section evaluates our decentralized application-level adaptive scheduler (called DQN for short in this section) by comparing it with three baseline scheduling methods that are designed for single DNN execution: two static scheduling settings used by Android Neural Networks API (NNAPI) [8] (`NNAPI LOWER_POWER` that minimizes the power consumption for each DNN and `NNAPI FAST_SINGLE_ANSWER` that minimizes the inference latency for each DNN) and an offline profiling-based scheduling method (`Best Standalone` that based on offline profiling selects the best setting for each individual DNN among all delegate settings introduced in Section 6.1). This evaluation has three objectives as follows: 1) demonstrating that as the *first* decentralized DNN co-run scheduling method, DQN outperforms all baseline scheduling approaches that are designed for single DNN execution in multiple representative DNN co-run scenarios (Section 6.2); 2) verifying DQN's convergence and fast converging speed, and studying the underlying reason why DQN outperforms baseline scheduling methods by a reward convergence analysis (Section 6.3); 3) proving DQN's benefits remain even if the DNNs co-run with uncontrolled apps with both predictable and unpredictable workloads (Section 6.4).

6.1 Evaluation Methodology

Benchmarks. Table 1 characterizes the nine DNN models from various domains used in the evaluation[1]. All models are in TensorFlow Lite [3] format. These DNN models form three groups: `Image`, `Audio & Image`, and `Video & Image` with three models in each group. Our evaluation runs models in each group simultaneously to simulate the real-world DNN co-run scenario. For example, Group 1 (G1) simulates an intelligent camera running varied AI capabilities simultaneously, pose detection (`SinglePose`), object detection (`YOLO-v5`), and image classification (`EfficientNet`). Other groups simulate more complex scenarios with audio and image or video and image co-processing. In addition, these DNNs have varied model sizes, standalone latency, and power consumption, representing three different cases: relatively balanced workloads, mild imbalanced workloads, and severe imbalanced workloads, respectively. Therefore, they show different behaviors in the evaluation. Please find more discussions in Section 6.2.

Table 1: **Nine DNN Models Used in Our Evaluation.** They form three groups. DNN models in each group are executed simultaneously.

Group	Models	Sizes (KB)
G1: Image	SinglePose [1] (SP)	9,154
	YOLO-v5 [5]	7,428
	EfficientNet [23] (ENet)	6,265
G2: Audio&Image	YamNet [24]	4,031
	MobileNetv1 [12] (MNv1)	4,188
	WDSR [29]	1,252
G3: Video&Image	Movenet [16]	24,440
	Esrgan [26]	4,877
	MobileNetv2 [21] (MNv2)	13,666

Software settings.

Our evaluation considers two co-run scenarios: *controllable DNN tasks co-run* and *uncontrollable tasks co-run. Controllable DNN tasks* refer to Apps that incorporate our RL agents, while *uncontrollable tasks* refer to Apps that do not involve our RL agent. *Uncontrollable tasks* may or may not use DNNs.

[1]These DNNs are collected from Tensorflow Hub [2] and GitHubs [22].

Table 3: **Absolute Energy Factor of DQN.** This table reports the absolute energy of DQN in Figure 3, Figure 6, Figure 7.

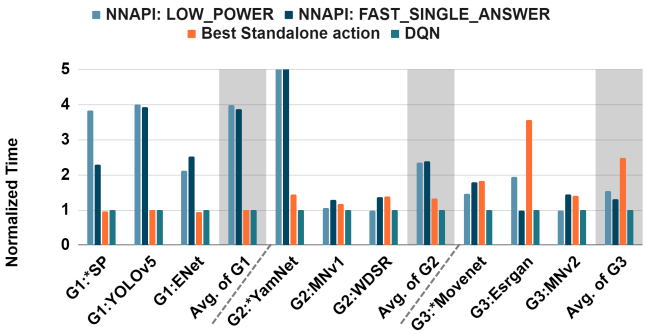
Controllable DNN Tasks Co-Run. We build an Android demo app with Java that can run each DNN individually. Users can control this demo app to start and stop DNN inference. This demo app relies on TensorFlow Lite (TFLite) [3] to run DNNs. Our evaluation employs multiple delegate settings in TFLite to run DNNs: using 1, 2, 3, or 4 CPU threads[2], respectively, and using two NNAPI [8] modes, LOWER_POWER or FAST_SINGLE_ANSWER, respectively. Particularly, NNAPI is designed for accelerating TensorFlow Lite DNN execution on mobile devices with supported hardware accelerators including GPU, DSP, and NPU. It automatically partitions a DNN model, maps each partition to a processor, and calls corresponding kernel codes for that processor. Thus, we can treat it as *static offline scheduling* for each individual DNN. Our evaluation particularly employs two NNAPI modes as the baseline, `LOWER_POWER` which minimizes the power usage, and `FAST_SINGLE_ANSWER` which minimizes the inference latency. Besides them, our evaluation also employs an offline profiling-based scheduling method as a baseline: `Best Standalone` that selects the best setting (i.e., with the best energy factor defined as $power\_consumption \times latency$) for each individual DNN among all delegate settings (including using 1 to 4 CPU threads and two NNAPI modes) based on offline profiling results[3].

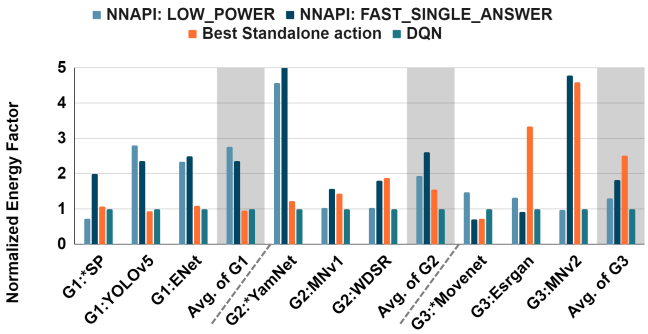
Uncontrollable Tasks Co-Run. We select two widely used real-world applications `TikTok` and `Web Browser` to experiment with two popular user behaviors, watching social media video and browsing web pages. Here we select the default web browser in Android, Google Chrome as our target.

[2]The evaluated mobile chip has 8 CPU cores, but the Android OS only allows background Apps to access the 4 small CPU cores. Thus, we make it consistent throughout our evaluations: the foregrounds Apps access the 4 cores (prioritize to access the big core, medium core, then small cores), and the background Apps access the 4 small cores.

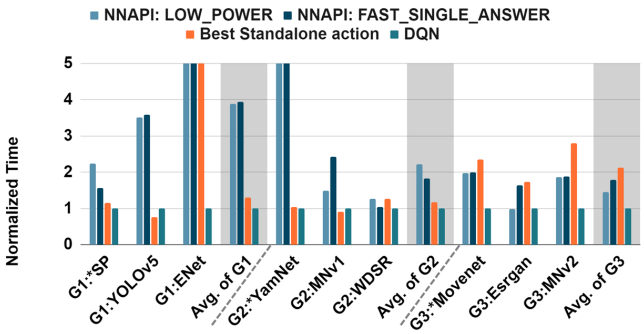
[3]we profile the power values through the Android Developer API "dumpsys batterystats".



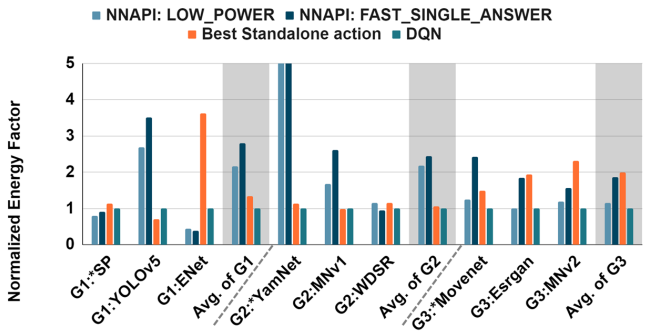
(a) Normalized Average Inference Time on Samsung Galaxy Tab S8+



(b) Normalized Energy Factor on Samsung Galaxy Tab S8+



(c) Normalized Average Inference Time on Samsung Galaxy S21 FE



(d) Normalized Energy Factor on Samsung Galaxy S21 FE

Figure 3: **Overall Comparison between DQN and Three Baselines on Three DNN Groups.** Compare (a) normalized average inference time and (b) rewards on Samsung Galaxy Tab S8+ and the same metrics (c) and (d) on Samsung Galaxy S21 FE when each group co-running three DNN apps (* denotes this DNN runs in the foreground and the others run in the background).

Evaluation platforms. DQN is evaluated on two edge devices: (1) `Samsung Galaxy S21 FE 5G` mobile phone, equipped with Android 12 OS, and Qualcomm SM8350 Snapdragon 888 5G SoC with Octa-core CPU (1x2.84 GHz Cortex-X1 & 3x2.42 GHz Cortex-A78 & 4x1.80 GHz Cortex-A55), Adreno 660 GPU (Version 1), and Hexagon 780 DSP. Its storage capacity is 128GB with 6GB RAM and its voltage is 4.3V. (2) `Samsung Tab S8+ tablet`, equipped with Android 12 OS as well, and Qualcomm SM8450 Snapdragon 8 Gen 1 SoC with Octa-core (1x3.00 GHz Cortex-X2 & 3x2.50 GHz Cortex-A710 & 4x1.80 GHz Cortex-A510), Adreno 730 GPU, and Hexagon DSP. Its storage capacity is 128GB with 8GB RAM and its voltage is 4.1V.

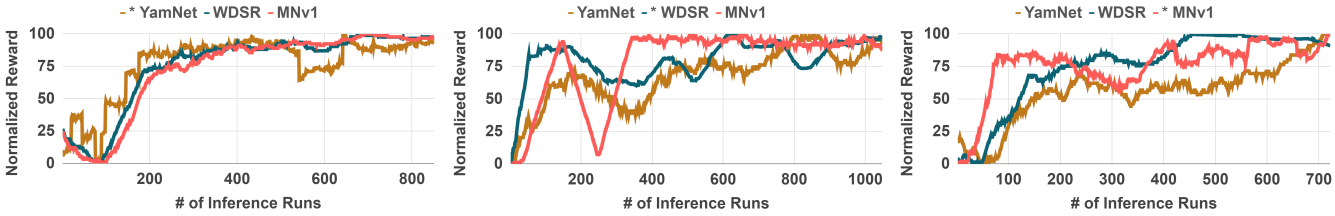
6.2 Overall DQN Scheduling Performance

This section evaluates DQN on the three groups of co-run DNNs in Table 1 by comparing it with the three scheduling baselines aforementioned: `NNAPI LOWER_POWER`, `NNAPI FAST_SINGLE_ANSWER`, and `Best Standalone`. Figure 3 shows the comparison results, in which the x-axis shows the three DNNs in each group and the average performance of each group. It is worth noting that the *star (*)* before the DNN name indicates that this DNN model is executed in the foreground (and two other DNNs in the same group are executed in the background) for this co-run[4]. We intentionally use this setting to simulate the real-world Apps co-run on the Android system (and bring the OS impact on the user-level scheduling into account).

Figure 3 employs two metrics to compare our decentralized DQN system with three baselines: `average inference latency` (as shown in Figure 3a and Figure 3c) and `energy factor` (as shown in Figure 3b and Figure 3d). The energy factor is defined as $power\_consumption \times latency$ for each inference, which is also used as our reward function in each DQN agent, the lower the better. To improve the readability, we normalize the results in Figure 3 by setting DQN performance as 1. Table 2 and 3 summarizes the absolute values for reference.

Figure 3 shows that for the average inference latency, our decentralized DQN-based scheduler achieves up to 4× speedup over two baselines of NNAPI (`NNAPI LOWER_POWER` and `NNAPI FAST_SINGLE_ANSWER`), and 2.7× speedup over

[4]Android OS grants foreground and background Apps different priorities/limitations, e.g., normally, background Apps have lower priority than foreground ones, and background Apps cannot access the big core of CPUs.



(a) YamNet at Foreground (b) WDSR at Foreground (c) MNv1 at Foreground

Figure 4: **Reward Convergence Trend for the Three Apps Co-Run in G2.** It reports DQN's normalized reward trend to prove DQN converges in different situations. It uses DNNs in G2 and places each DNN in the foreground.

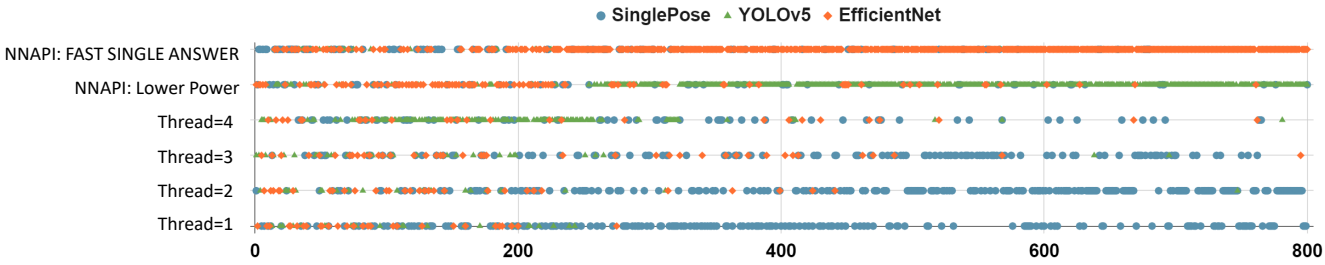


Figure 5: **Selected Action Convergence Trend.** This figure shows the action selection through runs for co-running results in G1 (all of them are in the background). The action selection will be converged into one or two options.

Table 4: **Selection Rates of Actions of Last 100 Runs of Figure 5.**

	Thread = 1	Thread = 2	Thread = 3	Thread = 4;	NNAPI: LOW_POWER	NNAPI: FAST_SINGLE_ANSWER
SinglePose	14%	75%	6%	1%	1%	3%
YOLO_v5	0%	1%	1%	0%	98%	0%
EfficientNet	0%	3%	0%	3%	0%	94%

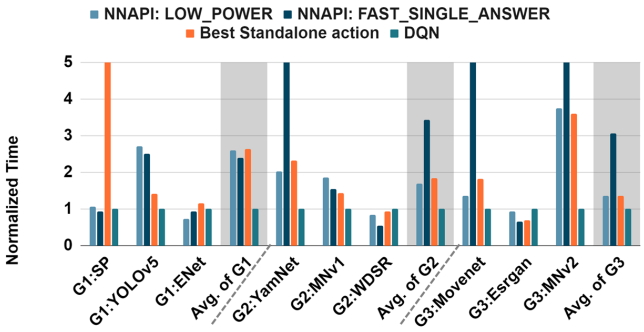
`Standalone Best` action selection, respectively, for average results of three co-running DNN groups (gray area). For the energy factor, our decentralized DQN-based scheduler achieves up to 3× energy saving over `NNAPI LOWER_POWER` and `NNAPI FAST_SINGLE_ANSWER`, and 2.6× energy saving over `Standalone Best` action selection, respectively, for average results of three co-run DNN groups. Comparing the DQN performance across three groups, we can see that as the workload imbalance increases (from G1 to G3), the benefit of DQN over `Best Standalone` grows while its benefit over both NNAPI schedulers drops. This is mainly because `Best Standalone` partitions each DNN workload into more processing units than NNAPI schedulers, so it reduces the resource competition caused by the workload imbalance. DQN has a similar effect. Moreover, although the average inference latency and energy factor vary for different groups (and each DNN model) under various settings, our decentralized DQN-based scheduler always performs better than baseline methods. These results prove that DQN is robust enough to deliver high-quality scheduling results for various DNN applications and environment settings (e.g., varied foreground/background DNN settings, DNN structures/target domains, and executing devices). The following sections further verify this claim.

6.3 Reward Convergence Analysis

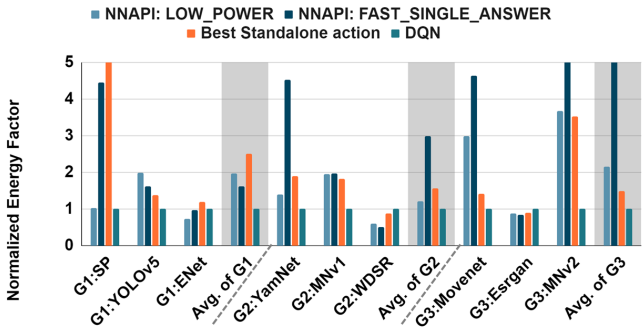
This reward convergence analysis has three objectives: 1) to verify the rewards of multiple agents converging empirically, 2) to measure the DQN convergence speed[5], and 3) to study why DQN outperforms baseline scheduling by analyzing its trend of action selection.

We verify the convergence and measure the convergence speed by taking Group 2 (in Table 1) as an example due to the space limitation and other groups show similar trends. Figure 4 shows the convergence trends of DQN training on co-running three DNNs in Group 1 under three different set-

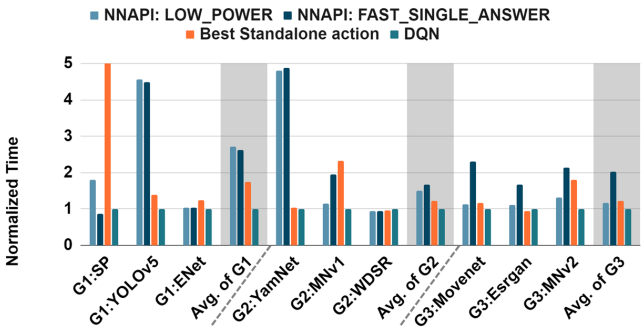
[5]Theoretical convergence proof only proves all DQN converges eventually without showing the convergence speed.



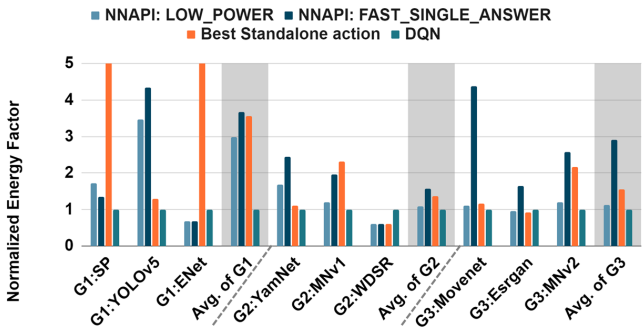
(a) Normalized Average Inference Time on Samsung Galaxy Tab S8+



(b) Normalized Energy Factor on Samsung Galaxy Tab S8+



(c) Normalized Average Inference Time on Samsung Galaxy S21 FE



(d) Normalized Energy Factor on Samsung Galaxy S21 FE

Figure 6: **Co-Run Three DNN Groups with Uncontrollable App TikTok.** Compare (a) normalized average inference time and (b) rewards on Samsung Galaxy Tab S8+ and the same metrics (c) and (d) on Samsung Galaxy S21 FE when each DNNs group co-running with uncontrollable app TikTok that plays video posts on the foreground.

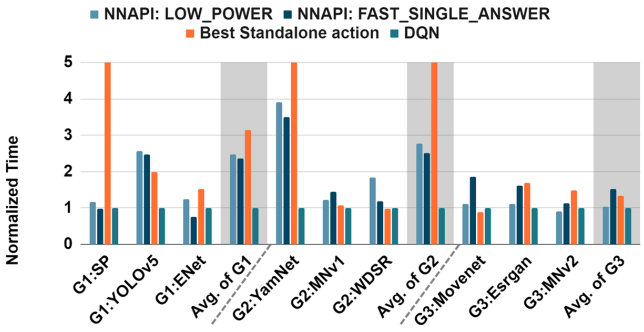
tings that place `YamNet`, `WDSR`, or `MNv1` at the foreground, respectively. The x-axis is the number of DQN inference runs (which is equivalent to the number of DNN inference runs), and the y-axis is the average action selection rewards of 100 times. Regardless of the environment settings, the DQN agents can reach convergence within 800-1000 inference runs. The scheduling time overhead for a single execution of the DNN App includes the forward- and backward-propagation phases of the DQN agent, which typically take 1.2 ms on average and only contribute to 0.5-5% of the overall DNN App execution time (which ranges 20-176ms). Additionally, the energy overhead amounts to approximately 0.5-2% of the DNN App execution. This convergence time is trivial compared to the time required to profile and configure each model manually.

We next study why the DQN agent can outperform the single DNN scheduling baselines by analyzing its trend of action selections. We take Group 1 (in Table 1) with `SinglePose`, `YOLOv5`, and `EfficientNet` as an example this time. All models run in the background, and the evaluation results are shown in Figure 5. In addition, Table 4 shows the percentage of action selection in the last one hundred runs to give an insight into action selection after the model is converged.

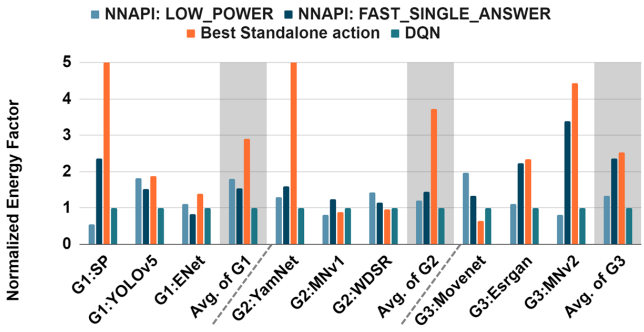
Figure 5 and Table 4 offer us two key insights in DQN: first, even though each DNN starts with multiple selections, their decision is converged into one or two actions, and second, a precise boundary exists between the actions only using CPU and those cooperating with GPU. The regular pattern of the action selection in the first insight implies that the DQN model converges at the end, empirically proving that the multi-agent DQN game converges (in another setting). The second insight tells us that DQN can effectively avoid computing resource contention. For example, when YOLOv5 and EfficientNet run on GPUs, DQN is able to schedule SinglePose on CPUs, thus preventing competition for the limited resource of accelerators; while other baseline scheduling methods fail to do this, resulting in GPU contention.

6.4 DQN Performance w/ Uncontrollable Apps

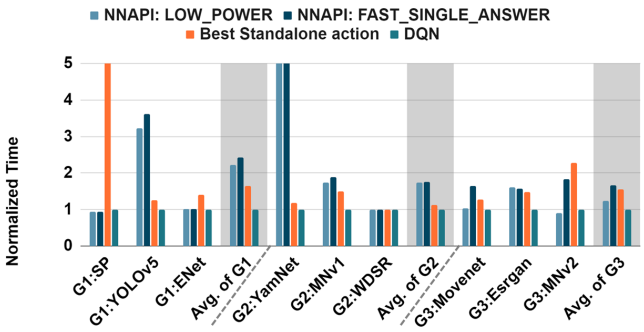
This section evaluates the performance of our decentralized DQN scheduler under uncontrollable application co-running situations. More specifically, we aim to 1) compare the performance between our decentralized DQN scheduler and those



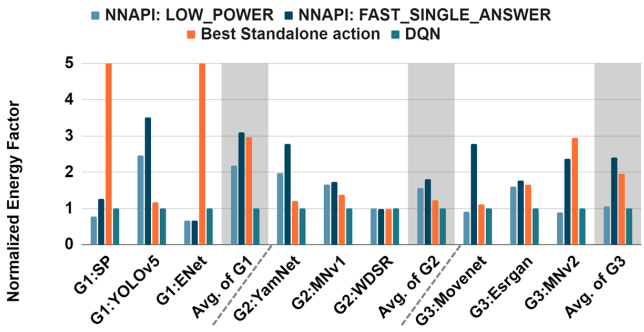
(a) Normalized Average Inference Time on Samsung Galaxy Tab S8+



(b) Normalized Energy Factor on Samsung Galaxy Tab S8+



(c) Normalized Average Inference Time on Samsung Galaxy S21 FE



(d) Normalized Energy Factor on Samsung Galaxy S21 FE

Figure 7: **Co-Run Three DNN Groups with Uncontrollable App Web Browser (Google Chrome).** Compare (a) normalized average inference time and (b) rewards on Samsung Galaxy Tab S8+ and the same metrics (c) and (d) on Samsung Galaxy S21 FE when each DNNs group co-running with the uncontrollable app Google Chrome randomly browsing pages on the foreground.

baselines under the popular real-world Apps co-running circumstance, and 2) illustrate our DQN solution has strong adaptivity when co-running with Apps with dynamically changing workloads.

Specifically, we simulate the real-world environment by simultaneously running DNNs and other apps with predictable workloads (i.e., repeatedly playing a TikTok video post), and unpredictable workloads (i.e., randomly browsing webpages in a web browser, Google Chrome). Both TikTok and Google Chrome run in the foreground, while DNNs (and their demo applications) run in the background. TikTok and Google Chrome require CPU and accelerators (e.g., GPUs), thus careful workload scheduling of DNNs is desired if we would like to achieve optimized system performance. To verify the predictability of TikTok and the unpredictability of Google Chrome, respectively, we use `GPUWatch` to monitor both applications' execution and find that the major task, video processing in Tiktok requires a stable amount of GPU resources, while Google Chrome only consumes GPU resources when users touch or swipe across the screen, resulting in irregular GPU usage.

Figure 6 and Figure 7 compare DQN with all three baselines aforementioned, `NNAPI LOWER_POWER`, `NNAPI FAST_SINGLE_ANSWER`, and `Best Standalone` on two platforms under two uncontrollable cases (more predictable TickTok and more unpredictable Google Chrome), respectively. Our decentralized DQN-based approach outperforms all baselines for both cases in terms of both latency and energy for all three groups of DNNs. For the Tiktok case, DQN shows better performance because the DQN agent has more convincing history data that can predict more accurate action for the next step. The Google Chrome case empirically proves that our decentralized DQN-based approach is robust enough to handle DNNs co-run with an app that has unpredictable workloads.

Compare with a Heuristic-Based Adaptive Method. To confirm that simple heuristic-based adaptation is insufficient for the scheduling problem, we implement a heuristic method called "trial and set" (T&S). In T&S, each action performs X (50 in our experiments) inference runs and selects the action with the minimum observed online energy factor in subsequent inferences. We compare it with our DQN results on G2 in each of three settings: three DNNs in G2 co-run (see

Table 5: **Comparisons with simple Heuristic-based adaptation.** This table reports the average latency and energy factor for G2 in three co-run settings described in Figures 3, 6, and 7

Co-run Setting →		No other Apps		With Web Browser		With TikTok	
DNN Apps ↓	Metrics ↓	T&S (X=50)	DQN	T&S (X=50)	DQN	T&S (X=50)	DQN
YamNet	Time (ms)	3.690	4.250	127.120	20.482	53.400	23.050
	Energy Factor	0.461	0.502	15.890	3.392	4.429	2.707
SSD_MNv1	Time (ms)	8.260	6.170	191.740	8.248	60.670	30.860
	Energy Factor	1.161	0.734	24.351	1.284	8.037	3.890
WDSR	Time (ms)	126.290	6.750	56.320	5.042	142.000	114.220
	Energy Factor	15.701	0.714	8.599	0.729	18.034	3.948
Avg. Energy Factor		5.774	0.65	48.840	5.405	10.166	3.514

Figure 3), G2 co-run with a predictable App (see Figure 6), and G2 co-run with an unpredictable App (see Figure 7). Each execution of the DNN-based app conducts 250 inferences in total. Table 5 shows the results. The result shows that the simple adaptation by T&S is insufficient for fitting the continuously changing execution environments. The schedules it picks cause $3-10\times$ larger energy factors as well as frequently substantial slowdowns compared to the results by DQN.

7 Related Work

DNN workload under the stochastic runtime variance has been addressed in Autoscale [15]. The authors propose a lightweight scaling engine for DNN inference on a cloud-edge environment. It applies an offline-trained Q-table that observes DNN characteristics and runtime variance as states and selects execution targets as action. It is, however, only for single DNN execution.

Multi-tenancy DNNs [28] have been an active research topic in recent years. NestDNN [9] proposes an efficient scheduler that works with different model pruning ratios. The scheduling decision is guided by the proposed minimum total cost and minmax cost. The solution enhances the multi-DNN inference accuracy and video frame processing rate while reducing energy consumption. NeuOS [4] proposes a layer-by-layer multi-DNN scheduler. At each layer boundary, the system will determine the power configuration for each DNN based on their deadlines. Band [14] presents a model analyzer and scheduler to organize a multi-DNN workload on a heterogeneous platform. The model analyzer partitions multiple DNN models into several subgraphs and dynamically designates them with an eligible execution target. The scheduling decision is based on subgraph execution latency estimation using their tensor size and FLOPS.

Those solutions are however all centralized approaches, assuming the set of DNNs is fixed and there is a central runtime scheduler managing all the instances, making them inapplicable to the multi-instance DNN scheduling on open mobile systems.

8 Conclusion

This paper proposes the first-known decentralized application-level adaptive scheduler for multi-instance DNNs on open mobile devices. It builds on DQN, a reinforcement learning algorithm that actively explores and learns the relations between the states, actions, and rewards in a dynamic environment. The exploration uncovers a set of insights. It shows that it is possible for a decentralized scheduler to work effectively without direct knowledge of other apps in multi-instance DNN scheduling. The DQN-based scheduling works well regardless of the differences among underlying systems, hardware, and execution settings. The algorithm is shown to converge quickly and effective in improving co-run efficiency. As an application-level solution, it is ready to be immediately adopted across various mobile systems.

UnFaaSener: Latency and Cost Aware Offloading of Functions from Serverless Platforms

Ghazal Sadeghian Mohamed Elsakhawy Mohanna Shahrad[†] Joe Hattori[‡] Mohammad Shahrad

University of British Columbia *McGill University*[†] *University of Tokyo*[‡]

Abstract

We present UnFaaSener, a lightweight framework that enables serverless users to reduce their bills by harvesting non-serverless compute resources such as their VMs, on-premise servers, or personal computers. UnFaaSener is not a new serverless platform, nor does it require any support from today's production serverless platforms. It uses existing pub/sub services as the glue between the serverless application and offloading hosts. UnFaaSener's asynchronous scheduler takes into consideration the projected resource availability of the offloading hosts, various latency and cost components of serverless versus offloaded execution, the structure of the serverless application, and the developer's QoS expectations to find the most optimal offloading decisions. These decisions are then stored to be retrieved and propagated through the execution flow of the serverless application. The system supports partial offloading at the resolution of each function and utilizes several design choices to establish confidence and adaptiveness. We evaluate the effectiveness of UnFaaSener for serverless applications with various structures. UnFaaSener was able to deliver cost savings of up to 89.8% based on the invocation pattern and the structure of the application, when we limited the offloading cap to 90% in our experiments.

1 Introduction

Serverless computing [54] allows developers to quickly build scalable, event-driven applications and pay for only what they use. It also removes the provisioning and maintenance burdens of the traditional cloud system. Developers have identified and embraced this game-changing cloud paradigm. According to Datadog's June 2022 analysis of cloud user telemetry [33], more than 70% of organizations using AWS and over 50% of Azure and Google Cloud users have adopted serverless offerings. A year prior, the serverless adoption numbers for these three leading cloud providers were just above 50%, 35%, and 20%, respectively [32].

In addition to increased adoption, serverless applications are also becoming increasingly complex. In 2019, the majority of serverless applications were composed of just one function and 80% had three or fewer functions [72]. Today, complex serverless workflows are no more rare. A recent study of open-source serverless projects has identified 31% of studied applications to have workflow structures [35]. From 2019 to 2022 the popularity of serverless DAGs has grown by 6× at Azure [59]. The increased complexity of serverless applications can be attributed to the maturation of serverless offerings and the increased proficiency of developers.

With a developer-focused perspective, this work is motivated by a relatively simple question: *why should serverless functions be bound to be executed within the serverless platforms?* If serverless functions are designed to be primarily stateless, the serverless model disaggregates storage from compute, the serverless isolation/virtualization mechanisms are lightweight [17], and the model is event-driven, it begs asking whether offloading execution of serverless functions off the serverless platform can make economic sense.

Many organizations and development teams use serverless offerings in conjunction with other cloud service types, such as VMs or microservices' containers [24, 36]. Reports from different cloud providers indicate that the majority of VMs in public clouds are heavily under-utilized [30, 44]. Despite low VM utilization, public cloud providers have been able to improve data center efficiency using advanced resource oversubscription to co-locate many underutilized VMs with predictable guarantees [30, 48, 55], or through dynamic capacity harvesting from those underutilized VMs to sell to others [39, 74, 80]. Such strategies help the provider operate at higher efficiency, but cloud users still have to pay for their full static allocations. If a team is already paying an hourly rate for renting a VM and that VM is not fully utilized, it could be harnessed to run their own serverless functions. Additionally, an organization may have on-premise computational capacity that already incurs capital and operating costs, which can similarly be leveraged to execute migratable serverless functions.

The merits of the proposed serverless function offloading are clear, but determining when to migrate functions depends on various factors. For example, offloading one or more func-

tions in a latency-sensitive chain of short functions could lead to QoS violations due to added network latency. In contrast, for a serverless DAG with imbalanced branches, offloading those executions off the critical path may be worthwhile if the cost of data movement and added latency are acceptable. While these examples focus on latency, some serverless applications, such as nightly builds, may have little to no latency requirements, making offloading more viable. Ultimately, how and when functions of a serverless application can be offloaded depends on a long list of factors. Serverless providers do not have an incentive to enable such functionality as it would negatively impact their profitability, and developers would rather not deal with the complexity as it goes against the serverless philosophy of freeing them from provisioning concerns. We believe that there is real value to be delivered in this junction by providing developers with a system that adaptively and transparently offloads their serverless functions to their own alternative execution hosts.

We design and build UnFaaSener, **the first holistic serverless offloading system without any change to today's serverless platforms**. This system performs adaptive offloading of a developer's functions to their own alternative hosts. UnFaaSener does this by dynamically considering latency and cost implications of offloading as well as resource availability predictions on hosts against goals conveyed by the developer (e.g., saving maximum cost, or respecting a certain latency QoS). We build UnFaaSener to use existing services on a popular serverless platform, and run various serverless applications on it. It is available at https://github.com/ubc-cirrus-lab/unfaasener.

2 Background

2.1 The Status Quo

Execution of serverless functions. Your serverless functions run within the serverless platform you operate on. Depending on the provider, your functions might be allocated to run in lightweight VMs, containers, or other isolation abstractions that themselves use dedicated allocations or internally harvested resources [86]. Interestingly, your functions will not be allocated to any underutilized VMs that you already pay for. If you have computational resources on a different cloud or on-premise, those are not used to host your functions either. If a developer decides to tap into these capacities to reduce their serverless bill, they need to build their applications differently and effectively do resource provisioning. This defeats the purpose of using serverless in the first place.

Offloading to and from serverless. Serverless's unparalleled horizontal scaling and pay-per-use pricing model enables cheap acceleration of bursty, massively parallel workloads. Researchers have developed general purpose (e.g., gg [37]) and domain-specific frameworks (e.g., ExCamera [38] and NumPyWren [73]) for this purpose. Offloading to serverless is popular for edge [26, 52, 82] and network function virtualization (NFV) [16, 70, 85] applications. Researchers have also proposed offloading from serverless to the edge [41].

The idea of offloading from VMs to serverless has also been proposed. Most of these works utilize serverless as a backup when scaling out VMs [43, 47, 63, 84, 87], however, some others simultaneously offload a small portion of traffic to serverless [67]. As VMs are the primary deployment in these works, the benefits of serverless functions, such as high scalability can not be fully exploited, and the scope of the applications is limited to the capacity of the VMs. To fully exploit serverless advantages, researchers have suggested hybrid VM-serverless deployment of applications [56, 75]. In these systems, however, a secondary custom scheduler is added before the serverless scheduler, which limits the scalability of the system and comes with security concerns.

The systems mentioned earlier are not designed for resource harvesting. However, a number of works have proposed modifying the serverless platform to offload serverless on the harvested resources [78, 83, 86]. We identify this as a limitation, as one cannot expect serverless providers to change their platforms and reduce their profitability. Besides that, the offloading will be limited to hosts located only within the scope of the platform scheduler (same cluster, region, or zone of the same cloud, depending on the provider's architecture). UnFaaSener is designed to work with existing serverless platforms, without requiring any change. By harvesting the idle resources of any host within or outside the cloud hosting serverless functions, UnFaaSener opportunistically achieves cost reductions for a wide range of general-purpose applications, from single functions to applications in a form of complex DAGs (consisting of multiple branches, merging points, and dynamic fan-out patterns).

2.2 The Serverless Cost Model

Understanding the serverless cost model is imperative for building a mental model of how UnFaaSener offers cost savings. We provide a summary here and refer the reader to related work for more detailed descriptions [57].

Capacity cost: Developers are required to set the memory size of their serverless functions. This indirectly sets the CPU share, too, as the CPU-to-memory allocation ratio is fixed in current serverless systems [21]. Multiplying the execution time by the configured memory size determines the GB-seconds usage. There is a cost charged per GB-seconds; e.g., $\$1.67 \times 10^{-5}$ for AWS Lambda on x86 [3]. Some providers enforce a minimum execution time per invocation (e.g., 100 ms for Azure Functions). Execution times are also rounded-up; e.g., to the nearest 1 ms for Azure Functions and to the nearest 100 ms for Google Cloud Functions.

Invocation cost: Each invocation also incurs a cost; e.g., $0.2 and $0.4 per million requests for Azure Functions and Google Cloud Functions, respectively.

Free tier: Typically, serverless providers offer monthly free tiers: AWS, Azure, and Google Cloud provide 400,000 GB-

s per month. The free tier also includes no invocation cost for the first 1 million requests in AWS Lambda and Azure functions, and the first 2 million for Google Cloud Functions.

Saving cost by offloading: If a developer's serverless usage is low enough to fit within the monthly free tier offered by cloud providers, they should not run UnFaaSener. Beyond that, offloading functions to alternative hosts will eliminate the capacity and invocation costs associated with it.

3 UnFaaSener Design Challenges

Let us decompose the sub-problems that need to be solved to enable adaptive offloading of serverless functions to achieve maximum cost reduction with minimum impact on latency, and with no provider support:

1. ***Enabling flexible offloading*** (§4): The very first requirement is to enable partial offloading of requests for each function of a serverless application to arbitrary hosts. The solution should support various serverless applications, ranging from those with a single function to complex workflows (typically DAGs).
2. ***Asynchronous Scheduler*** (§5): To deliver a practical solution, UnFaaSener's design should satisfy the following:

(a) The system should work with no scheduling or load balancing support from the provider.

(b) As offloading is opportunistic, serverless execution should be the default case to ensure high scalability and low latency for the common case.

(c) The serverless platform should remain the end-point for the incoming traffic to the application to enforce network-based access control rules.

(d) Given that invocation patterns can be sporadic [72], continuously performing scheduling tasks on a dedicated VM/container is not an option, as the incurred cost can easily exceed the cost savings of function offloading.

We need a scheduling mechanism that resides outside the serverless platform, is activated when necessary, invokes the solver if needed for new decisions, and reflects the offloading decisions to be used by functions.

3. ***Determining optimal offloading*** (§6): Optimal offloading decisions depend on various factors such as application structure, function resource requirements, execution times, invocation patterns, host resource availability, communication latencies and costs. Additionally, the diverse range of developers using public clouds and the variety of serverless applications lead to different notions of optimality. Optimizing for latency vs. cost, mean vs. tail, etc., should all be expressible. A solver is required to take these inputs and determine the host(s) for function execution.
4. ***Monitoring and prediction of hosts' resource availabilities*** (§7.1, §7.2): Considering the delays associated with the distributed nature of UnFaaSener's multi-node, or even multi-cloud deployment, each host's resource availability should be forecasted with a high degree of confidence.

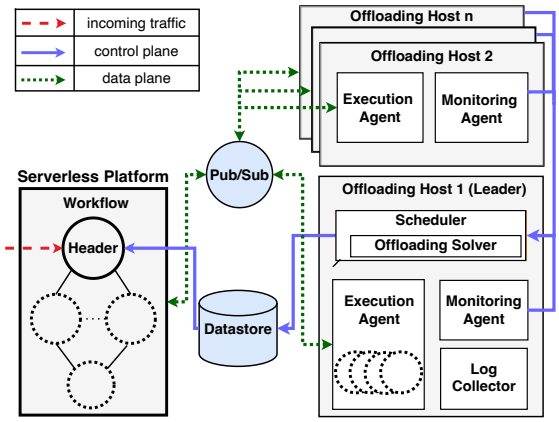

Figure 1: UnFaaSener's system diagram.

5. ***Managing execution-related tasks on the host side*** (§7.3): Each host is responsible for various mechanical tasks, such as pulling the function on a cold start, setting up an appropriate execution environment, enforcing resource limits, executing the function, implementing keep-alive policies, queuing incoming requests, and invoking the next function on the appropriate host. While this aspect of the system may not be particularly novel in terms of research, it is crucial for the overall performance of the system.

Figure 1 provides an overview of UnFaaSener's different system components. In the next sections, we describe how the design challenges stated earlier shaped our design decisions. In total, UnFaaSener includes ∼6.3 K-SLOC: 5.4K lines of Python, 0.8K lines of C++, and less than 100 lines of Shell.

4 Enabling Flexible Offloading

There is no universal approach to build and deploy a serverless application with more than one function. One can either use different messaging systems (e.g., AWS SNS), or rely on higher level abstractions delivered by services such as AWS Step Functions [5] and Google Workflows [10]. For us, it is critical to compose the application in a way that facilitates dynamically offloading arbitrary functions to user-specified hosts. Additionally, complexities of offloading functions to varying end-points, supporting dynamic DAG structures, or rate limiting should be kept hidden from the developers as much as possible. In this section, we explain how UnFaaSener achieves these goals. We motivate and explain design decisions that let us inject offloading decisions, propagate future decisions, and merge branches for DAGs. Throughout the section, we will use a simple example (shown in Figure 2) to demonstrate each implementation aspect.

Pub/Sub as the glue. Using a topic-based publisher/subscriber (pub/sub) messaging pattern enables us to control where each function has to be executed without changing

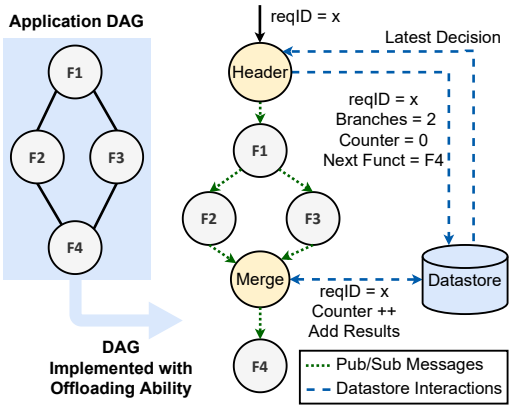

Figure 2: DAG conversion to support dynamic offloading.

the serverless platform. To do so, UnFaaSener first assigns a unique pub/sub topic to each offloading host (e.g., user's VMs) as a unique subscriber. Pub/sub's flexibility enables adding, removing, or hot-swapping hosts. This means an offloading host can be substituted by subscribing to the same topic without modifying pub/sub topics. Second, a few lines of code are inserted at the end of any non-terminal function to enable publishing to serverless or to any specific offloading host. We call this the *routing epilogue*. Finally, the routing decision for each function needs to be delivered to its parent function's routing epilogue. To do this, UnFaaSener adds a lightweight header function as the entry point of the DAG. Its role is to communicate the routing decisions made by the asynchronous scheduler to all functions by piggybacking the decisions to the incoming invocation.

The availability of pub/sub services across major clouds (e.g., AWS SNS and Google Pub/Sub) and strong support for it in various programming languages was a major driving factor for us to facilitate portability of UnFaaSener. Furthermore, the use of pub/sub provides a degree of fault tolerance by requiring subscriber acknowledgment. If no acknowledgment is received within a set timeframe, pub/sub automatically tries to resend the message. We evaluate pub/sub latency in §9.8.

Routing epilogue. The routing epilogue is a general code snippet added to the end of all non-terminal functions in the application. The code snippet in Figure 3 shows the routing epilogue for a Python function. The routing epilogue adds only a conditional statement in the critical path of execution, resulting in negligible added latency compared to the regular call to the subsequent function. Based on the routing character sent to this function by the header function, the role of this code piece is to route the invocation to a serverless endpoint or to any offloading host. The former is encoded by a `"0"` character, and the latter is determined by the host ID embedded in the character. This works as UnFaaSener names pub/sub topics for offloading hosts to follow the same convention: e.g., `hostTopic1`, `hostTopic2`, etc.

Header function. As illustrated in Figure 2, UnFaaSener adds a header function to the head of the DAG. The role of the header is to generate the routing decisions to be used by the

```
...
if (routing == "0"):    # run next function in
     serverless
    topic = publisher.topic_path(projectID, "
    F3")
    publish_future = publisher.publish(topic,
    data=message, reqID=reqID, routing=
    routingData.encode('utf-8'))
    publish_future.result()
else:   # offload next function to a host
    hostNumber = ord(routing) - 64
    hostTopic = "hostTopic" + str(hostNumber)
    topic = publisher.topic_path(projectID,
    hostTopic)
    publish_future = publisher.publish(topic,
    data=message, reqID=reqID, invokedFunction
    ="F3",routing=routingData.encode('utf-8'))
    publish_future.result()
```

Figure 3: The routing epilogue appended to a function.

routing epilogue of non-terminal functions. It also takes care of creating entities for the merging points, as described next.

Merge function. In a generic serverless DAG, a function may have several predecessors. A challenge is dealing with predecessors finishing at different times. Since serverless functions are primarily stateless, we need to persist information sent by predecessors. One way to solve this is using stateful functions, such as AWS Step Functions [5] and Azure Durable Functions [22], to join on predecessors. To provide a merging mechanism that works for predecessors executed on different hosts UnFaaSener uses a database; specifically, a NoSQL database (Google Datastore) in our current implementation.

As shown in Figure 2, the header function creates a new entity (data object) for each merging point in the Datastore by passing the metadata containing the request ID, the number of branches, and the subsequent function to be invoked after that merging point. The merge function, which is added between the predecessors and the child function, is invoked by each predecessor. It keeps track of the content and number of responses from the predecessors using the Datastore entity. It determines the completion of the last predecessor by comparing the number of times it was invoked by the same request ID to the predecessor count stored for it by the header function in Datastore. The merge function then triggers the next function and removes that entity from the Datastore.

DAG description. The developer provides UnFaaSener with a DAG description JSON file, which defines the structure of the DAG. The code snippet in §A.2 shows the workflow description for one of our benchmark applications.

5 Asynchronous Scheduler

In this section, we describe UnFaaSener's scheduler and how we address the challenges stated earlier in §3.

An asynchronous scheduler off the critical path. To address challenges 2(a), 2(b), and 2(c), we design UnFaaSener's scheduler to only activate when making offloading decisions.

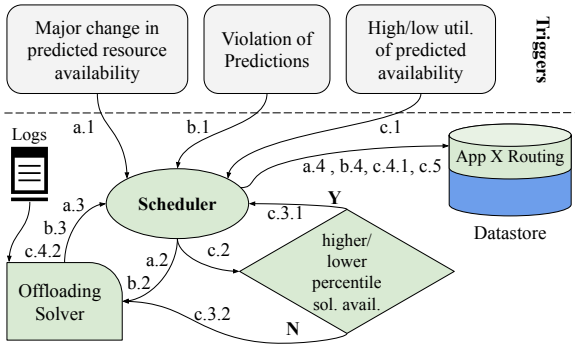

Figure 4: Different events triggering the asynchronous scheduler alongside the decision-making flow for each.

New offloading decisions do not need to be determined for every single invocation, and the header function (§4) can rely on the most recent decisions available in the Datastore.

Run in an offloading host. To run UnFaaSener, one or more offloading hosts are needed. Otherwise, there is no offloading and subsequently no cost reduction. Now, if there are already offloading host(s) available, we can leverage them to host the asynchronous scheduler as well. This addresses challenge 2(d) stated in §3. When there are more than one offloading hosts, the developer can tag one of them as the leader at the setup stage. If the leader host is not specified by the developer or if the leader fails, we use the Raft [64] consensus algorithm to elect the next leader in the order of the highest average available resources since deployment.

Triggering rules. The offloading solver, which will be presented in the next section, determines the most optimal offloading decisions theoretically. However, serverless workloads can be highly dynamic. The request inter-arrival times are shown to be highly variable [72], function execution times for certain applications can be heavily input-dependent [62], and the relatively short median execution time for serverless functions [32, 72] amplifies the relative performance jitter in the presence of third-party API calls. The resource utilization of offloading hosts can change frequently, as well. To prevent the solver from being constantly re-invoked, we pick minimal triggering rules and rely on pre-solved scenarios. Figure 4 shows how system events trigger the scheduler.

A common case requiring new offloading decisions is variations in the invocation rate. UnFaaSener's Log Collector (§8) maintains an updated view of each application's invocation rate distribution on the leader host. Whenever the offloading solver is run, it solves the same problem for different percentiles of the invocation rate distribution: 25^{th}, 50^{th}, 75^{th}, and 95^{th} percentiles. The scheduler uses the 50^{th} percentile solutions for determining offloading decisions. Later, if the utilization of predicted available resources was too high (85%) or too low (20%), the scheduler can quickly pick the solution for a higher or lower invocation percentile, respectively. We found this simple mechanism effective for rapid flow control without re-running the solver. In the high load case, if the offloading decisions assuming the 95^{th} percentile rate is still not low enough, the solver is triggered.

6 Offloading Solver

In §3, we discussed the offloading solver that sits at the core of UnFaaSener and is responsible for determining which functions to offload, to where, and to what degree. At a high level, the solver is a non-linear optimizer that considers execution times, latencies, costs, resource demands, and availabilities to determine the optimal offloading decisions. We describe various design choices for UnFaaSener's solver in this section.

Supporting different optimization goals: Any optimization has an objective function. As one can imagine, the wide range of service-level objectives (SLOs) in public cloud offerings and the broad spectrum of serverless applications (e.g., from latency-sensitive speech recognition [46] to cost-oriented nightly builds [58, 60]) prevents using a one-size-fits-all objective function. As a result, we built UnFaaSener's solver to support two different modes of operation: the **cost mode** and the **latency mode**. In the cost mode, the goal is to get maximum cost reduction without considering any constraints on the added latency. In the latency mode, the solver aims to optimize for maximum cost reduction in the face of a specific tolerance window for the added latency. By default, the tolerance window is set to the median latency of the workflow (the start of the first function to the end of the last function) when executed fully on serverless. This value is easily modifiable by the user, and we evaluate the impact of changing it in §9.3. Users have the flexibility to modify existing optimization modes or introduce their own.

Considering locality: The solver can be re-invoked based on changes in the resource availability of the hosts, change in traffic patterns, etc. Each invocation of the solver should not result in vastly different offloading decisions. Instead, the solver should consider the current offloading host(s) of each function and minimize migrations as much as possible. This is because offloading a function to a new host would incur additional latency to pull the code and build a container image. The solver has a locality parameter, α, to control the degree of emphasis placed on the locality.

Robustness to performance variations: The solver consumes the data gathered by the Log Collector (§8) to determine the most optimal offloading. These logs contain observations for execution times on the serverless platform and various hosts, as well as communication latencies. Execution time for serverless functions has been shown to be highly variable [42, 66]. The latency of pub/sub, which we use to build our flexible offloading framework, can be highly variable too (we evaluate this in §9.8). In this context, using only the mean or median of limited observations can potentially misguide the solver, specially in the latency mode, where a latency QoS should be respected. Thus, the solver first checks the similarity between serverless and host execution time distributions using the Kolmogorov–Smirnov (KS) test, a non-parametric

method that makes no assumptions about the normality of the data distributions. If the KS test reveals distinct distributions for more than 70% of offloaded workflow functions, the solver uses mean statistics. However, if the distributions are not distinguishable for more than 30% of offloaded functions, the solver solves for the following three scenarios using non-parametric confidence intervals (95% confidence level [61]) and reports the average of three solutions as the final answer:

1. **Best case:** This is to model the situation where everything goes well for offloading to hosts. The lower confidence interval bound for each host's execution records, and upper confidence interval bound for serverless execution records are used by the solver.
2. **Worst case:** Here, confidence intervals are chosen so that we account for the low-end cost reduction and high-end added latency for offloading each function. Thus, the choices for confidence interval bounds are opposite to the best case mode.
3. **Mean case:** Here, the mean of system logs for each unique function-host pair is used.

The total offloading decision percentage for each function is limited to 90%, whether using a single or triple solver. Keeping some traffic on the serverless platform allows for 1) continuously observing execution times and latencies in spite of a varying workload, and 2) keeping some serverless function images warm in case the host(s) becomes unavailable.

Multi-host offloading: When multiple hosts are available, maximum cost reduction may require offloading the same function to more than one host. In such a case, each host will be in charge of a portion of the incoming traffic to that function. Here, the solver considers the resource availability of multiple hosts and recommends partial (as opposed to binary) offloading decisions.

Optimization formulation: We have reviewed various design aspects of the solver. Let us go over the formulation of the optimization problem, shown in Algorithm 1. The latency mode optimization has an additional constraint (Constraint 4) for comparing the added latency with the latency tolerance.

Intuitively, the solver aims to find offloading decisions that lead to maximum cost reduction, without violating resource or QoS constraints. Offloading decisions are partial (as opposed to binary) to ensure delivering cost savings even with limited host capacity. Cost is defined as the serverless execution cost, which the solver can try to minimize; unlike the host cost, which is already paid for. The predicted serverless cost is based on the invocation rate and execution time history, as well as the capacity required by the function. Therefore, the solver will prioritize offloading the function with higher resource usage, higher execution time, or higher invocation rate, as it will result in a higher cost reduction.

Implementation: We implemented the solver in Python to leverage its rich optimization and data manipulation packages. We used the GEKKO [19] package for mixed integer nonlinear programming (MINLP), used the CriticalPath [76] package for slack analysis, and used the Pandas [1] package for storing logs and efficiently performing complex statistical operations.

Algorithm 1 Optimization algorithm used by the Solver.

α: Locality Weight
μ: Adjusted Average CPU Utilization
$d^t_{n,i}$: Func_i offloading percent on host_n at time_t
rps_i: Request per second for Func_i
$\text{ExecTime}_{n,i}$: Execution time of Func_i on host_n
Scenarios: All offloading scenarios based on partial decisions.
host_n **or** serverless $\leftarrow$ scenario$[i]$ ▷ The assigned placement for Func_i in a scenario.
Directed Paths: All paths starting from an initial node and ending at a terminal node in a DAG
$\text{CommLatency}_{\text{scenario}[m],\text{scenario}[n]}$: Communication latency between Func_m on scenario$[m]$ and Func_n on scenario$[n]$.
$\text{Slack}_{\text{path}} = \text{Duration}_{\text{critical path}} - \text{Duration}_{\text{path}}$
$\text{ExecLatency}_{n,i} = \text{ExecTime}_{n,i} - \text{ServerlessExec}_i$ ▷ Added latency by executing Func_i on host_n versus serverless execution.
procedure CALCCOST($d^t_{n,i}$)
  Cost = 0 ▷ Assumes hosts with fixed cost regardless of utilization, e.g., a VM billed at an hourly rate.
  for $\text{Func}_i \in$ functions **do**
    $\text{offloading}_i = 0$
    for $n \in$ offloadingHosts **do**
      $\text{offloading}_i \leftarrow \text{offloading}_i + \frac{d^t_{n,i}}{100}$
      $\text{Cost} \leftarrow \text{Cost} + \alpha \times \left|\min(d^t_{n,i}, 1) - \min(d_{n,i}{}^{t-1}, 1)\right|$
    $\text{Cost} \leftarrow \text{Cost} + (1-\alpha) \times \text{cost}_{\text{Func}_i} \times \text{rps}_i \times (0.9 - \text{offloading}_i)$
Constraint 1: $\sum_{\text{Func}_i \in functions} \mu \times \text{ExecTime}_{n,i} \times \text{rps}_i \times \frac{d^t_{n,i}}{100} \leq \text{AvailableCPU}_{\text{host}_n}$
Constraint 2: $\sum_{\text{Func}_i \in functions} \text{Mem}_i \times \text{ExecTime}_{n,i} \times \text{rps}_i \times \frac{d^t_{n,i}}{100} \leq \text{AvailableMem}_{\text{host}_n}$
Constraint 3: $\sum_{n \in \text{offloading hosts}} d^t_{n,i} \leq 90$
Constraint 4: (only for the latency mode)
for scenario $\in$ Scenarios **do**
  for path $\in$ Directed Paths **do**
    latency = 0
    for $\text{Func}_i \in$ path **do**
      if scenario$[i]$!= serverless **then**
        $\text{host}_n \leftarrow$ scenario$[i]$
        $\text{latency} \leftarrow \text{latency} + \min(d^t_{n,i}, 1) \times \text{ExecLatency}_{n,i}$
      for $\text{Func}_j \in$path **and** $\text{Func}_j \in$predecessors$_i$ **do**
        $\text{latency} \leftarrow \text{latency} + \text{CommLatency}_{\text{scenario}[i],\text{scenario}[j]}$
    $\text{latency} \leq \text{Slack}_{path} + \text{LatencyTolerance}$
Decision: $d^{*t}_{n,i}$ (OptimalValue) $\leftarrow \underset{d^t_{n,i}}{\text{argmin}}$ CALCCOST($d^t_{n,i}$)

7 Host Agents

Let us explain UnFaaSener's different host agents.

7.1 Resource Monitor Agent

Implemented in C++, this lightweight agent tracks the CPU and memory usage at the host. It distinguishes between UnFaaSener-related processes (including containers running offloaded functions) and host processes to create differentiated scheduler triggers, described in §5. The monitoring period is 100 ms in our implementation

7.2 Resource Predictor Agent

The predictor agent, also written in C++, is tightly coupled with the monitor agent. It periodically (every 1 s in our implementation) predicts the maximum resource utilization in the next time window. UnFaaSener's effectiveness in cost reduction is as good as the accuracy of the predictions made by this agent. If predictions are too conservative, the host's available capacity will not be well utilized, limiting cost reductions. Conversely, aggressive predictions risk causing resource contention between offloaded functions and host processes. We formulate this trade-off using the following metrics:

1. Reclamation Efficiency (RE): *RE* represents how much of the available resources could be reclaimed based on the predicted usage. If predictions always match the peak resource usage, *RE* would be 100%.
2. Violation Rate (V): If the predicted usage in a window is lower than the materialized peak usage, the *RE* is capped at 100% and a prediction violation event is logged. *V* denotes the percentage of predictions leading to a violation.

An ideal predictor would yield $RE = 100\%$ and $V = 0\%$. For each resource dimension (e.g., CPU and memory), the objective function combining the two looks like this:

$$PredictionScore = w \times RE + (1-w) \times (100 - V) \quad (1)$$

Here, w denotes the resource reclamation weight. By default, UnFaaSener gives equal importance to reclamation efficiency maximization and violation minimization ($w = 0.5$) as it does not make any assumptions about the host workloads. Further knowledge about the workload or user's tolerance of slowdown for it can change this. We do not explore this angle in this work and only use $w = 0.5$. We evaluate the prediction quality and performance of various prediction policies in §9.9 and derive the one best suited to UnFaaSener.

7.3 Execution Agent

The execution agent subscribes to the pub/sub topic of its host and is notified on incoming invocations. If that function's code is not present on the host, the execution agent proceeds to download the function's code and metadata (runtime and memory limit) with a call to the Google Cloud Functions' API. Once the function's code and metadata are retrieved, a new docker container image is built using the skeleton container for the specified runtime (e.g., Python 3.10). We use Docker Hub [8] to host skeleton images. The agent leverages Docker's build utility to generate a local image of the runtime that contains the function's code and dependencies. As the image generation step is computationally expensive, the generated images are kept on the host for future use. Prior work has shown that even employing simple keep-alive policies can notably reduce cold starts [40, 69, 72]. The execution agent stops an idle container when the time since the end of the last execution exceeds the keep-alive window (10 minutes), or when capacity is needed to execute a different function.

UnFaaSener's execution agent supports concurrent execution of multiple instances of the same or different functions. However, the agent queues incoming requests on the host if the predicted resource availability is more than 90% utilized, or if the current degree of concurrency is at or beyond the concurrency limit. The execution agent has a feedback mechanism to set the concurrency limit dynamically based on observed CPU utilization and performance degradation of offloaded functions. It starts with assuming one CPU thread per function, the concurrency limit is thus set to the number of cores available in the host. Over time, the agent has access to average container CPU utilization reported by the monitoring agent. It also has access to execution time trends for functions allowing it to measure any slowdown. Combining the two, it calculates the adjusted average CPU utilization as:

$$\mu = \min(1, \text{AvgFuncCPUUtil} + 0.03 \times (e^{\Delta \text{ExecTime}} - 1)) \quad (2)$$

From this, the concurrency limit is calculated as $\frac{\text{Core Count}}{\mu}$. The insight for this asymmetric feedback mechanism is as follows: if no performance degradation is sensed, μ directly reflects the average utilization of docker containers hosting offloaded functions. However, with slight degradation, μ is increased super linearly to reduce the concurrency limit. More details on this process is provided in §A.1.

UnFaaSener's approach of using pre-solved offloading decisions accelerates the scheduling path. This approach also makes the scheduler early binding [50]. The distributed nature of the system introduces some delay from when a burst hits to the time that the host scheduler updates the offloading decisions. This can create a request build-up on the hosts' queues. To prevent QoS violations, the execution agent monitors requests in the queue and if their wait time exceeds a specified window (2 s by default), that request and all its descendant function calls are redirected to the serverless platform.

In §4 we described how using the subscription retry policy of pub/sub can provide a degree of fault tolerance. If no acknowledgment is received within the specified number of retries (default 5), the message is redirected to the subscriber's *dead-letter* topic, provided by pub/sub. We have designated the topic of $host_{(i+1)\%num_{hosts}}$ as the *dead-letter* topic for $host_i$. Additionally, to prevent duplicate execution on the host side, we have made use of the *exactly-once delivery* feature. However, our current implementation lacks complete handling of a host failure scenario. Although no further offloading occurs to the failed host, any invocations previously acknowledged

and queued on that host will be lost.

Offloaded function execution logs are stored locally and periodically published to a Datastore entity every one thousand logs for backup. This enables a smooth transition to a new leader host in case of primary host failure.

8 Log Collection

The log collector runs periodically (every 1 minute in our implementation) on the leader host, collecting execution and latency logs for serverless as well as host executions logs. The logs for serverless executions are collected using the Google Cloud CLI (gcloud [27]). Aside from execution time information, serverless logs contain timestamps for the invocation of the header function that runs exclusively on serverless. These timestamps are used to calculate the invocation rate distribution for the workflow, which is used by the solver.

Host execution logs are needed by the solver to enforce the latency tolerance QoS (discussed in §6). As mentioned in §7.3, the execution agent writes execution records (start time, end time, invocation ID, and function ID) to local log caches, and asynchronously backs them up on the execution log Datastore entity. In the event of leader failure, the log collector retrieves execution records from the Datastore entity and stores them in a pandas dataframe, similar to how local log caches store host logs. This stored data is readily accessible for the offloading solver upon activation. To accelerate statistical operations, the dataframe stores a maximum of N most recent data points per function-host, with $N = 50$ yielding favorable results in our experiments.

9 Evaluation

9.1 Setup, Methodology, and Benchmarks

UnFaaSener has many components and serverless settings are complex. We try to carefully distill various design and performance aspects of UnFaaSener without confusing ourselves or the reader with unnecessary complexity. Each experiment conveys specific points to help readers build a mental model. The majority of our evaluations are from real deployment, but we also conduct some simulations to stress certain parts of the system with more usage scenarios. Any reported cost normalization is based on the scenario where all the functions of the workflow run on serverless.

9.1.1 Benchmark Applications

We used five real-world serverless applications to evaluate UnFaaSener; 1) DNA Visualization [28], a script that performs visualization of the input DNA sequence file, 2) Image Processing [51], an application that performs a sequence of operations on input images, 3) Text2Speech Censoring [34] turns short text segments into speech and censors any profanities within the text segment, 4) Regression Tuning [12], which solves a regression problem using Keras [25], and 5) Video Analytics [13], an application that performs object recognition on images generated from a video stream. Table 1 shows the diverse range of structures covered by these applications. The dynamic fanout column in the table captures whether the application has a sub-graph with parametrized fanout.

Benchmark	Branch	Dyn. Fanout	DAG Structure
DNA Visualization	✗	✗	
Image Processing	✗	✗	Text2Speech	✓	✗	Regression Tuning	✓	✗	
Video Analytics	✗	✓	

Table 1: Benchmark applications were chosen to represent various structures present in today's serverless.

9.1.2 Workload Invocation and Traffic

We use FaaSProfiler [9, 71], a serverless testing tool used by prior work [50, 66, 72], to invoke traffic patterns precisely. Depending on the nature of the experiment, we use different invocation patterns. For evaluating high-level trade-offs or assessing the extremes, using a uniform invocation rate suffices. For those with co-location scenarios, we use the 2021 Azure Functions Invocation Trace [6, 86].

9.1.3 Ensuring fair comparisons

We take the following steps to make sure that our reported gains are not inflated: 1) All cost numbers include the cost of functions added by our system; 2) all latency numbers are end-to-end and include the latency overhead introduced by UnFaaSener; 3) each function is tuned [2] for the most cost-optimal memory configuration. By making the baseline serverless functions as cost-efficient as it gets, we ensure that UnFaaSener's cost savings are not an artifact of comparing to bloated functions; 4) when comparing UnFaaSener to alternative solutions (§9.5), we ensure that each implementation is minimal and tuned to the specific offering; 5) we invoke each application with a set of random inputs; 6) we ignore the bootstrapping phase measurements, as UnFaaSener tends to offload more during this phase, leading to more cost savings.

9.2 Latency Mode vs. Cost Mode

Here, we use a VM with 4 vCPUs and 16 GB of memory to demonstrate how even a relatively small host can be used by UnFaaSener to offer cost savings. Figure 5 shows the normalized execution cost and end-to-end latency values associated with running three applications in latency and cost modes. For each application, we chose the invocation frequencies such that the maximum offloading (with a low rate) and minimum offloading (with a high enough rate) are stressed.

As expected, using the cost mode leads to more savings than the latency mode. It comes at the expense of potentially increased latency since the solver considers no latency constraint when making offloading decisions in the cost mode.

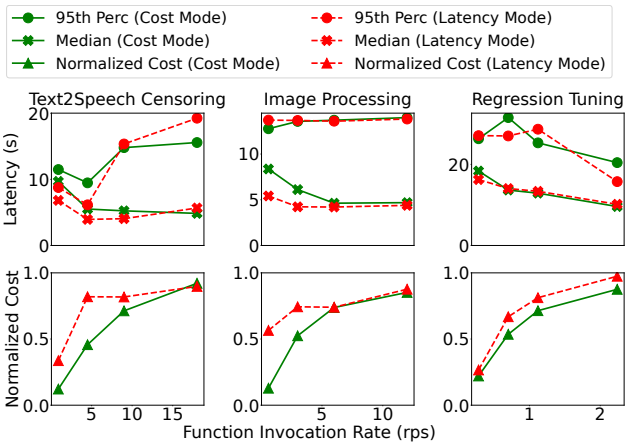

Figure 5: UnFaaSener's cost savings and end-to-end latency in two optimization modes.

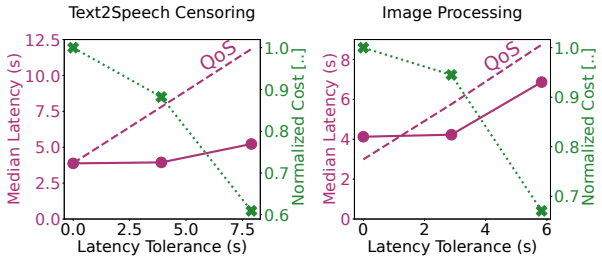

Figure 6: Increasing the latency tolerance in the latency mode leads to more offloading, and thus more savings.

Even in the latency mode, UnFaaSener can reduce the cost, but is limited by the default latency tolerance. As the invocation rates increase, the cost savings achieved by UnFaaSener decrease. This is because UnFaaSener is designed to harvest the unused computing resources of already-allocated hosts. Therefore, when the invocation rates are high, the system is fully utilizing the resources, leaving little or no unused capacity to be harvested.

Later in §9.3, we show how changing the latency tolerance affects the results in the latency mode.

We measured the added latency of the header function to be ∼50ms. The end-to-end latency values include this overhead.

9.3 Latency Mode and Tolerance Window

In the latency mode, the solver tries respecting a tolerance on the added latency when making offloading decisions. Figure 6 shows the effect of changing the tolerance window on the cost (green cross markers) and median latency (purple circle markers). We studied its effect on two of our benchmarks: Image Processing and Text2Speech Censoring. The tolerance windows are set to zero, the median, and twice the median latency of each workflow when solely run on the serverless platform (baseline latency). The QoS (baseline + tolerance) for these applications is depicted with purple dashed lines.

Overall, UnFaaSener manages to offload in a controlled fashion and complies with the set tolerance window; except for when latency tolerance of 0 is set for Image Processing. Image Processing is a chain and thus every offloading is on the critical path (see Table 1). This is unlike Text2Speech that has asymmetric branches, because of which it enjoys higher cost reductions and a higher safety margin from the QoS line.

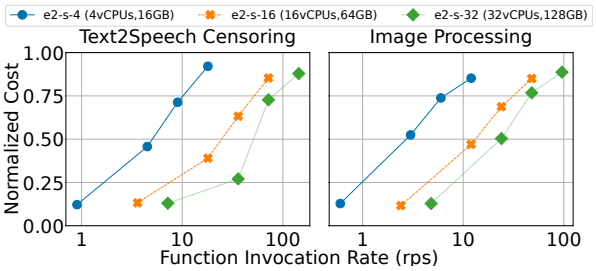

Figure 7: UnFaaSener leverages larger hosts effectively to increase offloading (reduce cost).

9.4 Impact of Host Size

The results presented so far were gathered on a relatively small host. This was to show that even with a small host, or equivalently, with a small leftover capacity, UnFaaSener can offer cost savings. It is worth asking how those results scale if we use a larger host. To answer this, we scale up the cost-mode experiments presented in §9.2 on two larger hosts. To prevent factors other than the resource capacity, we picked larger hosts from the same VM family as the small host (Google Cloud's *e2-standard* family). For brevity, we only show the cost saving results for two benchmark applications in Figure 7. The X-axis is logarithmic, and multiplying invocation rates appears as a shift to the right. As seen, with increased host size, the cost saving curve is shifted to the right consistently.

9.5 Comparison to Alternative Solutions

The primary objective of UnFaaSener is reducing the cost by offloading to pre-paid hosts. To evaluate whether we accomplished this goal, we compare the maximum cost savings, which is also the worst case latency, offered in the cost mode with two popular serverless workflow platforms: AWS Step Functions and Google Workflows. We also compare it to using AWS Lambda functions glued with AWS SNS, and Google Cloud functions glued with Google Pub/Sub. The latter is the underlying setup for UnFaaSener. Furthermore, we present results for UnFaaSener's latency mode using the default tolerance window. Figure 8 compares the average latency and cost per invocation for each benchmark and platform. We could not port Text2Speech Censoring benchmark to AWS as this benchmark utilizes Google Translate's text-to-speech API [11]. The cost mode is all about cost reduction. We see that UnFaaSener is able to trade latency with cost effectively, lowering the cost by about an order of magnitude. Using the latency mode limits this cost reduction depending on the latency tolerance expressed by developers (§9.2 and §9.3), and helps cut down on average latency compared to the cost mode, but the cost savings are not as significant. It is worth noting that DNA Visualization, a single-function application, experiences no added latency as it has low coordination overhead.

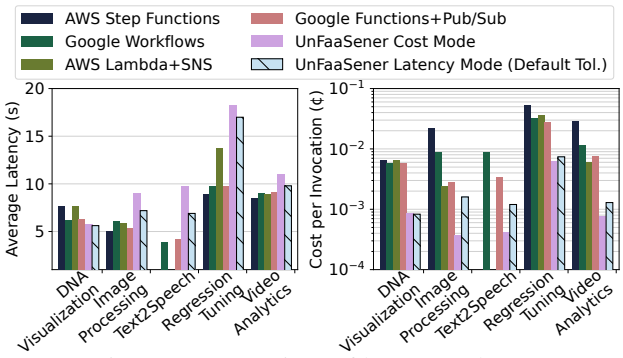

Figure 8: Comparison of latency and cost.

Finally, we see that using workflow coordination services comes with major cost implications. This is because, in addition to the capacity and invocation cost elements mentioned in §2.2, the developer has to pay for state transitions in these offerings [4, 15].

9.6 Adaptive Cost Saving

We are interested in assessing the responsiveness of UnFaaSener to host processes. We use the host with 16 vCPUs from earlier in this experiment. We replay a sample trace from the 2021 Azure Functions traces [6] using FaaSProfiler [9] to invoke the Image Processing application. At second 110, the Graph Analytics workload from CloudSuite 3.0 [7, 65] is run on the host for about 80 seconds. The workload uses Apache Spark to perform graph analytics on a large-scale Twitter dataset and uses all 16 vCPUs as well as 15 GB of memory. Before and after this window, the host is mostly idle and fully available for offloading.

Figure 9 shows the cost for each execution of the Image Processing workflow over time. The timespan for the execution of the heavy host workload is marked with dashed lines. Soon after 110 s, the execution agent slows down admitting new requests and the monitoring agent triggers the scheduler with a prediction failure trigger due to a sudden host load spike. New predictions are made, and the solver makes new offloading decisions for minimal offloading. This is reflected in increased cost during that period. After the VM workload ends, the predictor remains cautious briefly before declaring the majority of the host's resources as available. Offloading to the VM resumes as before. The two orders of magnitude difference in cost is attributed to the non-offloadable header function taking less than 100 ms to execute, while the rest of the application takes 3-4 seconds.

9.7 Host Interference

To measure the impact of UnFaaSener on host processes, we run Text2Speech and Image Processing applications on the 16-core host described in §9.4. We invoke them with the similar rates to those used in that section, and adhere to using the cost mode which guarantees maximal offloading, and equivalently, maximum host-side interference. We use three standard benchmark applications on the host to measure the impact

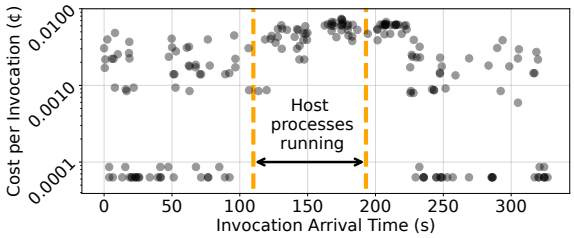

Figure 9: UnFaaSener adaptively adjusts offloading to respect host processes.

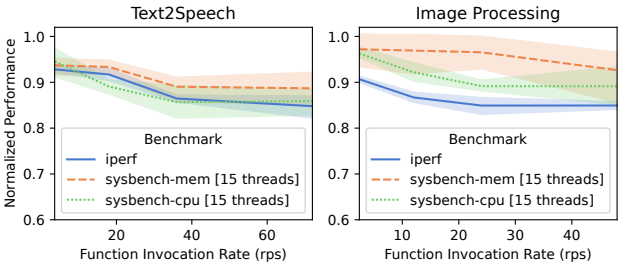

Figure 10: Degradation of host processes is a function of traffic rate and the resource requirements of the functions.

on CPU, memory bandwidth, and network performance. For the first two, we use Sysbench [53], in CPU and memory test modes, respectively, each with 15 active threads. For network, we use the Iperf [79] benchmark. Figure 10 shows the performance of these benchmarks when normalized to that of an idle host without UnFaaSener running. Across experiments, the maximum average degradation at maximum offloading is less than 15%. We find this degradation reasonable considering that 1) benchmarks used are highly sensitive and 2) the developer is in the loop and aware of the operation of UnFaaSener resource harvesting. We observe that sysbench-mem benchmark experiences significantly higher degradation for the Text2Speech serverless application. We pinpointed this to Text2Speech having a function with a 2 GB memory configuration, whereas the largest function for Image Processing requires 256 MB of memory.

9.8 Pub/Sub Latency Overhead

Using pub/sub allows us to invoke functions on and from offloading hosts. Here, we characterize the latency overhead of the Google Pub/Sub [14], used by UnFaaSener.

In our experiment, the publisher is a Google Cloud function in the East Coast sending payloads to three subscribers: 1) another Google Cloud function in the same region, 2) a Google Cloud VM in the same region, and 3) a private VM in the West Coast. We test each publisher-subscriber pair with two message sizes (10 KB and 1 MB) and two invocation rates (0.1 rps and 5 rps). These values were driven by a recent characterization of production serverless DAGs [59]. We chose 10 KB and 1 MB message sizes to estimate high-end values for regular and high-fanout DAGs [59], respectively. Similarly, 5 rps and 0.1 rps rates were chosen as high and medium average invocation rates based on that characterization. We collected 250 samples per scenario (3,000 samples in total).

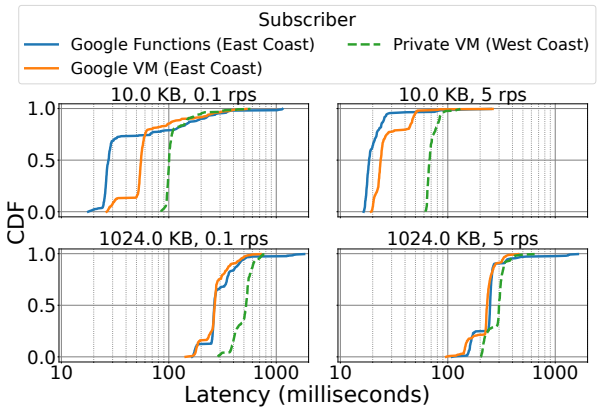

Figure 11: Pub/sub latency depends on message size, subscriber type, distance, and messaging rate.

Figure 11 compares the distribution of latency depending on the subscriber. Higher message size (1 MB vs. 10 KB), longer distance (West vs. East Coast), and very low invocation rate (0.1 rps vs 5 rps) increase the latency. The latter is likely caused by higher chances of lost connections between the publisher, forwarder, and subscriber during longer invocation periods. The wide distributions in Figure 11 reveal Pub/Sub's high performance variability. Even for two Google Cloud functions in the same region, the latency varies from less than 20 ms to more than a second. Such non-deterministic variations in Pub/Sub latency alongside high performance variations of serverless functions motivated us to use confidence intervals statistics for the solver.

9.9 VM Resource Prediction Policy

The predictor agent runs on each host to forecast the maximum resource utilization anticipated for host processes. It has two predictors: one for CPU and another for memory.

We dedicate this section to compare various prediction policies and determine their fitness to be used by the Predictor agent. To assess prediction policies for a wide range of VM usage scenarios we rely on simulations. We use the Azure Public Dataset [29, 30] to simulate different prediction policies for 1 million VMs over a 30-day period. The dataset includes 5-minute VM CPU utilization readings (min, average, and max utilization per reading) and has no memory readings. CPU utilization is inherently more variable than memory utilization. Besides, CPU utilization percentages can experience a wider variation range due to CPU being the typical resource bottleneck in public clouds [45]. These factors make forecasting CPU utilization a harder task.

We implement eight common time series forecasting methods and use traces from 100,000 VMs to train the best policy parameters for them. These trained policy parameters are used as the initial parameters for test VMs and during the lifetime of each test VM the parameters are periodically retuned per VM. A brief description of explored methods and their corresponding parameters (shown in curly brackets) is listed below. For all policies, we also consider a safeguard margin (m) to allow exploring conservative predictions. To derive this margin despite inherent differences between various prediction methods, we also included m as a training parameter.

Simple Exponential Smoothing (SES) {pars: m, α}:

$$s_{n+1} = \alpha x_n + (1-\alpha)s_n,\ x_{n+1} = s_{n+1} \times (1+m) \quad (3)$$

Simple Moving Average (SMA) {pars: m, N}:

$$x_{n+1} = \frac{1+m}{N} \sum_{n-N+1}^{n} x_i \quad (4)$$

The averaging window is limited to the existing number of observation if there are less than N observations.

Histogram (Hist) {pars: m, p, d}: Recent work [68, 72, 81] has demonstrated the superior performance of histogram-based time series forecasting. We implemented a histogram with a 1% utilization resolution. At each prediction window, the max observed utilization observed gets rounded to determine the histogram bin to be incremented. A certain percentile of the histogram (p) is then used to determine the prediction for the next window. A high percentile reduces violations, but reduces reclamation efficiency. Old observations in the histogram are depreciated using the decay factor (d).

Markov Chain (MC) {pars: m, r, o}: Markov Chains have been used for time series forecasting in various problem domains [18, 23, 49]. We build a simple MC predictor for CPU prediction. A state transition matrix (STM) captures the history of state transitions. Each state is a range of CPU utilization percentages; with state resolution (r) of 5%, there are a total of $\frac{100}{5} = 20$ states. The current state is determined based on the latest utilization observation: $i = \lceil 100\%/x_n \rceil$, and the forecasted utilization is:

$$x_{n+1} = \frac{\sum_{j=1}^{\lceil 100\%/r \rceil} STM_{i,j} \times (j+o)}{\sum_{j=1}^{\lceil 100\%/r \rceil} STM_{i,j}} \times (1+m) \quad (5)$$

Here, o is an offset to compensate quantization of values.

Other predictors: We also implemented Double Exponential Smoothing, Autoregressive, Passive Aggressive Regression, and ARIMA predictors. We do not present their description and results for brevity due to their mediocre performance compared to SES and SMA despite more complexity.

Figure 12 compares prediction scores for these four policies. It also shows an Oracle policy where future is known, in which case RE is always 100% and V is always 0%. We only include VMs with a minimum lifetime of 30 minutes (65% of all VMs), as 5-minute readings mean that shorter lifetimes require 4 or fewer predictions; too few to draw meaningful statistical conclusions from. We see that any active prediction policy is significantly better than relying on the latest observation of peak utilization. While we picked MC for delivering slightly better scores, we do not observe considerable differences among these policies. To better understand what limits prediction scores, we look at resource reclamation efficiency and prediction violations of the MC prediction policy separately, as a function of VM lifetime (Figure 13). Results here include any VM with lifetime of at least 15 minutes (91%

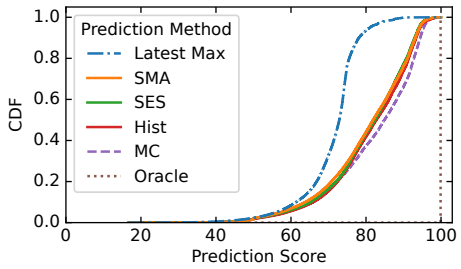

Figure 12: Prediction scores for simulated policies.

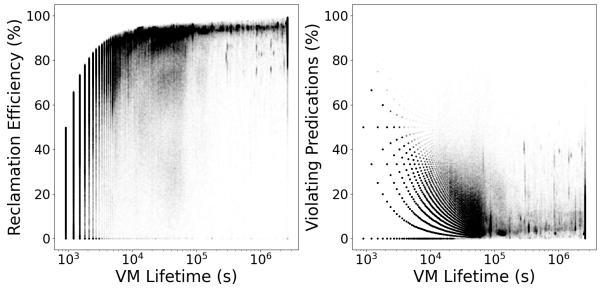

Figure 13: Resource reclamation efficiency and prediction violations as a function of VM lifetime for 1 million VMs.

of all 1 million VMs). We observe that with increased VM lifetime, the resource efficiency is increased and violations are reduced. This is not surprising, as with longer history, policy parameters can be better trained for each VM.

10 Related Work

Table 2 compares UnFaaSener with the related works targeting offloading in the serverless domain. For a category of related work, the application is primarily deployed on VMs and serverless plays the backup role at scale-out, while new VMs are being provisioned [43, 47, 63, 84, 87]. LIBRA [67] extends these works by simultaneously utilizing FaaS for the low-rate bursty portion of the traffic. Reliance on VMs as the primary infrastructure limits the scope of such systems to specific domains (as seen in Table 2), and in effect distances them from serverless's high scalability and pay-per-use features.

Another category of work proposes building hybrid IaaS-FaaS deployments [56, 75]. The main drawback of these systems is adding a second scheduling/control layer on top of that of serverless platforms. Moving away from the scheduler of public serverless offerings as the primary scheduler and adding a new layer limits the scalability of these approaches, and comes with reliability and security implications. UnFaaSener relies on the serverless scheduler to ensure a secure and scalable gateway to external events, and by using pre-solved decisions, eliminates added scheduling overheads.

Lastly, a category of work proposes modifying the serverless platform to enable serverless functions to use resource-harvesting VMs [86], idle resources from over-allocated serverless functions [83], and users' VMs on the same platform [78]. These proposals modify cloud providers extensively, which is out of reach of end users, and limit offloading to the scheduler's scope, usually within the same cluster. UnFaaSener works on top of existing serverless systems, requires no change to the platform, and puts no limit on the location of hosts it is harvesting resources from.

11 Discussion

Threat model. UnFaaSener offloads users' functions to their own offloading hosts. This simplifies the threat model by eliminating co-location of different teams' applications on the same host. Developers have full control: they specify offloading hosts, install host agents, and can unsubscribe hosts at any time. UnFaaSener's execution agent runs offloaded functions in separate Docker containers for isolation, but this also brings security implications [77]. In this context, we assume that 1) the host, which belongs to the same development team, is not malicious and 2) the developer is aware of the data protection implications of offloading functions.

12 Conclusion

UnFaaSener enables serverless developers to leverage the unused capacity of their VMs or on-premise servers, yielding substantial cost savings without modifying existing serverless platforms. UnFaaSener lays a foundation for researchers to explore the potential of the proposed serverless offloading mechanism for diverse purposes beyond cost optimization.

A Appendix

A.1 Dynamic Concurrency Feedback Details

As mentioned in §7.3, the execution agent uses a feedback mechanism to dynamically set the concurrency limit. Execution time changes during the time (ΔExecTime), which is used as feedback in Equation 2, is calculated as:

$\overline{E_n}^t \leftarrow$ Current Average Execution Time for Function$_n$
${E_n}^t \leftarrow$ Current Execution Time for Function$_n$
$\overline{E_n}^{t+1} = 0.8 \times \overline{E_n}^t + 0.2 \times {E_n}^t$
$\Delta {E_n}^t = \overline{E_n}^t - {E_n}^{t-1}$
$\Delta\text{ExecTime} = \sum_{n \in \text{functions}} \Delta {E_n}^t$

In order to prevent frequent changes in the concurrency limit, we quantized the value of the μ calculated by Equation 2 into $[0.33, 0.66, 1]$. The weight of the exponential term in Equation 2 (0.03) was determined empirically, considering this quantization. Figure 14 shows the feedback mechanism used for setting the concurrency limit.

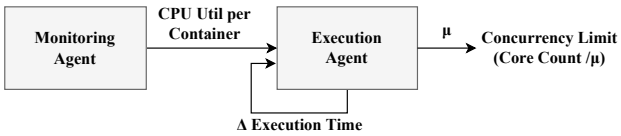

Figure 14: The feedback mechanism for dynamic concurrency.

LLFree: Scalable and Optionally-Persistent Page-Frame Allocation

Abstract

Within the operating-system's memory-management subsystem, the page-frame allocator is the most fundamental component. It administers the physical-memory frames, which are required to populate the page-table tree. Although the appearance of heterogeneous, nonvolatile, and huge memories has drastically changed the memory hierarchy, we still manage our physical memory with the seminal methods from the 1960s.

With this paper, we argue that it is time to revisit the design of page-frame allocators. We demonstrate that the Linux frame allocator not only scales poorly on multi-core systems, but it also comes with a high memory overhead, suffers from huge-frame fragmentation, and uses scattered data structures that hinder its usage as a persistent-memory allocator. With LLFree, we provide a new lock- and log-free allocator design that scales well, has a small memory footprint, and is readily applicable to nonvolatile memory. LLFree uses cache-friendly data structures and exhibits antifragmentation behavior without inducing additional performance overheads. Compared to the Linux frame allocator, LLFree reduces the allocation time for concurrent 4 KiB allocations by up to 88 percent and for 2 MiB allocations by up to 98 percent. For memory compaction, LLFree decreases the number of required page movements by 64 percent.

1 Introduction

In any virtual-memory subsystem, the allocation of *physical memory* is a vital base primitive. Classically, the OS hands out physical memory in *page frames* of MMU-imposed sizes and uses simple free lists [42, 50] (Windows, Darwin) or specialized buddy-allocators [28] (Linux, FreeBSD) to manage multiple frame sizes. However, recent hardware trends (i.e., high core counts and NVRAM) challenge these *frame-allocator* designs.

One significant trend is the appearance of fast [49] byte-addressable *nonvolatile RAM (NVRAM)* in the form of Intel Optane DIMMs. Inspired by their persistence property, new programming models [5, 39, 45, 52], file systems [10, 40, 48], and crash-tolerant data structures [8, 13, 46] were proposed and evaluated. And while Intel's announcement [25] to wind down its Optane business will make NVRAM harder to obtain in the next years, it has been shown that low-cost, high-capacity NVRAM is feasible and has significant potential [1, 23, 31]. Furthermore, multiple researchers realized that persistence and scalability are deeply entangled properties [26, 29] that benefit both from lock-free algorithms [8, 16, 46] and constructive avoidance of inconsistent intermediate states.

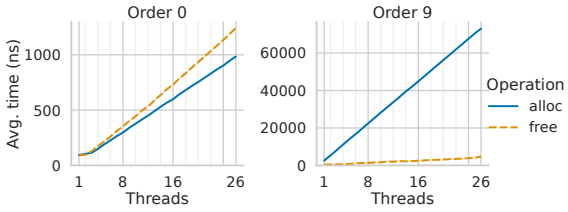

Figure 1: Linux frame allocator performance for concurrent allocations of 4 KiB (order 0) and 2 MiB (order 9) huge frames.

Together with many cores competing for resources, large-capacity NVRAM modules provoke the question of how, at which costs, and with what guarantees the OS hands out the available memory, which might be used for persistent data. For example, for databases, current virtual-memory subsystems can have a significant impact on their design [12, 35], query-processing speeds [14] and buffer management [12, 32]. Therefore, we believe it is time to revisit the whole virtual-memory stack, starting from the bottom; the frame allocator.

First, we investigated whether the Linux frame allocator [18] and its underlying buddy system [28] still match today's requirements, not only for safely allocating frames from NVRAM but also for the scalable management of DRAM. Fig. 1 shows the multi-core scalability of bulk allocations. With all 26 cores allocating in parallel, 4 KiB allocations slow down by a factor of *ten* (94 ns→984 ns), while 2 MiB alloca-

tions are even 27 times slower! This poor scalability affects many multicore and memory-heavy workloads [7]. The root causes are the scattered allocator state and the usage of global locks, both of which are also problematic [16, 17] for a crash-tolerant NVRAM adaptation.

About this paper

We propose LLFREE, a persistent, lock- and log–free page-frame allocator that: (1) focuses on *memory-management unit (MMU)*-specific memory sizes, (2) scales well on multi-core systems by reducing memory sharing, (3) is memory efficient due to its small amount of metadata, (4) has automatic huge-frame defragmentation, and (5) is always in a consistent state and, thus, well suited for persistent memory. In this paper, we claim the following contributions:

- We explore the weaknesses of the Linux buddy allocator and simpler list-based frame allocators.
- We derive design principles for hardware-centric lock- and log-free physical memory management.
- With LLFREE, we provide a page-frame allocator that is suited for both volatile and nonvolatile memory.
- We replace the Linux buddy allocator with LLFREE and conduct a comprehensive evaluation to compare the two allocators in terms of performance, scalability, spatial overhead, fragmentation behavior, and crash consistency.

2 Problem Analysis: Linux Frame Allocator

The page-frame allocator must provide physical-memory *frames*, which have MMU-specific granularities, are naturally aligned, and are used to set up virtual address spaces. For this paper, we will stick to the AMD64 MMU and its frame sizes (4 KiB, 2 MiB, 1 GiB), which we call *natural (allocation) sizes*. However, the general design can be adapted to other page sizes. For 4 KiB, we will use the term *base frame*, for 2 MiB *huge frame*, and for 1 GiB *giant frame*, respectively. While some kernels (e.g., Windows and Darwin) use simple free lists [42, 50], Linux (and FreeBSD) use the buddy system [18, 28].

Linux Buddy Allocator A buddy allocator avoids external fragmentation by allowing only allocation sizes of the form $2^o \times P$, where P is the smallest size and o is the allocation *order*. For each order, the buddy system keeps a bucket of naturally-aligned free blocks. If an allocation hits an empty bucket o, a block from the bucket $o+1$ is requested and halved into two *buddies*, whose start addresses differ only in a single bit. One buddy is returned, the other is put into the order-o bucket. The free operation tries to recursively merge the block with already freed buddy blocks before putting the block into a bucket. To speed up merging, buckets are usually implemented as doubly-linked lists and a one-bit flag is used to track which blocks are available for merging.

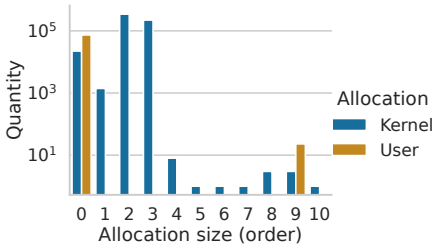

Figure 2: Requested allocation sizes during system startup and a 120 s memcached+memtier benchmark.

Linux employs one buddy allocator per memory zone (e.g., for each NUMA node), supports the orders $o \in \{0, \ldots, 10\}$, and uses the base-frame size as P. Therefore, the supported sizes are between 4 KiB and 4 MiB on AMD64. Unlike a general-purpose buddy allocator, Linux does not store the list pointers within the free memory, as this would require all memory to be mapped, which is not supported by all architectures. Instead, it uses the `struct page` for its metadata.[1] Also, each zone allocator is protected by a spin lock, which serializes all split and merge operations. In order to reduce contention on these locks, Linux further employs per-CPU caches for the most frequently-used orders.

Problem 1: Mixing of Concerns Linux's frame allocator is not only used for hardware-sized page frames but *also* for allocating contiguous physical-memory ranges of various orders. Although this was necessary for allocating *direct-memory access (DMA)* buffers before the widespread adoption of I/O-MMUs, there is no technical requirement for this anymore. However, the Linux developers still use those non-native sizes to allocate larger kernel objects (e.g., stacks). To get a feeling for this, we recorded the requested sizes during boot and a subsequent `memcached` benchmark (see Fig. 2): We see that userspace memory gets only requested for the natural orders 0 and 9, whereas the kernel mostly requests non-natural orders. Allocating contiguous blocks of frames for kernel objects might still be beneficial to save TLB entries (Linux identity-maps all physical memory into the kernel space with giant frames). However, by mixing frame- and kernel-object allocation, the allocator has to provide all orders via its interface, which leads to a number of secondary problems.

Problem 2: Merge Cost Because there are nine buddy orders between the base and huge frames, the transition between both is costly: In the worst case, starting from 512 4 KiB frames, it takes 511 buddy-merge operations to form a single 2 MiB frame. For each merge and under lock, we have to manipulate list pointers in five cache lines; four are in `struct pages` that are usually not yet in the cache.

Problem 3: Scalability Furthermore, as we have seen in Fig. 1, these already costly operations scale poorly if re-

[1] With `struct page`, Linux has a per-frame information store that is used and repurposed by different subsystems. On AMD64, it is 64 bytes large.

quested by multiple threads. The reason for this is the contention at the mentioned per-zone lock, which Linux tries to mitigate by maintaining per-CPU caches for some orders. Each per-CPU cache keeps a list of free blocks, which are drained on memory pressure or if the cache exceeds a watermark. While for a long time, only order-0 allocations were cached, Linux 5.13 extended the caches to order 1-3 and order 9 (2 MiB). However, allocation-heavy workloads easily overwhelm these per-CPU caches. Also, they aggravate fragmentation and complexity.

Problem 4: Huge-Frame Fragmentation Although the buddy system prioritizes the smallest-fitting bucket, it has a problem with huge-page fragmentation: For example, if a single 4 KiB piece of an otherwise free 2 MiB frame is in use, the other 511 base frames exist as 9 blocks of different orders (4 KiB to 1 MiB). Since buckets are unsorted sets and the allocator has no concept of "almost-full huge pages", those blocks have equal chances of being allocated as any other block from any other huge frame. As a result, the buddy system does not specifically aim to minimize the fragmentation of huge frames. We will discuss this further in Sec. 5.6.

The per-CPU caches aggravate fragmentation as they delay merge operations. Even if the last missing 4 KiB frame of a 2 MiB frame has already been freed, it may reside in a per-CPU cache that would have to be flushed to complete the huge frame. Furthermore, as the per-CPU cache hides memory from the buddy allocator, we cannot employ an intra-bucket heuristic that increases the likelihood of a huge-frame merge (e.g., appending to the end of the bucket list). On the contrary, a recently freed block that *could* complete a 2 MiB frame is more likely to be allocated again.

In order to reduce huge-page fragmentation, Linux has supported "high-atomic page blocks" since 2015 to isolate larger blocks and prevent them from being fragmented by small allocations. Furthermore, Linux also employs active defragmentation (memory compaction), where a background task iterates through a memory zone and moves pages to the beginning, clearing larger chunks at the end. However, both induce additional complexity.

Problem 5: Persistent Allocations Given its current structure, the Linux frame allocator is unsuitable for persistent allocations. For persistent NVRAM zones, the allocator must be able to recover its state in case of a power loss to ensure the persistence of the required metadata. This is challenging [17] for complex algorithms (such as lock-protected recursive frame merging), distributed state (such as doubly linked lists), or redundancy (such as per-CPU caches). While in theory, each of these problems could be solved with extra logging protocols [36, 41, 45], the performance, memory, and complexity impact of doing so would be excessive. Also, this logging overhead would have to be paid for every regular operation despite crashes being usually extremely rare. Thus, we do not consider this as a realistic option. To our knowledge, there are currently no persistent (page-frame) allocators that achieve allocation times close to their volatile counterparts [3, 9, 33, 36, 41, 45, 52].

Problem Summary: Complexity In the end, the Linux physical-memory allocator suffers from complexity. Mixing the concerns of frame-sized and other allocation quantities (Problem 1) motivates the buddy structure, which, however, leads to high merge costs (Problem 2) and lock-based, doubly-linked traversals that hamper multi-core scalability (Problem 3). This is mitigated by an increasing number of per-CPU caches, which (combined with the buddy system) unfortunately worsens huge-frame fragmentation (Problem 4), requiring additional mechanisms such as high-atomic page blocks and memory compaction that further increase the complexity. All this results in a design that is unsuitable for persistent allocations (Problem 5) due to redundant and distributed storage of data and state.

All these design decisions were most probably well-founded when they were made. We argue that the time has come to revisit the design and structure of the most fundamental memory manager in our systems, the page-frame allocator.

3 The LLFree Page-Frame Allocator

We originally designed LLFree as a page-frame allocator for natural frame sizes (4 KiB, 2 MiB) only, with the goal of high scalability and suitability for persistent allocations. For the Linux integration, we later had to extend it to support also non-natural allocation orders, which to our surprise, worked out without having to compromise on any of our design goals. In the following, we describe the original design, while the integration particularities are left to Sec. 4.

3.1 Design Principles

For our allocator, we specified three major design principles:

Respect Hardware The hardware characteristics define both the structural elements for and the features of the software implementation. We leverage MMU-defined frame sizes, cache-line granularity in data structures, and available atomics in algorithms.

Avoid Sharing On systems with multiple CPUs, both true and false sharing are major bottlenecks for scalability, becoming even more significant on NUMA systems. Locks are a frequent cause of sharing. We reduce access to shared data structures and do not use locks.

Careful Redundancy Redundant information (such as software caches and replicas) must be kept in sync. This is especially difficult to accomplish when targeting crash consistency on persistent memory since a potential crash can disrupt the synchronization of these redundant data structures. Therefore, we strictly limit redundancy for the state that is required for crash recovery.

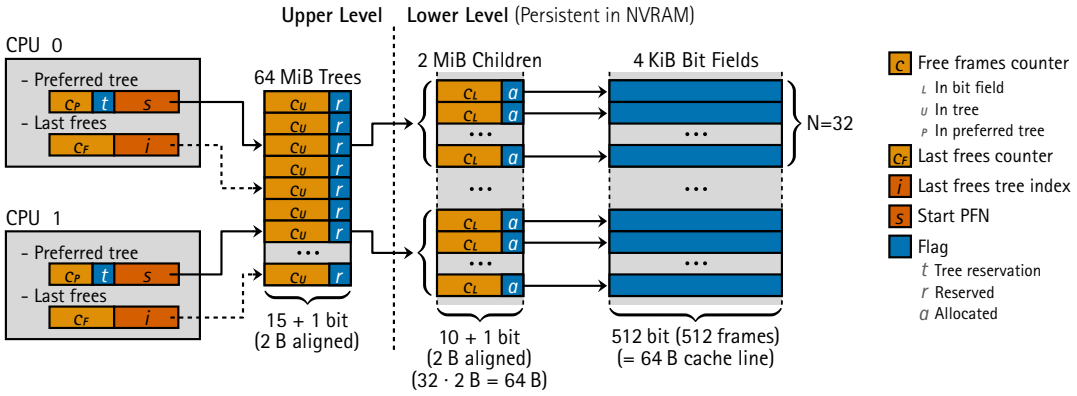

Figure 3: Architecture of the LLFREE allocator: The tree entries, child entries, and bit fields are stored consecutively in large arrays. From a PFN, we can directly extract the indices of the corresponding tree entry, child entry, bit field, and the frame's allocated bit within.

We do not claim fundamental novelty for these principles: The first two are well established in the domain of scalable OS kernel development; their benefits have been reported many times [6, 15, 22, 47]. This does not particularly hold for the third principle, which is more targeted at reaching crash consistency than scalability. On the contrary, employing rather than limiting redundancy is a common technique in kernel design to avoid sharing and *improve* scalability (as we have seen in the previous section), so there is a trade-off between the two. This deep entangling of persistence and scalability, as well as the importance of avoiding intermediate states for crash consistency on NVRAM, has already been reported in the domain of data structures and algorithms [8, 16, 26, 29, 46]. The contribution of this paper is the rigorous combination and application of these principles and dealing with their trade-offs in the design of a page-frame allocator that is *both* scalable on DRAM *and* optionally crash-consistent on NVRAM.

3.2 LLFREE: Design Overview

Fig. 3 depicts the architecture of LLFREE, which has been designed for the natural allocation orders 0 (4 KiB base frames) and 9 (2 MiB huge frames). Conceptually, LLFREE is divided into two levels: A *lower level* that performs the actual allocations and an *upper level* that implements allocation strategies to avoid sharing and fragmentation. Roughly speaking, the lower level takes responsibility for crash consistency – only its state needs to be kept persistent on a crash-consistent NVRAM zone – while the upper level provides for scalability.

3.2.1 Lower Level - Allocation Mechanisms

The lower level manages de/allocation of base and huge frames. For this, it employs a table entry and a bit field of 512 bits (Fig. 3: 2 MiB Children, 4 KiB Bit Fields) for every huge frame to mark the free (0) and taken (1) base frames from this huge frame. The number of free base frames is also maintained in the counter c_L. Base frames are allocated by first atomically decrementing c_L (this prevents races for the last free frame) and then searching the bit field for a 0 bit, an operation supported by special processor instructions. Huge frames are allocated by just changing the counter c_L from 512 to 0 and setting the *allocated flat* flag a, all within a single 16-bit *compare-and-swap (CAS)* operation. The bit field remains untouched, and all-zero in this case, the necessary bookkeeping (e.g., for crash recovery) is done in the a flag.

Thus, in most cases, the lower-level allocator needs to touch only two cache lines for de/allocating a base frame (table entry, bit field) and just one cache line for a huge frame (table entry).[2] Still, even if the current child/tree does not contain enough frames for an allocation, our sequential search fits well with the processor's cache-line prefetching.

3.2.2 Upper Level - Allocation Strategies

The upper level provides for scalability by using allocation strategies that constructively minimize (false) sharing and huge-frame fragmentation. Technically, it manages the physical memory as an array of chunks we call *trees* (Fig. 3): Each tree root refers to a lower-level table with N children that, in turn, refer to N bit fields, each managing 512 frames, similar to a page-table tree. We chose $N = 32$ so that child arrays (in the lower level) occupy a single cache line; hence a tree manages 16 384 base frames, respectively 64 MiB.

Each tree root contains the count c_U of free base frames (for allocation strategies), as well as a reserved flag r (for per-CPU pinning). Our early benchmarks showed that allocations suffer from false sharing when entries in the lower-level child array are updated concurrently. Hence, to avoid sharing, each CPU can pin ($r = 1$) a preferred tree for its allocations.

If there are no free frames left in the preferred tree, a new tree has to be reserved. The reservation algorithm follows a search heuristic to avoid fragmentation of huge frames by using c_U to classify trees into one of three classes:

[2] One additional cache-line access will happen in the upper level.

allocated	Almost all frames are taken ($c_U < 12.5\,\%$).
free	Almost all frames are free ($c_U > 87.5\,\%$).
partial	Everything in between.

The heuristic prioritizes *partial* trees over *free* and *allocated* ones. Thereby, (almost) *free* trees have a higher chance of becoming entirely free over time. However, we still select *free* trees before *allocated* ones for a new CPU-preferred tree, as the latter bear a high probability that allocations might (soon) fail again, especially for huge frames. This is a trade-off between performance and fragmentation.

The thresholds determining whether a tree is *free*, *partial*, or *allocated* are configurable. Our benchmarks showed that the thresholds of 12.5 percent (2048 free base frames for $N = 32$) for *free* and 87.5 percent for *allocated* ones are sufficient to avoid fragmentation (Sec. 5.6). The actual search for an appropriate tree is done in the following order:

1. First, the *neighborhood* of the current CPU tree is searched for *partial* or *free* trees, with *neighborhood* being defined as the 31 other tree roots that reside on the same cache line.
2. If this does not succeed, the whole trees array is sequentially searched (first-fit) for a *partial* tree.
3. If no *partial* tree is found, the search is repeated for a *free* tree or an *allocated* one with enough free pages.
4. As last resort, the allocator drains (unreserves) the trees of other CPUs and steals them.

Note, however, that even the slow path of reserving a new tree does not require locks and can be done fully parallel, as the reservation itself requires only the atomic update of the reserved flag of an entry. Given a memory zone of 256 GiB, the algorithm accesses 128 cache lines in the worst case.

CPU-Local Tree Roots: Despite using per-CPU reservations, the updates on the tree array can still suffer from false sharing when multiple CPUs concurrently update the free counters of entries sharing a cache line. This can be solved in two ways: either by aligning the 2 B tree entries to the cache line size (64 B on x86) or by splitting the counter into a global and a CPU-local part. We followed the second approach to keep the memory and cache overhead low. On tree reservation, a CPU moves the free counter c_U of the reserved tree to its CPU-local data c_P and sets c_U to zero. Allocations and frees from this CPU now change only the local counter c_P. Allocations from other CPUs no longer happen, as the tree is reserved, but foreign frees from previous allocations may still happen. In this case, only the global counter c_U in the trees array is incremented, which avoids invalidating the cache line of the respective local entry. The counters are synchronized if a local allocation runs out of memory ($c_P = 0$) or, in rare cases, by remotely draining a reserved tree from another CPU, which also clears the tree's reservation.

Besides the local free counter c_P, the CPU-local entries also contain an *in-tree reservation* flag t, and the *start PFN*, combined into a single 64 bit data type. The *start PFN* contains the last allocated base frame number; it acts as a last-fit pointer to speed up allocations in the child array (divide by 512) and also identifies the reserved tree (divide by $512 \cdot N$).

The t flag is atomically set during the reservation of a new per-CPU tree to prevent races with remote draining or parallel reservation attempts. The latter could only happen if the zone is too small for one tree per core. If this is the case, the per-CPU data is shared between multiple cores and the t-flag coordinates the allocation of a new tree.[3]

Reserve-on-Free: While per-CPU trees prevent contention and false sharing for concurrent allocations, frees must always go to the tree that was the origin of the respective frame. If the source CPU of the frame has meanwhile switched to a new tree or the free is invoked from another CPU, this tree is not the per-CPU tree. Especially on memory-intensive workloads, frees thereby may still suffer from false sharing.

To mitigate this, LLFREE provides a *reserve-on-free* heuristic that assumes that allocation and free workloads exhibit locality: A CPU reserves a tree as its preferred tree after F consecutive free operations targeted it, expecting that subsequent frees will also affect this tree (c_F and i in Fig. 3). The threshold $F = 4$ performed best in our benchmarks.

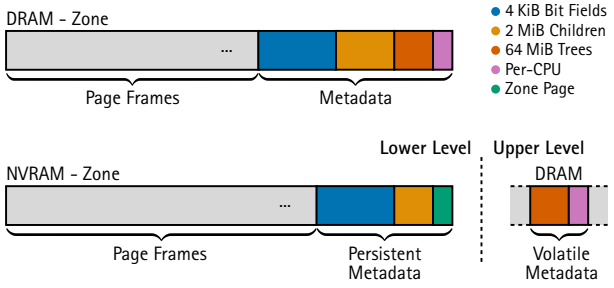

Figure 4: Layout of LLFREE-managed memory zones in persistent and non-persistent memory.

3.2.3 Crash Consistency

LLFREE optionally provides crash-consistency on NVRAM zones. For a crash-consistent NVRAM zone, only the allocator's lower level (cf. Fig. 3) has to be stored within the persistent memory – plus one extra zone page storing a magic identifier, the size of the memory region, and a startup/shutdown marker to detect if the system needs to be recovered after a power loss. The upper level always resides in DRAM to reduce access latencies and avoid unnecessary writes to NVRAM. It is restored into DRAM from the lower-level information. Fig. 4 depicts the zone layout for persistent and non-persistent memory zones.

[3] On Linux-x86, this holds only for the 16 MiB DMA zone, which Linux still offers for compatibility with legacy 16-bit ISA devices.

The key point of LLFree's design is that all transactions authoritatively happen within a single atomic change of a single cache line. For base frames, this is the atomic change in the respective bit field, while huge-frame de/allocation is implemented by the atomic change of a and c_L in the child entry. This ensures *memory consistency* as each authoritative change is visible to all cache-coherent cores, and all derived information (i.e., counter values) are altered by atomic commutative operations, which are not affected by reordering.

The single–cache-line property also makes it easy to implement *persistence consistency* on all systems that provide a *persist granularity* [38] of at least one cache line to be written atomically to the NVRAM at the end of the operation, which is considered to be the minimum standard for NVRAM hardware [10, 38]. In case of a recovery, each entry in the child array is checked for the a flag: If it is set, the child entry is the authoritative information – the entry is a huge page with $c_L = 0$ (the bit field is all-zero). Otherwise, the entry describes a set of base pages – the bit field is the authoritative information, which is used to restore the value of c_L. The upper-level state can then be restored from the child array.

While a crash during a de/allocation would never result in an unrecoverable allocator state, it could lead to a lost frame. This would happen if in an allocation the bit has already been set, but the frame has not yet reached the caller, or if the deallocation has been invoked but not yet cleared the bit. The theoretical worst-case bound for this effect is the maximum number of parallel operations, that is, the number of CPUs. This could be mitigated by two-phase de/allocation protocols, which, however, would also change the interface of the page allocator. Crashes are rare events – and a crash during the critical phase of a page-frame allocation even more so (the endangered code sequences take only a few clock cycles). Hence, the probability of an actual frame loss during the lifetime of a system is extremely low, while even in the case of such an incident, the costs would be acceptable.

4 Implementation

We implemented LLFree as a Rust module, integrated it with (and extended it for) the Linux kernel, and replaced the original Linux buddy allocator with LLFree. Its allocate and free algorithms, discussed in the previous section, can be found in the appendix (Fig. 14).

4.1 Approach

As the Linux community has started to adopt the Rust language, we took the chance to explore how well it is suited for a performance-critical low-level kernel module. Compared to C, Rust has much more restricted (i.e., safer) memory management and avoids undefined behavior. We are convinced that these properties, which prevent entire classes of memory bugs, simplified the development of the allocator.

The modular LLFree implementation contains a test environment that initializes the allocator on a virtual memory mapping in user space for unit testing and benchmarking. This made it possible to profile and find performance bottlenecks early on. Besides standard unit tests, we developed specific race-condition tests for the possible orders of atomic operations, which proved quite helpful in finding several design and logic errors.

Following this approach, we were able to quickly implement and compare strategies for the upper and lower level of the allocator. The final implementation consists of 2 199 lines of safe Rust code (with 25 unsafe lines for initialization and address translations) and 1 318 lines of unit tests. The Linux buddy allocator is written in C and mainly contained in `page_alloc.c` (excluding reclaiming and memory compaction), which alone has 6 060 lines of code – without any tests. However, the buddy allocator is tightly coupled with other memory subsystem components, making it difficult to estimate its actual contribution to this source base.

4.2 Replacing the Linux Buddy Allocator

We modified Linux to boot with our LLFree allocator. The integration required some modifications to LLFree (support for non-natural orders), but especially to Linux itself due to the tightly coupled implementation of the buddy allocator. Nonetheless, the system seems stable for everyday workloads.

4.2.1 LLFree Changes

LLFree was specifically designed for the natural orders defined by the hardware. Linux, however, requires supporting all orders up to 10, which we implemented as follows: Orders 1 to 6 (2 to 64 frames) can be allocated similarly to order 0. The allocation now searches for a large enough, aligned set of zeros in the bit fields and allocates it, toggling the bits with a single 64-bit CAS operation.

Orders 7 and 8 (128 and 256 frames) are allocated with an optimistic lock-free algorithm using 2–4 atomic operations. If one fails due to a race, the others are safely reverted, and the search continues. However, these orders are rarely allocated (cf. Fig. 2), and contention could only occur if a tree is stolen during an allocation or we explicitly share a tree among multiple CPUs. Hence, an actual conflict is a rare event.[4]

Order 10 was implemented by allocating two aligned child entries at once, similar to an order 9 allocation. As these child entries are only 16 bit large (with alignment), this is done with a single 32-bit CAS operation. If a higher-order allocation fails because the tree is fragmented, another one is reserved. In this case, the allocator searches for a *free* tree that is not fragmented before falling back on *partial* ones.

[4] This also breaks our assumption for persistence consistency from Sec. 3.2.3 for orders 7 and 8. However, we can safely ignore this for now, as non-natural orders are only employed by the kernel, which currently does not use persistence.

4.2.2 Linux Changes

During boot, the data structures for the LLFREE allocator are allocated by the early-boot `memblock` allocator and initialized. Like the buddy allocator, we create one LLFREE instance per memory zone and store a pointer to its data directly in the `struct zone`. Most further changes in the code base are to conditionally disable and replace the buddy allocator, its per-CPU caches, zone locks, and high-atomic page blocks when our implementation is activated (via a Kconfig option). In total, the LLFREE module, a thin wrapper around the LLFREE allocator, added 942 lines. Outside this module, we changed 415 lines with 296 alone in `page_alloc.c`.

Most functionalities, including page reclamation, were easily adapted to the new allocator. However, some higher-level services that directly use the buddy allocator's internal data structures, e.g., its free lists, turned out impossible to adapt without completely rewriting them. Hence, we disabled them for both allocators in the benchmarks. First, this includes the memory fragmentation heuristic that decides whether active memory compaction should be executed. The heuristic uses the internal counters of the buddy-allocator's free lists. However, the need for active memory compaction is an exceptional state, only triggered when the allocator is highly fragmented with almost no huge pages left. It does not happen in our benchmarks. Instead, we compare fragmentation and compaction costs in Sec. 5.6. Second, we deactivated the out-of-memory (OOM) handler, as its checks directly rely on the internal free lists of the buddy allocator. Considering the complexity of the OOM procedure, we consider its redesign is outside the scope of this paper. Our benchmarks do not trigger OOM events for both allocators.

To make the higher order allocation speeds in Linux competitive, we had to implement two workarounds: The first reduces the number of write accesses to the `struct page` entries. As an aid for kernel-internal debugging (e.g., detecting double frees), Linux reinitializes the flags of *all* `struct pages` backing a higher order allocation, which is a costly and mostly unnecessary overhead. Linux also differentiates between standard allocations, which can be freed in parts, and *compound* allocations, which can only be freed at once. For *compound* allocations, all but the first `struct page` are marked as *tail* page. This scattered, redundant encoding of *compound* frames is costly, especially for huge frames. Modifying all 512 entries (i.e., 512 cache lines) for every de/allocation is detrimental to the overall performance, making it hard to distinguish and compare the allocation speeds of both allocators. Thus, we benchmarked standard allocations and disabled the flag reinitialization. The latter did not have any observable consequences.

The second bottleneck that affected especially LLFREE is the updating of the vmstat free-frames counter, which provides an estimate of the available free memory. This counter is updated for de/allocations that escape the per-CPU caches. To reduce congestion, each CPU has a local counter absorbing updates up to a certain threshold. However, its current value of 125 is too small for huge frames. We increased the threshold by 1024 (the size of the order 9 per-CPU caches). Because the LLFREE allocator does not use these caches, the global counter remains as accurate as with the buddy allocator using the original value, as the latter may hide as many frames in its per-CPU caches.

5 Evaluation

In our evaluation, we show that LLFREE scales well for different allocation patterns and sizes. We also look at the fragmentation behavior, quantify the memory overhead, and investigate crash recovery for the NVRAM case.

5.1 Evaluation Setup and Benchmarks

Our test system is a DELL PowerEdge R750 with two Gen 3 Intel(R) Xeon(R) Gold 5320 CPUs (2× 26 physical cores @ 2.20 GHz). Each of the two NUMA nodes has four 32 GiB DRAM DIMMs (total: 256 GiB DRAM) and four 128 GiB Optane Gen 2 DIMMs (total: 1 TiB NVRAM). We assume the eADR persistence guarantees offered by the Gen 3 Xeon Gold architecture [24] (memory consistency ↦ persistence consistency) and omit explicit persisting cache flushes (`clwb`) in the implementation, as this also provides for a more direct comparison of DRAM and NVRAM allocation speeds.[5] For stable results, we disable proactive memory zeroing (a recently introduced optional hardening feature) and hyper-threading, which yields similar general performance characteristics, with the exception that memory sharing is costlier between physical cores than between logical ones. We execute our benchmarks on the modified Linux 6.0 kernel with and without LLFREE. As Linux instantiates allocators per memory zone (e.g., NUMA-1-DRAM) that do not impact each other, we perform isolated tests with a single NUMA-node allocator.

As allocator performance is highly work-load specific, we created three synthetic benchmarks that cover a wide range of allocation patterns: (1) For the *bulk* benchmark, all cores allocate half of the available memory at once and directly free it up again; this process is repeated. (2) The *random* benchmark allocates all memory(similar to the bulk benchmark) and frees the frames in random order; we only measure free operations. (3) For the *repeat* benchmark, each core allocates and frees a single frame as fast as possible. *Repeat* has been deliberately constructed as a best-case scenario for the Linux buddy allocator, as it maximizes the expected benefit of the local per-CPU caches. Nevertheless, this is the least realistic scenario: Common is lazy allocation (due to demand paging) with bulk/random free (at program termination).

[5] Note that LLFREE could also work with weaker persistency (Sec. 3.2.3).

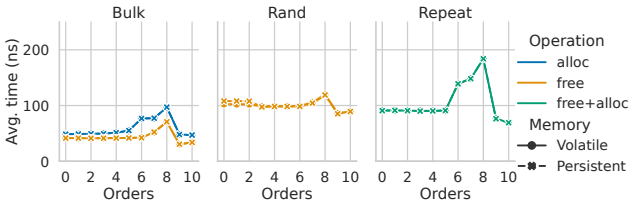

Figure 5: Per-order allocation time of standalone LLFREE on DRAM and NVRAM (8 cores, 128 GiB)

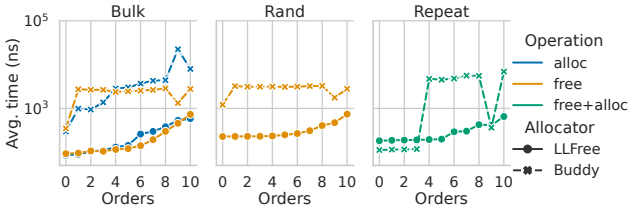

Figure 6: Per-order allocation time of Linux-integrated LLFREE (8 cores, 128 GiB DRAM, logarithmic scale)

As individual operations execute fast, per-operation time measurements would distort the results. Therefore, we measure the time for all operations and divide it by their number. Since LLFREE benefits from free locality, we expect the random benchmark to be especially challenging.

5.2 Allocation Sizes

First, we look at the allocation speeds of the different request sizes (4 KiB – 4 MiB). For this, eight CPU-pinned threads manage 128 GiB of DRAM or DAX-mapped Optane memory. The benchmarks are executed both in our userspace benchmark environment to measure the *standalone* performance of LLFREE and with a kernel module in the modified Linux.

Fig. 5 shows the average time per operation for the userspace benchmarks. For bulk and repeat, *one* operation costs less than 100 ns, while order 8 (1 MiB), which is the furthest from the next lower natural order, is the most expensive one. Due to random's cache-miss and invalidation behavior, a free operation can take up to 120 ns. Even though Optane is known to have around twice the random-access latency of DRAM [49], the resulting allocator performance is very similar for DRAM and NVRAM, as most updates remain in the L3 caches.

After these userspace results, we replaced the Linux buddy allocator with LLFREE for a quantitative in-situ comparison. This integration induces higher management overheads (e.g., updating `struct page`), which causes additional cache misses compared to the previous userspace benchmark. As Linux's allocator is not crash-consistent, we now only look at DRAM performance. Again, eight cores on the first NUMA node execute the respective benchmark in parallel.

Fig. 6 shows that LLFREE is about one order of magnitude faster than the original Linux allocator for the bulk and random benchmarks. For the repeat benchmark, where a single frame is reallocated repeatedly, the per-CPU caches (order 0-3, 9) make the buddy allocator faster than LLFREE (e.g., for order 0: 112 ns vs.183 ns). This stems not only from the caching itself but also from the fact that some statistics (i.e., `vmstat` counters, NUMA hit/miss rates) are not updated if the cache services a frame request. Nevertheless, for sizes that are not covered by per-CPU caches, LLFREE is about 100 times faster in the repeat benchmark.

However, the per-CPU caches are not beneficial for all workloads: In the bulk benchmark, we see that for order-9 allocations, the buddy allocator is about ten times slower than orders 8 and 10. An in-depth analysis revealed the problem: As the order-9 caches only have a capacity of two, the cache-refill operation is invoked for every other frame. This refill batches the allocation of multiple frames - two in this case - into a single critical section, reducing the number of acquire and release operations to the buddy lock. However, this critical section also contains a check for all `struct pages` of the allocated frames, which is especially expensive for higher-order allocations. Therefore, the lock is held longer, increasing lock contention compared to the other orders without caches that perform these checks after releasing the lock.

If we compare Fig. 5 and Fig. 6, we see that there is still potential for improvement in Linux's allocation path. As the other overheads scale linearly with the number of covered 4 KiB frames (for updating `struct page`), we are currently unable to fully harvest LLFREE's performance for 2 MiB frames. For example, while 4 KiB random frees are equally fast within the kernel, freeing a huge frame takes 4.48 times longer.

5.3 Multicore Scalability

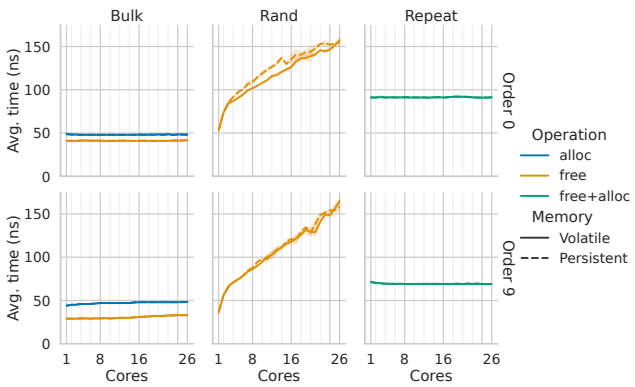

Figure 7: Average time per core count on orders 0 and 9 and 128 GiB memory of LLFREE in volatile and persistent memory

To evaluate multicore scalability, we focus on the two natural frame sizes and scale the number of requesting cores from 1 to 26. Again, Fig. 7 shows the raw LLFREE performance (in

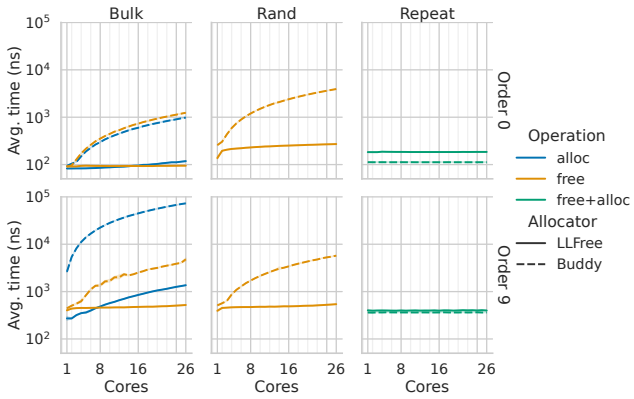

Figure 8: Average time per core count on orders 0 and 9 and 128 GiB memory in the Linux kernel on a logarithmic scale

userspace) on DRAM and NVRAM, while Fig. 8 (log-scale!) shows the in-kernel performance on DRAM.

For the bulk and repeat userspace benchmarks (Fig. 7), we see that LLFREE's operation times remain almost constant, independent of the number of cores, and the memory type has only an insignificant influence on the performance. Here, LLFREE's allocation and free reservation system avoids most sharing. Only for random, where cache invalidations and update conflicts on child counters are more frequent, we see a significant impact of more workers. However, even with 26 workers that request frames in parallel, a DRAM allocation/free of either order takes less than 170 ns.

In Fig. 8, we see that the Linux performance is heavily influenced by its per-CPU caches for the natural sizes. For the repeat benchmark, which is the best case for per-CPU caches, we see that LLFREE is up to 65.18 percent (26 cores, 4 KiB) slower than Linux. However, for bulk and random, which exceed the capacity of the per-CPU caches, the Linux allocator shows severe performance drops for more cores as memory is now requested directly from the buddy system. While the single-core performance for 4 KiB is still almost equal, Linux takes 7.3/13.5 (bulk allocations/random frees) *times* longer with 26 cores than LLFREE. For 26 cores requesting 2 MiB frames, this changes to 52.5/9.6 times.

5.4 List-Based Allocators

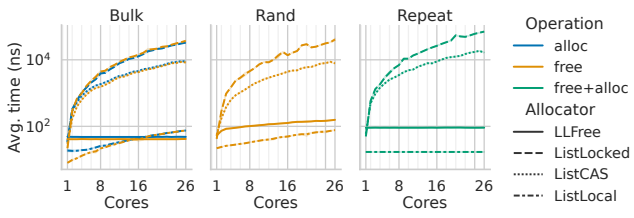

Figure 9: Average speed of the list and LLFREE allocators per core count for order 0 on 128 GiB DRAM

Besides the buddy system, simple free lists are a common design for page-frame allocators in commodity (Windows [50], Darwin [42]) and research (Twizzler [5]) operating systems. Like Linux, they mitigate lock contention on the global structures by additional core-local lists. To compare these allocator concepts with LLFREE, we built three prototypical list-based allocator implementations and evaluated their scalability. (1) The *ListLocked* allocator, consisting of a lock-based shared singly-linked list (Windows, Darwin), (2) the *ListCAS* allocator, which uses a LIFO lock-free list instead [44] (supposed to be preferable over locking), and (3) the *ListLocal* allocator, a theoretical allocator that maintains per-core lists only, does not need any protection and never drains (ideal case). All list allocators store their next pointers in a 64 B aligned array, similar to Linux's `struct page` array.

In Fig. 9, we see the results of this comparison on a logarithmic scale. As expected, the locked variant has the worst performance due to the high degree of lock contention. However, while replacing the lock with atomic operations improves the situation by 81 percent (26 cores, random), we see that this still does not solve the fundamental scaling issue; contention basically just moves from the lock to the cache line that contains the head pointer of the list.

To our surprise, LLFREE even outperforms (from 16 cores onwards) the ideal *ListLocal* variant, which is not even suited as a global frame allocator, but takes 36 percent more time on 26 cores for *bulk* allocations. This is caused by the state dispersion of linked lists: Virtually every allocation and free touches at least one new cache line – compared to LLFREE's cache-friendly structure, where in the best case, 512 allocations reuse the same three cache lines. In the *random* benchmarks, LLFREE also suffers from cache misses due to non-local frees (the worst case for LLFREE).

5.5 Allocator State Dispersion

To compare allocators' temporal and spatial costs, we propose the *state-dispersion* metric – a quantitative measure denoting the byte count utilized for metadata storage. Intuitively, state dispersion is the number of bytes accessed for a full enumeration of the internal state. However, it is critical to understand that state dispersion does not directly translate to memory overhead, given that allocators often repurpose the free memory or overload other shared data structures (i.e., `struct page`) for their metadata, whereby the plain memory overhead becomes a less meaningful metric. However, an allocator exhibiting high state dispersion will likely induce more cache misses during its operation, impacting run-time efficiency. This, of course, does not only depend on the size of the state but also its spatial distribution.

In Tab. 1, we break down the state dispersion of LLFREE and the Linux allocator into the different components. To put these numbers into perspective, we also show how the disper-

Allocator	Per Zone	Per CPU	Per 1 GiB	1 Zone 128 GiB 52CPUs	Full Scan: Accessed Cache Lines
LLFree				**4.1 MiB**	**67 754**
4 KiB Bit Fields			32.0 KiB	4.0 MiB	65 536
2 MiB Counters			1.0 KiB	128.0 KiB	2 048
64 MiB Trees		128 B	32 B	10.5 KiB	168
Global	128 B			128 B	2
Linux Buddy Allocator				**516.0 MiB**	**33 555 169**
Free Lists	988 B		4.0 MiB	512.0 MiB	33 554 448
Allocated Flag			32.0 KiB	4.0 MiB	(within above)
Pageblock Bits			256 B	32.0 KiB	512
Per-CPU Caches	8 B	256 B		13.0 KiB	209

Table 1: Allocator-State Dispersion and Cache Overhead

sion scales to our benchmark machine (52 cores, 128 GiB, 1 memory zone) and how many distinct 64B cache lines would be accessed for a complete enumeration in this setting.

Due to LLFree's usage of bit fields and counter arrays, its state disperses only to 4.14 MiB (0.0032 % of DRAM) on the benchmark machine. The primary contributor to this are the 4 KiB bit fields (4 MiB). Thus, even a full-state scan can comfortably fit within the machine's 35 MiB L3 cache, for which only 67 754 cache lines need to be loaded. Also, as LLFree does not repurpose memory, it does not require physical memory to be mapped by the kernel, and its state dispersion is equal to its memory overhead.

In contrast, the Linux allocator stores most of its state in `struct page`. There, it requires one flag and repurposes the 16 bytes of the LRU list pointers (double-linked list) for its per-order free lists and for the per-CPU page caches. Due to the scattered nature of linked lists, the Linux allocator (potentially) spreads its state over 516 MiB (0.39 % of DRAM). Even worse, as each `struct page` resides on its own cache line, a complete state scan would have loaded 33 555 169 cache lines. Hence, in comparison to LLFree, Linux's allocator state not only disperses over 125 times more memory, but even requires 495 times more cache lines to be loaded for the full scan.

Furthermore, as LLFree does not rely on the `struct page`, this also raises the question if they could be shrunk or eliminated. These records currently occupy 1.56 percent of DRAM. Unfortunately, removing the allocator's dependency on `struct page` does not directly result in smaller per-frame records, as other kernel subsystems reuse the LRU list pointers for various purposes when the frame is allocated (in the Linux source code, `struct page` is basically a mess of `unions`). Therefore, shrinking or even eliminating `struct page` is a deeply cross-cutting and challenging task.

Nevertheless, an allocator that, like LLFree, does not require a per-frame record significantly eases this challenge, since we then would only need per-frame records for *allocated* frames. For example, with Linux's current move to `struct folio` [11], which describes a bundle of physically contiguous frames, it could become possible to allocate this record dynamically. In this sense, we see LLFree as an important first step into untangling `struct page` dependencies. However, its complete elimination remains a topic of further research.

5.6 Fragmentation and Compaction Cost

Next, we look at the huge-frame fragmentation behavior of both allocators. For this, we first define a metric for this fragmentation and for the memory-compaction cost that would be required to remove this fragmentation. To measure fragmentation, we count the number of huge frames that can be allocated if we drain all caches but perform no memory compaction. We then compare this to the number of *possible* huge frames that could be allocated with compaction to get an idea of the fragmentation level in the system.

To gauge the compaction cost, we consider the minimal number of 4 KiB copy operations required to free up the *possible* maximum of huge frames. To calculate this metric, we (1) count the number of free 4 KiB frames in each possible huge frame, (2) sort the resulting array, and (3) match the "fullest" with the "emptiest" huge frames while counting the number of required copy operations. Please note that Linux skips step 1 and 2 and moves memory to the beginning of the zone, which results in suboptimal memory compaction. With LLFree, however, sorting the children array (see Fig. 3) would bring us close to the optimal variant.

To compare both allocators, we conduct the following synthetic benchmark: First, we generate an initial memory configuration that is a worst-case scenario for a maximally fragmented physical memory. For this, we allocate 90 percent of a 125 GiB region before freeing up half of all 4 KiB frames randomly again. Starting with this fragmented state, we perform 100 iterations, each freeing 10 percent of the allocated memory in the form of randomly-selected 4 KiB frames and reallocating the same amount again as individual 4 KiB frames. After each iteration, we drain the CPU-local caches (buddy), respectively the tree reservations (LLFree), and measure the huge-frame fragmentation and the compaction cost. Note that we still leave the Linux memory compactor turned off (as stated in Sec. 4.2.2). Like in our other benchmarks, we do not trigger unfulfillable allocation requests, which would require synchronous compaction. We measured the hypothetical compaction costs for each iteration for both allocators using the described offline calculation.

Fig. 10 shows the change of both metrics over time. The Linux allocator can recover only a single huge frame in this benchmark, although the whole memory was cycled ten times over (100 iterations). Also, the compaction cost decreased only by 3.3 percent, indicating that huge frames are only getting slowly defragmented over time. Additionally, our scenario benefits Linux as we drain the per-CPU caches and use the optimal compaction-cost metric. In contrast, LLFree can recover 46.6 percent of the initially polluted huge frames over

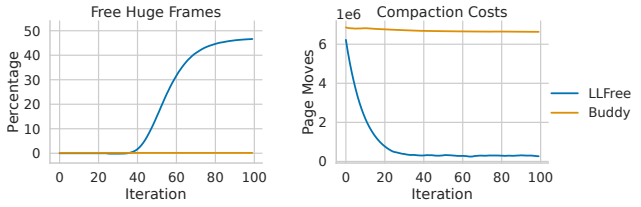

Figure 10: Free huge frames (left) and compaction cost (right) over iterations that randomly reallocate 10% of the allocated memory.

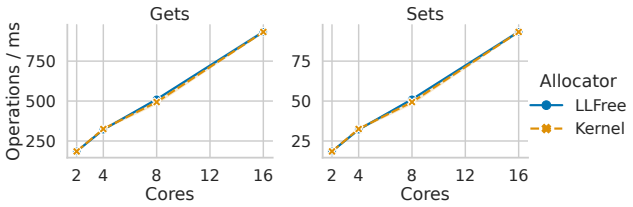

Figure 11: Number of Gets / Sets per millisecond for the *memtier* benchmark.

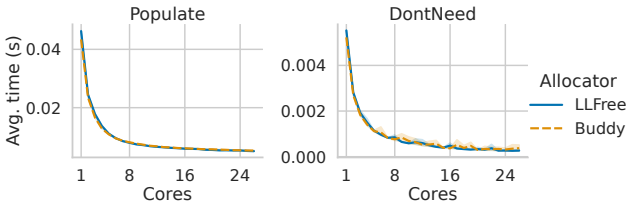

Figure 12: Average time to populate/free a 128 GiB memory map in the *write* benchmark.

the benchmark. Although it looks like defragmentation only starts to kick in around iteration 50, a look at the compaction cost indicates that entropy decreases right from the beginning; there are just no completely free huge-frame frames yet. After performing reallocations summing up to the total amount of memory (10 iterations), we are at 39.1 percent compaction cost and after 50 iterations, we would only require 4.9 percent of the initially-required copy operations.

Overall, we see that LLFREE shows a passive defragmentation behavior steered by our subtree-allocation policy. As a buddy system does not track the "fullness" of split-up buckets, it cannot imitate this on the cheap.

5.7 Crash Recovery

As validating crash consistency by real system crashes is too time-consuming to obtain robust results, we simulate LLFREE's recovery (Sec. 3.2.3) for regular shutdowns and crashes using a userspace benchmark on a DAX-mapped NVRAM region: For this, (1) we initialize the allocator on a 128 GiB region, (2) allocate half of it randomly, and (3) allocate and free memory repeatedly as in Sec. 5.6. For regular shutdowns, the process terminates after (2), while we simulate crashes by randomly killing the benchmark with `SIGKILL` during (3). Afterward, another process recovers the allocator's state from the persistent memory.

In total, we injected 1 000 crashes and LLFREE could recover its state in all cases; in about half of the experiments, we actually lost frames (at most one per core), which is expected, as the cores spent all their time in alloc/free. For the recovery procedure, LLFREE iterates through the bit fields to correct the child counters, which takes on average 2 460 µs. In comparison, a regular NVRAM re-initialization, where LLFREE only needs to iterate over the child tables, takes only 477 µs. Recovery was done single-threaded but could be parallelized and partially performed in the background if recovery times should become an issue.

5.8 Application-Level Benchmarks

As a real-world application benchmark, we used `memtier`[6], which evaluates the performance of the *memcached* key-value store. It measures the throughput of *Get* and *Set* requests. Unfortunately, we see no significant difference as shown in Fig. 11. As the page allocator is primarily used by the page-fault handler, which lazily allocates memory, the overhead of the other involved memory management components might overshadow any performance gains.

To investigate this hypothesis further, we created the *write* benchmark, which maps a large memory region and populates it in parallel. The population is done by writing a non-zero value into the first byte of the page, triggering a page fault and subsequent allocation request. For unmapping, the `madvice/DONTNEED` syscall is used. The benchmark is executed for 1–26 cores, with the memory region split evenly between the cores. Again, the results in Fig. 12 show no significant difference between the buddy and LLFREE allocators, just like the *memtier* benchmark.

Utilizing the *perf* profiler, we measured where most of the runtime is spent. The flame graph in Fig. 13 shows that the page allocator (yellow) only accounts for 5.3 percent of the runtime. Primarily dominant are the `struct mm` rw-lock (orange, 17.3 %) and the updates of the LRU, cgroups, reverse mappings, and `struct page` flags (green, 28.7 %). Because most `struct page` update macros are inlined, the actual time is probably higher. These memory-management bottlenecks are consistent with other research [7, 12, 14, 32, 35].

6 Discussion

Our results show (besides crash consistency) that LLFREE provides excellent scalability in user- and kernel-level benchmarks, achieved by its consequent lock-free and cache-friendly design. Nevertheless, these benefits are not yet visible in end-to-end benchmarks, even though there are applications

[6] https://github.com/RedisLabs/memtier_benchmark

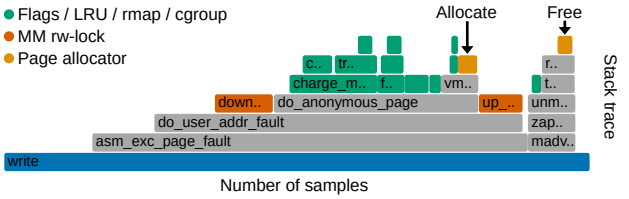

Figure 13: Flame graph for the write benchmark with the Buddy allocator on 8 cores and 128 GiB DRAM.

for which OS-level memory de/allocation performance already *is* a big issue [12, 14, 32, 35].

We argue that, given the deep entangling and grown complexity, the scalability problem could only be solved in a bottom-up manner and provide LLFREE and its design concepts as a first step in this direction. We believe if nonvolatile memories will play a role *some* day, their kernel-level management has to be designed together with volatile memory – and see LLFREE as an important step in this direction. Finally, our results also show that the conjunction of striving for scalability *and* persistence [8, 16, 46] works out particularly well in kernel design if considered from the very beginning.

7 Related Work

Many general-purpose allocators [3, 9, 33, 36, 41, 45, 52] for nonvolatile memory have been proposed. In contrast to LLFREE, all of them use logging to ensure crash consistency, which increases NVM wear [49], and locks for multithreaded operation; some reduce lock contention by using multiple allocator instances [36, 41], per-CPU/thread free lists [3, 9] or range locking [52]. From these, *PAllocator* [36] has similarities to LLFREE as it comes with antifragmentation measures and, similar to our lower level, stores only parts of its state in NVRAM and recovers its volatile state on boot. Nevertheless, all of these persistent allocators are general-purpose userspace allocators and, thus, have different design goals compared to a kernel page-frame allocator like LLFREE.

On the OS side, *Twizzler* [5] is explicitly built around nonvolatile memory but nevertheless does not contain a persistent page-frame allocator. Instead, the system rebuilds the allocator state from the persistent objects on each reboot in DRAM. To our knowledge, LLFREE is the first persistent page-frame allocator to be used within the operating system.

While the immunity to external fragmentation was one of the original motivations for paging [2], its extension to different frame sizes brought back the problem. To ease active huge-frame reclamation, placement strategies [19–21] categorize allocations (i.e., movable, reclaimable) and spatially cluster them onto separate huge frames. For this, Linux has multiple free lists per buddy order, each of which serves a different category. LLFREE currently does not support such categorization. However, it could easily be extended for this by specialized trees (see Sec. 3.2.2). For Linux, strategies with better clustering characteristics have been suggested [37].

Other measures to reduce huge-frame fragmentation include proactive compaction [30] and anticipated continuous memory reservation [27, 34]. Even hardware solutions have been proposed, such as building huge frames of noncontinuous memory [43], or an additional level in address translation [51] similar to nested paging [4]. In contrast, LLFREE is a pure software solution that passively defragments huge frames while being fast and crash-consistent at the same time.

8 Conclusion

The page-frame allocator, which manages the physical memory, is at the core of all memory management in modern operating systems. However, as we have shown in the example of Linux, its classical lock-based design with many lists and distributed metadata has not kept up with the progress in hardware towards massive-parallel systems with large amounts of heterogeneous volatile and nonvolatile memories. This results in internal complexity, poor scalability, high memory fragmentation, and general unfitness for achieving crash-consistent allocations on nonvolatile memories.

We presented LLFREE, a new log- and lock-free page-frame allocator that, by its lockless and cache-centric design, achieves excellent scalability for parallel allocations (53 times faster than the Linux buddy allocator for parallel 2 MiB DRAM allocations on 26 cores), while constructively keeping huge-page fragmentation low. All de/allocations manifest in memory by a one–cache-line transaction, whereby LLFREE can provide crash-consistency for persistent NVRAM without logging and at near-DRAM speed on eADR systems. Our integration of LLFREE into Linux was successful, but it also revealed many further bottlenecks of its memory-management subsystem and the deep entangling of the buddy allocator with it. These topics demand further investigation and redesign. We consider LLFREE a crucial first step towards a complete structural rethinking of the OS memory management.

Appendix

(1) If reserved counter $c_P \geq 2^o$ then $c_P \leftarrow c_P - 2^o$ and continue with (2).
  (a) Otherwise, sync with global c_U and repeat (1) if the counter is now large enough.
  (b) Otherwise, reserve a new tree and repeat (1).
(2) Search the corresponding children array sequentially for an entry with $c_L \geq 2^o$. If this search fails, reserve a new subtree and repeat (1).
  (a) For base frames, decrement c_L, search the corresponding bit field for a zero bit, and set it.
  (b) For huge frames set $c_L = 0$ and $a = 1$.
(3) Return the allocated *page-frame number (PFN)* or `NULL`.

(a) The allocation of an order o frame.

(1) Check the corresponding child entry.
  (a) For base frames, check if $c_L \leq 512 - 2^o$ and $a = 0$, and continue with (2).
  (b) For huge frames, check for $a = 1$, set it to zero, and continue with (4).
(2) Toggle the corresponding bits in the layer-one bit field.
(3) Increment the child counter ($c_L \leftarrow c_L + 2^o$).
(4) Increment the reserved c_P or the global c_U if this free is in another tree.
  (a) When a global, *partial* tree entry is updated, reserve it if the past F allocations also affected it.

A Artifact Appendix

Abstract

The artifact contains the necessary tools and resources required to evaluate LLFree, a new lock- and log-free allocator design that scales well, has a small memory footprint, and is readily applicable to non-volatile memory. To simplify the evaluation, the artifact is packaged as a Docker image, which includes the different benchmarks from the paper's evaluation and any dependencies. These benchmarks are designed to stress the allocator in various scenarios. They allow other researchers to compare the performance of LLFree with the traditional Buddy allocator and reproduce our experimental results. Additionally, this image contains the raw data and scripts for the paper's figures, making our evaluation as transparent as possible.

Scope

These benchmarks show that the LLFree allocator out scales the buddy allocator on systems and workloads with high parallelism. However, executing them in a virtual machine (even with KVM) leads to less accurate results. Therefore, in the paper, we built and tested the modified Linux on raw hardware. Nonetheless, the results should show similar trends as in the paper's evaluation.

Contents

The Docker image includes all required dependencies and scripts for building and running the benchmarks, as well as generating relevant plots and data. It also features a Python script (run.py) that serves as the central command center to manage the building, benchmarking, and plotting processes. The allocator can be tested in both user space and within a custom-built Linux kernel that incorporates LLFree executed in a QEMU+KVM vm. For the latter, the image contains a QEMU+KVM virtual machine and scripts to boot it and run the kernel benchmarks. It further contains the raw data and plots from the benchmarks shown in the paper.

Hosting

The docker image and the repositories of the allocator, the modified Linux kernel, and the benchmarks are hosted on GitHub:

- **Docker Image**: This image contains an execution environment that makes it easy to run and evaluate the benchmarks.
- **llfree-bench**: The benchmark scripts and results.
  (tag = `atc23-artifact-eval`)
  - The artifact instructions can be found in `artifact-eval/README.md`.

- **llfree-rs**: The Rust implementation of the LLFree allocator.
  (tag = `atc23-artifact-eval`)
- **llfree-linux**: The modified Linux Kernel that can be configured to use LLFree instead of the Buddy allocator.
  (tag = `atc23-artifact-eval`)
- **linux-alloc-bench**: Kernel module for benchmarking the page allocator.
  (tag = `atc23-artifact-eval`)

Requirements

As our benchmarks are packaged in a Docker image and do not rely on specific hardware, the only prerequisites are:

- A Linux-based system for KVM. We have tested this on Linux 6.0, 6.1, and 6.2.
- At least 8 physical cores and 32GB RAM (more is better). Lower specifications should work, but the results may be less meaningful.
- Hyperthreading and TurboBoost should be disabled for more stable results. As the VM is not configured for this, the kernel benchmarks might be especially affected.
- A properly installed and running Docker daemon.

Next Steps

The artifact instructions can be found in the *llfree-bench* repository under artifact-eval/README.md. The *artifact-eval* directory also contains all the scripts mentioned in the document and also the Dockerfile for building the image by oneself if desired.

SingularFS: A Billion-Scale Distributed File System Using a Single Metadata Server

Hao Guo Youyou Lu* Wenhao Lv Xiaojian Liao Shaoxun Zeng Jiwu Shu
Tsinghua University

Abstract

Billion-scale distributed file systems play an important role in modern datacenters, and it is desirable and possible to support these file systems with a single metadata server. However, fully exploiting its performance faces unique challenges, including crash consistency overhead, lock contention in a shared directory, and NUMA locality.

This paper presents SingularFS, a billion-scale distributed file system using a single metadata server. It includes three key techniques. First, SingularFS proposes *log-free metadata operations* to eliminate additional crash consistency overheads for most metadata operations. Second, SingularFS designs *hierarchical concurrency control* to maximize the parallelism of metadata operations. Third, SingularFS introduces *hybrid inode partition* to reduce inter-NUMA access and intra-NUMA lock contention. Our extensive evaluation shows that SingularFS consistently provides high performance for metadata operations on both private and shared directories, and has a steadily high throughput for the billion-scale directory tree.

1 Introduction

In modern datacenters, the vast majority of distributed file systems are within billions of files, and we call them billion-scale distributed file systems [33]. It is possible to support these file systems with one single metadata server, which typically has enough capacity to hold terabytes of metadata. However, the performance of a single metadata server requires further attention, as metadata operations account for more than half of all file system operations [16, 17, 26].

We find it challenging to store billions of files without sacrificing performance in a single metadata server, so most distributed file systems support billions of files by scaling metadata servers [17, 19, 22, 25, 31]. In this paper, we explore the design space of a billion-scale distributed file system that achieves high performance in a single metadata server.

Remote direct memory access (RDMA) and persistent memory (PM) provide new opportunities for the performance of metadata servers. However, existing solutions fail to fully exploit them and provide desirable metadata performance. Our experiments show that both local PM file systems and distributed file systems have performance limitations in both private and shared directories. Specifically, for the state-of-the-art local PM file system, NOVA [32], its file `create` throughput in a shared directory drops to only 0.14× of its throughput in private directories, even for the million-scale directory tree without the impact of networking.

Exploiting the performance of a single metadata server brings several challenges to the design of file systems. First, the overhead to ensure crash consistency is extremely heavy for a single metadata server that aims to support billions of files. Second, operations in a shared directory, which are common in distributed file systems, suffer from limited parallelism and low performance caused by severe lock contention on the directory `dirent`s and inode. Third, The NUMA architecture is under-exploited for file systems, especially for metadata operations in a single metadata server.

This paper presents SingularFS, a billion-scale distributed file system using a single metadata server. With only one metadata server, SingularFS achieves 8.36M/18.80M IOPS for file `create`/`stat` operations, which outperforms InfiniFS with 32 metadata servers reported in its paper [19], without sacrificing multi-server scalability. To address the challenges mentioned above, SingularFS optimizes the directory tree and the metadata operations with the following designs.

First, we propose *log-free metadata operations* to remove the additional crash consistency overheads from most metadata operations. The key idea is to identify possible metadata inconsistency by leveraging both the single-object update atomicity of the key-value storage backend and the metadata semantic dependency of the parent inode and child inodes.

Second, we design *hierarchical concurrency control* to maximize the parallelism of metadata operations in a shared directory with less synchronization overhead. The key idea of this protocol is to synchronize inode operations in a more fine-grained way. Specifically, inode *writer* uses the per-inode read-write lock to synchronize with other operations, and

*Youyou Lu is the corresponding author (luyouyou@tsinghua.edu.cn).

inode timestamp *updater* and *reader* use a lock-free protocol to do extra synchronization between themselves.

Third, we introduce *hybrid inode partition* to reduce inter-NUMA access and intra-NUMA lock contention. The key idea is to separate the timestamps from the directory inode and group it with the directory's child inodes to the same NUMA node, thus ensuring NUMA locality of file operations. SingularFS further partitions the intra-NUMA data structure to reduce its lock contention.

In summary, this paper makes the following contributions:

- We identify the challenges to fully exploiting the performance of a single metadata server.
- We propose SingularFS, an efficient distributed file system using a single metadata server, featured with log-free metadata operations (§3.2), hierarchical concurrency control (§3.3), and hybrid inode partition (§3.4).
- We implement and evaluate SingularFS to demonstrate that SingularFS outperforms existing distributed file systems in latency and throughput of metadata operations, has comparable latency and throughput with local PM file systems in file operations, provides high throughput scalability in a shared directory, and maintains a steadily high throughput for a billion-scale directory tree (§5).

2 Background and Motivation

2.1 Background

Billion-scale file systems are fundamental building blocks for cloud service vendors and smaller datacenters. Even in some huge datacenters such as Alibaba [19], massive files are managed with small storage clusters, which are within billion-scale. One single metadata server is sufficient to contain all the metadata at this scale, and it has the following benefits compared to using more metadata servers:

- *Implementation and performance.* Distributed transactions and load balancing across metadata servers are avoided, which simplifies the implementation and improves the performance.
- *TCO reduction.* The installation, maintenance, and daily cost of a single metadata server are cheaper than multiple metadata servers.

New network and storage hardware, such as RDMA and PM, provides new opportunities for metadata performance. NVIDIA's latest generation NIC, ConnectX-6, exhibits a speed of 215Mpps for small packets [4]. RedN [23] also illustrates that ConnectX-6 shows a 112M verbs/s throughput in 64B RDMA writes. The only available PM product, Intel Optane DIMM, shows at least 29.06Mops/s and 8.75Mops/s read/write throughput with the access granularity of less than 256B [2] while maintaining memory semantics and data persistence. As inodes are typically tiny in file systems (e.g., 128B in Ext4), achieving high small-granularity access performance allows us to build a high-performance distributed file system with a single metadata server.

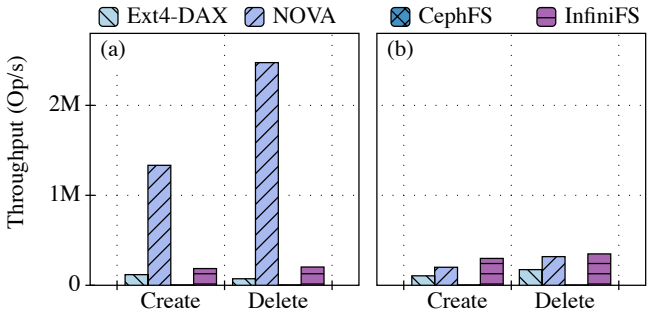

Figure 1: Per-NUMA file `create` and `delete` throughput of local PM file systems and distributed file systems (a) in a private directory for each client, (b) in a shared directory.

2.2 Analysis of Existing Solutions

In this section, we analyze the limitations of existing solutions that discourage them to support a billion-scale distributed file system with a single metadata server.

There are mainly two categories of existing solutions, local PM file systems, and distributed file systems. For each type, we select two typical file systems for comparison, namely Ext4-DAX and NOVA [32] for local PM file systems, and CephFS [31] and InfiniFS [19] for distributed file systems. We gradually increase the number of client threads until each file system achieves the peak throughput. The testbed and configuration details are further described in §5.1.

Figure 1 shows the per-NUMA file `create` and `delete` throughput of the compared file systems with clients operating on private directories and a shared directory, respectively. We make the following observations:

1) The overhead of crash consistency limits the throughput of multi-inode metadata update operations. Ext4-DAX uses write-ahead-logging (WAL) to guarantee its crash consistency, while InfiniFS and CephFS leverage the transaction support of their storage backend. These methods all introduce extra costs for the multi-inode metadata update operations. NOVA reduces the crash consistency cost by using the log-structured metadata architecture, making its file `create`/`delete` throughput 7.17×/12.19× higher than other file systems with private directories. However, it cannot completely get rid of the journaling overhead when coordinating multi-inode update operations. Also, it introduces extra garbage collection overhead.

2) The lock contention limits the throughput of metadata operations in a shared directory. For file `create` and `delete` operations, NOVA shows 0.17×/0.13× throughput in a shared directory than in private directories. This is because NOVA directly acquires the shared directory's write lock when performing these operations, which aggravates lock contention. The other three file systems show no significant performance

degradation. This is because they either directly use the journal for concurrency control (e.g., Ext4-DAX) or leverage the transaction support of the storage backend (e.g., CephFS and InfiniFS). These methods coordinate all the metadata operations similarly no matter they are in private directories or a shared directory, limiting the performance in both scenarios.

3) File systems fail to scale to multiple NUMA nodes while maintaining NUMA locality of metadata operations. For the compared file systems, NOVA doesn't provide support for multiple NUMA nodes. Although Ext4-DAX can be mounted to a RAID 0 device spanning across the PM DIMMs on all NUMA nodes, the simple striped layout of RAID 0 can not ensure NUMA locality for metadata operations. For InfiniFS and CephFS, they scatter the metadata objects to all the PM DIMMs without specific NUMA-aware partition rules, resulting in low NUMA locality as well.

2.3 Challenges

Based on the three observations in §2.2, we find three challenges to fully exploiting the performance of a single metadata server in distributed file systems, as discussed below.

Challenge 1. *The overhead to ensure crash consistency is extremely heavy for a single metadata server that aims to support billions of files.*

File systems use journaling or the log-structured design to provide crash consistency. In the journaling approach, data is written twice and checkpointed in order. In the log-structured approach, data is written in newly-allocated places, while leaving the old places as garbage. Unfortunately, garbage collection causes high overhead. Intensive prior research aims to reduce the overhead of the crash consistency mechanisms [14, 18, 21]. However, we need to further reduce this overhead to exploit the potential of a single server to support billions of files.

Challenge 2. *Operations in a shared directory, which are common in distributed file systems, suffer from limited parallelism and low performance caused by severe lock contention on the directory* `dirent`*s and inode.*

In HPC and big data applications, it is common for the workloads to concurrently access a large shared directory, such as N-N checkpointing [9] and image processing [1]. The concurrency of metadata operations in a shared directory significantly influences the overall performance of these applications. However, concurrent inode `create` and `delete` operations in a shared directory need to update their common parent's directory entries (`dirent`s) and inode, which causes high lock contention. Such contention limits the parallelism and performance as demonstrated in §2.2.

The previously-proposed solutions are not suitable for the case of a single metadata server. Previous works use partition strategy either inside `dirent`s [34] or between metadata server daemons [22, 31] to increase parallelism. However, partitioning inside `dirent`s can't reduce the lock contention of the common parent inode, and partitioning the super directories between metadata server daemons can not be used for one metadata server.

Challenge 3. *The NUMA architecture is under-exploited for file systems, especially for metadata operations in a single metadata server.*

NUMA-aware design is important for metadata performance when a server is used only for metadata storage and processing. On the one hand, NUMA locality is of great importance for fully utilizing the performance potentials of PM. Previous works illustrate that remote PM access introduces a significant performance drop in bandwidth and small-granularity throughput, especially for writes [28, 35], which makes metadata operations more vulnerable compared to data operations. On the other hand, our analysis in §2.2 shows that file systems fail to scale to multiple NUMA nodes while keeping NUMA locality of metadata operations, which is because of their coarse-grained partition strategy such as striping.

Existing methods are not desirable for overcoming this challenge. Randomly scattering the inodes into multiple NUMA nodes can't avoid this issue, as some operations like inode `create` and `delete` need to update multiple inodes, which causes inter-NUMA metadata access. Other methods like in-DRAM cache [28], thread migration [30], or thread delegation [35] all waste extra resources for coordination or data structure maintenance.

3 Design and Implementation

With the overall goal of exploiting the performance of a single metadata server, we design SingularFS with three key design principles as below:

- **Guaranteeing crash consistency without logs.** SingularFS performs most metadata operations without extra crash consistency mechanisms such as logs. This reduces their overheads while still maintaining POSIX semantics.
- **Maximizing parallelism in a shared directory.** By utilizing hierarchical concurrency control, SingularFS maximizes the parallelism of metadata operations in a shared directory with less synchronization overhead.
- **Reducing inter-NUMA access and intra-NUMA lock contention.** SingularFS takes a hybrid approach to metadata partition. This ensures NUMA locality of file operations and reduces lock contention within data structures to further increase the parallelism in a shared directory.

3.1 Overview

SingularFS is a billion-scale distributed file system using a single metadata server, exploiting the single-server performance while not sacrificing multi-server scalability. Figure 2

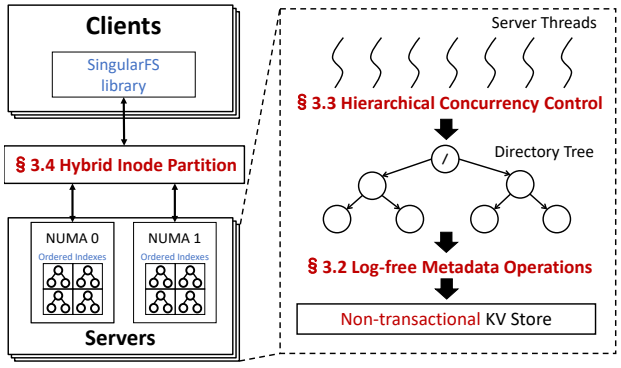

Figure 2: SingularFS architecture.

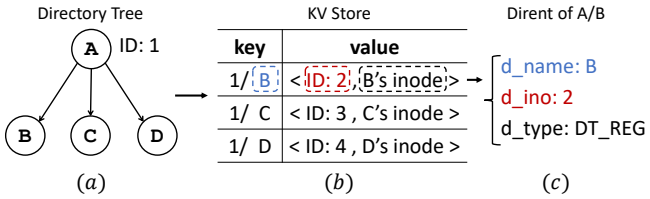

Figure 3: (a) An example of the directory tree. (b) The format of directory A's child inodes in KV Store. For the inode with ID = *i*, the keys of its child inodes share the same prefix *i*. (c) The way to reassemble `dirents` in a `readdir` operation. SingularFS first does prefix matching with the target directory's ID to get the child KV pairs, then uses the keys to generate `d_name` and reads the values to get `d_ino` and `d_type`.

presents the architecture of SingularFS, which contains two components, clients and servers. Servers maintain a global file system directory tree inside PM. Clients perform file system operations through POSIX-like interfaces offered by the user-space library. Servers and clients are equipped with RDMA NICs for network communication.

Storage backend. SingularFS uses a generic key-value store (KV Store) as its storage backend. The KV Store should be able to execute point queries and prefix matching. Besides, it should guarantee the atomicity of single-object operations at a low runtime cost.

SingularFS differs from other file systems with KV Store backends [17, 19, 24, 25] in two ways. First, instead of relying on the transaction provided by the KV Store backends (Non-transactional KV Store in Figure 2), SingularFS uses a lightweight approach for metadata operations (§3.2, §3.3). Second, instead of using one ordered KV Store per metadata server, SingularFS leverages hybrid inode partition to convert the shared index into multiple ordered indexes scattered to NUMA nodes, aiming at reducing inter-NUMA access and intra-NUMA lock contention (§3.4).

Regular metadata operations. We use this term to refer to metadata operations other than `rename`. Leveraging the timestamp dependency of modified inodes, SingularFS uses ordered metadata update to guarantee their crash consistency without logs (§3.2). For concurrency control, SingularFS takes a hierarchical method by utilizing both the per-inode read-write lock and lock-free timestamp update (§3.3).

Rename. SingularFS uses journaling to guarantee the crash consistency of `rename`. As an optimization, ordered metadata update (§3.2) is adopted to guarantee the crash consistency of the two parent directories involved in `rename`, reducing the number of logged inodes from 4 to 2. SingularFS uses strict two-phase locking for concurrency control of `rename`.

Inode. SingularFS adds two fields, the born time *btime* and the death time *dtime*, to the inode to identify metadata inconsistencies leveraging the timestamp dependency (§3.2). Besides, SingularFS partitions the directory inode to timestamp metadata (`atime`, `ctime`, and `mtime`) and access metadata (inode ID, permission, *btime*, *dtime*, etc.), and places the timestamp metadata of the parent directory with its child inodes into the same NUMA node to ensure NUMA locality of file operations (§3.4).

Inodes are all stored in the KV Store backend. Directory access metadata and file inodes are indexed by key <`parent inode ID`+`name`>, and directory timestamp metadata is indexed by key <`inode ID`>. The root directory has a unique inode ID 0. Path resolution is done by recursively fetching the directory access metadata from the root to the target inode.

Dirent. Directory entries (`dirents`) are omitted from directory metadata blocks but co-located with the keys and values of child inode objects. Thus, `dirent` update and inode update are fused into one key-value update operation. As shown in Figure 3, in a `readdir` operation, SingularFS reassembles the `dirents` of the target directory by adopting prefix matching provided by the KV Store backend.

Data management. SingularFS employs a decoupled structure for metadata and data. Therefore, existing approaches for data management can be directly adopted by SingularFS. Currently, SingularFS uses the object store [31] to manage data. It indexes data blocks with key <`inode ID`+`block no`>.

3.2 Log-free Metadata Operations

In this section, we first analyze and classify the metadata write operations. Then, we demonstrate the timestamp dependency of the parent directory and child inodes and propose the core of log-free metadata operations, i.e., ordered metadata update.

3.2.1 Analysis of Metadata Write Operations

As illustrated in Table 1, metadata write operations in SingularFS can be classified into three categories according to the number of modified inodes.

1. *Single-node operations.* These operations only update the target inode itself (e.g., file `open/close/read/write`).
2. *Double-node operations.* These operations update the target inode, as well as the timestamps of its parent directory (e.g., file `create/delete`). Note that in SingularFS,

Operation Type	Metadata Write Operations	Modified Inodes		
		Target Inode	Parent Directory	Other Inodes
Single-node	`open/close/read/write/chmod/chown/utimens`	•		
Double-node	`mkdir/rmdir/create/delete`	•	•	
Rename	`rename`	•	•	•

Table 1: Classification of metadata write operations according to the modified inodes.

parent `dirents` are co-located with the child inode objects (§3.1), so there is no need to update the `dirents` separately for these operations.

3. *Rename operation.* This operation updates the original inode, the new inode, and their parent directories.

According to the real workloads shown in InfiniFS [19] and HopsFS [20], regular metadata operations, which include read operations, *single-node operations*, and *double-node operations*, account for more than 90% of all file system operations. Based on this observation, we design log-free metadata operations to guarantee the crash consistency of regular metadata operations.

Since the crash consistency of *single-node operations* can be directly guaranteed by the KV Store backend, in this section, we seek to guarantee the crash consistency of *double-node operations* without incurring additional overheads.

3.2.2 Ordered Metadata Update

As *double-node operations* set the parent directory's `ctime` to the target inode's *btime* or *dtime*, we observe that the timestamps of the parent directory and child inodes have the following dependency:

> *For an inode d, d.*`ctime` $\geq \max(c.btime, c.dtime)$*, where c is any of d's child inodes.*

Based on this observation, we update the metadata in order, to guarantee the crash consistency of *double-node operations* without incurring the logging overhead.

inode creation. As shown in Figure 4(a), inode creation includes two atomic steps. First, we insert the inode with *btime* = t_0, where t_0 is the current timestamp. Second, we set the `ctime` and `mtime` of its parent directory to t_0.

inode deletion. As shown in Figure 4(b), inode deletion includes three atomic steps. First, we invalidate the target inode and set its *dtime* to the current timestamp t_0. Second, we set the `ctime` and `mtime` of its parent directory to t_0. Finally, we physically remove the target inode from KV Store.

Crash recovery. When a crash occurs between the two steps in inode creation, or between step 1 and step 2 in inode deletion, the inconsistency can be identified by checking if the maximum *btime* and *dtime* of child inodes > `ctime` of the parent directory, and fixed by setting the `ctime` and `mtime` of the parent directory to the maximum value. When a crash occurs between step 2 and step 3 in inode deletion, the inconsistency can be identified by checking if the target inode is invalid and fixed by physically removing the invalid inode.

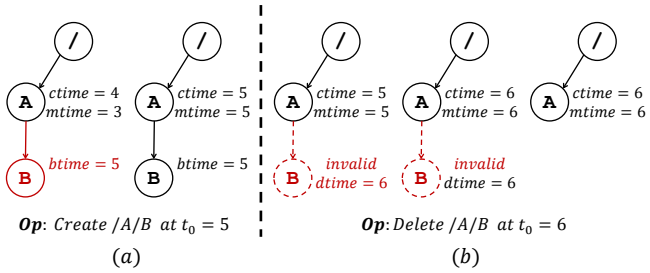

Figure 4: The process of inode creation and inode deletion in log-free metadata operations. (a) Inode creation includes two steps. First, insert the target inode with *btime* = current timestamp t_0. Then, update the timestamps of the parent directory to t_0. (b) Inode deletion includes three steps. First, mark the target inode as invalid and set its *dtime* to the current timestamp t_0. Then, update the timestamps of the parent directory to t_0. Finally, physically remove the target inode. The inconsistency of the directory tree is marked with red lines.

In order to detect and fix all the inconsistencies mentioned above, the most straightforward approach is to scan the whole directory tree. However, this process can be costly. SingularFS detects and fixes the inconsistency lazily when the inconsistent directory is accessed, as described in §4.

3.3 Hierarchical Concurrency Control

In traditional file systems, it is challenging to maximize the parallelism of *double-node operations* in a shared directory, as they cause contention over the parent `dirent` and timestamps. In SingularFS, the update of the parent `dirent` is co-located with the update of the child inode, whose concurrency is guaranteed by the KV Store backend. Therefore, the remaining challenge lies in the concurrent timestamp update.

We observe that *double-node operations* only modify the parent directory's `ctime` and `mtime`, whose size is 16B in total. Therefore, the concurrency control of the timestamp updates could be executed in a lock-free manner by leveraging the 16B atomic compare-and-swap instruction.

We divide operations on a target inode into three categories, *updater*, *writer*, and *reader*. *updater* contains inode update operations that involve only the target inode's `ctime` and `mtime`, and *writer* contains all other update operations. *reader* contains all inode read operations. For example, *double-node operations* like file `create/delete` are both *writers* of the target inode and *updaters* of the parent directory, and file `stat` is a *reader* of the target inode.

```
1  struct Inode {
2      ...
3      uint64 ctime; # aligned at a 16B boundary.
4      uint64 mtime;
5      ...
6  }
7
8  def writer(this: Inode *):
9      this->write_lock() # sync with other operations.
10     modify_inode(this)
11     this->write_unlock()
12
13 def updater(this: Inode *, timestamp: uint64):
14     this->read_lock() # sync with writer
15     while True:
16         # acquire timestamp snapshot.
17         cur = { this->ctime, this->mtime }
18         nxt = { timestamp, timestamp }
19         # update ctime and mtime atomically.
20         if (cur[0] >= timestamp or
21             cmpxchg16b(&this->ctime, cur, nxt)):
22             break
23     this->read_unlock()
24
25 def reader(this: Inode *):
26     this->read_lock() # sync with writer
27     while True:
28         # use ctime as the version number.
29         last_ctime = this->ctime
30         compiler_barrier()
31         inode = *this
32         compiler_barrier()
33         # OCC-like method.
34         cur_ctime = this->ctime
35         if cur_ctime == last_ctime:
36             break
37     this->read_unlock()
38     return inode
```

Algorithm 1: **Hierarchical concurrency control algorithm.**

Algorithm 1 shows the hierarchical concurrency control algorithm among *writer*, *updater*, and *reader*.

Writer-other synchronization. Synchronization between *writers* and other operations is handled by the per-inode read-write locks. The *writer* acquires the write lock to guarantee exclusive access to the target inode (line 9). *Updaters* and *readers* acquire the read lock to avoid concurrent *writer* doing inode update or remove operations (line 14, line 26).

Updater-updater synchronization. With the purpose of minimizing the length of the critical section, *updaters* use atomic instructions to synchronize between themselves in a lock-free manner. As the *updater* only updates the ctime and mtime of the target inode, they are placed in a 16B-aligned block (line 3), and the *updater* uses `cmpxchg16b` to atomically update `ctime` and `mtime` to the maximum of the timestamp parameter and the original value (lines 15-22). Specifically, the *updater* first acquires the current snapshot of `ctime` and `mtime` (line 17). If the current `ctime` is not less than the timestamp parameter, there is no need to update the timestamps as they have been updated by another *updater* with a later timestamp (line 20). If the current `ctime` is less than the timestamp parameter and there is no concurrent *updater* in the critical area (line 21), then update the timestamps atomically.

Updater-reader synchronization. We observe that `ctime` monotonically increases when *updaters* modify the inode, so it has the same semantic as a version number. Based on this observation, we adopt optimistic concurrency control (OCC) to synchronize between *readers* and *updaters* without locks. Specifically, `ctime` is fetched by the *reader* before and after getting the whole inode (line 29, line 34). The *reader* validates the inode by comparing the two `ctime`s (line 35).

3.4 Hybrid Inode Partition

In this section, we first show how to partition the inodes among NUMA nodes and execute multi-object directory operations introduced by the partition. Then, we propose the intra-NUMA data structure.

3.4.1 Inter-NUMA Inode Partition

Partition for NUMA locality of file operations. As file operations account for the majority of all metadata operations [19], we seek to guarantee their NUMA locality.

For *single-node* file operations, we delegate metadata requests to the corresponding NUMA node to ensure their NUMA locality. However, this does not work for *double-node* file operations (`create/delete`), as the two related inodes may reside in different NUMA nodes. Fortunately, in SingularFS, these operations only modify the parent directory's `ctime` and `mtime`, so NUMA locality of them can be guaranteed by grouping the parent directory's `ctime` and `mtime` with the child file inodes to the same NUMA node.

Therefore, SingularFS partitions the directory inode into timestamp metadata (`atime`, `ctime`, and `mtime`) and access metadata (inode ID, permission, *btime*, *dtime*, etc.). For each directory, SingularFS aggregates the directory timestamp metadata, its child file inodes, as well as its child directories' access metadata into a metadata group. The objects within a metadata group are placed in the same NUMA node. SingularFS uses consistent hashing to distribute the groups to NUMA nodes of the metadata server, thus achieving NUMA locality of file operations.

Multi-object directory operations. As the directory metadata is partitioned into two parts (i.e., two objects in the KV Store backend), the KV Store backend cannot intrinsically guarantee crash consistency for updates on the two parts. To solve this problem without incurring extra cost, SingularFS performs these operations in certain orders.

1. *Directory* ***`mkdir`*** *and* ***`rmdir`***. Three objects are involved in these operations, specifically the target directory's access metadata and timestamp metadata, as well as the parent directory's timestamp metadata. Note that when a directory is created, all its timestamps are set to its *btime*, which is inside the access metadata of the target directory. Leveraging this, SingularFS creates the target directory's timestamp metadata after creating its access metadata. After a crash, the target directory's timestamp metadata is re-generated with its access metadata.

2. *Directory* `set_permission`. Two objects are involved in this operation, specifically directory access metadata and timestamp metadata. To guarantee the crash consistency, we expand the semantic of *btime* to the maximum of born time and last `set_permission` time. When executing `set_permission`, SingularFS first updates the target directory's permission fields and its *btime* at the same time. Then, SingularFS updates its `ctime`. On crash recovery, SingularFS identifies whether the directory's *btime* is greater than its `ctime` and fixes them if needed.

3.4.2 Intra-NUMA Inode Partition

Partition for less lock contention. To generate `dirents` of a particular directory, SingularFS relies on the range query operation, which is supported by the ordered index. However, typical B+-tree-based ordered indexes suffer from high lock contention caused by traversing and node splits when updates prevail in workloads. To reduce such intra-NUMA lock contention while keeping the functionality of the range query, inside each NUMA node, SingularFS uses the hash algorithm to scatter all metadata uniformly to *n* ordered indexes, where *n* is a configurable parameter.

When executing point queries, SingularFS queries the value from the key's corresponding index calculated by its hash. When performing range queries, such as in directory `readdir` operation, SingularFS makes range queries in all the indexes and merges the results.

Optimization for removal. Directory `rmdir` requires determining whether the target directory is empty. As the `dirents` are co-located with the child inodes, this process can be implemented using prefix matching. However, with intra-NUMA inode partition, we would have to perform prefix matching in all *n* ordered indexes, which could be costly.

We optimize this process by adding a `num_dents` variable to the metadata of each directory, identifying the number of `dirents`. The crash consistency of this variable is easily guaranteed because it can be recovered by executing a complete prefix matching for the directory.

`num_dents` should meet two requirements for concurrency safety. First, it must allow concurrent updates from *updaters*. To achieve this goal, directory *updaters* use `fetch_and_add` and `fetch_and_sub` to synchronize with each other. Second, its value must be correct when a `rmdir` occurs. Since `rmdir` is a *writer* of the target inode, there can be no concurrent *updaters* when SingularFS is executing `rmdir`. Therefore, `num_dents` will keep unchanged during `rmdir` and it is safe for us to use its value to judge the directory's emptiness.

4 Crash Recovery

Algorithm 2 shows the overall crash recovery algorithm for a single directory inode in SingularFS. It mainly consists of three aspects: Parent timestamp recovery (lines 9-14) and

```
1  def recover(ino: Inode):
2      ino.num_dents = 0
3      # re-create incomplete timestamp metadata
4      recreate_timestamp_meta(ino)
5      # inconsistency caused by set_permission
6      if ino.btime > ino.ctime:
7          ino.ctime = ino.btime
8      for c in ino.child_inodes:
9          if (c.valid and c.btime > ino.ctime) or
10             (!c.valid and c.dtime > ino.ctime):
11             # crash before timestamp update.
12             ino.ctime = max(c.btime, c.dtime)
13             ino.mtime = max(c.btime, c.dtime)
14             redo(c) # create / delete.
15         else if not c.valid:
16             remove(c) # invalid inode
17         ino.num_dents += 1 # maintain num_dents
```

Algorithm 2: **Crash recovery algorithm for inode `ino`.**

invalid inode removal (lines 15-16) in log-free metadata operations, directory timestamp metadata recovery (lines 4-7) in inter-NUMA inode partition, and `num_dents` maintenance (line 2, line 17) in intra-NUMA inode partition.

SingularFS detects and fixes the inconsistent directory only when it is accessed. Specifically, SingularFS maintains a global `restartCnt` variable, which increases by one at each restart. Inside each directory inode, we keep a local `restartCnt` padded in the directory read-write lock. Locking a directory also sets its local `restartCnt` to the global value. After a crash, an inconsistent directory will contain an outdated `restartCnt`. Such inconsistency will be detected and fixed according to Algorithm 2 on the next access.

5 Evaluation

In this section, we evaluate SingularFS to answer the following questions:

- How does SingularFS compare to local PM file systems and distributed file systems utilizing RDMA and PM on metadata performance? (§5.2)
- How does SingularFS scale on concurrent racing metadata operations in a shared directory? (§5.3)
- How do the techniques employed by SingularFS impact its metadata performance? (§5.4)
- How does SingularFS perform with a billion-scale directory tree? (§5.5)
- What is the performance of `rename` in SingularFS? (§5.6)
- What is the end-to-end performance of SingularFS? (§5.7)
- What is the overhead of crash recovery? (§5.8)

5.1 Experimental Setup

Hardware configuration. In the experiments, unless otherwise stated, we use one server node and one or two client nodes. The metadata server and data server are co-located. Each server node has two Intel Xeon Gold 6330 CPUs, with 28 cores per socket. Hyperthreading is disabled on servers, for it aggravates contention and degrades the overall performance.

Each socket has four 128GB Intel Optane DC Persistent Memory (DCPMM) DIMMs, 256GB DRAM, and one 200Gb/s Mellanox ConnectX-6 NIC. The Optane DIMMs are configured in App Direct mode.

Each client node has two Intel Xeon Platinum 8360Y CPUs, with 36 cores (72 threads) per socket, so as to issue as many requests as possible to saturate the metadata server. Each socket has 256GB DRAM and one 200Gb/s Mellanox ConnectX-6 NIC. All the clients and servers are connected with a Mellanox QM8790 switch. For ConnectX-6 NICs, the driver and firmware versions are OFED 5.5-1.0.3.2 and 20.32.1010.

Compared systems. We use two types of baseline file system in the comparison, specifically local PM file systems and distributed file systems.

For local PM file systems, we choose Ext4-DAX and NOVA [32]. For these file systems, we clear the VFS cache before each directory and file `stat` operation to mitigate its impact and ensure that the acquired performance reflects the actual metadata performance of the file system.

For distributed file systems, we choose CephFS [31] and InfiniFS [19]. For CephFS, we use version 15.2.16 with RDMA enabled. The latency of CephFS is obtained by running it in RDMA mode, while the throughput is obtained by running it in IPoIB mode because we find that CephFS will always crash if run in RDMA mode for a relatively long time. For InfiniFS, we add support for RDMA and multiple NICs with eRPC [13]. Since InfiniFS uses RocksDB [5] storage backend, we run it on Ext4-DAX mounted on top of a RAID 0 device spanning across all the PM DIMMs.

We use P-Masstree [15] as the ordered index of SingularFS and set the per-NUMA index number n to 8. For SingularFS and InfiniFS, we use 56 worker threads executing in-line requests, and clients connect to them in a round-robin way. SingularFS stores its data objects in PM for fairness.

Benchmark. We use mdtest v3.3.0 provided by IOR [3] to evaluate the metadata performance of the aforementioned file systems. We use OpenMPI v4.1.2 to generate parallel mdtest client processes, which are placed on the metadata server for local PM file systems and scattered across all the client nodes for distributed file systems. We use the POSIX interface for local PM file systems. For distributed file systems, we use either the intercepted POSIX syscall [6] or the client libraries (e.g., libcephfs of CephFS). Our experiments create files of zero length like the previous works [17, 19, 25] because we focus on the insights into metadata performance. For end-to-end benchmarks, we use Filebench [27] to evaluate the overall performance.

For lack of multi-NUMA support in some of the compared file systems (e.g., NOVA and CephFS), we compare their per-NUMA throughput instead of overall throughput to guarantee the fairness of the comparison. For Ext4-DAX and NOVA, we limit their CPU and PM resources to a single NUMA node and use the results directly as their per-NUMA performance.

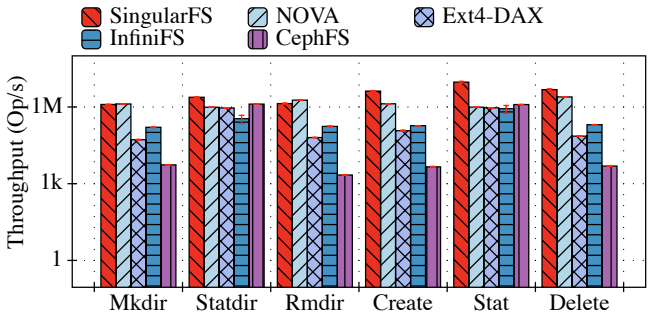

Figure 5: Per-NUMA throughput of metadata operations in private directories. The Y-axis is log-scaled.

For CephFS, we restrict its server-side PM and NIC resources and directly use the results as its per-NUMA performance. For SingularFS and InfiniFS, we do not limit their hardware resources and average their throughput results to get their per-NUMA performance.

5.2 Metadata Performance

In this section, we compare the overall metadata performance of the file systems mentioned above. We use mdtest to measure the performance of directory `mkdir/stat/rmdir` and file `create/stat/delete` operations. Each client handles 2 million directories and 2 million files in its private directory. For CephFS and InfiniFS, we get their peak performance by modestly reducing the directory and file quantity per client process, as they show a relatively low performance at the aforementioned scale.

5.2.1 Throughput

In this section, we evaluate the throughput of metadata operations in different file systems. We gradually increase the number of client processes to achieve the peak per-NUMA throughput for each file system.

Figure 5 shows the per-NUMA metadata throughput of different file systems in private directories. From the figure, we make the following observations:

1) SingularFS outperforms local PM file systems in file `create` and `delete` operations and outperforms the distributed file systems by more than an order of magnitude. SingularFS achieves 3.13×/1.93× and 22.49×/23.57× higher throughput for file `create`/`delete` operations than NOVA and InfiniFS. This is because the log-free metadata operations in SingularFS removes the extra transaction logic from the critical path of these operations, which saves both PM bandwidth and the CPU cycles spent writing logs and waiting for persistence. Inter-NUMA inode partition also guarantees NUMA locality of file operations, reducing inter-NUMA communication. These two designs make SingularFS fully exploit the single-server performance of file metadata write operations.

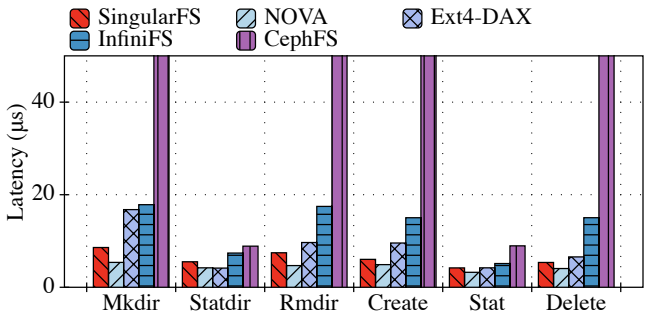

Figure 6: Latency of metadata operations. Note that the result of SingularFS, CephFS, and InfiniFS includes the network delay, while the result of Ext4-DAX and NOVA doesn't.

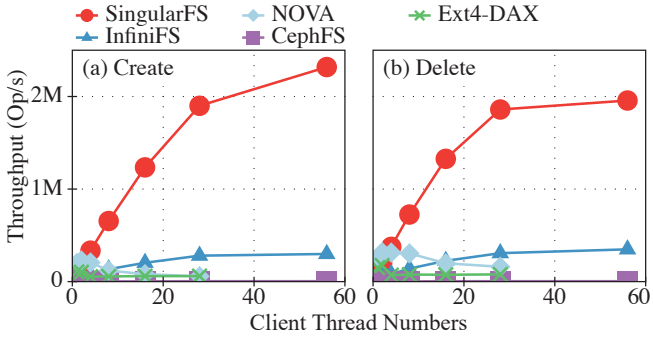

Figure 7: Per-NUMA throughput scalability of file `create` and `delete` in a shared directory.

2) The throughput of directory `mkdir` and `rmdir` is much lower than file `create` and `delete`, but still comparable with local PM file systems (0.96×/0.73× than NOVA) and much higher than distributed file systems (7.82×/7.77× higher than InfiniFS). This is because these operations need to write both the target directory's access metadata and its timestamp metadata, which are not guaranteed to be in the same NUMA node. However, these metadata update operations are transformed into several simple KV writes by utilizing log-free metadata operations, accelerating this process.

3) SingularFS outperforms local PM file systems and distributed file systems in the case of metadata read operations. For file `stat` operation, SingularFS achieves 9.54×/10.10× higher throughput than NOVA/Ext4-DAX, and 7.54×/10.97× higher throughput than CephFS/InfiniFS. This is because by adopting log-free metadata operations and hierarchical concurrency control, SingularFS separates the transaction logic from KV Store. This enables SingularFS to use a lightweight KV Store backend (e.g., P-Masstree [15]) to accelerate the `stat` operation.

4) SingularFS demonstrates high NUMA scalability. Using inter-NUMA inode partition, SingularFS guarantees NUMA locality for file operations. Although it utilizes all the hardware resources rather than just one NUMA node, its per-NUMA throughput of file operations still outperforms that of file systems running on one NUMA node.

5.2.2 Latency

In this section, we evaluate the latency of metadata operations in different file systems. We launch one mdtest client to measure the latency of each metadata operation.

Figure 6 shows the average latency of different metadata operations of the compared file systems. From this figure, we make the following observations:

1) Compared with local PM file systems, SingularFS achieves comparable latency with Ext4-DAX and NOVA in file operations. This is because SingularFS has a shorter server-side critical path for metadata write operations by leveraging log-free metadata operations and inter-NUMA inode partition. SingularFS also has a low latency for read operations by guaranteeing NUMA locality of file metadata. Even though suffering from the µs-level inherent latency of RDMA, SingularFS still achieves comparable latency with local PM file systems for file operations.

2) Compared with distributed file systems, SingularFS achieves lower latency than CephFS and InfiniFS. This is because with the lightweight KV Store and log-free metadata operations, SingularFS has a more lightweight software stack than CephFS and InfiniFS, contributing to its lower latency.

5.3 Scalability in a Shared Directory

In this section, we evaluate the throughput scalability of concurrent racing metadata operations in a shared directory. In the evaluation process, we gradually increase the number of mdtest clients and get the per-NUMA throughput for file `create` and `delete` operations in a shared directory.

Figure 7 shows the throughput scalability of file `create` and `delete` in a shared directory in different file systems. From the figure, we make the following observations:

1) SingularFS shows much better throughput scalability in a shared directory than other file systems, outperforming them by at least 7.76×/5.61× on file `create`/`delete` operations. This is because SingularFS leverages hierarchical concurrency control to maximize the parallelism of metadata operations in a shared directory, and adopts intra-NUMA inode partition to reduce lock contention inside the intra-NUMA data structure. These two methods contribute to the shared-directory scalability of SingularFS.

2) SingularFS achieves nearly the theoretical peak performance in a shared directory. The file `create`/`delete` throughput of SingularFS in a shared directory converges to around 4Mops/s for the whole metadata server, which is close to the per-NUMA peak throughput of SingularFS illustrated in Figure 5. This is because all the inodes in a shared directory are placed in the same NUMA node. Therefore, all the operations are handled in the same NUMA node, and the upper bound for performance is the per-NUMA peak performance of SingularFS.

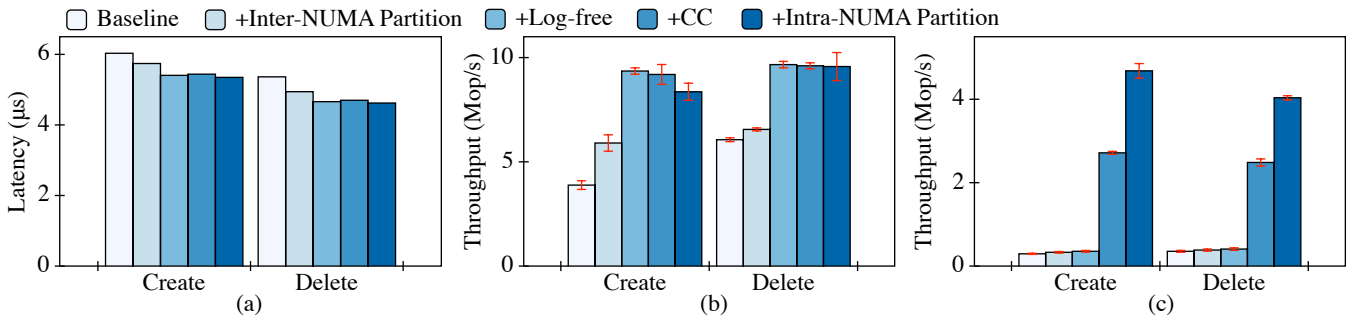

Figure 8: Performance breakdown. (a) Average latency. (b) Throughput in private directories. (c) Throughput in a shared directory. Design techniques are accumulated.

5.4 Factor Analysis

In this section, we analyze how our designs contribute to the latency and throughput by breaking down the performance gap between the *Baseline* and SingularFS. We apply our designs one by one to the *Baseline*, and measure the average latency and throughput of file `create` and `delete`. For the latency breakdown evaluation, we initiate one mdtest client to operate on 2 million files in a directory. For the throughput breakdown evaluation in private directories, we initiate 112 mdtest clients, and each client handles 2 million files in its private directory. For the throughput breakdown evaluation in a shared directory, we gradually increase the client number from 1 to 112 to achieve the peak throughput of each configuration. Each client operates on 2 million files in a shared directory. The results are not averaged to per-NUMA performance.

We implement the *Baseline* based on the framework of SingularFS, but without the key design features. It uses P-Masstree running on Ext4-DAX mounted on top of a RAID 0 device built from all the PM DIMMs, with pessimistic two-phase locking (2PL) and WAL for transaction support. In these three figures, *+Log-free* stands for utilizing log-free metadata operations instead of WAL to guarantee crash consistency. *+CC* represents adopting hierarchical concurrency control instead of simply using 2PL to do concurrency control. *+Inter-NUMA partition* and *+Intra-NUMA partition* are the two design parts of hybrid inode partition.

5.4.1 Private Directories

As shown in Figure 8(a) and Figure 8(b), SingularFS has much higher throughput and lower latency against *Baseline*. Specifically, for file `create` operation, SingularFS achieves 2.15× higher throughput with 1.13× lower average latency. For file `delete` operation, SingularFS achieves 1.58× higher throughput with 1.16× lower average latency. Here, we separately analyze all the design techniques in terms of file `create` workload (file `delete` has the same conclusions).

Inter-NUMA inode partition improves the throughput by 1.52× and reduces the average latency by 1.05×, since it guarantees NUMA locality of file operations, thus reducing the frequency of inter-NUMA PM access.

By using log-free metadata operations to guarantee crash consistency, SingularFS gains another 1.58× and 1.06× improvement in terms of throughput and average latency. This is because WAL is replaced in the critical path with log-free metadata operations, reducing the bandwidth waste of PM for logs and saving the CPU cycles of log persistence.

Hierarchical concurrency control and intra-NUMA partition bring a 10% throughput drop and a minor latency increase since they introduce extra synchronization overhead when there are few conflicts. Besides, the intra-NUMA inode partition has a negative effect on the cache friendliness of the overall data structure, accounting for the throughput drop.

5.4.2 Shared Directory

Figure 8(c) shows the throughput of file `create` and file `delete` in a shared directory. Compared with *Baseline*, SingularFS achieves 15.93×/11.40× higher throughput for file `create/delete` operations separately.

Inter-NUMA inode partition and log-free metadata operations contribute to 1.21×/1.15× throughput increase for file `create/delete` operations by reducing the length of the critical area, which shortens the critical area. However, the major bottleneck still lies in the lock contention of the shared directory. Hierarchical concurrency control mitigates this lock contention, thus increasing the throughput by 7.66×/6.09×. This is the peak throughput of P-Masstree in the case of high lock contention brought by the common prefix. The intra-NUMA inode partition mitigates this lock contention and contributes to another 1.72×/1.62× higher throughput.

5.5 Billion-scale Directory Tree

In this section, we demonstrate that SingularFS can efficiently support the billion-scale directory tree. We repeatedly `create` and `stat` 50 million files per NUMA node to increase the directory tree size until the file system is full.

Figure 9 shows the evaluation results. We make the following observations from the figure:

1) SingularFS delivers a steadily high throughput for file `create` and file `stat` operations with the billion-scale direc-

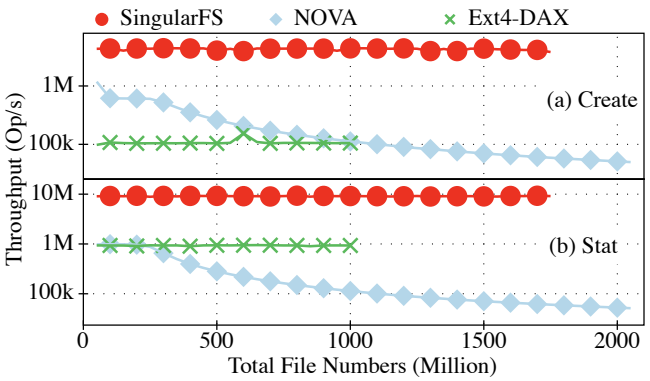

Figure 9: Per-NUMA throughput of file `create` and `stat` for the billion-scale directory tree. The Y-axis is log-scaled.

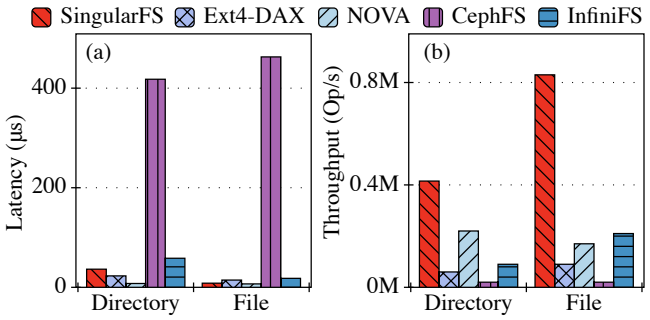

Figure 10: Performance of directory `rename` and file `rename`. (a) Latency. (b) Per-NUMA throughput.

tory tree. Specifically, it shows a steady per-NUMA throughput of ~4.40Mops/s for file `create` and ~9.10Mops/s for file `stat`, which is 41.90×/9.83× higher than Ext4-DAX. Although NOVA shows a relatively high throughput when the directory tree is nearly empty, its throughput is not even as high as Ext4-DAX when there is a billion-scale directory tree.

2) SingularFS shows similar directory tree scalability to local PM file systems. SingularFS supports 1.75 billion files per NUMA node, which is higher than Ext4-DAX (1 billion files) and lower than NOVA (2.05 billion files). The reason why SingularFS supports fewer files than NOVA is that SingularFS uses a KV Store to store the inodes, while NOVA uses per-core linked lists. The index of SingularFS has a higher capacity overhead than NOVA. However, it provides significantly higher performance.

5.6 Rename

In this section, we evaluate the latency and per-NUMA throughput of directory `rename` and file `rename` in SingularFS. In the experiments, each client renames 1 million directories and 1 million files from one directory to another.

Figure 10 shows the overall results. From the figure, we make the following observations:

1) For file `rename`, SingularFS shows comparable latency

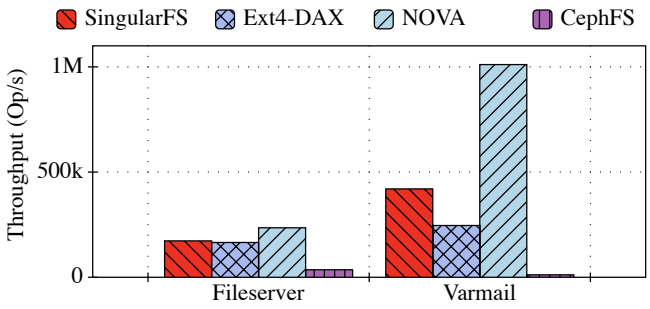

Figure 11: Per-NUMA throughput of Fileserver and Varmail workloads in Filebench.

with local PM file systems and at least 3.95× higher per-NUMA throughput than other file systems. Although SingularFS uses journaling to ensure crash consistency, the journal is lightweight as it only contains the two target KV pairs. Logs of the parent directories are omitted with log-free metadata operations. However, because of the journaling overhead and inevitable inter-NUMA access, the throughput of file `rename` is 0.17×/0.15× of file `create`/`delete`, lower than a half of their throughput (i.e., theoretical throughput limit).

2) The latency and throughput of directory `rename` are both worse than those of file `rename`. This is because SingularFS adopts the directory metadata cache like the previous works [17, 19, 25]. Directory `rename` causes cache invalidation and path re-resolution, reducing its performance.

5.7 End-to-end Performance

In this section, we test the end-to-end performance of SingularFS. Specifically, we run the per-NUMA throughput of Filebench Fileserver and Varmail workloads on SingularFS and baseline systems. We set the file number of Varmail to 100K. The result of InfiniFS is not included as it focuses on metadata service rather than the whole file system.

Figure 11 shows the results. From the figure, we make the following observations:

1) SingularFS outperforms CephFS and Ext4-DAX in both workloads. Specifically, SingularFS outperforms Ext4-DAX by 1.05× in Fileserver and 1.71× in Varmail. With its metadata design, SingularFS gets more performance gains in Varmail, which is metadata-intensive.

2) SingularFS shows 0.74× and 0.41× the throughput of NOVA in Fileserver and Varmail respectively. The lower performance of SingularFS stems from the existing inter-client metadata dependencies (e.g., client 1 creates a file, then client 2 deletes it) within the workload, which makes the high performance of the metadata server hard to be fully exploited. As the metadata server is under-saturated, the latency of metadata operation becomes the primary influence on the overall performance. Because SingularFS is accessed over the network, it has higher metadata operation latency (as discussed in §5.2.2) and thus lower throughput than NOVA.

Method	*Launch*	*Consistent*	*Inconsistent*
Scan	32.1s	5.3µs	-
Lazy	0s	5.3µs	30.8ms

Table 2: Recovery overhead. *Launch*: recovery time during launch. *Consistent*: latency of file `create` that does not require recovery. *Inconsistent*: latency for file `create` to detect and fix the inconsistent parent directory.

5.8 Crash Recovery

In this section, we evaluate the impact of lazy recovery on the latency of metadata operations, compared to scanning the directory tree. In the experiments, the server crash results in one inconsistent directory with 100K files in it. For lazy recovery, SingularFS detects and fixes this inconsistent directory while doing file `create` in it. For scan, the server scans the whole directory tree during launch. The directory tree size is 100M.

Table 2 shows the results. From the table, we make the following observations:

1) The time of lazy recovery is much shorter than scanning the directory tree. This is because SingularFS only scans the 100K files in the inconsistent directory on lazy recovery. However, all the 100M files must be accessed when scanning the whole directory tree, contributing to its high latency. This issue is even more severe in the billion-scale directory tree.

2) The lazy recovery time is still orders of magnitude higher than metadata operations. This is because SingularFS still needs to scan the 100K files in the inconsistent directory during lazy recovery. The recovery time is expected to be lower if the inconsistent directory contains fewer files.

6 Related Work

The efficiency of file systems has always been an interesting and important research topic, both for local PM file systems [10, 11, 32, 35] and distributed file systems [7, 17, 19, 22, 25, 31]. Different from the works mentioned above, SingularFS improves metadata efficiency by optimizing the transactions in metadata operations with ordered updates and improving NUMA locality of metadata operations. In this section, we focus on these two aspects of related work.

Transactions and Ordering in metadata operations. Transactions are a way to guarantee the atomicity and crash consistency of metadata operations. For local PM file systems, BPFS [10] relies on copy-on-write (CoW) and 8-byte in-place atomic updates to provide metadata consistency. PMFS [11], in contrast, uses larger in-place atomic updates with journaling, while NOVA [32] uses a log-structured data structure for metadata consistency. For distributed file systems, HopsFS [20] relies on both row-level locking and the NDB backend for strong metadata consistency semantics, while InfiniFS [19] leverages the transaction mechanism of the key-value storage backend and the two-phase commit protocol separately for local and distributed metadata transactions. CephFS [7, 31] and CFS [29] also leverage their storage backend to guarantee the atomicity and crash consistency of metadata operations. These methods have considerable CPU overhead, and SingularFS mitigates this overhead by using log-free metadata operations to guarantee crash consistency with minimal cost and adopting hierarchical concurrency control to maximize parallelism.

Ordering is another way to support crash consistency. Soft Updates [12] ensures that data and metadata are written to disks in an ordered way, so as to enable recovery after a crash. One of the obstacles to using Soft Updates is the complexity of keeping general orders between different metadata blocks. In comparison, SingularFS only needs to keep the orders of timestamp metadata, and thus is more practical in use.

NUMA-aware file systems. Several recent studies propose approaches for mitigating the NUMA effect in PM file systems. NThread [30] uses thread migration to alleviate the NUMA issues of the PM file systems. Assise [8] uses on-die DMA engines for remote PM writes to bypass hardware cache coherence. OdinFS [35] uses NUMA-aware delegation threads to handle PM access with large granularity. These approaches are mainly for data service in the file system, and can not be easily applied to metadata service, because metadata operations 1) are not more costly than thread migration, 2) have a more complex indexing logic other than simple read/write, 3) have small access granularity. SingularFS uses hybrid inode partition to ensure NUMA locality of file operations while minimizing the extra cost of scheduling.

7 Conclusion

This paper presents SingularFS, a billion-scale distributed file system using a single metadata server. SingularFS uses log-free metadata operations to eliminate additional crash consistency overheads for most metadata operations; then uses hierarchical concurrency control to maximize the parallelism of metadata operations; and finally, takes hybrid inode partition to reduce inter-NUMA access and intra-NUMA lock contention. Our extensive evaluation shows that SingularFS consistently provides high performance for metadata operations on both private and shared directories, and has a steadily high throughput for the billion-scale directory tree.

The Hitchhiker's Guide to Operating Systems

Yanyan Jiang
Nanjing University

Abstract

This paper presents a principled approach to operating system teaching that complements the existing practices. Our methodology takes state transition systems as first-class citizens in operating systems teaching and demonstrates how to effectively convey non-trivial research systems to junior OS learners within this framework. This paper also presents the design and implementation of a minimal operating system model with nine system calls covering process-based isolation, thread-based concurrency, and crash consistency, with a model checker and interactive state space explorer for exhaustively examining all possible system behaviors.

1 Introduction

> "Everything should be made as simple as possible, but no simpler." —*Albert Einstein*

The teaching foundation of operating system design and implementation has been well-established for decades. From Tanenbaum's "*Operating Systems: Design and Implementation* (1987)" [45] to Arpaci-Dusseau's "*Operating Systems: Three Easy Pieces* (2018)" [3], students approach operating systems by studying the layered design of abstractions over processors, memory, and storage systems.

In parallel, researchers have observed the emergence of fast, scalable, reliable, and secure systems over the past few decades. This progress has been driven by the development of innovative system technologies, such as hardware/software co-design [24, 43], cross-stack integration [20, 23], program analysis [11, 48], and formal methods [30, 31], among others.

This paper attempts to share these exciting ideas with junior operating system learners under a unified theme by "adding a layer of indirection." Our key insight is to view all components of a computer system–including hardware, applications, and the operating systems that connect them–as state transition systems. By analyzing these components as informal yet mathematically rigorous objects, we aim to bridge the gap between theoretical concepts and practical system implementations.

This model-driven approach is grounded in several innovative philosophies on operating systems education, which are outlined below:

Everything is a state machine (Section 2). The key idea of this paper is to consider state transition systems as the foremost concept in teaching operating systems. The state-machine abstraction is fundamental: the state of a modern multi-processor system is essentially determined by register/memory bit values, driven by the non-deterministic selection of a single CPU executing a single-step instruction[1]. The same abstraction is also applicable to any multi-threaded program.

Consequently, we argue that it is beneficial to *view the operating system as both a state machine and a manager of state machines*. An operating system essentially leverages application-invisible data structures (e.g., a page table) to multiplex CPUs across processes and threads. This approach provides a rigorous explanation of process management APIs: `fork`/`execve`/`exit` functions simply clone, reset, and destroy live state machines. This abstraction also encourages in-depth discussions about `fork` [4] and the initial process state after `execve`.

By adopting this state-machine-centric perspective, we can explain research systems with a clear and rigorous foundation. For instance, every debugger [12], trace [8], and profiler [9] essentially "observes" runtime state snapshots, facilitating discussions on interactive query debuggers [39], deterministic full-system replay [16], time-travel failure reproduction [11], snapshot-based fault tolerance [38], and state space exploration [7] in an introductory-level operating system course.

Emulate state machines with executable models (Section 3). Since state machine is a mathematically rigorous concept, we could always *emulate* the execution of real state machines. Although emulation has been widely adopted in operating sys-

[1] Under the assumption of race-freedom that instructions are serializable.

System Call	Description
fork()	Create current thread's heap and context clone
spawn(f,xs)	Spawn a heap-sharing thread executing $f(xs)$
sched()	Switch to a non-deterministic thread
choose(xs)	Return a non-deterministic choice among xs
write(xs)	Write strings xs to standard output
bread(k)	Return the value of block k
bwrite(k,v)	Write block k with value v to a buffer
sync()	Persist all outstanding block writes to storage
crash()	Simulate a non-deterministic system crash

Table 1: System calls in the operating system model.

tem teaching[2], this paper takes one step further by emulating a "fully functional" operating system model with processes, threads, a debug console, and block storage. The system calls are listed in Table 1. The executable model approach has the following advantages:

First, *executable model is a foundation for exploring operating system concepts*. Synchronization primitives like Peterson's algorithm [34], condition variable, and semaphore can be implemented over shared memory. The non-trivial state copy behavior of `fork()` [4] can be reproduced under this model. A file system checker can be carried out upon a simulated `crash()`.

Second, *executable model is a behavioral specification of real operating systems*; it is the golden standard on the application-observable behaviors. A model facilitates discussions on the abstractions–the concrete implementation of the `fork()` function may employ copy-on-write, but this should remain transparent to a process. Such a model also motivates the key idea behind formally verified systems like seL4 [25] and Hyperkernel [31].

Enumeration demystifies operating systems (Section 4). We design our emulator to handle all sources of non-determinism in a coherent way: every system call (not merely `choose`) returns a set of possible choices as callbacks. Consequently, we can exhaustively enumerate all possible system behaviors with little implementation effort.

Such a design finally leads to our MOSAIC (Modeled Operating System And Interactive Checker) *operating system model and checker*. MOSAIC adds lightweight formal methods [21,47] to operating systems teaching. MOSAIC is capable of checking fork-based process parallelism, thread-based shared memory concurrency, and crash consistency [36]. The model checker's output can be piped to an interactive state space explorer that can be embedded in a Jupyter notebook (Figure 3); thus, all non-trivial corner cases of the operating system model can be rigorously explained.

In summary, this paper makes the following contributions:

1. We propose a new "state-machine first" approach in the breakdown of operating system teaching: (1) model systems as state machines, (2) realize models by emulation, and (3) explore models by enumeration. This approach enabled us to introduce non-trivial research systems to junior operating system learners.

2. We design and implement MOSAIC, a minimal (500 lines of code, including comments) executable operating system model and checker, which strikes a balance between understandability and functionality. MOSAIC can rigorously explain non-trivial textbook cases concerning concurrency, virtualization, and persistence. MOSAIC is available via

   `https://github.com/jiangyy/mosaic`.

3. We incorporated these ideas in a first undergraduate operating system course (Section 5). This course became one of the most popular operating system courses in China and has attracted over 2,000,000 video views since its initial release in 2020.

2 State Machines: First-class Citizens of Operating Systems

Philosophy 1: Everything is a state machine.

This paper's key contribution is the "state-machine first" approach to operating systems. By regarding both user-level applications and kernels as state machines (Section 2.1), it became obvious that operating systems are state machine managers (Section 2.2). This section also discusses modern computer systems and tools under the state machine perspective (Section 2.3).

2.1 Introducing State Machines in the Operating System Class

Program as a state machine. Every program run essentially boils down to the execution of binary instructions, whose behavior is rigorously defined by a state machine in which states are register/memory values and transitions are the execution of one instruction at the program counter. We *implement* this idea on Linux (Figure 1) to provide a definition of system calls: system call is a state transition (e.g., via a trap instruction or any process-kernel communication mechanism [44]) for accessing the "exterior" of the state machine, e.g., writing data to the operating system or changing the state machine's memory address space (via `mmap` or `mprotect`) and existence (via `exit`). Without system calls, the program (state machine) is a "closed world" that can only perform arithmetic and logical operations over memory and register values.

[2]We loved the emulated process scheduler, virtual memory, and file systems in the "Three Easy Pieces" [3].

```
1  #include "sys/syscall.h"
2  mov $SYS_write, %rax  // write(
3  mov $1,         %rdi  //   fd=1,
4  mov $hello,     %rsi  //   buf=hello,
5  mov $16,        %rdx  //   count=16
6  syscall               // );
7  // "ret" here yields SIGSEGV
8  mov $SYS_exit,  %rax  // exit(
9  mov $1,         %rdi  //   status=1
10 syscall               // );
11 hello: ; .ascii "Hello, OS World\n"
```

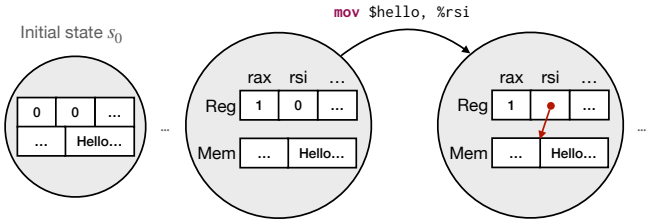

Figure 1: A minimal "Hello World" program and its corresponding state machine.

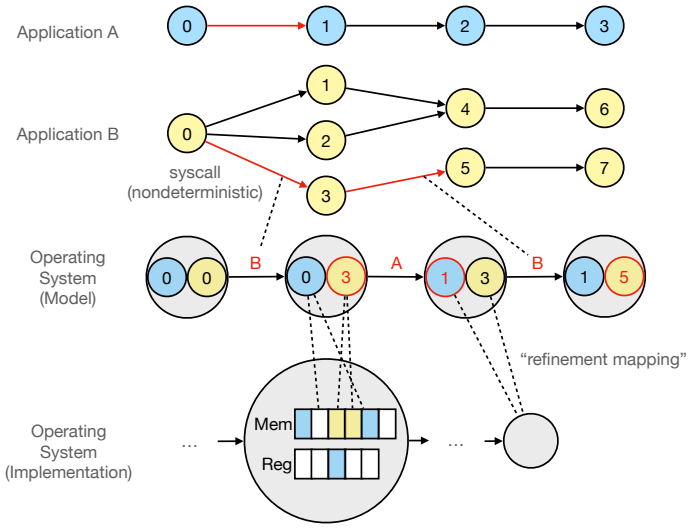

Figure 2: Operating system as a state machine manager. In this example, the operating system "executes" state transitions $0 \to 1$ and $0 \to 3 \to 5$ for applications A and B, respectively.

Bare-metal as a state machine. The bare-metal hardware shares a similar model with binaries: a CPU essentially operates as an infinite loop of instruction execution, which is also the case for a full-system emulator [5]. In contrast to user-level programs that can perform system calls, bare-metal kernels (including operating systems) access the "external world" via port or memory-mapped I/O and can be interrupted as if a trap instruction is non-deterministically injected.

Discussions. The advantage of introducing the state machine model early in an operating system course is that it fosters a tendency of *rigorous thinking*–state transition systems are well-defined mathematical objects. Specifically, we motivate the students to think of what is the mathematically precise definition of the process initial state. We explain that any process's initial state is well-defined by its binary executable and the Application Binary Interface. We also demonstrate how to inspect the initial state of the code in Figure 1 using `stepi` in GDB and memory mapping files in procfs. We further encourage students to consider more involved details of process states, such as the reasons behind the inability to perform a function return (using a `ret` instruction) and the necessity of wrapping C `main` functions with a `__libc_start_main`.

2.2 Operating System as a State Machine Manager

Computer system stack on state machines. Virtualization is the most fundamental mechanism of modern operating systems. Each application in an operating system can be regarded as a state machine whose initial memory layout and state transitions are specified by its binary executable. The operating system should give the application the illusion that the state transition system runs continuously following its specification, even though instruction execution could be non-deterministically interrupted at any time.

The state-machine approach provides a natural "implementation" of virtualization: by making state snapshots of all processes available and scheduling a process through "moving" a state machine to the CPU. The trap/interrupt handler plays such a role: it stores the state machine's registers in the operating system's private memory space, ensuring the system-wide invariant that all application states can be reconstructed. Subsequently, the operating system can continue processing interrupts, executing system calls, and resuming any process based on a predefined scheduling policy.

These arguments conclude our claim that "everything is a state machine" and gives us a new picture of understanding operating systems, as shown in Figure 2:

1. Application code is the developer's specification of a state machine.

2. Operating system code is the designer's specification of a state machine manager, a "superset" state machine container of all application state machines.

3. The operating system provides system calls as services and leverages application-invisible states (e.g., page table) to give processes the illusion of continuous state machine execution.

Process APIs on state machines. Following the idea that running applications are state machines, the need for process APIs became obvious: an operating system must provide

mechanisms for manipulating the set of live state machines. We found that the state machine language[3] precisely and concisely explains UNIX process APIs:

1. `fork()` makes a "full copy" of the currently running state machine. Registers and the address space should appear to be deeply copied. References to operating system objects (e.g., file descriptors and signal handlers) should also be copied, but with caution [4].

2. `posix_spawn(...)` creates a new state machine (always resets to the initial state of an application) with controllable state sharing with the parent.

3. `execve(path, argv, envp)` resets a running state machine to the initial state specified by the binary file `path`, with arguments `argv` and environment list `envp` placed in memory following the Application Binary Interface.

4. `exit(status)` removes the currently running state machine from the operating system, reclaims used resources, and notifies any waiting process with the exit `status`.

2.3 State Machines Meet Operating Systems

We discovered that the state-machine approach is not only beneficial for clarifying operating system concepts, but it can also serve as a fundamental basis for explaining non-trivial research systems to students:

Understanding system execution. Theoretically, executing a state transition system (be it an application or an operating system kernel) results in an execution trace composed of state snapshots connected by state transitions

$$tr = s_0 \to s_i \to \ldots \to s_{i+1} \to \ldots,$$

as if we single-instruction debug the program and save a core dump after each instruction execution. Such a trace contains *all* information needed for understanding this specific program execution.

However, such a massive trace (billions of instructions executed per second and megabytes of snapshots) is impractical and unnecessary to keep for any engineering practice. Debuggers provide the break/watchpoint mechanism to efficiently stop at interested program points (sometimes with hardware assistance like debug registers) and let the developer examine the program states interactively.

Understanding a program's execution usually only requires a tiny fraction of information in the full trace *tr*. The trade-off space of "what parts of *tr* to observe" leads to many important mechanisms incorporated in the engineering of modern operating systems, which are explained below.

[3]For brevity, we removed less critical mechanisms including signals, process groups, and access control in this discussion. However, all of them can be explained under the state machine perspective whenever needed.

Playing with snapshots. `fork` provides a verbatim copy of a program's state s_i with reasonably low cost. Holding such program state snapshots yields interesting applications. One is the Zygote process of Android [14], which copies initialized Java virtual machine state to avoid repetitive and time-consuming bootstrap-time class loading. Another example is that one can take periodical clean-state snapshots (e.g., in the idle state of an event loop) and fall back to a snapshot when an unexpected error occurs [38].

Time-travel debugging. Developers use a debugger to interactively examine *tr*, which can be enhanced by a query language [39]. Debuggers can also enable time-travel debugging by recording the differences between consecutive states, essentially creating an undo log. Time-travel debugging is already implemented in GDB [12]. Observing that non-deterministic transitions are only a tiny fraction of *tr*, one can also keep track of their locations and choices to enable a deterministic replay [16, 33].

Trace and profiler. One can insert probes exclusively at state transitions relevant to the application logic (e.g., function calls and returns) and gather diagnostic data (e.g., call stack traces). Trace utilities such as ftrace and Kprobe in Linux [8] are widely used for debugging production failures.

One can place probes only at application logic relevant state transitions (e.g., function calls and returns) to collect diagnostic information (e.g., call stack trace). Such trace tools like ftrace and Kprobe in Linux [8] are widely used in debugging production failures.

The overhead associated with tracing can be further reduced through sampling, which involves periodically activating probes within a specified time interval. Such profilers generate summaries of the sampled program states and are extremely useful in diagnosing performance issues.

Runtime checkers. Runtime checkers can also be considered as functions that accept *tr* as input and check it against specific bug patterns. A broad spectrum of checkers operate in this manner: AddressSanitizer [40] asserts the absence of out-of-bounds and use-after-free memory accesses. ThreadSanitizer [41] confirms that there are no conflicting shared memory accesses unordered by happens-before relations. Lockdep [29] checks whether all observed lock acquisition orderings do not form a cycle.

Symbolic execution and program verification. It is obvious that system calls can exhibit non-deterministic behavior. However, it is less emphasized that such non-determinism can be rigorously quantified; for instance, a read system call returns only a finite number of possibilities. Thus, we can enumerate all possible state transitions to capture all potential program behaviors; however, this approach is only feasible in a theoretical context. Even reading a 32-bit integer results in 2^{32} distinct states.

Using a compact representation of a vast number of states (e.g., using a symbolic value x to represent an "arbitrary"

value of variable `x`) and imposing constraints on symbolic values across branches results in a symbolic program verifier [7].

3 An Executable Operating System Model

> **Philosophy 2**: Emulate state machines with executable models.

As state machines are mathematically rigorous constructs, their usefulness is not limited to merely clarifying operating system concepts. It is also feasible to develop *executable* state machines that accurately emulate the behavior of processes and operating systems.

Specifically, we leverage modern programming language mechanisms like coroutines for lightweight in-process context switches to implement a lightweight executable operating system model with emulated threads, processes, and devices (Section 3.1). This section also discusses how instructors could use a model to simplify non-trivial textbook cases (Section 3.2) and use models as behavioral specifications of real systems (Section 3.3).

3.1 Emulating an Operating System

State machines (processes) and system calls. We implement our operating system model in Python, a popular programming language among students. A process is emulated by a generator (stackless coroutine) object where process memory is its local variables. System calls (Table 1) are emulated by `yield` in which the generator saves its local state (local variables and program counter) in a closure and transfers control to its caller[4]:

```
def main(msg):  # an emulated application process
  i = 0
  while (i := i + 1):
    yield 'SYS_write', msg, i  # write(msg, i)
    yield 'SYS_sched',  # sched()
```

Our operating system model, as a state machine manager, maintains a set of processes (continuable generators) and is an infinite loop of `yield` trap handler, just like any real operating system:

```
class OperatingSystem:
  def __init__(self, procs):  # OS initialization
    self._procs = procs
    self._current = procs[0]

  def run(self):  # the OS main loop
    while True:
      syscall, *args = self._current.__next__()
      match syscall:
        case 'SYS_write':  # write to debug console
          print(*args)
        case 'SYS_sched':  # switch to a random process
          self._current = random.choice(self._procs)

OperatingSystem([main('ping'), main('pong')]).run()
```

[4] In the MOSAIC implementation, the process code is stored in a standalone Python file. Applications invoke system calls in Table 1 as ordinary function calls like `x = sys_choose(['Head', 'Tail'])`, and MOSAIC rewrites the AST by replacing all system call nodes to `yield`.

Process APIs. Because deep-copying a generator object is not allowed in Python, we implement `fork()` by creating a new `OperatingSystem` object and replaying all executed system calls to obtain a deep copy of the process. This requires `OperatingSystem` to keep track of the non-deterministic choices of all previously executed system calls. Processes have increasing IDs starting from 1,000, and the child process ID is returned on `fork()`. There is no `exit()` because returned generators are never scheduled and are considered exited. There is also no `execve()` because its functionality largely overlaps with `spawn()` and `fork()`.

Threads and shared memory. The shared memory among threads is emulated by the global `heap` variable, whose value is updated before switching to a process/thread by

```
globals()['heap'] = self._current.heap,
```

and readers may notice that this `heap` models a "page table base register" which is changed on context switches. `spawn(f, *xs)` creates a new generator calling `f` with arguments `xs` and a shared `heap`. The replay-based `fork()` obtains a deep copy of the heap in the freshly allocated `OperatingSystem` object.

Devices. Writing to the debug console appends the message to a buffer. Reading from the debug console can be implemented by `choose()` from possible inputs. The emulated block device is a key-value mapping, which maps each block's ID (any string like `inode` or even emojis) to its contents (any serializable data structure including strings and lists). All block device writes are first appended to a queue to simulate real disks with a volatile buffer [36]. Write-back happens only when `sync()` is called.

3.2 Modeling Operating System Concepts

Such a surprisingly simple model can simplify textbook cases that require non-trivial interactions across system layers and are thus challenging to debug or even reproduce–we can selectively model the essential elements of the system to minimize the complexity:

A `fork()` in the road [4]. Fork is no longer simple, considering it conducts a full state copy of libraries and references (handles) to operating system objects. Below is such a non-trivial case related to the buffer mechanism in the standard C libraries:

```
for (int i = 0; i < 2; i++) {
  int pid = fork();
```

```
  printf("%d\n", pid);
}
```

```
(unix) $ ./a.out
1000
1001
0
0
1002
0
```

```
(unix) $ ./a.out | wc -l
8  # ???
```

Debugging the internal implementation of libc (even with a much simpler implementation like musl [1]) to understand this case requires substantial engineering efforts. Alternatively, we first model this case by removing all low-level details of process creation and focusing on the behavior of a fork-cloned buffer:

```
def main():
  heap.buf = ''
  for _ in range(2):
    pid = sys_fork()  # heap.buf is deeply copied
    sys_sched()  # non-deterministic context switch
    heap.buf += f'{pid}\n'  # or sys_write()
  sys_write(heap.buf)  # flush buffer at exit
```

The executable model always gives a process schedule to explain its outputs[5]. After fully understanding the model, students can examine the system call traces and debug the libc source code with less pain.

Understanding synchronization. Synchronization primitives (mutexes, condition variables, semaphores, etc.) are usually informally introduced in a textbook or an operating system course. Implementing them upon our operating system model gives them a rigorous semantics specification[6]. Below displays a model of the buggy producer-consumer implementation from Chapter 30 of "The Three Easy Pieces" [3], in which a consumer may erroneously wake up another consumer (instead of a producer), resulting in a deadlock:

```
def Tworker(name, delta):
  for _ in range(N):
    while heap.mutex == '🔒':  # mutex_lock()
      sys_sched()              # |- spin wait
    heap.mutex = '🔒'          # |

    while not (0 <= heap.count + delta <= BUFSIZE):
      sys_sched()
      heap.mutex = '🔓'          # cond_wait()
      heap.cond.append(name)     # |
      while name in heap.cond:   # |- spin wait
        sys_sched()              # |
      while heap.mutex == '🔒':  # |- reacquire lock
        sys_sched()              # |
      heap.mutex = '🔒'          # |

    if heap.cond:                # cond_signal()
      t = sys_choose(heap.cond)  # |
      heap.cond.remove(t)        # |- wake up anyone
    sys_sched()

    heap.count += delta  # produce or consume

    heap.mutex = '🔓'  # mutex_unlock()
    sys_sched()

def main():
  heap.mutex = '🔓'  # 🔒 or 🔓
  heap.count = 0  # filled buffer
  heap.cond = []  # condition variable's wait list
  sys_spawn(Tworker, 'Tp', 1)  # delta=1, producer
  sys_spawn(Tworker, 'Tc1', -1)  # delta=-1, consumer
  sys_spawn(Tworker, 'Tc2', -1)  # delta=-1, consumer
```

At first glance, this model seems to diverge from the textbook example, as all synchronization primitives are denoted by spin-wait constructs (Lines 3-4, 11-12, and 13-14). However, this is intentional: spin wait reflects the specification that the thread could not make any progress unless the synchronization condition is satisfied (e.g., a mutex is in the unlocked state or a condition variable has been signaled). Blocking wait is merely one possible implementation. Such a model also captures a detail often overlooked by students: a condition variable contains an implicit re-acquisition of its associated mutex (Lines 13–15) after being signaled. An executable model facilitates the development of rigorous concepts in operating systems.

The incorrect use of condition variable is also non-trivial: manifesting the bug requires at least three threads (a producer and two consumers) and $N \geq 2$. Such a fact can be easily verified by the model checker (Section 4.1). Running this model under a uniform-random scheduler, there is only approximately an 8% chance of triggering the deadlock in which all three threads T_p, T_{c_1}, and T_{c_2} are spinning on Line 11.

Finally, we found that emojis in the code can improve the readability of program states: "🔒" intuitively indicates that a thread holds this mutex. Other cases include using 🙋 in Peterson's algorithm [34] (instead of `flag[2]` and integer values `0` or `1`) to indicate a thread "raising hand" to enter the critical section and 💥👍👮 to denote success or failure.

File system consistency and journaling. The emulated block device enabled us to implement ideas in file systems without tedious low-level device details. Recall that the block device is conceptually a `dict`. Thus, we can assign blocks with intuitive names like `'bitmap1'` to indicate a bitmap block in the persistent storage. We can also use this `dict` as a file system by mapping file names (e.g., `'/tmp/a.txt'`) to their metadata and contents (e.g., `('symlink', '/etc/passwd')`) when the actual storage layout is not relevant. Below is a simplified model of xv6 [10] log commit:

```
def main():
  # 1. log the write to block #B
```

[5]The model checker (Section 4.1) can be used to exhaustively examine all process schedules and understand the possible outputs.

[6]Our model assumes that the execution of statements between consecutive `sched()` appears to be atomic and uninterruptible.

```
  head = sys_bread(0)  # blocks #1, #2, ... are the log
  free = max(log.values(), default=0) + 1  # allocate log
  sys_bwrite(free, f'contents for #{B}')
  sys_sync()

  # 2. write updated log head
  head = head | {B: free}
  sys_bwrite(0, head)
  sys_sync()

  # 3. install transactions
  for k, v in head.items():
    content = sys_bread(v)
    sys_bwrite(k, content)
  sys_sync()

  # 4. clear log head
  sys_bwrite(0, {})
  sys_sync()
```

With the model checking feature (Section 4.1), all possible crash behaviors and potential file system inconsistencies can be exhaustively explored.

3.3 Application: Specification of Systems

An operating system model can be useful beyond explaining textbook cases. A model also provides a *behavioral specification* for real operating systems, like a high-level reference implementation. For example, it could be proved that the mutex model in Section 3.2 has the following two properties:

1. Safety: as long as a thread holds a mutex, any other thread's lock acquisition never returns.

2. Liveness: a thread eventually acquires a mutex if threads with acquired locks eventually release them under a fair (random) scheduler.

Because everything is a state machine (and thus a well-defined mathematical object), it could be theoretically possible to *prove* that a real system's implementation is consistent with a model by constructing a refinement mapping[7]. This is exactly the idea behind formally verified systems like seL4 [25] (with a Haskell executable model) and Hyperkernel [31] (with a Python executable model), which all modeled operating systems as a state machine. Even though the technical details of the research work may be too involved for first-time operating system learners, state machines still facilitate grasping the fundamental concepts underlying them–one could always perform a "brute-force prove" by enumerating all reachable vertices on the state transition graph for finite systems.

Models are also useful as a behavioral reference for real system implementations. A more practical "refinement mapping" is to feed the same workload to both a model and a real system. Cross-checking the model and system traces validates the implementation's correctness. For example, executing the same

[7] One fundamental result of program verification is that refinement mappings between high-level and low-level specifications always exist [2].

```
1 Q ← {[]};                          // the queue of traces pending checking
2 S ← ∅;                             // the set of checked states
3 while ¬Q.empty() do
4     tr ← Q.pop() ;
5     ⟨s, choices⟩ ← replay(tr);
6     if s ∉ S then
7         S ← S ∪ {s};               // add the unexplored state to S
8         for c ∈ choices do
9             Q.push(tr :: c);       // extend tr with c and append to Q
```

Algorithm 1: The MOSAIC model checker

`fork()` sequence (assuming that all forks succeed) should yield identical process trees for both the model and a student's operating system kernel. Such an approach is also known as the lightweight formal method [22] and has been widely adopted in validating practical systems [6].

4 One Model Checker to Rule Them All

> **Philosophy 3**: Enumeration demystifies operating systems.

The executable model's behavior can be exhaustively explored by enumerating all possible non-deterministic choices. This section presents such a model checker (Section 4.1) and its application to operating system teaching (Section 4.2), followed by short quantitative experiments in Section 4.3.

4.1 MOSAIC Model Checker Design and Implementation

Instead of executing a system call immediately, all MOSAIC systems calls return a `dict` mapping possible choices (which can be regarded as labeled transitions in the state machine) to lambda callbacks for actually performing the system call, even if there is only one unique choice:

```
def sys_sched(self):
  return {  # all possible choices
    f't{i+1}': (lambda i=i: self._switch_to(i)) # callback
      for i, th in enumerate(self._threads)
        if is_runnable(th.context)
  }

def sys_fork(self, *args):
  return {  # only one choice
    'fork': (lambda: self._do_fork())
  }
```

Such a design yields a simple replay-based state space explorer as shown in Algorithm 1. The algorithm is a straightforward breadth-first search that memorizes traversed states in S. A trace is a chronological list of each system call's selected choice. Replaying a trace will always reach the next system

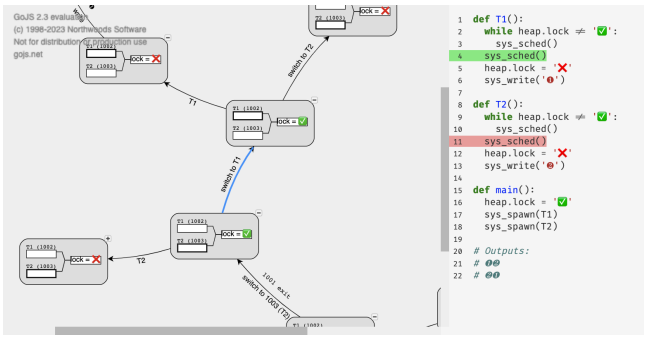

Figure 3: The interactive thread interleaving space explorer on MOSAIC's results of checking a spin lock implementation. Process and thread states are plotted as vertices. Thread program counters are highlighted on the source code like a debugger. Clicking a vertex expands its children.

call's non-deterministic choices (Line 5), or there is no choice ($choices = \varnothing$) when all processes and threads are terminated.

For finite-state models, the algorithm always terminates and produces a state transition graph whose vertices are traces in S and edges are labeled with c in Line 9. MOSAIC serializes the state transition graph as a JSON file. Both states (generator states, heaps, debug console output, and storage state) and transitions (labeled edges) are serialized. We encourage the students to follow the UNIX philosophy and pipe the text output to different backends:

1. Simply `grep stdout | sort | uniq -c` for a quick (and dirty, perhaps unsound) check for all possible debug console outputs.

2. Any JSON query or viewer like `jq` [15] to extract fields of interest (e.g., variable values or block device contents).

3. Our interactive state explorer (Figure 3) in which one can selectively expand nodes in the state transition graph. This interactive explorer is particularly handy for class demonstration.

4.2 Model Checking for Fun and Profits

The ability to exhaustively explore the state space makes a model checker suitable for rigorously explaining non-trivial cases in operating systems. A few such cases are shown below.

Processes and TOCTTOU attack. Both UNIX and our operating system model lack a mechanism (e.g., transactions [13, 37]) to enforce the atomicity across system calls and may be subject to time-of-check to time-of-use attacks. We demonstrate such a case of process-level race from [46]:

```
1 def main():
2   sys_bwrite('/etc/passwd', ('plain', 'secret...'))
3   sys_bwrite('file', ('plain', 'data...'))
4   pid = sys_fork()
5   sys_sched()
6   if pid == 0:  # attacker: symlink file -> /etc/passwd
7     sys_bwrite('file', ('symlink', '/etc/passwd'))
8   else:  # sendmail (root): write to plain file
9     filetype, contents = sys_bread('file')  # for check
10    if filetype == 'plain':
11      sys_sched()  # TOCTTOU interval
12      filetype, contents = sys_bread('file')  # for use
13      match filetype:
14        case 'symlink': filename = contents
15        case 'plain': filename = 'file'
16      sys_bwrite(filename, 'mail')
17      sys_write(f'{filename} written')
18    else:
19      sys_write('rejected')
```

MOSAIC reveals that "`/etc/passwd written`" is possible and gives such a process schedule. The exhaustive search can also reveal that the two `sys_sched` in Lines 6 and 10 are essential to produce such a result.

Hardness of shared-memory concurrency. Understanding thread interleaving can be difficult. Restoring the global ordering of shared memory accesses on thread-local read/write sequences is NP-Complete [17]. One interesting case is the possible outcomes of concurrent `tot++`, assuming that loads and stores are atomic (i.e., a sequentially consistent memory model) and the compiler does not merge multiple `tot++`:

```
def Tsum():
  for _ in range(N):
    tmp = heap.tot  # load(tot)
    sys_sched()
    heap.tot = tmp + 1  # store(tot)
    sys_sched()

def main():
  heap.tot = 0
  for _ in range(T):
    sys_spawn(Tsum)
```

MOSAIC reveals that `tot` can be 2 regardless of N and T (for $N, T \geq 2$) and gives such a thread schedule in which one thread "holds" a value of 2 in the last iteration of the loop and does not write it back until all other threads are terminated. We used the $N = 3, T = 2$ case as an exam problem, and approximately half of the students got wrong.

Persistence and crash consistency. Upon `crash()`, MOSAIC automatically explores all 2^n possible crash disks, assuming that any of the n buffered block I/O requests could be lost [36]. By modeling a file operation that involves multiple block updates (inode, bitmap, and data), an instructor can clearly and rigorously illustrate potential inconsistencies in a file system upon a system crash. Below is a textbook case in Chapter 42 of "The Three Easy Pieces" [3]:

```
def main():
  # intially, file has a single block #1
  sys_bwrite('file.inode', 'i [#1]')
  sys_bwrite('used', '#1')
  sys_bwrite('#1', '#1 (old)')
```

Subject	Parameters	# State	Memory	Time
fork-buf (7 LOC)	$n=1$ ($p=2$)	15	17.0 MB	<0.1s

	$n=10$			Timeout (>60s)

Table 2: Evaluation subjects and results. p, t, n denote the number of processes, threads, and loop iterations, respectively. All experiments were performed on an i7-6700 Linux PC with 4 GB RAM running Python 3.11. Each configuration is repeated for 10 times, and the average number is reported.

```
6   sys_sync()
7
8   # append a block #2 to the file
9   sys_bwrite('file.inode', 'i [#1 #2]')  # inode
10  sys_bwrite('used', '#1 #2')  # bitmap
11  sys_bwrite('#1', '#1 (new)')  # data block 1
12  sys_bwrite('#2', '#2 (new)')  # data block 2
13  sys_crash()  # system crash
14
15  # display file system state at crash recovery
16  inode = sys_bread('file.inode')
17  used = sys_bread('used')
18  sys_write(f'{inode:10}; used: {used:5} | ')
19  for i in [1, 2]:
20    if f'#{i}' in inode:
21      b = sys_bread(f'#{i}')
22      sys_write(f'{b} ')
```

MOSAIC's self-explanatory outputs verified that the one-page informal arguments in the textbook are indeed exhaustive and correctly covered all possible cases. MOSAIC can also check the journal implementation in Section 3.2 by adding `crash()` to the code and reveal that removing the `sync()` in Line 6 may result in file system inconsistency.

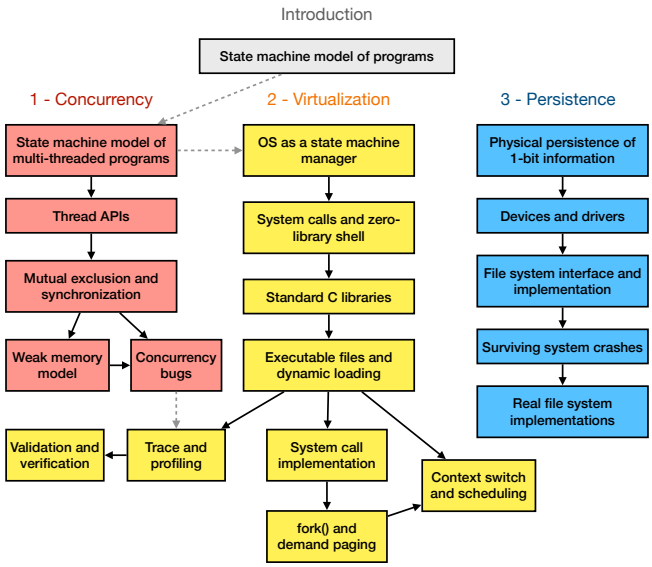

Figure 4: Major modules and their dependencies in our operating system course. The concept of state-machine is a good foundation for thread-based concurrency, and thus we introduce concurrency first in the course.

4.3 Experiments

We evaluate the performance of MOSAIC by checking the six representative models in Sections 3.2 and 4.2. Both experimental subjects and results are listed in Table 2. As expected, MOSAIC cannot address the state space explosion problem and has no comparable performance with a state-of-the-art software model checker with dedicated optimizations. Furthermore, programs that extensively fork is significantly slower (benchmarks fork-buf and tocttou) because our `fork()` is implemented by a full-system replay. Nevertheless, checking thousands of nodes per minute could be considered sufficiently useful for instructional purposes, and our design choice is to make a functional model checker minimal and elegant.

5 A New Operating System Course

We design a new operating system course from scratch based on "The Three Easy Pieces" [3] and our teaching philosophies: everything is a state machine, emulate state machines with executable models, and enumeration demystifies operating systems. The course syllabus is shown in Figure 4. This section presents the impacts of the state machine perspective (Section 5.1) and model checker (Section 5.2) in the course design, followed by discussions in Section 5.3.

5.1 State Machines and Operating Systems

In addition to introducing the key concepts in operating systems using state machines, the state machine perspective also

brings the following advantages in establishing a high-level understanding of important concepts regarding computer systems in a natural and coherent way.

Don't panic in hacking real systems! All students had a hard time in debugging real (even minimal) systems, including but not limited to operating system kernel, even if we provided skeletal code, tool chain, and state visualization scripts.

The state-machine perspective provides a natural reflex on how to deal with bugs or unexpected behavior in real systems: All bugs in computer systems are essentially some anomaly in the state-machine's execution trace. Given an unlimited amount of time, one just seeks the *first* abnormal state, and the root cause is right there. We teach students this (impractical) debugging principle and motivate students to consider clever tricks to make this procedure fast, robust, and easy.

For example, the essence of printf-debugging is to provide a high-level digest of the state-machine trace, which helps in narrowing down the scope of the initial anomalous state. One can also employ defensive programming by inserting assertions to the validity of states. These lessons are usually less taught in an operating system class but are essential for surviving hacking or implementing a large-scale system.

One classroom story is using a profiler (i.e., "frequent" state sampler) in diagnosing an unexpected 100% CPU usage on an idle workload in a production system in on a specific machine. The `perf` tool [9] attributes the hot spot to an `xhci`-related function, which leads us to a short-circuited USB port.

Concurrency meets state machines. The model checking community has long represented concurrent programs as state transition systems, and model checking is widely recognized as a computationally intensive technique that frequently encounters state explosion issues. Nevertheless, employing exhaustive enumeration is not the sole efficient approach to harness the capabilities of state machines.

The concept of data race, an important topic in operating system courses, refers to the simultaneous access of a shared memory location by two threads or processors (with at least one performing a write). Data races are considered harmful in systems programming.

When one checks a state machine trace against data races, it is essential to examine all types of state transitions that could lead to memory access [41]. However, two sources of memory access may be overlooked by students: (1) fetching an instruction from the program counter and (2) stack operations, including function and interrupt returns.

We let the students experience a subtle data race in an operating system kernel lab that requires students to migrate a process from one processor to another. The destination processor could not immediately schedule the process. Otherwise, there will be a data race on the kernel's interrupt stack.

Demystifying compilers. It is not obvious to students that C programs can also be represented by state transition systems. We use the example in Figure 5 (a non-recursive "Tower of Hanoi" implementation) to illustrate that the "runtime state" of C programs consists of static variables, heap memory, and a list of stack frames. State transitions are small-step expression evaluations at the top-most stack frame's program counter.

```c
void hanoi(int n, int from, int to, int via) {
  if (n == 1) {
    printf("%d -> %d\n", from, to);
  } else {
    hanoi(n - 1, from, via, to);
    hanoi(1, from, to, via);
    hanoi(n - 1, via, to, from);
  }
}
```

```c
typedef struct { int pc, n, from, to, via; } Frame;
#define call(...) ({*(++top) = (Frame) {0, __VA_ARGS__};})
#define ret()     ({top--;})
#define jmp(loc)  ({f->pc = (loc) - 1;})

void hanoi_nr(int n, int from, int to, int via) {
  Frame stk[64], *top = stk - 1, *f;
  call(n, from, to, via);
  while ((f = top) >= stk) {
    switch (f->pc) {
      case 0: if (f->n == 1) {
        printf("%d -> %d\n", f->from, f->to); jmp(4);
      } break;
      case 1: call(f->n - 1, f->from, f->via, f->to); break;
      case 2: call(1, f->from, f->to, f->via); break;
      case 3: call(f->n - 1, f->via, f->to, f->from); break;
      case 4: ret(); break;
      default: assert(0);
    }
    f->pc++;
  }
}
```

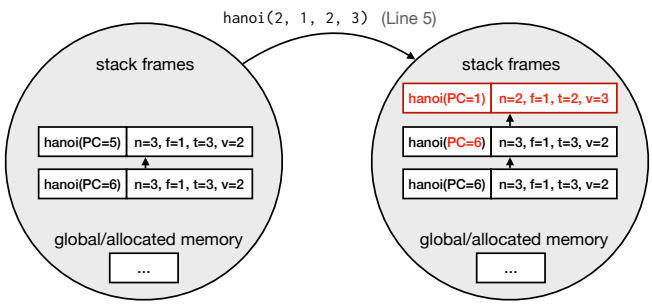

Figure 5: State machine perspective of C programs. `hanoi_nr` is also an "executable model" emulating recursions for rigorously understanding the semantics of C programs.

Compilers should always generate *equivalent* assembly (low-level state machine specification) from source code (high-level state machine specification). Therefore, a fundamental question is what kinds of translation are allowed for an optimized compiler. Notably, such deliberations are frequently neglected throughout the undergraduate curriculum, including in courses specifically addressing compilers.

With the conceptual model of state machines, the correctness of translation is essentially the equivalence between two state machines. This naturally leads to the definition of external observable equivalence between systems: given that system calls are the only way of influencing the remaining parts of the system, two programs are considered equivalent if they generate identical system call traces for the same inputs, and one program terminates if and only if the other program terminates. This principle serves as the core concept behind a verified compiler such as CompCert [27].

5.2 Modeling and Model Checking in Action

Models and emulation are everywhere. Models in an operating system course may not be limited to Python-implement system calls. We advocate using minimal but functionally "working" models, even they are implemented using a lower-level programming language.

One particular example is that we long had difficulties in explaining the ELF dynamic linker and loader to the students due to the unnecessarily excessive complexity of the ELF format. We identified that the problem stems from the fact that the ELF design is intended to be read exclusively by machines, rather than humans.

Therefore, we design a simplified binary format implemented using GNU C preprocessor and assembly. The binary file contains merely a magic number, a `NULL`-terminating symbol table whose entries are macros like `IMPORT(printf)` or `EXPORT(main)`, followed by assembly instructions. By reusing GCC and binary utilities, we implement the full toolchain of linker, loader, and an `objdump` equivalent in 200 lines of C code. Student and social media feedback indicate that such a model significantly flattens the learning curve of dynamic loading.

Formal method meets operating systems. We motivate the need for a model checker by making substantial (boring) efforts to draw a state transition graph to prove the safety and liveness of Peterson's mutex algorithm [34]. It is then obvious that a program like MOSAIC can replace human labor by emulation. We received positive feedback from students on their first contact with the model-checking approach, particularly the interactive visualizer (Figure 3), which is embedded in a Jupyter notebook for in-class demonstrations. The machine-generated state transition graph is also generally more reliable than the informal arguments in popular textbooks [42].

Another advantage of a model checker over existing teaching methods is the immediate feedback when answering "what if" questions related to changes in assumptions, implementations, and other factors. We encourage students to extensively experiment with the model, e.g., to see if the system breaks with added `sched()` or removed `sync()`.

The gap between models and real systems. We also teach students that models do not fully reflect the real world. Models are good at making *all* assumptions explicit, e.g., MOSAIC assumes the atomicity of statements between consecutive `sched()` calls and a sequentially consistent memory model.

The discrepancies between a model and an actual system are explained by careful examination of these assumptions. Peterson's algorithm is correct only under proper assumptions–specifically, a sequentially consistent memory model as if context switches only happen on instruction boundaries. For Peterson's algorithm, we provide an equivalent C implementation to illustrate how compiler and memory barriers may impact the program's behavior.

5.3 Student Acceptance and Discussions

Student Feedback. After publicizing the course lecture notes, demonstrations, and videos on the Internet, we received an excessive amount of positive feedback. Comments included statements like, "It is remarkable that such a comprehensive explanation of operating system principles can be provided in an undergraduate-level course." Students conveyed that they "gained valuable insights on overcoming the panic in hacking large-scale systems in this course."

There are also controversial arguments on the appropriateness of incorporating state machines as a key concept in operating system courses. However, we have also received feedback from the industry professionals supporting our approach by indicating that state machines are one of the most fundamental abstractions for controlling complexity in building production systems.

Since the first public release of the course in 2020, the video has received more than 2,000,000 plays on the Internet. Moreover, this course has been conferred the "Test-of-Time Teaching Award of the Department," as chosen by alumni who evaluated all courses in their curriculum.

Usefulness of models. Modeling is a versatile technique for establishing concepts and understanding. Modeling can also control the complexity by selectively hiding low-level implementation details. Another major advantage of executable models is making operating system concepts *rigorous*. Concepts (e.g., mutex, condition variable, and crash consistency) can be defined by "all possible behaviors on a model."

One may argue that any model behavior can be manifested by real workloads, and thus students should have first-hand experiences on real systems. We consider understanding the model (and thus the concepts) a critical step before students can hack real systems. Otherwise, the excessive and irrelevant implementation details can be a significant source of distraction.

Limitations. The "state-machine perspective" motivates the key insights and high-level designs of operating systems well. However, such over-simplification may yield students overlooking the challenges of implementing real systems. Therefore, we still consider the "hands-on approach," [26] in which students implement their own operating system kernel on

emulated bare metal, an indispensable part of an operating system course[8].

MOSAIC only models a small fraction of an operating system. More are missing, and one has to model them explicitly: file descriptors, signals, futexes, RAID, network stack, etc. Theoretically, it could be possible to model them in MOSAIC; however, we preferred simplicity in our model design and leaving these mechanisms to user-level applications like we did in Sections 3.2 and 4.2.

The implementation of MOSAIC also has limitations: `main` must be a Python generator (rather than a stackful coroutine). Thus, system calls are not allowed in functions being called by `main`. MOSAIC also assumes that the program being checked is deterministic. Non-determinism beyond system calls (e.g., random numbers) results in unsound model-checking results. Considering that MOSAIC is a pedagogical model checker and an instructor can easily bypass these limitations; thus, they are not a significant obstacle to adopting MOSAIC in practice.

6 Related Work

Emerging from the logic and programming language community, formal methods (mainly model checking and formal verification) has been widely adopted in the validation and verification of computer systems [6, 25, 27, 31, 47]. The key idea of formal methods is to treat specifications, models, and implementations as unambiguously-defined mathematical objects and *prove* properties by exhaustive search or axiomatic reasoning.

Despite a growing trend of formal method applications for computer systems, the teaching practice of "classical" operating systems remains classical on the layered abstractions of computer systems [3, 42] and the "hands-on" approach [26] in which students hack teaching operating system kernels [10, 19, 35] over emulators like QEMU [5] to fully understand all low-level implementation techniques.

There are attempts to incorporate model checking in teaching computer systems. Hamberg and Vaandrager [18] modeled textbook concurrency control algorithms using the Uppaal modeling language and checker. Michael et al. [28] target real Java programs on a message-passing model and check against all possibilities of message reorderings, drops, and duplications. Both concurrent programs and distributed systems are classical application scenarios of a model checker. To the best of our knowledge, we are the first to apply formal methods throughout an entire operating system course.

MOSAIC models a fully functional operating system by the unified treatment of non-determinism in system calls (Section 4.1). MOSAIC can check the interactions between processes, threads, and devices. Such a design resembles the EXPLODE system [47] for model checking real storage systems, in which all non-determinism and fault injection are implemented upon `choose()`.

As a pedagogical model checker, MOSAIC's primary use is to explain real operating system behaviors by mapping the model's execution traces (e.g., examples in Sections 3.2 and 4.2) to real systems. Such an approach belongs to the paradigm of lightweight formal methods [21, 22], which strongly emphasizes practicability rather than the full soundness of a proof. Lightweight formal methods have been proven effective against validating excessively complex real systems [6]. Like other pedagogical model checkers [28], we intentionally trade off the performance with understandability. Compared with fully verified systems [31], MOSAIC is functional but with magnitudes less code.

Emulation is also a widely-adopted approach in operating system teaching, which facilitates students establishing a correct and rigorous understanding of concepts. The exercises of "Three Easy Pieces" [3] are based on a substantial amount of independent emulators. MOSAIC as a unified model, on the other hand, can model (and check) the interplay between different levels of system mechanisms, e.g., how file system operations and process-level race result in a TOCTTOU attack in Section 4.2.

Finally, (replicated) state machines also play a fundamental role in distributed systems [32]. Formal methods became increasingly necessary in handling the counter-intuitive corner cases often overlooked by informal arguments. We believe that getting familiar early with such a paradigm on rigorous modeling and reasoning in a first operating system course can inspire the future generation of system researchers.

7 Conclusion

This paper presents a state-machine-first and model-based approach to teaching operating systems. By leveraging modeling and model checking, we can define operating system concepts rigorously, explore system behaviors exhaustively, and motivate non-trivial research systems intuitively under a unified framework in a first operating system course. We believe that this paper's teaching philosophies have the potential to lead a paradigm shift in the teaching of operating systems.

Acknowledgments

We would like to thank Haibo Chen, Yubin Xia, the anonymous reviewers, and our shepherd, David Cock, for their valuable and constructive feedback on this work. This work is supported in part by National Natural Science Foundation of China (Grant #61932021, #62025202, #62272218), Fundamental Research Funds for the Central Universities (#2022300287, #020214380102), State Key Laboratory for Novel Software Technology, and the Xiaomi Foundation.

[8] Students all had a hard time debugging a bare-metal kernel. Such experiences further motivate the need for debugging aids and dynamic analysis in Section 2.3.

Abstract

Scaling model parameters improves model quality at the price of high computation overhead. Sparsely activated models, usually in the form of Mixture of Experts (MoE) architecture, have sub-linear scaling of computation cost with model size, thus providing opportunities to train and serve a larger model at lower cost than their dense counterparts. However, distributed MoE training and inference is inefficient, mainly due to the interleaved all-to-all communication during model computation.

This paper makes two main contributions. First, we systematically analyze all-to-all overhead in distributed MoE and present the main causes for it to be the bottleneck in training and inference, respectively. Second, we design and build Lina to address the all-to-all bottleneck head-on. Lina opportunistically prioritizes all-to-all over the concurrent allreduce whenever feasible using tensor partitioning, so all-to-all and training step time is improved. Lina further exploits the inherent pattern of expert selection to dynamically schedule resources during inference, so that the transfer size and bandwidth of all-to-all across devices are balanced amid the highly skewed expert popularity in practice. Experiments on an A100 GPU testbed show that Lina reduces the training step time by up to 1.73x and reduces the 95%ile inference time by an average of 1.63x over the state-of-the-art systems.

1 Introduction

Recent advances in deep learning have shown that a model's quality typically improves with more parameters [15, 21, 23, 29, 47]. Many new frontiers in Computer Vision (CV) and Natural Language Processing (NLP) have been explored using large dense models [22, 38, 44]. While effective in terms of model quality, the computation cost of model training and serving is extremely high. ChatGPT [1], an impressive chatbot released by OpenAI, is estimated to spend 3 million dollars per month to serve user requests. Wider adoption and development of these models are impeded by the exorbitant compute cost.

Following the basic idea of curbing the computation cost of massive models, *sparsely activated* models have recently been introduced [13, 23, 33, 44]. The *Mixture-of-Experts* (MoE) structure is now one of the most popular ways to implement sparse activation [13, 14, 44, 55]. For each input, instead of using all parameters, an MoE model selects just a few of them, i.e. *experts*, for processing. This leads to sub-linear scaling of FLOPs needed with model size. Recent literature [9, 22, 26, 30, 38, 54] has proven the potential of MoE models. For instance, Google develops a family of language models named GLaM using MoE [22]. Compared to GPT-3 with 175 billion parameters, the largest GLaM has 1.2 trillion parameters while only consuming 1/3 of the energy for training. Meanwhile, GLaM still achieves better zero-shot and one-shot performance than GPT-3. Microsoft reports that their MoE-based language models achieve a 5x training cost reduction compared to a dense model with the same model quality [38].

Given the uptake of MoE, there have been several systems for efficient MoE training and inference, including Google's Mesh TensorFlow [43], Meta's FairScale [10], Microsoft's DeepSpeed [2] and Tutel [7], etc. They provide APIs for users to replace the conventional dense layers with MoE layers with minimal code changes. They adopt both data parallelism and expert parallelism to accelerate the training and inference. That is, each device (e.g. GPU) is assigned with a unique expert, and uses all-to-all to receive inputs from other devices and then sends the gradients back to them accordingly. During training, allreduce is then used to aggregate non-expert gradients in the backward pass.

We focus on the efficiency of distributed MoE training and inference in this work. As some [25, 31, 41] has shown, the all-to-all operation is the main bottleneck. All-to-all blocks the subsequent computation operations and needs to be invoked two times in the forward pass and another two in the backward pass for each MoE layer. Interestingly, the main causes for all-to-all being the bottleneck are different in training and inference. In training, all-to-all and allreduce often contend for network bandwidth when they overlap in the backward pass,

leading to a prolonged blocking period to the computation. Inference, on the other hand, presents a highly-skewed expert popularity driven by real-world requests. Devices with popular experts have to handle much more data than others. Not only does it delay the launch of all-to-all, but it also causes imbalanced transfer size and bandwidth utilization across the devices, both of which are detrimental.

We are thus motivated to systematically tackle the all-to-all bottleneck. Our solution is Lina, a system that accelerates both MoE training and inference.

In training, we prioritize all-to-all over allreduce in order to improve its bandwidth. Existing MoE systems launch separate CUDA streams for the expert-parallel and data-parallel process groups which correspond to all-to-all for expert and allreduce for non-expert parameters, respectively. As there is no coordination between these streams, all-to-all and allreduce can overlap and fair-share the network bandwidth. Unlike allreduce, all-to-all is blocking and cannot be made parallel with the computation process. Thus, prioritizing all-to-all in the backward pass and avoid concurrent allreduce is crucial to reducing the blocking period.

To efficiently prioritize all-to-all, we adopt tensor partitioning which breaks down a tensor into smaller chunks, each of which forms a micro-op. With micro-ops, simple priority scheduling can be applied to guarantee full bandwidth for all-to-all while allowing allreduce micro-ops to make progress when all-to-all is not present. In addition, micro-ops allow the expert computation to be pipelined with all-to-all.

In inference, we dynamically schedule the resources for each expert in order to balance the workload of each device, thereby alleviating the imbalanced all-to-all transfer size and bandwidth. Intuitively popular experts should be given more resources while the rest may be served with less resources. The key challenge here is to efficiently and accurately obtain the expert popularity *before* the selection is actually done by the gating network, for every batch of input at each MoE layer, so scheduling benefit can be maximized with minimal overheads. Fortunately, we find the experts selected by each token across the layers demonstrate clear patterns, which allow us to estimate the expert distribution of the upcoming layer based on the past selection results from the preceding layers. We adopt a two-phase scheduling approach that fine-tunes the estimation based allocation only when the actual expert popularity deviates too far.

We build Lina based on DeepSpeed MoE [2] and PyTorch, and evaluate it on a cluster with up to 16 Ampere A100 GPUs with 40GB memory and 100Gbps InfiniBand. Results show that Lina accelerates all-to-all by at least 2.21x, and achieves on average 1.57x speedup in overall training step time compared to state-of-the-art system DeepSpeed. The median and 95%ile inference time is reduced by 1.45x and 1.63x.

Our contributions can be summarized as follows:

- We present an in-depth empirical analysis of distributed MoE to show the main causes for all-to-all to be the performance bottleneck in training and inference.
- We propose to prioritize all-to-all over allreduce in order to improve its bandwidth and reduce its blocking period in distributed training. Lina's scheduler incorporates tensor partitioning and pipelining to perform micro-op scheduling.
- We examine the pattern in expert selection of MoE layer and propose to estimate the expert popularity to conduct resource scheduling in advance during inference. Lina adopts a two-phase scheduling scheme to minimize the overhead.
- We implement a concrete prototype system and conduct comprehensive testbed experiments to demonstrate the benefits of our design in a realistic GPU cluster setting.

2 Background and Motivation

We start with an introduction on MoE and a widely-adopted distributed system for MoE model in §2.1. Then, we motivate our idea by analyzing the performance bottleneck (i.e. all-to-all) in distributed MoE training and inference in §2.2.

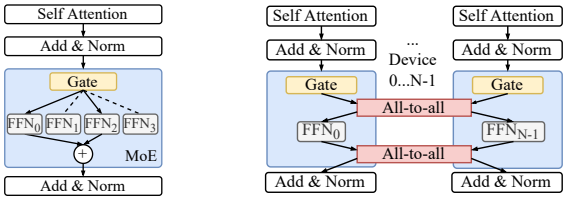
2.1 A Primer on MoE

Mixture-of-Experts (MoE) has been adapted to different types of DNN models , and exhibits great potential in improving the performance of language models in particular. GShard [31] and Switch Transformer [23] are two seminal works on scaling Transformer-based language models with MoE layers. We focus on MoE in Transformer-based models in this work.

Transformer-based models normally use an MoE layer to replace the feed-forward network (FFN) layer. An MoE layer consists of multiple FFNs each serving as an *expert*, and a gating network (Figure 1a). Every expert is a fully-connected two-layer network using ReLU activation but with different parameters. The gating network takes in the embedding vector of each token and multiplies them with its trainable matrix. Based on the results, it dispatches the token to a small number of experts (usually one or two). The final output of the MoE layer is the weighted sum of outputs from the selected expert(s). The sparsity nature of MoE improves the model scaling in size without increasing the training cost and naturally leads to a dynamically-changing model graph.

Load balancing loss. In MoE training, an auxiliary loss is introduced to evaluate the token distribution among the experts [23]. The objective is to achieve a uniform distribution of tokens across the experts, thereby preventing an excessive concentration of tokens in a single expert. By minimizing this loss term, we encourage but do not enforce the gating network to produce a perfectly balanced token distribution.

The standard practice is to calculate the auxiliary loss of each MoE layer and sum them with the training loss using an appropriate weight. Previous research has demonstrated the effectiveness of this approach [16,33,45]. However, it should be noted that achieving a perfectly balanced distribution, where the auxiliary loss converges to zero, is challenging [18, 53].



(a) There are four experts and the gate selects two experts.

(b) Distributed MoE. Data parallelism and expert parallelism are used.

Figure 1: MoE layer in Transformer-based models.

# Experts	Model	Training (ms)		Inference (ms)	
GPUs	#Layers & Params	All-to-all	Ratio	All-to-all	Ratio
4	12L + 117M	259	36.7%	73	27.4%
	24L + 233M	589	35.4%	103	26.2%
	36L + 349M	979	38.2%	153	28.3%
16	12L + 419M	333	39.5%	102	32.5%
	24L + 838M	715	37.6%	177	31.7%
	36L + 1.2B	1145	36.8%	243	27.4%

Table 1: The completion time of all-to-all and its ratio in training and inference task of Transformer-XL [20] in different number of experts per layer. Training and inference have the same batch size here. Each FFN layer is replaced with MoE and the number of experts is equal to the number of GPUs similar to the common practice [23]. A100 GPUs with 40GB memory and 100Gb/s InfiniBand are used. We use the MoE implementation in DeepSpeed.

During MoE inference, the trained gating network is utilized to dispatch tokens to the experts based on their respective embeddings. This process is solely driven by the characteristics of the token embeddings.

Hybrid parallelism in distributed MoE. Training and serving MoE models in a distributed manner are necessary due to the tremendous compute requirement of large-scale language models [12]. For efficiency, both data parallelism and MoE-specific *expert parallelism* (as a form of model parallelism) are applied [23,31]. Existing MoE systems [2,7,10,23,31,43] allocate one unique compute device (e.g., GPU) for each expert in expert parallelism. An all-to-all communication is then needed to send tokens to their experts selected by the gating network, and another all-to-all is needed to send tokens back to the device they belong to in data parallelism to finish the rest of the forward pass as shown in Figure 1b.

2.2 Bottleneck Analysis

Much prior work has identified that the introduction of all-to-all in MoE causes performance inefficiency in Transformer-based models [7, 41, 54]. We extract the completion time of all-to-all operations in both training and inference in our GPU cluster as shown in Table 1. All our experiments in this section use the same testbed and settings. Overall, all-to-all takes an average of 34.1% — a significant fraction of the step time. Interestingly, though the bottleneck brought by all-to-all is universal in both MoE training and inference, the causes differ. In the following, we motivate our work by analyzing how all-to-all affects the efficiency of training and inference, respectively.

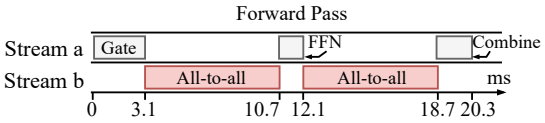


Figure 2: Timeline of forward pass an MoE layer. We simplify the presentation by bundling GPU kernels here: The computation kernels are grouped by their roles in the MoE layer into Gate, FFN and Combine. The Combine operation involves reshaping the tensors and computing the weighted output. The timeline is taken from a sample run of the 419M-parameter model in Table 1.

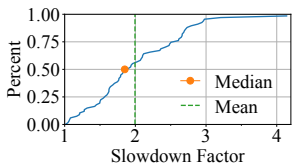

Figure 3: CDF of how much all-to-all is prolonged when it overlaps with allreduce operation. We mark the median and average slowdown factors.

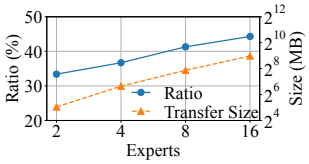

Figure 4: The proportion of all-to-all's completion time over training step time when the number of experts grows. Dashed line plots the data size in one all-to-all operation.

Synchronous all-to-all with large data transfer. The common characteristic shared by MoE training and inference is all-to-all's large data transfer. All-to-all is an irreplaceable synchronous component to handle the data exchange among devices in MoE layer. Each MoE layer has two all-to-all operations to send the tokens to the experts and then restore the position of tokens, as introduced in §2.1. The data transfers in the two all-to-all operations have the same size because the expert's FFN architecture ensures that its input data size is the same as the output data size. Figure 2 shows an empirical timeline view of the forward pass of MoE model in our cluster. All-to-all takes 74.9% of the end-to-end running time of one MoE layer. Expert FFN computation and the combine operation follow when all-to-all operation completes. MoE training and inference suffer from such inefficiency consistently. GPU is mostly idle during this period: We use the PyTorch Profiler [6] to profile the GPU activities for 20 steps in each experiment in Table 1, and find that the average GPU SM efficiency during all-to-all is 3.7%. Besides, the data transfer size grows linearly with the number of experts. Figure 4 presents the empirical evidence of all-to-all's transfer size as the number of experts grows from 2 to 16 (128). With the increasing number of experts, the time taken by all-to-all grows from 33.4% to 44.5% of the step time.

Problem in training: Prolonged all-to-all with allreduce. The unique challenge in MoE training is that applying the hybrid parallelism creates a particularly severe impact to all-to-all in backward pass. Non-MoE layers in *data parallelism* need *allreduce* to aggregate the gradients, while *expert parallelism* requires all-to-all to exchange tokens to compute expert gradients. Since the two operations control their own process groups independently, two dedicated CUDA streams are launched concurrently. This is demonstrated in Figure 5 with the timeline of backward pass in a sample run of MoE training. As the two operations overlap, they contend for the network bandwidth and their completion times are severely

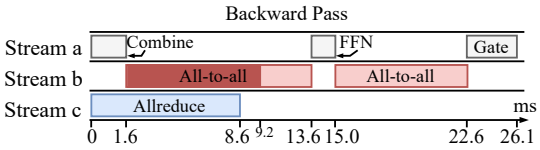

Figure 5: Timeline of backward propagating an MoE layer under hybrid parallelism. The first all-to-all is prolonged by the allreduce operation in Stream b. The shadowed part is its original completion time.

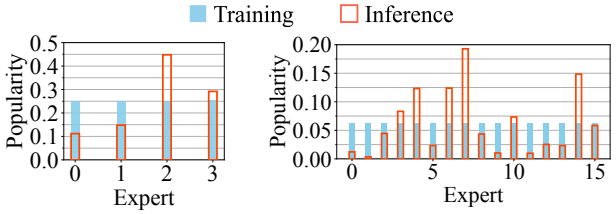


(a) 4-expert MoE. **(b)** 16-expert MoE.

Figure 6: Sampled expert popularity. The distribution is computed as the ratio between the number of tokens received by the expert and total number of tokens in one batch. We use the Enwik8 test set [3] for evaluation.

prolonged. To make matters worse, we find that the slowdown factor varies significantly. We collect the completion times of 1,500 all-to-all operations in backward pass on our testbed and plot the CDF of the slowdown factor they endure with allreduce in Figure 3. Observe that the median slowdown is over 1.83x and the worst is 4.14x.

Problem in inference: Skewed expert popularity. The main cause of all-to-all being the bottleneck in MoE inference is the skewed expert popularity. The token-to-expert distribution in inference is purely workload-driven, and we empirically find that the expert popularity is highly skewed in sharp contrast to training. We sample the expert popularity of the same MoE model in training and inference in Figure 6. In training, the distribution is nearly the same across all experts after hundreds of steps due to the use of load balancing loss. In inference, however, the most popular expert receives 4.02x and 5.56x tokens of the least popular ones in 4-expert and 16-expert inference tasks. With the same network and computation capacity, devices hosting popular experts take much longer to perform expert computation. In this experiment, the maximum idle time of the least popular expert is 29.4% of the inference time of that batch. Thus, within one batch, tokens to the less occupied experts have to wait for others to complete on the more popular experts, degrading the all-to-all performance significantly. Further, under uniform expert-device allocation, devices hosting popular experts have more tokens using their links for all-to-all, while the links of other devices are underutilized.

3 Design Overview

Lina is designed to accelerate all-to-all in distributed MoE. It attacks both the bandwidth contention with allreduce in training, as well as the straggler with unbalanced all-to-all bandwidth in inference. We focus specifically on MoE implementations that leverage both data and expert parallelism.

MoE training. We aim to improve the *bandwidth* of all-to-all in order to reduce the blocking period of the computation operations. Our key idea here is to *prioritize all-to-all* so it does not fair-share bandwidth with concurrent allreduce (§4). This is achieved using tensor-partitioning. We partition all-to-all and allreduce tensors into small chunks, each of which then forms a *micro-op*. Lina schedules an allreduce micro-op only when there is no all-to-all waiting or ongoing so that all-to-all is guaranteed the full network bandwidth during its lifetime. Without prior information, tensor-partitioning and micro-ops can ensure that in most cases all-to-all can launch immediately and allreduce is not deferred excessively.

MoE inference. We propose to dynamically adjust the device allocation for experts based on the *expert popularity*, so that is not all-to-all is not delayed by the trailing tokens, and its bandwidth utilization across links is balanced (§5). We exploit the expert selection pattern across adjacent layers to estimate the expert popularity. Based upon the estimation, Lina performs scheduling at each layer to allocates proportionally more devices for popular experts and pack unpopular ones to fewer devices, and coordinate all-to-all correspondingly.

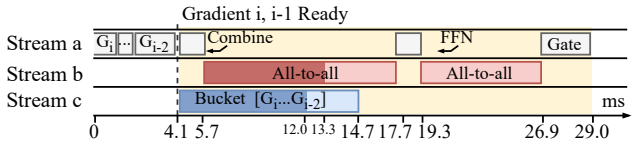
4 Prioritizing All-to-All Training

We have shown that all-to-all is slowed down significantly if it overlaps with allreduce in the backward pass in MoE training. Lina partitions the communication operations into small micro-ops and schedule them strategically in order to prioritize all-to-all without impeding allreduce and the computation process. We introduce the design challenges in §4.1. In §4.2, we present Lina's communication scheduler that uses tensor partitioning and pipelining to improve the training efficiency.

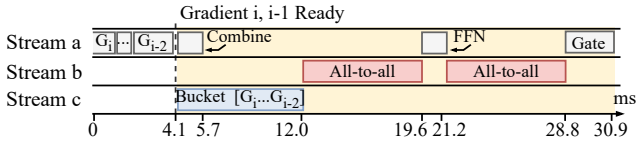
4.1 Design Challenge

Intuitively, Lina can prioritize all-to-all and avoid concurrent execution with allreduce with strict priority scheduling. All-to-all is always dispatched first if both are present in the queue, and subsequent operations have to wait until the running one finish to make sure allreduce does not share the bandwidth.

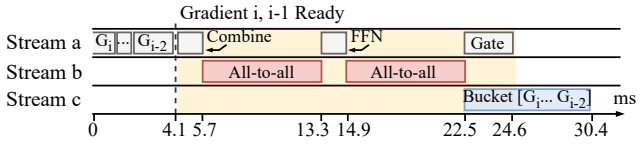
It turns out that simply prioritizing all-to-all is not as efficient as one may expect. For work-conservation, when an allreduce arrives first, it should be launched immediately. The problem is when an all-to-all arrives later, though ideally one would preempt the allreduce due to priority scheduling, this is not possible in current multi-GPU communication libraries such as NCCL [4]. The communication primitives are highly optimized and upon being called, their complete transmission strategies are settled and pushed to the CUDA streams. There is no control knob inside each primitive to adjust how it shares resources (e.g. CUDA cores, network bandwidth) with others. Thus, as the example in Figure 7b shows (based on testbed



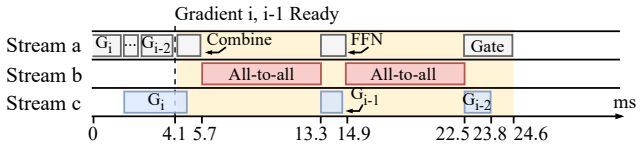
(a) Baseline. Shadowed all-to-all and allreduce are their completion times without concurrent operations. Computing the entire MoE layer's gradients ends at 29.0ms.



(b) Naively prioritizing all-to-all without concurrent transmission can lead to worse results; computing the MoE layer's gradients ends at 30.9ms. The completion time is profiled. Theoretically, the completion time should be the same as Figure 7a.



(c) Deferring allreduce to after the second all-to-all leads to better training efficiency; computing the MoE layer's gradients ends at 24.6ms.

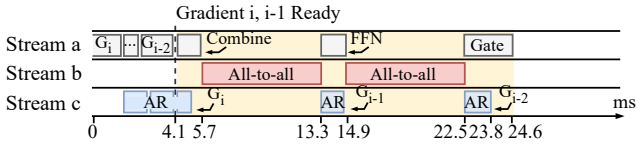


(d) Scheduling results if the arrival time and running time of communication operations are known a priori. The allreduce completes much faster than (c).

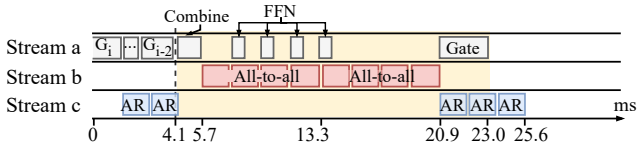
Figure 7: Backward pass of MoE training. The yellow background is the period of computing the gradients of the MoE layer. Stream a is responsible for the computation process and streams b and c are for communication. This timeline is extracted from a real run of the 419M-parameter benchmark model in Table 1.

experiments), naively prioritizing all-to-all actually leads to a longer completion time for the first all-to-all and training step time compared to the baseline in Figure 7a.

A potential solution is to obtain the arrival time and running time of the upcoming all-to-all and allreduce, and orchestrate them accordingly to maximize the efficiency. Assuming we know that the allreduce for gradient i can complete before all-to-all and the completion time of gradient $i-1$'s allreduce is shorter than FFN computation. Then we can schedule gradient $i-1$'s allreduce to the gap between the two all-to-all operations at 13.3ms as depicted in Figure 7d. Obtaining the precise knowledge of arrival and running times is, however, a daunting task. ML frameworks such as PyTorch fuse gradients into buckets based on a user-defined bucket size to optimize allreduce efficiency. Yet in large Transformer-based models, gradient sizes are also large; since bucketing is done on the gradient boundary, the actual bucket size for allreduce varies wildly [5]. Moreover, the implementation details of allreduce make it difficult to acquire a reliable running time estimate as prior work has found out [19].



(a) Prioritize all-to-all and partition allreduce tensors. Instead of bucketing gradients, we partition gradient i into three chunks when it is computed.



(b) Tensor partitioning for all-to-all and pipeline the FFN computation.

Figure 8: We show the scheduling results from Figure 7a with tensor partitioning. All-to-all and allreduce micro-ops are of the same size.

The other design choice is to blindly defer allreduce until an even number of all-to-all finish as there should be a larger gap between the backward pass of two MoE layers relative to FFN's backward computation. Figure 7c shows the best scheduling result based on the baseline in Figure 7a. In this case, allreduce can be launched when the second all-to-all finishes and completes before the first all-to-all of the next MoE layer (not shown in the figure). Yet, in other (worse) cases, allreduce may still block the all-to-all of the upcoming MoE layer if it takes relatively longer. In the extreme case, no allreduce can be launched until all four all-to-all operations of the current step finish. Since devices have to wait for allreduce before moving onto the optimization phase, this incurs more delay and is undesirable for wait-free backward pass [51].

4.2 Tensor Partitioning and Micro-Ops

To resolve the above challenges, we propose tensor partitioning that breaks down a communication operation into micro-ops, which can be easily prioritized with high efficiency.

Tensor partitioning. Unlike tensor bucketing which fuses multiple gradients for an allreduce, Lina partitions each gradient tensor into equal-sized small chunks and executes individual allreduce *micro-ops* independently. This brings two advantages. First, it resolves the varying bucket size problem for allreduce since each micro-op is uniform in size now. Second, micro-ops naturally make better use of bandwidth [36] without causing too much delay to allreduce under priority scheduling. Consider the same setup from Figure 7a, in Figure 8a we partition gradients into five chunks. Before the first all-to-all arrives, Lina launches three allreduce micro-ops; after the first all-to-all ends, it starts another micro-op to opportunistically make use of the expert computation time. Compared to the scheduling result without micro-ops in Figure 7c, allreduce for gradient $i-2$ now completes 6.6ms or 21.7% faster without prolonging all-to-all. Tensor partitioning does incur overhead due to the partition and concatenation operations before and after an allreduce, but it is mild: the

overall overhead in Figure 8a's case is 764us. §7.2.2 has more details of the overhead analysis.

Pipelining micro-ops. Intuitively, we can also partition all-to-all which provides an opportunity to pipeline the expert FFN and further reduce the time that computation is blocked. Specifically, we can pipeline the expert computation and all-to-all micro-ops (Figure 8b). Since the FFN computation is in token granularity, the expert can start computing with a subset of the tokens after one all-to-all micro-op. With pipelining, we can eliminate the FFN time which is 1.6ms in this example.

Expert packing. Ideally, the FFN and all-to-all micro-ops should take a similar time so that both compute capacity and network bandwidth are fully utilized without any bubbles in the pipeline. However, we notice that a single FFN micro-op takes much less time than its corresponding all-to-all micro-op (Figure 8b). In Lina, we consider packing multiple experts on each device whenever possible to maximize the pipelining efficiency. Lina adopts the following approach: starting with one expert per device, it iteratively increases the number of experts per device in powers of two, until the FFN computation exceeds that of the all-to-all micro-op. In case of GPU memory shortage, we adopt DRAM-offloading [42] to transfer expert parameters that are not currently in use to host memory.

5 Scheduling Resources in Inference

Recall in §2.2, we have shown empirically that skewed expert popularity leads to unbalanced processing times across tokens of the same batch in MoE inference, which delays all-to-all and causes imbalanced bandwidth for it severely. The root cause lies in the data granularity mismatch between the expert and the attention layers in the model: an expert processes individual tokens, but the attention layer processes an entire sequence as a whole. Our design question is thus: How can we ensure that each token within the same batch experiences the same end-to-end completion time no matter its expert selection result? We will first discuss the challenge of achieving this through dynamic resource scheduling (§5.1), and then present our design that exploits the unique token-level expert selection pattern to address the challenge in §5.2.

5.1 Design Challenge

To cope with skewed expert popularity, intuitively one must accordingly adjust the resource allocation for experts. This adjustment also needs to be done for each input sequence as the expert popularity distribution varies across sequences. An immediate question is: how can we know the expert popularity distribution, before the input is processed by the gating network?

This question is challenging for two reasons. First, even for a given batch of input, expert popularity varies across MoE layers of the model. We collect the expert popularity of different MoE layers for 1000 batches of input requests. Table 2 shows the top-4 popular experts of two 12-expert inference tasks: text generation and translation. Observe that each MoE layer of the same task (model) has completely different popular experts. This also suggests that dynamic resource scheduling has to be done before each MoE layer in order to be effective. Moreover, scheduling resources according to the actual expert selection results, as some might be thinking, incurs delay in collecting information, making scheduling decisions, and coordinating the all-to-all amongst all experts with respect to the new expert-device mapping, all of which are blocking operations and are performed at each layer. This is far from optimal (as will be shown in §7.3.1). Thus, we need to know as much as possible the expert popularity *before* the gating network selects experts in each layer, so these overheads can be largely overlapped with MoE computation.

5.2 Popularity based Scheduling

Lina tackles the design challenge by exploiting the token-level expert selection pattern which we empirically establish now. Building upon this, we design a resource scheduler that replicates popular experts on proportionally more devices in order to better balance the workload.

Pattern in expert selection. Experts in MoE models are trained to specialize in different types of input. We find that a token's expert selection demonstrates a pattern across the MoE layers. Tokens that have selected the same expert in layer i tend to select the same expert again in layer $i+1$. We trace the expert selection of sampled tokens. For each group of tokens that have selected the same expert in layer i, we calculate the ratio of them that in the next layer also select one of the same top-k experts ranked locally among the same group. Figure 9 plots this ratio averaged over token groups in two 12-layer MoE models. We see 41.94% tokens exhibit this pattern when k is 1 and 54.59% when k is 2, and deeper layers see more tokens with this pattern.

This observation makes intuition sense. The gating network has a simple architecture, and their routing or expert selection decision is made (largely) based on relatively simple features, such as the parts of speech of a word (noun, verb, etc.), and the meaning of the word (number, time, etc.) [32]. These features are fixed for each token. Meanwhile, experts focus on the local syntax information of each token rather than the cross-dependency within a sequence. For all these reasons, similar tokens naturally tend to be processed by the same or similar experts in each layer.

Estimating expert popularity. Though this pattern may not be sufficient to predict a particular token's expert selection accurately, it provides enough clues for us to estimate the overall expert popularity for a given batch. Specifically, Lina's estimation approach works as follows. In the profiling stage, we collect the expert selection results of all tokens when the load balancing loss is minimized and becomes stable. We then

Model& Dataset	Layer	Top-4			
Transformer-XL & Enwik8 (Text generation)	3	9	4	5	10
	4	5	7	8	10
	8	9	2	3	13
	12	4	5	15	8
BERT-Large & WMT En-De (Translation)	6	7	6	10	1
	8	10	6	2	15
	10	9	4	11	8
	12	1	8	10	14

Table 2: Top-4 popular experts in sampled MoE layer of two MoE models.

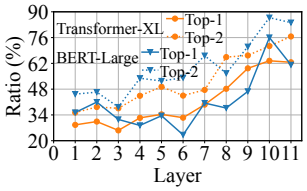


Figure 9: Ratio of tokens that select one of the top-k experts in layer $i+1$ given that they have selected the same expert in layer i.

group tokens that select the same experts from layer $i-l$ to layer i, which represent a unique sample path of experts used. For each sample path j, we compute the expert popularity distribution Ψ_j^{i+1} for layer $i+1$. Here l is the path length to control the accuracy-cost tradeoff in profiling: a larger path length leads to more accurate estimation for layer $i+1$ at the expense of higher data collection and computation costs.

Then based on the profiled distributions $\{\Psi\}$, Lina can estimate the next layer's expert selection distribution for each sample path of experts traversed by a token in inference (starting from the l-th layer of the model). In each layer i, for a sample path j, we pick the top-k expert(s) of the subsequent layer from Ψ_j^{i+1} and use their probabilities $\{P_j^{i+1}(e)\}$ to represent expert popularity for resource scheduling, where e denotes an expert. The reason why we only consider top-k experts is that they demand the most resources, and the remaining experts have low popularity (Figure 9). Note that this estimation happens before any MoE layer computation takes place.

Two-phase scheduling. During inference, Lina dynamically conducts layer-wise resource scheduling in two phases.

The first phase happens right after the expert popularity estimation at each MoE layer, when Lina relies on the estimation to replicate popular experts on more devices and pack unpopular ones onto fewer devices. Specifically, the total number of devices for expert e is determined by:

$$n_e = N \times \sum_{t=1}^{N_t} P_{j(t)}^{i+1}(e)/N_t, \tag{1}$$

That is, for the current batch of input with N_t tokens, using estimation from each token t's sample path $j(t)$ up to layer i, the overall popularity of expert e is estimated as $\sum_{t=1}^{N_t} P_{j(t)}^{i+1}(e)/N_t$ for layer $i+1$ accounting for all tokens. This requires the same proportion of devices assuming the expert parallelism degree is 1 (i.e. the number of devices equals the number of experts). For experts with the estimation n_e, we adopt the first-fit-decreasing heuristic to pack them into the empty devices so the total devices used are minimized. It is possible that some experts, being extremely unpopular (for this batch), are not amongst the top-k list of any tokens and thus do not have their n_e estimation. They are assigned evenly to the remaining free devices if any; otherwise are randomly assigned to a device.

In phase two, Lina fine-tunes the estimation-based scheduling decision after the gating network selects the actual experts. It checks if the selection result deviates significantly from the estimation, by comparing the overall top-$2k$ experts. If the two lists are identical, no fine-tuning is needed and inference continues. Otherwise, the scheduler re-computes the resource allocation with the actual expert popularity now available following the same logic in phase 1. The fine-tuning phase does incur delay to collect the gating outputs and check against the estimation, which is necessary to deal with inaccurate estimation that turns out to be much more detrimental to performance, if left unchecked (§7.3).

6 Implementation

We implement Lina on DeepSpeed MoE and PyTorch using C++ and Python. PyTorch 1.10, CUDA 11, and NCCL 2.10 are used. We modify PyTorch's implementation of distributed training to support Lina in DeepSpeed. The implementation has ∼7500 LoC.

6.1 Training

Lina's communication scheduler for training is deployed on all devices and runs a single thread. Since the communication scheduling is purely local in scope, no coordination is needed across the scheduler instances on different devices.

Communication scheduler. Each scheduler instance maintains a priority queue to schedule the micro-ops. The micro-op size is passed in as a hyperparameter. Lina uses the built-in APIs `chunk` and `cat` in LibTorch to partition the data in the token dimension. We avoid putting chunks from different gradients into the same micro-op to simplify the subsequent concatenation operation. Moreover, the scheduler stops launching allreduce micro-ops if the combining computation in backward pass, since this implies all-to-all is imminent. We pipeline all-to-all micro-op in the MoE layer. FFN is ready to start right after each all-to-all micro-op.

Expert packing coordinator. We embed a packing controller in the MoE model and it runs a single thread. Expert packing is dynamically adjusted after 10 training steps. In the forward pass, the controller records the completion times of all-to-all and FFN micro-ops. When FFN micro-ops are shorter than all-to-all, the controller starts to pack experts. First, we initialize the new process groups. Second, the controller inserts a one-time synchronous all-to-all to exchange expert parameters between packed devices that would be invoked at the upcoming iteration. Finally, multi-stream parallel execution is adopted for both forward and backward passes when more than one expert are hosted on a device.

6.2 Inference

Resource scheduler. The inference scheduler runs on a dedicated thread on device 0 of the cluster and manages resource scheduling. Each device saves the weights of all experts in

their host DRAM and the collected layer-wise expert popularity distribution using multiple `unordered_map`, one for each layer. If GPU memory is in shortage, a device only loads one expert and the profiled distribution of one layer at a time.

In phase one of scheduling, all relevant communication happens by piggybacking the information on the regular all-to-all to reduce overheads. For each MoE layer, each device appends the popularity estimation to the first all-to-all for device 0. The scheduler computes the new expert-device mapping and instructs each device which expert and how many to host via the second all-to-all. We also include necessary information to coordinate all-to-all of the next layer, including the list of devices with the same expert, and how many tokens each replica should handle to balance the load. Devices then swap in the expert weights for the next layer. All these procedures are pipelined with model computation.

In phase two, each device updates the actual expert popularity in a separate NCCL `send` to the scheduler. If no fine-tuning is required, the scheduler broadcasts a resume signal. This only creates a negligible overhead as the transfer size is tiny. Otherwise, Lina broadcasts the fine-tuned expert-device mapping. The model computation is blocked during phase two until the scheduler's command is received.

All-to-all coordination. In inference, Lina uses all-to-all with an unequal split. That is, the transfer size to each device in all-to-all does not need to be the same. Using unequal split all-to-all can save the overhead of initializing multiple process groups. A placeholder data pointer is passed to all-to-all if no tokens are directed to a certain device.

Expert packing. Expert computation is sequential on devices hosting multiple experts. Each device loads the experts one at a time to perform computation and move on to the next packed expert. In this manner, Lina avoids placing extra strain on the GPU memory. The second all-to-all is launched when the computation for all packed experts is completed. We set a maximum number of experts per device to control the overhead of swapping the weights.

7 Evaluation

We present the testbed evaluation results here.

7.1 Setup

Testbed setup. Our testbed has four worker nodes. Each node has 4 Ampere A100 GPUs with 40GB memory and is equipped with 100Gbps InfiniBand.

MoE models. We convert three common Transformer-based dense language models to MoE ones for training.

- Transformer-XL [20]: a 24-layer encoder model.
- BERT2GPT2 [49]: a 12-layer encoder-decoder model.
- GPT-2 [39]: a 12-layer decoder model.

Besides, we consider two inference tasks.

- Transformer-XL [20]: The inference task is text generation with Enwik8 [3] test set.
- BERT-Large [21]: a 12-layer decoder model. The inference task is translation using WMT En-De [8] test set.

All FFN layers in these models are converted to MoE layers. We vary the number of experts in an MoE layer from 2, 4, 8, to 16. We adopt top-2 gating in training and top-1 gating in inference following [23], i.e. $k = 2$ in training and $k = 1$ in inference

Metrics. We consider four metrics to evaluate Lina.

- Training step time: Time to complete one step of training.
- Inference time: Time to complete one batch of inference.
- All-to-all time: The completion time of all-to-all.
- MoE layer time: Time to complete one MoE layer of computation and communication.

In collecting these metrics we use PyTorch Profiler to obtain CUDA kernel execution time and GPU activities. Training results are averaged over 50 steps after a 10-step warm-up period. Inference results are averaged over the test set. Since the optimization introduced by Lina does not affect the precision of model parameters, model accuracy is unaffected and we omit its evaluation.

Training configurations. Lina's micro-op communication scheduler adopts a tensor partition size of 30MB, which can minimize the period blocked by all-to-all in most cases. Expert packing is launched at the 10-th step of each training task and is adjusted every four steps.

Inference configurations. Lina's resource scheduler runs on device 0. The path length l in popularity estimation is 3; the maximum number of experts packed on a device is 4.

Baselines. We use the vanilla DeepSpeed [2] as the Baseline. We also provide a comparison to the open-source version of Tutel [7], which performs similarly with DeepSpeed. We enable hierarchical all-to-all for both Lina and DeepSpeed and disable Random Token Dropping [50] introduced by DeepSpeed.

7.2 Training

We start with Lina's training performance. Note that Lina is evaluated when the expert packing decision is stabilized; all settings here use 2 experts per device as the best strategy except Transformer-XL with 16 experts, which uses 4 experts per device. The number of GPUs is equal to the number of experts per layer in both Baseline and Lina.

7.2.1 Overall Performance

Training step time. Figure 10 shows Lina's speedup in step time over Baseline and Tutel. All other aspects of the models stay the same (e.g. sequence length, hidden states dimension, etc.). Compared to Baseline (DeepSpeed), step time is reduced by an average of 1.37x and 1.47x for the 4- and 16-expert cases, respectively, and by an average of 1.71x and

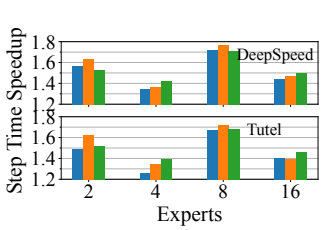

Figure 10: Speedup of training step time against two Baselines.

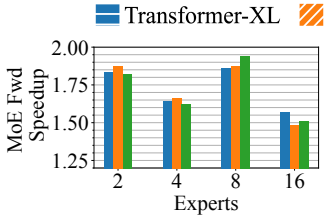

Figure 11: Speedup of MoE layer's forward pass completion time.

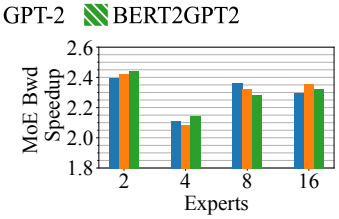

Figure 12: Speedup of MoE layer's backward pass completion time.

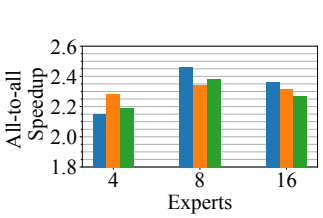

Figure 13: Speedup of all-to-all time in forward and backward pass.

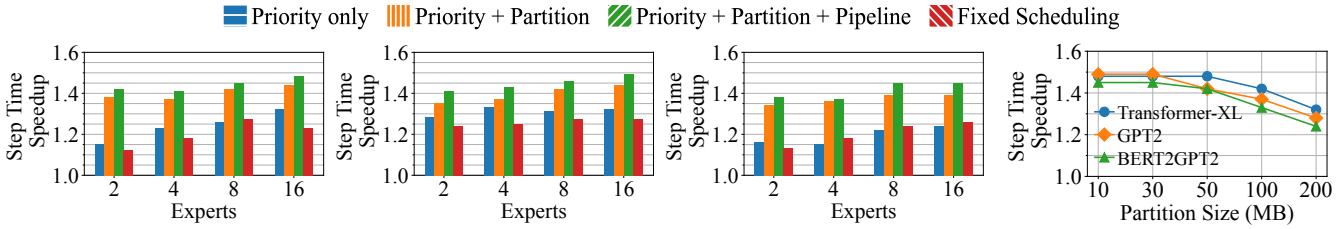


(a) Transformer-XL. **(b)** GPT-2. **(c)** BERT2GPT2.

Figure 14: Training step time speedup over Baseline with different design choices of the communication scheduler.

Figure 15: Partition size increases from 10MB to 200MB in 16-expert models.

1.73x for 2- and 8-expert models, respectively. The 2- and 8-expert cases see more significant gains as Lina's packs two experts per device as mentioned before. The 2-expert case thus boils down to pure data parallelism without any all-to-all; the 8-expert models avoid inter-node all-to-all as our servers have 4 GPUs each. Lina's speedup over Tutel is slightly smaller than that of DeepSpeed. Thus in the following we only use DeepSpeed as the Baseline.

MoE layer time. We specifically seek to understand Lina's gain in MoE layers in both the forward and backward pass. As Figures 11 and 12 show, similar to step time, the gain in the 2- and 8-expert cases is the largest. The forward and backward pass of MoE layers in the 2-expert case are accelerated by 1.84x and 2.41x, and in the 8-expert case by 1.89x and 2.32x, respectively. Since backward pass in Baseline suffers from the interference of allreduce while the forward pass does not, the improvement in the backward pass is more significant. Average GPU utilization in the MoE layer for 16-expert cases is improved by at least 16% as the period blocked by all-to-all is minimized with Lina.

GPU utilization and memory usage. We measure the average GPU utilization GPU memory usage. We observe an average of 17.6% improvement in GPU utilization due to the efficient scheduling of Lina. Expert packing would lead to usage increase in GPU memory. The peak memory of BERT2GPT2 is increased by 19.5% while Transformer-XL and GPT-2 use up all the memory and apply DRAM-offloading to store the packed expert parameters.

All-to-all time. We then zoom in on all-to-all time in backward pass, where Lina prioritizes all-to-all and avoids concurrent execution with allreduce. Expert packing also reduces the all-to-all transfer size. Figure 13 shows an average speedup of 2.21x, 2.39x, and 2.31x in 4-, 8-, and 16-expert cases in all-to-all time, respectively.

Expert	Model	Pipelining Efficiency		
		w/o Packing	w/ Packing (Experts per Device)	
16	Transformer-XL	33%	86%	4
	GPT-2	36%	85%	2
	BERTGPT2	34%	79%	2

Table 3: Pipelining efficiency comparison with and without expert packing.

Expert	Model	Average GPU Utilization(%)		GPU Memory Peak Usage(%)		
		Baseline	Lina	Baseline	Lina	DRAM-offloading
16	Transformer-XL	66.2	83.4	72.1	100	✓
	GPT2	62.3	78.2	83.8	100	✓
	BERT2GPT2	63.5	82.5	74.3	94.2	✗

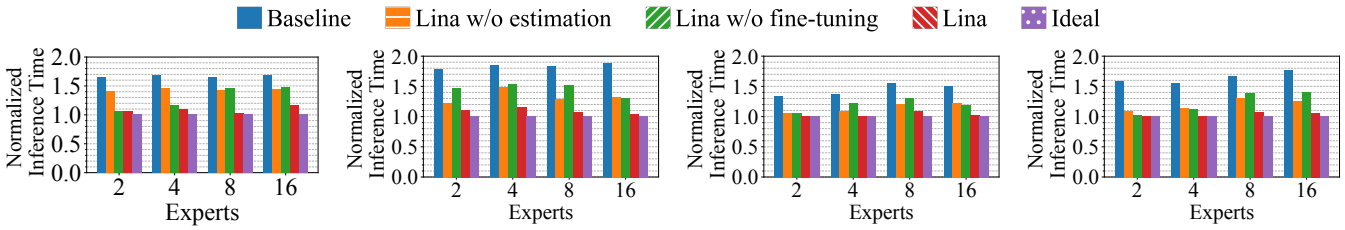
Table 4: GPU utilization and peak memory usage of 16-expert MoE models. GPU Memory Peak Usage is the ratio between the maximum usage and the total device memory. DRAM-offloading indicates if it is applied.

We also examine the pipelining efficiency between all-to-all and expert computation in Lina. We define the pipelining efficiency to be the fraction of non-idle time in the computation CUDA stream during the all-to-all duration. We calculate the pipelining efficiency of Lina before and after adopting expert packing in Table 3. The average improvement is 2.43x in 16-expert case, which also demonstrates the benefits of expert packing. The expert FFN micro-op time is thus closer to the all-to-all time. We find that two experts per device can achieve the best pipelining efficiency in most cases, justifying our settings mentioned before.

7.2.2 Communication Scheduler

We now present an in-depth analysis of Lina's priority-based micro-op scheduler, aiming to understand the benefit of each design choice. For fairness all experiments here are obtained without expert packing in Lina, i.e. one expert per device.

Tensor partitioning and pipelining. To justify our design, we incrementally add the key design choices to Baseline and see their corresponding gain: first priority scheduling, then tensor partitioning, and lastly pipelining. Besides, we



(a) Median inference time with Transformer-XL.

(b) 95%ile inference time with Transformer-XL.

(c) Median inference time with BERT-Large.

(d) 95%ile inference time with BERT-Large.

Figure 16: Median and tail inference time. We normalize the inference time with the ideal result. The median and tail inference time is the same in Ideal.

consider a fixed scheduling strategy where allreduce is always scheduled between pairs of all-to-all operations (i.e. two MoE layers) with tensor fusion enabled in PyTorch's `DistributedDataParallel` by default (same as Baseline).

Figure 14 shows the step time comparison. We make several interesting observations here. First, using priority brings about 10%–30% gain over Baseline in most cases, with an average of 24%. Priority scheduling in general presents more benefit when more devices and nodes are used in training. The main reason is that all-to-all's slowdown due to sharing bandwidth with allreduce is more severe as training scales out. Second, tensor partitioning significantly improves the benefit of prioritizing all-to-all: step time is reduced over Baseline by 1.36x, 1.36x, 1.41x and 1.42x in 2-, 4-, 8-, and 16-expert cases, respectively on average. On the other hand, pipelining's gain is limited as expected, since expert computation takes much less time than all-to-all without expert packing (recall §4.2). Overall, all three design choices can effectively reduce all-to-all's completion time.

We also observe that the relative benefit of priority scheduling and tensor partitioning is model-specific: GPT-2 enjoys much more gain from priority compared to tensor partitioning while the other two models do not exhibit such clear pattern. This is likely due to the degree of overlapping of all-to-all and allreduce: most allreduce can fit in between all-to-all operations in GPT-2, and as a result using priority scheduling alone is very beneficial.

Finally, the fixed scheduling strategy leads to the smallest gains in almost all cases. This is because (1) all-to-all still has to fair-share bandwidth with allreduce, and (2) tensors are not partitioned which aggravates the impact of allreduce. This demonstrates again the effectiveness of our design in prioritizing all-to-all with smaller tensors instead of using fixed heuristics that cannot opportunistically maximize efficiency.

Partition size. We also evaluate the impact of partition size on the communication scheduler. Figure 15 shows the step time of 16-expert models when we gradually increase the partition size from 10MB to 100MB. We find that a partition size beyond 50MB slows down Transformer-XL and BERT2GPT2 compared with 30 MB. As long as the period blocked by all-to-all is minimized, step time would be minimum. Therefore, for each model and setting, there are multiple optimal partition sizes. Ideally, the scheduler can more precisely control the operations with a smaller partition size. In practice, small partitions (below 10MB) may cause heavy transmission overhead in each micro-op and degrade the overall performance [37].

Overhead analysis. We provide a brief analysis of the overhead incurred by Lina's communication scheduler. First, the preprocessing and postprocessing, including tensor partitioning and concatenation, take an average 1.02% of the step time. Second, we measure the transmission overhead of micro-ops. We sum up running times of all the communication micro-ops and compare against those without partitioning in Baseline. The average completion time is lengthened by 1.7%.

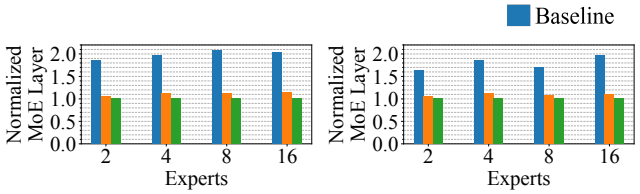
7.3 Inference

We then evaluate Lina's inference performance. Each experiment is repeated five times: two of which measure the end-to-end inference time, and the rest profile the different components with Profiler and collect statistics for overhead and estimation accuracy. This way the inference time is not affected by the profiling overhead.

7.3.1 Resource Scheduler

Inference time. Figure 16 shows the median and 95% inference time of Baseline and Lina. We also present the ideal inference time with a perfectly balanced load across devices in all MoE layers. This is obviously challenging to achieve with real-world requests. Thus we modify the gating network to constantly output a balanced expert selection to obtain this benchmark. We normalize all results to the Ideal value.

Lina's resource scheduler effectively balances the load among devices and achieve inference time close to Ideal. Compared to Baseline, median inference time is reduced by 1.54x and 1.45x for the 4- and 16-expert Transformer-XL, and by 1.36x and 1.46x for the 4- and 16-expert BERT-Large, respectively. The 95%ile inference time is reduced by 1.82x for 16-expert Transformer-XL and 1.68x for 16-expert BERT-Large. The reduction on tail inference time increases with more experts in a layer, because a wider MoE layer is more likely to present more skewed expert popularity, giving more room for Lina to optimize. Lastly, Lina's gap to Ideal can be explained for two reasons other than the overheads. First, Lina cannot perfectly balance load: the least popular experts are



(a) Transformer-XL. **(b)** BERT-Large.

Figure 17: 95%ile completion time of MoE layer.

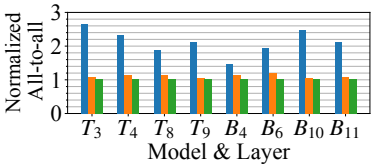


Figure 18: All-to-all time in 16-expert MoE. T is Transformer-XL and B is BERT-Large.

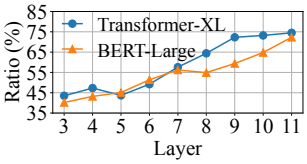

Figure 19: Estimation accuracy of 16-expert MoE.

randomly placed for example. Second, Lina starts to schedule from the fourth layer.

MoE layer and all-to-all time. With Lina, MoE layer time includes gate computation, phase two of scheduling, two all-to-all, and expert computation; phase one of the scheduling is largely overlapped with computation as explained in §6.2. The 95%ile MoE layer time is reduced by 1.87x and 1.77x in 8- and 16-expert Transformer-XL over Baseline and by 1.58x and 1.81x in 8- and 16-expert BERT-Large as in Figure 17. We also extract all-to-all time, which is a direct indicator of whether Lina balances load across devices effectively. We present the tail all-to-all time reduction of different layers in Figure 18. The average and maximum improvements are 1.96x and 2.50x over Baseline. These results confirm that Lina effectively balances the load of each device and all-to-all transfer size of each link.

Two-phase scheduling. We then evaluate the effectiveness of our resource scheduler's design. We consider separately Lina without estimation and without fine-tuning in order to understand their individual gains. Lina w/o estimation refers to scheduling using the actual routing decision computed by the gating network.

In Figure 16, we present the comparison of inference time for all schemes. Without estimation the median inference time is worsened by 24.0% and 18.6% for 16-expert Transformer-XL and BERT-Large in Lina. The scheduler works after the gating network and blocks all-to-all with the following computation until it completes. Thus the scheduling overhead manifests at each MoE layer, overweighing the additional gains brought by accurate popularity information. The tail inference time is less affected compared to the median, but still suffers without estimation.

Without fine-tuning, tail inference time is prolonged by 26.7% and 33.1% for 16-expert Transformer-XL and BERT-Large. This suggests that fine-tuning also plays an indispensable role when the estimation shows a large difference from the actual routing decision. For example, if the top-1 expert in the actual routing decision is estimated as an unpopular one packed with others, the Moe layer time would even be worse than Baseline. More discussions are presented in §7.3.2. The importance of fine-tuning depends heavily on estimation accuracy and number of expert in MoE layer.

Overhead analysis. We dissect the overhead of the resource scheduler, by considering the scheduling times of phase one and phase two separately. The scheduling time for both phases averages at ∼6.2ms since they share the same logic and coordination workflow. Yet, the overhead of phase one is largely overlapped with model computation. Though overhead of phase two with re-scheduling is more salient, it only kicks in for 23% of the cases on average, and is smaller than the idle time incurred by skewed expert popularity. The overhead of phase two without fine-tuning is merely 1.45ms.

Model	Path Length	Norm. Inference Time Median	Norm. Inference Time 95%ile	Fine-tuning (%)	Estimation Accuracy (%)
Transformer-XL	1	1.41	1.32	76.5	31.6
	3	1.16	1.04	25.7	60.4
	6	1.19	1.11	22.5	71.4
BERT-Large	1	1.34	1.35	71.3	28.3
	3	1.07	1.04	32.2	63.5
	6	1.09	1.11	27.1	66.0

Table 5: Lina's performance using different path lengths during estimation. Both models have 16 experts per layer. Inference time is normalized to Ideal.

7.3.2 Popularity Estimation

We now analyze Lina's popularity estimation method.

Estimation accuracy. We first examine the estimation accuracy across MoE layers. We resort to the same definition used in Lina's phase two scheduling: if the top-2 (recall $k = 1$ in inference) estimated experts are identical to the actual routing decision, we consider the estimation accurate. Figure 19 shows the accuracy for every MoE layer in two inference tasks. Overall, estimation accuracy is 58.41% and 54.16% for Transformer-XL and BERT-Large, respectively. The estimation accuracy is higher in the latter layers of the model, which is consistent with our observation in Figure 9. We also compare the complete popularity rankings given by the estimation to better understand its accuracy. Using 1000 random batches of the Transformer-XL model, we observe that errors usually happen at experts with a similar popularity. An average of 3.67 experts out of the estimation are incorrectly ordered. Therefore, the fine-tuning only requires little adjustment to the experts packed together. The effectiveness of Lina's estimation can be justified.

Sample path length. We also investigate the impact of sample path length l. The longer the sample path of expert selection is for making an estimation, the more accurate the result is. Table 5 shows Lina's performance degrades with $l = 1$, in terms of inference time, estimation accuracy, and the occurrence of phase two fine-tuning, compared with the default length of 3. Longer paths can elevate the estimation accuracy and further

Task	Dataset	Model	Norm. 95%ile Inference Time	Estimation Accuracy
Sentiment Analysis	IMDB Reviews [34]	BERT	1.08	64.4%
	Twitter [35]		1.11	62.3%
Translation (English)	WMT French [8]	T5 [40]	1.04	68.8%
	WMT Russian [8]		1.08	62.5%

Table 6: Lina's performance on different tasks and datasets. Inference time is normalized to Ideal. The path length is set to 3.

reduce the number of times of Lina's fine-tuning. However, due to the problem of a slower start, the reduction of inference time is not as noteworthy as the estimation accuracy. For a path length of 6, Lina shows a similar median and tail result as the performance with a path length of 3.

Generalizability. We proceed to evaluate how well Lina's popularity estimation approach can be generalized to different tasks. Table 6 shows the estimation accuracy of four tasks with different datasets. The 95%ile inference time can achieve at most 1.04x of the Ideal inference time and the estimation accuracy is at least 62.3%. Lina's estimation method relies on the patterns obtained from training stage. Therefore, it is tailored to each specific task and proves to be an effective approach to capturing the expert popularity prior.

8 Discussion

Parallelism in training. With the increasing scale of language models, the adoption of pipeline and tensor parallelisms has become essential [46]. Pipeline parallelism involves the use of blocking send and receive operations to transmit intermediate activations, while tensor parallelism utilizes blocking all-reduce operations to combine tensor partitions. Extensive research has been conducted on coordinating communication operations for dense models [7, 27, 52]. Lina focuses on sparsely-activated MoE with data and expert parallelism, which are orthogonal to existing work.

Estimation of expert popularity. The current estimation approach used by Lina relies on data collection during the training stage. While fine-tuning can assist in improving efficient expert placement decisions, an estimation method with improved accuracy and confidence would further reduce inference time. One potential approach is to leverage machine learning techniques to train a compact yet powerful model that can predict the expert selected by each token in every MoE layer ahead of time, when the requests are received.

9 Related Work

Existing MoE systems. Recent literature has proposed MoE-specific optimization techniques. DeepSpeed [41] enables distributed training for MoE models and leverages flexible combinations of parallelism strategies. It also introduces a novel MoE architecture called Pyramid-Residual MoE. PR-MoE applies experts only where they are most effective. Tutel [7] extends DeepSpeed and proposes an adaptive parallelism switching strategy specialized at MoE training tasks. It also includes a hierarchical all-to-all design to cope with the inter- and intra-node GPU topology for better efficiency. It is complementary with Lina.

FasterMoE [25] proposes a roofline performance model to analyze the end-to-end performance of MoE training systems. Guided by this model, they propose a dynamic shadowing approach that pulls popular expert parameters instead of sending tokens to the experts. They also design a topology-aware expert selection strategy that relieves network congestion by sending tokens to experts with lower latency.

Communication acceleration in distributed training. Our community has proposed several communication schedulers for generic distributed training [11, 17, 19, 24, 37, 48]. The objective is to better overlap the communication and computation operations in the backward pass and prioritize the communication of former layers over latter layers in the model. In Lina, we leverage the domain-specific insight that all-to-all should be prioritized over allreduce in MoE training, which is different from prior work. BytePS [28] proposes to reduce the communication traffic by utilizing the heterogeneous GPU/CPU resources in a training cluster. These acceleration techniques can be integrated into distributed MoE. Lina can also benefit from this idea, since more available bandwidth can be left to all-to-all operations.

10 Conclusion

We presented Lina, a new system that accelerates all-to-all in distributed MoE. Through a systematic analysis, we build Lina upon two key ideas: first to prioritize all-to-all over allreduce using tensor partitioning and pipelining to improve its bandwidth in training, and second to dynamically balance the workload with token-level expert selection pattern in inference. We implemented Lina over DeepSpeed and performed extensive testbed evaluation using A100 GPUs and 100Gbps InfiniBand to show that Lina significantly improves training efficiency and inference time.

SMARTMOE: Efficiently Training Sparsely-Activated Models through Combining Offline and Online Parallelization

Mingshu Zhai[◇] Jiaao He Zixuan Ma Zan Zong Runqing Zhang Jidong Zhai

Tsinghua University

Abstract

Deep neural networks are growing large for stronger model ability, consuming enormous computation resources to train them. Sparsely activated models have been increasingly proposed and deployed to reduce training costs while enlarging model size. Unfortunately, previous auto-parallelization approaches designed for dense neural networks can hardly be applied to these sparse models, as sparse models are data-sensitive and barely considered by prior works.

To address these challenges, we propose SMARTMOE to perform distributed training for sparsely activated models automatically. We find optimization opportunities in an enlarged space of hybrid parallelism, considering the workload of data-sensitive models. The space is decomposed into static pools offline, and choices to pick within a pool online. To construct an optimal pool ahead of training, we introduce a data-sensitive predicting method for performance modeling. Dynamic runtime selection of optimal parallel strategy is enabled by our efficient searching algorithm. We evaluate SMARTMOE on three platforms with up to 64 GPUs. It achieves up to 1.88× speedup in end-to-end training over the state-of-the-art MoE model training system FasterMoE.

1 Introduction

In recent years, a promising direction for deep neural network (DNN) design has been to increase model size. For example, pre-trained large models have shown extraordinary capabilities in natural language processing (NLP) tasks [1, 2, 13, 28].

As model size increases, training efficiency becomes increasingly important. From the system side, various parallel strategies (e.g., data [14, 18, 30, 33], pipeline [4, 10, 19, 24, 25], and tensor [35, 36, 38] parallelism) have been proposed to enable scalable distributed training. Furthermore, to hide underlying complex system details from researchers to allow them to focus on model design, automatic parallelization training systems [4, 24, 36, 41] have been proposed to automatically decide among various combinations of different parallel strategies to improve training efficacy. From the model design side, sparse architectures have been proposed to break the coherent relationship between model size and computation cost in DNN models with dense architectures. One of the most popular sparse models currently is Mixture-of-Experts (MoE) [12], which has significantly scaled up DNN models in many deep learning tasks, including natural language processing [3, 6, 15, 34], computer vision [11, 32], speech recognition [39, 40], and recommendation [22].

However, few efforts have been put into combining these two optimization directions. Existing training systems [8, 16, 38] typically adopt a specific expert parallelism to support distributed training of MoE models. Although expert parallelism mitigates the problem of high memory consumption of MoE models, training efficiency is affected. Several previous studies [9, 11, 17, 23, 27, 29] try to reduce the overhead of expert parallelism or combine expert parallelism with other parallel strategies, but all require special system expertise. Meanwhile, existing automatic parallelization training systems mainly target conventional DNN models with dense architectures. To improve both the user experience and the training efficiency of MoE models, it is indispensable to design an automatic parallelization training system for MoE models.

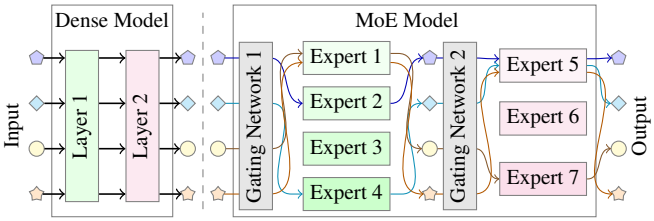

Figure 1: Dense Model Compared with MoE Model.

Figure 1 compares typical dense models with MoE models. In a dense model, the inputs are regarded as identical data to be processed by some layers. In an MoE model, the layers are replaced by multiple *expert sub-networks*. For each input, a special *gating network* is used to match it with the most

[◇]Tsinghua University, BNRist

suitable expert, and it is only processed by the selected expert. This leads to the dynamic and imbalanced property of MoE models, as the experts have different workloads. Some experts have to process more inputs than others, and this imbalanced situation is ever-changing across layers and iterations.

We identify the critical challenge of applying automatic parallelization techniques to MoE models due to the dynamic and imbalanced property, or being **data-sensitive**. While the training cost is fixed in dense models over any input, MoE models behave differently over different data, layers, and training steps. Because the gating network dynamically matches training inputs with experts, the workload of experts may vary a lot, resulting in varying costs for computation and communication. Unfortunately, current automatic parallelization approaches fail to efficiently deal with data-sensitive training of MoE models due to the following two limitations.

Limited Optimization Space. Being data-sensitive makes previous approaches of parallelism combinations perform differently and introduces more space and opportunities for optimizations. Compared to dense models, heterogeneous workloads on different expert sub-networks in MoE training lead to a much larger combination space of parallelism. We find that with the workload variance in mind, there are more opportunities of optimizing training performance. However, existing works [36, 41] assume that the workloads on sub-networks are homogeneous, and exclude many potentially faster candidates from their space for hybrid parallelism.

Large Searching Overhead. For data-sensitive models, the optimal execution plan changes frequently. However, for previous data-insensitive systems, the workload is static and can be determined by the model structure before training. Therefore, they adopt time-consuming algorithms, e.g., dynamic programming [24, 36] or integer linear programming (ILP) [41], to search for optimal execution plans. These algorithms commonly take minutes or even hours, only feasible to be performed offline. However, optimal execution plans for the dynamic workload should be identified between iterations that commonly take less than one second.

To address these challenges, we propose SMARTMOE, an automatic parallelization training system for sparsely activated models. We explore the space of hybrid parallelism with awareness of heterogeneous workloads, where more potentially faster candidate parallel strategies are included. To sustain high efficiency during the dynamic and imbalanced MoE training process, we propose a two-stage solution for parallelization. Based on a **static pool** that consists of mutual-convertible parallel strategies constructed offline, fast **dynamic adaption** is performed within the constructed pool at runtime to select the strategy that fits the current workload.

In the offline stage, we create a pool of strategies that guarantees good inherent performance and low switching overhead at runtime. Also, we design a workload-aware performance model to estimate the performance of the data-sensitive models without actually training them so that an optimal pool can be constructed ahead of training.

In the online stage, we develop light-weight algorithms to find the optimal parallel strategy for the current workload within the selected pool. The algorithms are performed periodically at runtime to determine whether we should employ a new parallel strategy, considering factors including switching cost and searching overhead.

We evaluate SMARTMOE on three different clusters with up to 64 GPUs. Results show that SMARTMOE achieves up to 1.88× speedup in end-to-end training compared with the state-of-the-art MoE model training system FasterMoE [9].

In summary, we make the following contributions:

- We enlarge the combination space of hybrid parallelism for data-sensitive models, enabling more potential to optimize training performance.
- We propose a two-stage adaptive auto-parallelization approach that performs hierarchical optimizations both offline and online.
- We introduce the awareness of workload to performance modeling, enabling performance prediction of training the data-sensitive models.
- We develop fast algorithms that can find optimal parallel strategies within a pool at runtime.
- We implement these techniques into an end-to-end MoE training system, SMARTMOE, and achieve up to 1.88× speedup over FasterMoE [9].

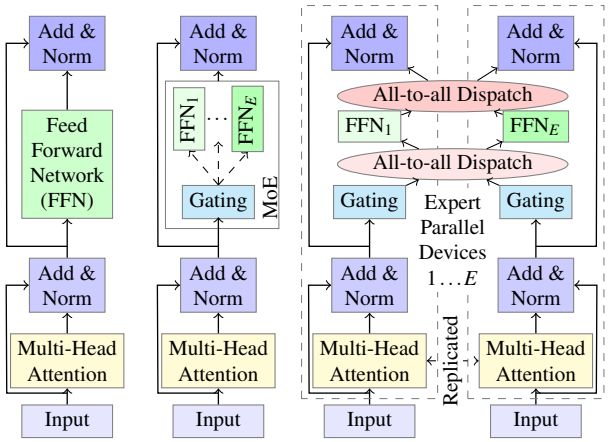
The rest of this paper is organized as follows. §2 introduces background and our motivation. §3 presents an overview of SMARTMOE. §4 introduces an enlarged space of hybrid parallelism for MoE model training. §5 discusses the scope of pool among the space of data-sensitive hybrid parallelism, and demonstrates our estimation-based approach of performance modeling. §6 illustrates our adaptive automatic parallelization methods. §7 evaluates SMARTMOE. More related works are described in §8, and §9 concludes this paper.

2 Background and Motivation

2.1 MoE Model and Expert Parallelism

The Mixture-of-Experts (MoE) was proposed decades ago [12] and applied to DNN models in recent years. It has been proven to be helpful in improving model accuracy in many deep learning tasks, including nature language processing [15], computer vision [11], speech recognition [39, 40] and recommendation [22]. In this paper, we focus on sparsely-gated MoE [34] models, the most widely used MoE technique, with instant demand for efficient distributed training.

The MoE technique is currently the most feasible way to enable the parameter size of a model and its computational cost to be scaled independently. A model can increase the number



(a) A Transformer Block (b) An MoE Transformer Block (c) Expert Parallelism for the MoE Transformer Block

Figure 2: An Example of MoE Model and Expert Parallelism.

of parameters by applying MoE, while keeping the floating-point operations (FLOPs) of one training iteration almost identical. For example, Figure 2 shows the model structure of the transformer model extended by MoE. A feed-forward network (FFN) is regarded as an expert, and the model contains multiple experts which are sparsely activated. A trainable gating network is added to dynamically match training samples with suitable experts. As each training sample is sent to a certain expert, which equals the original FFN in size, FLOPs required to train over the sample remains similar. Meanwhile, numerous experts can be employed in one MoE layer, greatly increasing the number of parameters.

Distributed training becomes a must to train MoE models, as the model is so large that it cannot be held in the memory of any single device. To support the distributed training, GShard [15] designs a specific method of parallelism for MoE models, namely **Expert Parallelism (EP)**. In fact, it is a combination of Data Parallelism and Tensor Model Parallelism specialized for the MoE scenario. As shown in Figure 2(c), the model is split up across the dimension of the experts' indices, and the input and output features are split along sample dimension. All-to-all communication is performed to dispatch the input samples to the desired expert models and put the output back to its original location, e.g. re-arranging words into sentences in language models.

Dynamic routing is the most unique feature of the MoE training workload. A trainable gating module dynamically assigns tokens to different experts in every iteration for every MoE layer, according to the input data. Therefore, the training workload varies at different layers and iterations. This dynamic nature of the MoE models makes it much different from a traditional neural network in distributed training.

2.2 Hybrid and Automatic Parallelization

Listed below are three common ways of parallelism to train typical dense deep neural networks.

Data Parallelism (DP). Each worker stores a complete copy of parameters, and the training samples assigned to each worker are different. Forward and backward computation are completed independently on each worker. Gradients on different workers are aggregated before being used in the optimization of the model. DP incurs significant memory and communication overhead as the model gets larger, because all the parameters are replicated and synchronized in every iteration. Some approaches [30, 37] reduce the memory footprint by splitting up the replicas, but the communication overhead is inevitable.

Pipeline Model Parallelism (PP). The model is divided into multiple stages with sequential data dependency. Each worker stores the parameters of its corresponding stage. The first worker reads batches of the training data, and workers with adjacent stages exchange intermediate results for forward or gradients for backward computation. To be efficient, PP has to have evenly distributed stages and bubble-free schedule, intensively studied by prior works [4, 10, 24, 25].

Tensor Model Parallelism (TP). Single operators of a model are partitioned across multiple workers. Each worker stores a part of the parameters of the operators and conducts part of its computation, e.g. a tile of a matrix. TP of different operators needs to be designed specifically by experts, and the partitioning method is critical to distributed training performance. Megatron [35] provides the best practice of TP on transformer models. Other works [36, 38] explores unified representation of TP and automatic generation of the most efficient partition.

To improve distributed training performance, **Hybrid Parallelism** is introduced, which combines a few of the above parallel strategies to better fit specific models and particular training hardware. We call an instance of hybrid parallelism a **parallel execution plan**. Given a model and a hardware specification, there can be multiple parallel execution plans, since multiple parallel strategies are available. For example, Megatron-v2 [26] achieves high-performance distributed training by expert-designed hybrid parallel execution plans, but only for transformer-based models.

Moreover, **automatic parallelization** is desired to make high-performance hybrid parallelism available to model developers with less expertise in distributed systems, Alpa [41] categorizes parallelism into inter-layer (PP) and intra-layer (DP and MP) levels, and automatically generates hybrid parallel execution plans by hierarchically optimizing over both levels. However, it is very time-consuming for current approaches to generate an optimal parallel execution plan, due to the lack of performance models and their excessive searching algorithms. Minutes, or even hours, are taken to generate an execution plan that may only cost milliseconds or seconds for an iteration.

In the end, we summarize three key challenges for any automatic parallelization training system.

Space of Hybrid Parallelism. Hybrid parallelism means combining multiple different parallel strategies into one ex-

ecution plan. Specifically, the hybrid of any two different strategies may involve complicated adaption, and introduce variance in performance. The more parallel strategies a system can handle, the more opportunities exist to find a faster execution plan.

Performance Modeling. Performance modeling helps explore a huge hybrid parallelism space efficiently, as it is infeasible to measure the cost of every possible execution plan without actually running it.

Besides, beyond being accurate as a basic requirement, a good performance model shall be giving extra information, or guidance, that can provide better understanding of the performance, and indicate the direction of generating a better execution plan.

Searching Algorithm. The huge space of hybrid parallelism shall be explored adequately to find an optimal or near-optimal execution plan. However, for large-scale model training, it is even unacceptable to enumerate every possible candidate. The algorithm's efficiency in finding a near-optimal execution plan is appreciated, primarily when performed frequently over different configurations.

2.3 Challenges of Automatic Parallelization for MoE Models

The aforementioned issues are even more challenging with MoE models. Unlike typical dense models, the dynamic nature of the MoE training workload makes them more complicated and invalidates existing automatic parallelization approaches. We use an example of MoE training in Figure 3 to explain the challenges.

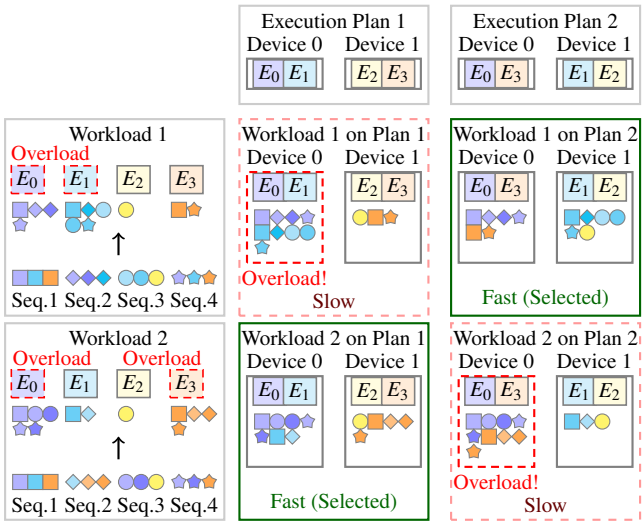


Figure 3: Example MoE Training Workloads and Related Parallel Execution Plans.

Larger Space of Hybrid Parallelism. The dynamic nature of MoE leads to heterogeneous workloads on different expert sub-networks, resulting in a larger space of hybrid parallelism for MoE models than that for dense models. For a 4-experts MoE layer, two possible execution plans are shown at the top of Figure 3. In the conventional view, these two plans are identical, as both devices contain two experts, so their memory consumption and computation costs are identical. However, the dynamic workload of MoE training can lead to computational bottlenecks occurring on different experts during the training process, resulting in performance differences between the two example execution plans. For example, execution plan 1 suffers from a load-imbalance problem over training workload 1, while execution plan 2 does not.

State-of-the-art MoE training systems [9, 11, 17, 23, 27, 29] fail to support execution plan 2, because none of them study the order to place expert sub-networks on multiple devices. State-of-the-art auto-parallelization systems [36, 41] also ignore execution plan 2, as both execution plans are treated as the same in their algorithms. To avoid missing efficient execution plans, exploring the space of hybrid parallelism with an awareness of the imbalanced dynamic workload of MoE models is necessary.

Workload-Aware Performance Modeling. Conventional performance modeling approaches only use model structure and hardware information to estimate the performance and lack consideration of the workload. However, the dynamic nature of MoE causes a strong relationship between ever-changing training workloads and efficiency, invalidating conventional performance modeling approaches of DNN operators. Looking back to the example in Figure 3, the efficiency of execution plans is different under two training workloads. Execution plan 1 becomes better in workload 2, though it is slower in workload 1. There is a strong connection between the efficiency of an execution plan and the training workload, being a unique feature of MoE models.

Current auto-parallelization algorithms [36, 41] search for an efficient execution plan ahead of training, lacking consideration of the dynamic workload. A dynamic workload-aware performance modeling approach is demanded to provide accurate estimation for the MoE training scenario.

Adaptive Automatic Parallelization. For data-insensitive dense models, parallelization is performed once before training to generate an optimal execution plan. However, since no single execution plan can fit all workloads in MoE training, using a fixed execution plan cannot be efficient throughout the MoE training process. Adaptive automatic parallelization is demanded, which employs runtime execution plans searching and switching to maintain high efficiency through the training process. Ideally, the searching and switching procedure is so efficient that a training system can change the execution plan at every iteration to achieve ultimately high performance.

However, it is hard to achieve the ideal case due to the following issues. First, state-of-the-art systems use time-consuming algorithms such as integer linear programming for an optimal execution plan, which cannot fit the time limit. Second, switching between different execution plans can be

expensive because of the high overhead of parameters exchange through inter-device links.

In existing distributed training systems [4, 23, 24, 26, 41], they select an execution plan before training without the ability of runtime execution plan adaption. Besides, the searching overhead of current auto-parallelization algorithms [36, 41] is too high to be used at runtime. Light-weight methods to generate and switch between execution plans according to the dynamic workload are appreciated for an MoE training system.

3 Overview

We propose SMARTMOE, an automatic parallel training system for sparsely activated models. Previous automatic parallelization systems only search for the optimal execution plans before training, while SMARTMOE uses a two-stage approach. Beyond prior works that generate optimal execution plans based on *model* architecture and *hardware* specification, we take the **workload** into account for data-sensitive models. We introduce an enlarged space for hybrid parallelism in §4. It introduces more opportunities for better training efficiency. With this enlarged space, SMARTMOE supports efficient execution plans for data-sensitive models. Moreover, to achieve efficient workload-aware parallelization, we split the process of automatic parallelization into two stages, performed offline and online, respectively. Figure 4 presents an overview of our two-stage algorithm.

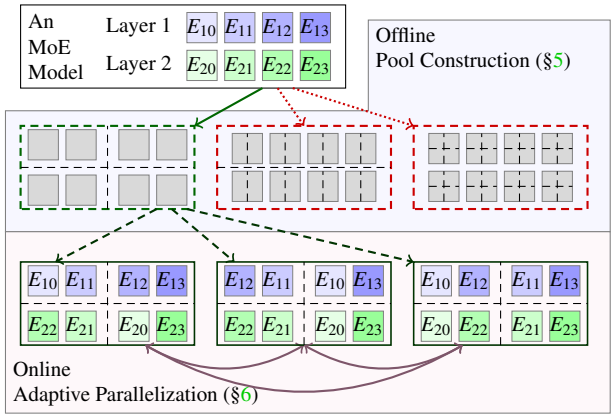

Figure 4: Overview of Two-Stage Auto-Parallelization.

Offline Pool Construction (§5). The imbalanced workload introduces potentially faster candidate execution plans. Among them, some pairs of execution plans are identified to be much more expensive to switch between than others and infeasible to be performed online. Therefore, SMARTMOE clusters a group of execution plans as a **pool**, among which the switching cost is moderate. SMARTMOE constructs a promising pool ahead of training, while keeping the ability of online adaption within the constructed pool.

An optimal pool has to be aware of the workload. We design a data-sensitive performance model to help construct good pools among numerous candidates, utilizing model specifications to estimate the workload without using statistics of actual workload. As the time limit is relatively relaxed before training, we exploit searching algorithms of conventional methods with our performance model to construct the pool.

Online Adaptive Parallelization (§6). A pool commonly contains an exponential number of execution plans to be selected, but online decisions should be made in milliseconds. We develop light-weight algorithms to meet the time limit. The algorithms can be intensively performed to ensure the execution plan fits the current workload and quickly find faster ones from the pool if available.

Online adaptive execution plan switching can only be practical considering the overhead itself. We find it a trade-off between the high efficiency of an execution plan and the latency to switch to it. We utilize temporal locality in the ever-changing workload of MoE model training to adjust parallel strategy at the proper time and achieve overall performance improvement.

4 Enlarged Space for Hybrid Parallelism

In most of the previous MoE model training systems, only expert parallelism is used for MoE models. A representative system of this class is FasterMoE [9], which focuses on optimizing expert parallelism. Fewer previous works support hybrid parallelism for MoE models. A notable system of this class is BaGuaLu [23], which combines expert and data parallelism to train MoE models on a full-scale supercomputer. Different from previous works, SMARTMOE supports hybrid parallelism for MoE models comprehensively.

SMARTMOE supports an arbitrary combination of data and tensor, pipeline and expert parallelism, beside a barely studied aspect of parallel strategies, namely **expert placement**. With the help of this enlarged space for hybrid parallelism, SMARTMOE could cover more efficient parallel execution plans than previous works.

Table 1: Configuration of Expert Slot.

Parallel Strategy	Capacity	# Slots	# Layers
Expert	1	E/N	L
Expert+Data	1	$D \times E/N$	L
Expert+Tensor	$1/T$	$T \times E/N$	L
Expert+Pipeline	1	$E/(N/P)$	L/P

SMARTMOE supports an arbitrary combination of existing parallelism using the concept of **expert slot**. An expert slot is a basic unit to store parameters of an expert sub-network on workers. To specify a parallel strategy for an MoE layer, the configuration of expert slot for every worker should be determined. Formally, we use three attributes to represent a configuration of expert slot:

- The capacity of each slot. It should be a fraction between 0 and 1, as each slot can store the partial or whole of an expert sub-network.
- The number of slots for each worker. It should be positive, as each worker contains one or more slots.
- The number of MoE layers for each worker. It should be a positive integer, depending on the model structure.

These attributes are powerful to represent classic parallel strategies and their combinations. Suppose a model contains L MoE layers and E experts in each layer. The training is done on a N workers cluster. D, T, P represent ways of data, tensor, and pipeline parallelism respectively. We showcase how to set attributes for different parallel strategies in Table 1. We also provide a concrete example in Figure 5, where $(L, E, N) = (2, 4, 4)$. In Figure 5(c), the setting is $(D, T, P) = (2, 1, 1)/(1, 2, 1)/(1, 1, 2)$, respectively. It is worth noting that only combinations of at most two parallel strategies are shown in the above examples. SMARTMOE can instantiate their arbitrary combinations, as they can be represented as specific configurations of the expert slot.

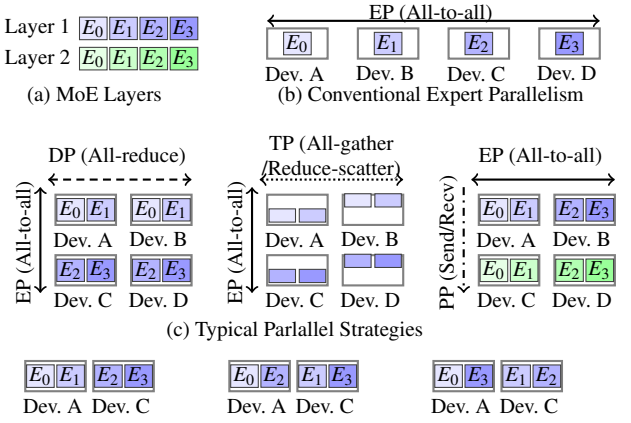

Figure 5: Hybrid Parallelism for MoE Models.

SMARTMOE explores a new parallel strategy, **expert placement**. The expert placement plan is an essential but understudied aspect of MoE model training. An expert placement plan refers to a mapping from expert sub-networks to expert slots, as shown in Figure 5(d). When the number of slots on each workers is more than one, an expert placement plan could influence performance because of the imbalanced workload. Recall the example in Figure 3. Two execution plans only differ in expert placement, but their efficiency significantly varies due to the imbalanced workloads. To the best of our knowledge, previous MoE training systems do not study the difference among different expert placements, i.e., expert sub-networks are stored in multiple slots in serial order.

As Figure 5 suggests, besides supporting combinations of existing parallelism (Figure 5(b,c)), SMARTMOE can explore various expert placement plans (Figure 5(d)) for better performance. In contrast, existing MoE training systems only work on limited cases of our space. For example, FasterMoE [9] focuses on runtime optimization of expert parallelism (Figure 5(b)). BaGuaLu [23] and DeepSpeed-MoE [29] adopt specific hybrid parallel strategies in Figure 5(c).

5 Offline Pool Construction

5.1 Design Principle of a Pool

A pool is a sub-space of hybrid parallelism that contains multiple execution plans with some parallel strategies fixed and leaving the others variable. The pool remains unchanged throughout the process of distributed training. For example, a pool can be a condition that over multiple nodes with multiple GPUs, pipeline parallelism shall be used across nodes, which is fixed. And any parallelism, such as data or model parallelism, can be used among GPUs within a node. SMARTMOE constructs a good pool before training and switches execution plans at runtime within this constructed pool.

The critical challenge of defining the scope of pools is dividing parallel strategies into two categories: fixed and variable. The fixed parallel strategies have inherent latency of execution plans, which are almost unaffected by dynamic workload. In contrast, runtime switching on the variable parallel strategies is necessary to fit the current workload. In addition, the overhead of runtime switching should be balanced with the performance gain.

In SMARTMOE, we define a pool as **a group of execution plans where expert placement is the only variable parallel strategy.** Expert placement, i.e., mapping from experts to devices, is found to be non-trivial due to the heterogeneous workload on experts. We identify that hybrid parallel strategies for typical dense models steadily impact performance. In contrast, expert placement could influence performance significantly when the workload changes dynamically. So, in the offline pool construction stage, SMARTMOE searches for an excellent combination of typical parallel strategies, while the expert placement plan is variable to be switched online.

This definition of the pool has two main advantages. First, the space of candidate execution plans has enough flexibility for online adaption. The number of possible expert placement plans is increased exponentially when there are more expert slots for each worker. It is promising to find a suitable execution plan according to the current imbalanced workload (Detailed in §6.1). Second, these candidate execution plans are mutual-convertible with minor overhead, avoiding introducing much runtime overhead. As they have the same configuration of expert slots, there is no need for memory allocation or release when switching. The switching overhead is only caused by parameter exchange between workers, and it is possible to maintain a moderate communication overhead (Detailed in §6.2).

5.2 Workload-Aware Performance Modeling

In the offline stage, SMARTMOE constructs a good pool before training. A critical step is using a performance model to estimate the efficiency of different pools. However, designing an accurate performance model offline is challenging because the performance of an execution plan is strongly related to the dynamic training workload, which cannot be obtained before training.

We introduce a method to estimate the training workload to address this challenge. Specifically, it estimates the distribution of expert selection, i.e., the outputs of gating networks, before training. So, it realizes workload-aware performance modeling of MoE layers without actual statistics of the training workload. With its help, we can accurately estimate the computation and communication costs of candidate pools before training. Finally, we apply the data-sensitive performance model over the candidate pools and enumerate the search space before initiating distributed training.

Semantics of the gating network guides the workload estimation. Based on the specific algorithm of any given gating network, the maximum amount of workload for any expert can be calculated without actually training the model. This upper bound of workload is commonly close to the actual workload and is the bottleneck of the training process. Therefore, using the maximum possible amount of workload, we can accurately predict the performance of a pool.

We take the most common *Choose Top-K along Experts Axis* gating approach as our instance, and our modeling method is applicable to many others [5]. The key idea is to understand the design of gating networks for accurate estimation of computation and communication costs. We classify state-of-the-art MoE gating networks into two classes and explain our estimation approach for them respectively.

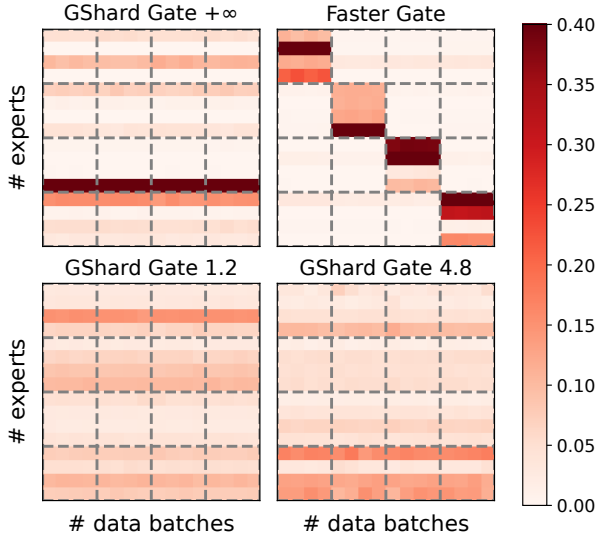

Figure 6: Expert Selections under Different Gating Networks.

One is load-balanced gating networks, which ensures a balanced workload on experts. GShard [15] gate, a commonly used gating method, represents this class. The critical design of the GShard gate is the *capacity factor*, which limits the proportion of training samples assigned to remote experts (i.e., experts placed in different devices with input samples). We visualize expert selections of GShard gate from a real training process in Figure 6. The capacity factor is set to 1.2, 4.8, and $+\infty$ (i.e., no capacity limit). Controlled by different capacity factors, the proportion of training samples assigned to the overloaded experts varies. Despite the variation, there is a definite load upper bound of the most overloaded expert, being the bottleneck of the whole layer. Therefore, we use that upper bound to estimate the performance of execution plans.

Another is topology-aware gating networks, which limit the size of cross-nodes communication in the all-to-all dispatching stage. Two state-of-the-art MoE models [7, 9] use topology-aware gates. In Figure 6, *Faster Gate* proposed by FasterMoE [9] is visualized. The example cluster has 16 devices on four nodes with a fat-tree network topology. To avoid suffering low bandwidth across nodes, it prefers to assign training samples to experts within the same node, as can be seen in the figure that most expert selection is in 4×4 blocks on the diagonal. We can estimate expert selection considering its hierarchical gating algorithm. As it also uses hardware specifications available to us, we follow its algorithm to compute the maximum possible communication volume and computation workload for each device and adopt these data for our performance prediction.

Generally, although the actual expert selection is unreachable, hyper-parameters of these gating networks can be used to depict the distribution of expert selection. The computation overhead of the most overloaded expert can be estimated according to the capacity factor, and the communication overhead of device pairs can be estimated according to constraints provided by topology-aware gating networks. After obtaining the distribution of expert selection, we adopt an existing performance model [9] to estimate the performance of execution plans. It is worth noting that the original model has to take the current workload information captured at runtime as its input. However, in SMARTMOE, we apply it to the estimated workload. With the help of our estimating method and the performance model, we apply exhaustively offline searching for a pool with the best-estimated performance.

6 Online Adaptive Parallelization

6.1 Light-Weight Searching

Adaptive parallelization is required for the MoE model to keep it on an optimal execution plan considering its current workload. The challenge of runtime adjustment is a much stricter time limit of searching overhead, as a single iteration

of an MoE layer typically takes only tens of milliseconds. Existing works fail to meet the time requirement of MoE models because they commonly apply time-consuming algorithms such as integer linear programming (ILP). In practice, the overhead of these methods is orders of magnitude greater than the latency of a single iteration. They are infeasible for MoE models because they shall be intensively performed at runtime to ensure the execution plan fits the current workload.

Defining a pool as only expert placement plans can be adjusted at runtime is a good equilibrium point: workload-guided expert placement plans effectively improve training efficiency, while switching between expert placement plans does not introduce much communication overhead. Based on the pool constructed offline, we make minor adjustments to fit the current workload. To keep moderate overhead, we design light-weight searching algorithms to transfer within the pool among execution plans. We invent a greedy algorithm to replace time-consuming methods such as ILP, which is intensively performed to ensure the execution plan fits the current workload.

Motivated by our observation in Figure 3, it is critical to generate a dedicated expert placement plan which fits the current workload. We formalize the expert placement problem as follows. Supposed that there are E experts and N devices, C_i training samples are assigned to expert i by the gating network. We need to decide the placement of each expert, where the placement of expert i is denoted as $P_i (i \subseteq \{0,1,\ldots,N-1\})$. The optimization goal is to minimize eq. (1), where $\frac{C_i}{\|P_i\|}$ denotes the number of training samples processed by each replicate of expert i, and overall training latency is determined by the most overloaded device j.

$$\max_{0 \le j < N} \{ \sum_{0 \le i < E, j \in P_i} \frac{C_i}{\|P_i\|} \} \tag{1}$$

Algorithm 1 Greedy Expert Placement

```
1:  function ExpertPlacementGreedy(E, N, C[E])
2:      samples[0...N] ← 0        ▷ current samples per device
3:      experts[0...N] ← 0        ▷ current experts per device
4:      P[0...E] ← ∅              ▷ placement of experts
5:      for i, C_i ∈ DescendingSort(C) do
6:          T_min ← ∞
7:          for all j do          ▷ decide the placement
8:              if experts[j] < E/N and samples[j] < T_min then
9:                  T_min ← samples[j]
10:                 p ← j
11:         P[i] ← P[i] ∪ p
12:         samples[p] ← tokens[p] + C_i
13:         experts[p] ← experts[p] + 1
14:     return P[0...E]
```

We propose a light-weight greedy approach in Algorithm 1. An intuitive idea is to avoid placing overloaded experts on the same device. Therefore, Algorithm 1 decides each expert's placement in the order of amounts of computation on experts. To avoid increasing memory overhead on certain devices, the number of experts placed in one device is limited to $\frac{E}{N}$. This algorithm's computational complexity is $O(NE)$, which is light enough for runtime searching.

We also propose a more accurate but costly dynamic programming approach. The state of dynamic programming is defined as $F(i,S)$, in which i denotes the number of devices that are fully used, S is a subset of N experts to denote which experts have been placed. And F represents the minimal size of the most overloaded device in the first i devices. Equation (2) shows the transfer function between states, which enumerates experts placed on device i for a minimum cost. In this dynamic programming approach, the number of states is $O(N \times 2^E)$, and $O(2^E)$ states are enumerated in one transfer, resulting in total computation complexity $O(N \times 4^E)$. This approach is guaranteed to find an optimal solution.

$$F(i,S) = \min_{S_0} \{ \max \{ F(i-1, S_0), \sum_{e \in S - S_0} C_e \} \} \tag{2}$$

To leverage the advantages of the two algorithms above, we design Algorithm 2 to combine them. The problem of placing E experts into N devices is divided into two steps: in the first step, E experts are placed into M virtual devices using the greedy algorithm; in the second step, M virtual devices are placed into N devices using the dynamic programming algorithm. The computation complexity of this hybrid algorithm is $O(ME + N \times 4^M)$. The number of virtual devices M is a tunable parameter, which controls the overhead of the searching algorithm. For example, modern clusters usually have tree topology: there are multiple devices within a compute node, and multiple nodes are working together. In this setting, the M can be set as the number of devices within a node, in which the greedy algorithm is used across nodes, and the dynamic programming algorithm is used within a node.

Algorithm 2 Hybrid Approach of Expert Placement

```
1:  function ExpertPlacementHybrid(E, N, C[E])
2:      M ← DEVICES_PER_NODE      ▷ tunable parameter
3:      P_0[E] ← ExpertPlacementGreedy(E, M, C[E])
4:      P[0...E] ← ∅
5:      for i ← 0, ..., M do      ▷ Use dynamic programming
        within a virtual device
6:          S ← {e | i ∈ P_0[e]}
7:          P_S ← P(F(M, S))      ▷ Get placement of DP state S
8:          P ← P ∪ P_S
9:      return P[0...E]
```

By properly tuning M according to hardware configuration and searching time limit, these algorithms can work together with minimum overhead and maximum effect.

6.2 Efficient Adaptive Training

The goal of the online stage is to obtain performance gain by applying an execution plan that fits the current workload while keeping moderate switching overhead between execution plans. A few configurations of SMARTMOE are important to ensure performance gain. We currently tune them manually by heuristics, as discussed below.

Threshold of Switching Overhead. Switching from the current expert placement plan to a newly generated one introduces non-negligible all-to-all communication overhead. However, in practice, some newly generated expert placement plans only make slight advancements over the current one while introducing much communication overhead. To address this problem, we set a tunable threshold to filter out new expert placement plans with minor improvement in eq. (1). In addition, if two new plans have the same latency in eq. (1), SMARTMOE chooses the one similar to the current plan to minimize the switching overhead.

Frequency of Online Searching. Although online searching fits the expert placement plan with the current workload, searching and switching costs extra time. One extreme case is to perform searching at every iteration, which can always fit the current workload with the best execution plan but introduces too much overhead. However, if the search interval is too large, the training throughput usually decreases as the workload changes. Fortunately, as a neural network, parameters of the gating network change slightly in adjacent iterations, which leads to a gradual change in the distribution of expert selections. Thanks to this temporal locality, we can conduct runtime searching every several iterations. Figure 12 reveals the trade-off between searching frequency and training performance in real model training. We currently select an appropriate frequency by experimentation.

Frequency of History Collecting. Our online searching algorithm depends on the history of expert selection. To obtain this data, SMARTMOE needs to dump the output of the gating network and synchronize among workers. These operations could be time-consuming if performed too frequently. In practice, we find an effective strategy is only collecting the history of expert selection at a few iterations immediately before the iteration of online adaption. This strategy also utilizes the temporal locality of the expert selection, and prevents collecting useless stale history.

7 Evaluation

7.1 Experimental Setup

Clusters. We evaluate SMARTMOE on three representative clusters, as shown in Table 2, which differ in accelerators, network topology, network bandwidth, and scale. Evaluation on these clusters demonstrates that optimization of SMARTMOE works on different hardware environments.

Table 2: Hardware Platforms for Evaluation.

Name	GPUs Per Node	Max GPUs	Infiniband Bandwidth
blinky	8× NVIDIA V100 PCIe	32	50Gb/s
pinky	4× NVIDIA V100 SXM	64	100Gb/s
inky	8× NVIDIA A100 SXM	32	200Gb/s

Models. The models used for evaluation are shown in Table 3. We choose models from two popular deep learning tasks for evaluation: one is GPT-MoE for natural language processing, and the other is Swin-MoE for computer vision. We use typical batch sizes for each of them. Model parameters are increased along with the number of GPUs. One of the most popular gating methods proposed by GShard [15] is used. GShard gate has a tunable parameter named *capacity factor*, which controls the degree of load imbalance problem (Smaller capacity factor results in a more balanced workload). This optimization is from the model design side to improve MoE model training performance. We apply the GShard gate with different capacity factors to evaluate our system-side optimization.

Table 3: Models Used for Evaluation.

Model	Task	Batch Size	# params (billion)	Capacity Factor
GPT-MoE	NLP	256/512	4.5/7.3/9.9/14.0	$1.2/2.4/4.8/+\infty$
Swin-MoE	CV	4096	0.54/1.0	

Baselines. We compare SmartMoE with four strong training systems. DeepSpeed-MoE [29] is an MoE training system with both system-side and model design-side optimization. It is implemented on DeepSpeed [31] and Megatron-LM [35]. For fairness of comparison, we only turn on the system-side optimization in the following experiments. Tutel [11] targets the scalability problem of MoE training, which achieves promising performance on large-scale MoE training. And Tutel designs Swin-MoE models by extending Swin-Transformer [20, 21] with the MoE technique. FasterMoE [9], the latest version of FastMoE [8], is one of the early efforts of data-sensitive optimization for MoE training. It proposes runtime smart scheduling and expert shadowing. For fairness of comparison, we manually tune hyper-parameters of FasterMoE to achieve good performance. Alpa [41] is a state-of-the-art general-purpose auto-parallelization training system, which hierarchically generates inter- and intra-operator parallel execution plans. It should be noticed that we do not directly compare our system with Alpa. Alpa is implemented on JAX, while the other systems we used are implemented on PyTorch. For fairness of comparison, we use parallelism recommended in the Alpa paper on our system to simulate its performance.

Evaluation Metrics. For end-to-end evaluation, we measure the training latency including forward, backward, gradient synchronization, and optimization stages in both MoE and dense layers in the real model training process. Instead of using randomly generated input samples, we apply real datasets for training to ensure that the dynamic workload in MoE lay-

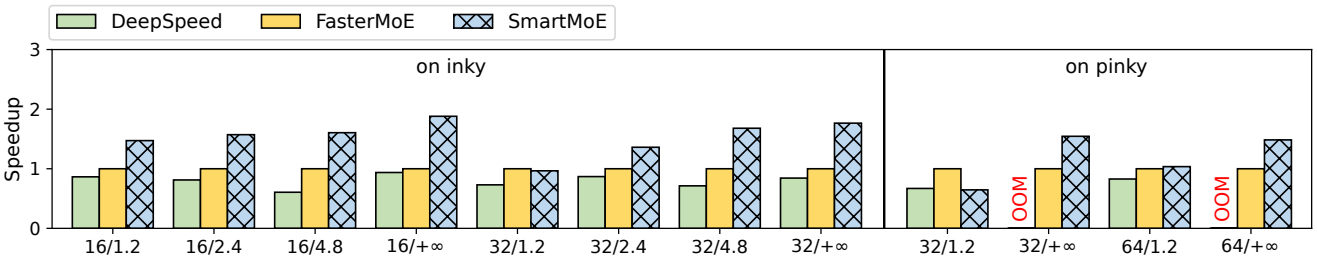

Figure 7: End-to-End Speedup of GPT-MoE Models.

ers represents real situations. For micro-benchmarks, training latency only includes the forward and backward stages in MoE layers. We use a comprehensive expert selection dataset, which is collected in real model training processes, including different model structures and gating methods.

7.2 End-to-End Speedup

We evaluate the end-to-end performance of two types of models on three different clusters. Evaluations are done in a form of weak scaling, where model sizes are increased along with the number of GPUs. And different capacity factors are applied at each scale. X/Y means evaluation on X devices with capacity factor Y. "OOM" means out-of-memory. The performance of FasterMoE is used as a baseline.

Figure 7 shows the end-to-end speedup of GPT-MoE models. SmartMoE achieves on average 1.53× speedup on *inky* cluster, and achieves on average 1.17× speedup on *pinky* cluster. Comparing *inky* cluster and *pinky* cluster, SmartMoE achieves higher speedup on *inky*, where SmartMoE achieves a maximum speedup of 1.88×. This can be explained by two reasons. First, the bandwidth gap between intra-node and inter-nodes links is greater, making hybrid parallelism more efficient. Second, *inky* has more GPUs in a node, increasing possible intra-node parallel strategies. Figure 8 shows the speedup of Swin-MoE models. SmartMoE achieves on average 1.14× speedup on *blinky* cluster.

Comparing different GShard capacity factors, SmartMoE achieves a more significant speedup when the capacity factor is higher. This reveals the tight relationship between model design and system-side optimization. Both of them improve training performance by alleviating the load-imbalance problem in MoE layers, so there are fewer optimization opportunities as the gate is set up with stricter load-balancing limits. In this case, SmartMoE brings improvement because it constructs a better pool. A good pool replaces the originally expensive all-to-all of expert parallelism by communication among fewer workers in hybrid parallelism. Systems with only runtime optimization (e.g. FasterMoE) could reduce the computation overhead by balancing workload, but they fail to reduce the communication overhead, as detailed in §7.5.

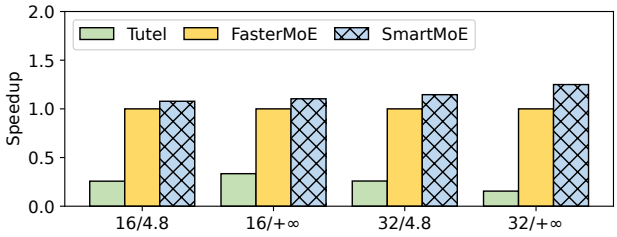

Figure 8: End-to-End Speedup of Swin-MoE Models.

7.3 Offline Parallelization Ablation Study

We study the effectiveness of our offline parallelization algorithm. In order to verify that SmartMoE can find a good pool, we compare performance of different auto-parallelization systems in Figure 9. X/Y means evaluation on X devices with capacity factor Y. The performance of FasterMoE is used as a baseline. To compare with the data-insensitive auto-parallelization approach, we use execution plans recommended by Alpa, in which expert parallelism is used within a node, and pipeline parallelism is used across nodes. To fairly compare the effect of offline parallelization, online optimizations of all systems are disabled. SmartMoE uses a random execution plan generated by the offline data-sensitive auto-parallelization approach. Both data-sensitive and insensitive approaches generate more efficient execution plans compared with pure expert parallelism, attributing to the high performance of hybrid parallelism. Meanwhile, the data-sensitive approach of SmartMoE achieves 2.67× speedup, while the data-insensitive approach only achieves 2.36× speedup.

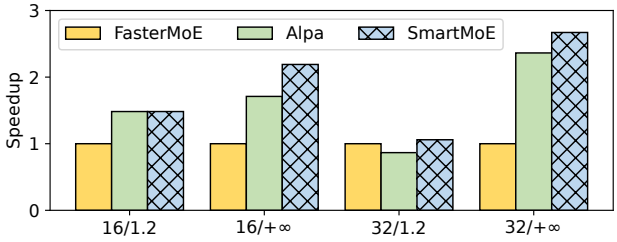

Figure 9: Performance of Offline Parallelization.

Figure 10 shows the accuracy of our data-sensitive performance model. $X-Y$ means evaluation on X devices with local batch size Y. We use MoE layers with expert selection recorded in a real training process to verify the accuracy of SmartMoE performance model. Different scales and batch sizes are used. For all configurations, it achieves $R^2 > 0.5$. Results show that the execution time of an MoE layer varies under different training data. However, the data-insensitive performance model of MoE operators only gives a constant estimation of execution time for each scale and batch size, as shown by vertical lines, inaccurate for most cases. In contrast, our data-sensitive performance model predicts execution time based on current training data. Results show that its accuracy is higher when workers are in the same node, because an unstable cross-node network prevents us from precisely modeling cross-node all-to-all communication latency.

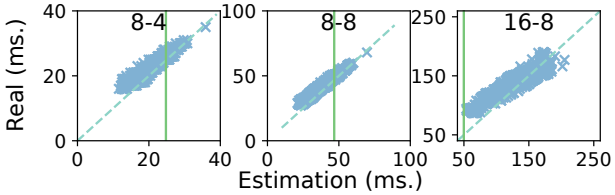

Figure 10: Accuracy of Performance Modeling.

7.4 Online Parallelization Ablation Study

Now we evaluate performance improvement from the adaptive automatic parallelization approach in SmartMoE. A 16-layer MoE model is trained on 64 V100 GPUs of *pinky*. We set the execution plan adjustment frequency to once every 10 iterations. Figure 11 shows the speedup of all 16 MoE layers. SmartMoE achieves on average 1.16× speedup per layer, and at most 1.43× speedup in layer 2. Performance opportunities differ among layers because they are trained to have different internal features. The overhead of execution plan adjustment is insignificant, because training with dynamic execution plans beats the static execution plan at every layer.

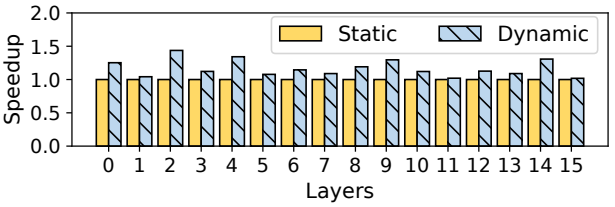

Figure 11: Speedup of Online Parallelization.

In another view, Figure 12 shows the latency of an MoE layer from iteration 1 to 1500. The performance of using either static or dynamic execution plans with different frequencies of adjustment is shown by curves. *dyn.X* denotes switching execution plans every X iteration. Before the first time of switching, the execution plan used is the same as the origin, which does not fit the workload dynamically, resulting in inefficient training. After switching execution plans, it immediately becomes efficient, because SmartMoE uses recent history of expert selections to guide switching. As training progresses, the distribution of expert selection gradually changes. We can find that for frequencies of 250 and 500 iterations, after switching, performance degrades as time increases. This suggests that the frequency of the execution plan adjustment should be high enough for the varying workload. But we also find that the switching overhead could hurt overall performance when adjustment frequency is too high. Moreover, it is interesting that the actual execution plan adjustment tends to be less frequent as the training progresses. For example, in Figure 12, the performance of different switching frequencies becomes more close after iteration 1000. We speculate the reason for this phenomenon is that the distribution of the expert selection becomes more stable after thousands of iterations. In conclusion, we think how to set a proper frequency of dynamic parallelization is still an open problem.

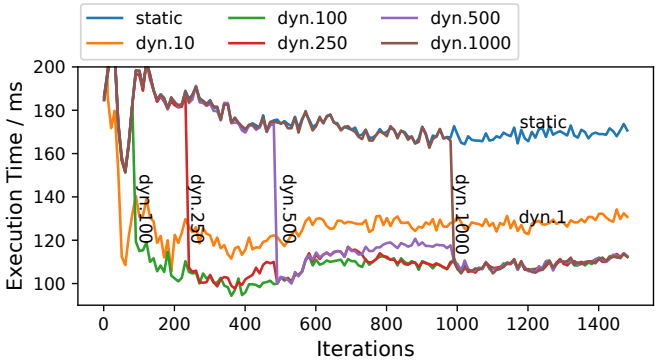

Figure 12: Performance of different adjusting frequencies.

7.5 Fine-Grained Performance Breakdown

We present a fine-grained performance breakdown in Figure 13. FasterMoE is the baseline implementation of MoE model training, which uses pure expert parallelism with simple runtime load-balancing strategies. Alpa represents state-of-the-art training systems with only offline parallelization. SmartMoE represents MoE model training with both offline and online parallelization. Baseline systems and SmartMoE are used to train two MoE models, which are only different in the capacity factor of the gate. The overhead of communication and computation for one iteration is measured separately.

As models with smaller capacity factor tend to have a more balanced workload, the execution time of three systems for the case $capacity = 1.2$ is shorter than its counterpart, $capacity = +\infty$. Because FasterMoE only supports pure expert parallelism, while Alpa and SmartMoE support hybrid parallelism, both communication and computation overhead are reduced by the latter. In the case, $capacity = 1.2$, the speedup of communication is more significant, because com-

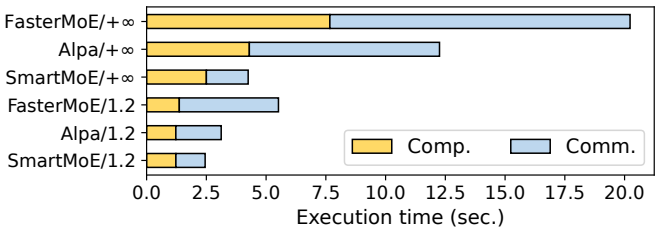

Figure 13: Fine-Grained Performance Breakdown.

putation is forced to be more balanced with the restricted expert selection. SMARTMOE outperforms Alpa because of workload-awareness.

7.6 Overhead Analysis

The overhead of SMARTMOE parallelization approaches is insignificant, compared with the end-to-end training time. Table 4 shows an execution time breakdown of a model which has 16 experts and is trained on a 16 V100 GPUs cluster.

Table 4: Execution Time Breakdown.

Searching	Switching	Forward and Backward		Alpa's Searching
		Original	Optimized	
0.05ms	20ms	75ms	67ms	825s

Searching algorithms cost less than 1ms, because there are only 16 experts. We test the searching algorithms for 1024 experts further, the cost of a single searching process is still less than 50ms. Switching costs 20ms in this example, because the size of expert sub-networks is non-negligible. For a single forward and backward step, the overhead of switching could influence training performance. However, the switching of execution plans brings on average 10% performance gain, which is 8*ms* in this example. After 3 steps, the end-to-end latency of adaptive parallelization is lower than the original one. Typically, tens of forward and backward steps are performed in one iteration, so the switching cost is acceptable for end-to-end training. We also evaluate the overhead of Alpa [41] for this example, which takes 825 seconds to generate an execution plan. The searching overhead of Alpa is orders of magnitude greater than our approaches.

8 Related Work

MoE training systems. Early efforts implement expert parallelism to enable MoE model training in the existing frameworks, including GSPMD [38] for TensorFlow and Fairseq [16], FastMoE [8] for PyTorch. More recent literature has proposed some MoE-specific optimization techniques from different perspectives. To optimize all-to-all communication in MoE training, DeepSpeed-MoE [29] proposes a hierarchical all-to-all algorithm to reduce latency. Lita [17] systematically analyzes all-to-all overhead in MoE training and designs a new communication scheduling scheme. For improving hardware utilization, Tutel [11] delivers adaptive parallelism and pipelining, and scales MoE training to thousands of GPUs. FasterMoE [9] provides a comprehensive performance analysis of MoE training and designs multiple techniques to alleviate load-imbalance problems.

Efforts above focus on the optimization of expert parallelism, which are complementary with SMARTMOE. To enable hybrid parallelism, Tutel [11] combines expert, data, and tensor model parallelism to scale up MoE training. BaGuaLu [23] combines expert and data parallelism to train an MoE model on a full-scale supercomputer. SMARTMOE implements more complete parallelism for MoE models, which brings more performance opportunities.

Automatic parallelization training systems. Previous works target different parallel strategies. Tofu [36] generates tensor model parallel execution plans by a novel DP algorithm. PipeDream [24] and DAPPLE [4] propose pipeline parallelism planners for efficient pipeline partitioning and scheduling. Alpa [41] generates more sophisticated execution plans, considering both inter-operator (i.e., pipeline) and intra-operator (i.e., data and tensor) parallelism.

These efforts are mainly designed for models with dense architecture. SMARTMOE analyzes unique challenges of automatic parallelization for models with sparse architecture, and designs specific techniques to address them.

9 Conclusion

We propose SMARTMOE, an automatic parallelization system for distributed training of sparsely activated models. We identify the key challenge of applying automatic parallelization for sparsely activated MoE models as their dynamic nature or being data-sensitive. To address this challenge, we propose a two-stage solution. The combination space of hybrid parallelism, which enables more potential for optimization, is decomposed by pools. To construct an optimal static pool before training, we design a workload-aware performance model to predict the training performance with estimations of gating networks. At runtime, we invent light-weight searching algorithms to change execution plans with minimum overhead. Compared with selected baselines, SMARTMOE achieves up to 1.88× speedup in end-to-end MoE model training.

Abstract

A wide range of *reinforcement learning* (RL) algorithms have been proposed, in which agents learn from interactions with a simulated environment. Executing such RL training loops is computationally expensive, but current RL systems fail to support the training loops of different RL algorithms efficiently on GPU clusters: they either hard-code algorithm-specific strategies for parallelization and distribution; or they accelerate only parts of the computation on GPUs (e.g., DNN policy updates). We observe that current systems lack an abstraction that decouples the *definition* of an RL algorithm from its *strategy* for distributed execution.

We describe MSRL, a distributed RL training system that uses the new abstraction of a *fragmented dataflow graph* (FDG) to execute RL algorithms in a flexible way. An FDG is a heterogeneous dataflow representation of an RL algorithm, which maps functions from the RL training loop to independent parallel dataflow *fragments*. Fragments account for the diverse nature of RL algorithms: each fragment can execute on a different device using its own low-level dataflow implementation, e.g., an operator graph of a DNN engine, a CUDA GPU kernel, or a multi-threaded CPU process. At deployment time, a *distribution policy* governs how fragments are mapped to devices, without changes to the algorithm implementation. Our experiments show that MSRL exposes trade-offs between different execution strategies, while surpassing the performance of existing RL systems.

1 Introduction

Reinforcement learning (RL) solves decision-making problems by having agents learn policies – typically represented as deep neural networks (DNNs) – on how to act in an environment [51]. RL has achieved remarkable outcomes: in game play, AlphaGo [49] defeated a world champion in the Go board game; in biology, AlphaFold [21] predicts three-dimensional structures for protein folding; in robotics, RL allows robots to perform dexterous manipulation without human intervention [15]; and the ChatGPT chatbot [41] uses a reinforcement step with PPO [47] to fine-tune its model.

Such advances in RL, however, come with high computational demands: AlphaStar trained 12 agents on 384 TPUs and 1,800 CPUs for 44 days to achieve grandmaster level in StarCraft II game play [54]; OpenAI Five trained to play Dota 2 games for 10 months with 1,536 GPUs and 172,800 CPUs [3].

Existing RL systems (e.g., SEED RL [8], Acme [18], Ray [34], RLlib [25], Podracer [16]) are therefore optimized for specific types of RL algorithms and the structure of their RL training loops. In particular, systems hardcode a strategy for parallelizing and distributing the RL computation:

Parallelization. Most RL systems only accelerate the DNN computation on GPUs or TPUs [8, 18, 25] using current DNN engines (e.g., PyTorch [42], TensorFlow [14], and MindSpore [19]). Other parts of RL algorithms (e.g., action generation, environment execution, and trajectory sampling) are executed as sequential Python functions on worker nodes, potentially becoming performance bottlenecks.

Some systems try to accelerate more parts of RL training loops: Podracer [16] uses the JAX [12] compilation framework to vectorize Python implementations of RL algorithms; WarpDrive [23] implement the entire RL training loop using CUDA on a GPU; and RLlib Flow [26] uses a set of parallel dataflow operators [58] to express an RL training loop. All of these approaches, however, require users to rewrite the *complete* RL algorithm (e.g., agents, learners, and environments) using a single API with a fixed set of dataflow operators.

Distribution. When distributing computation, current RL systems allocate algorithmic components (e.g., actors and learners) to workers in a fixed way: SEED RL [8] assumes that learners perform policy inference and training on TPUs, and actors execute on CPUs; Acme [18] only distributes actors and maintains a single learner; and TLeague [50] distributes learners but co-locates environments with actors on CPU workers. As we shown in §6, such decisions are algorithm-specific: since different algorithms deployed on a given set of resources exhibit diverse bottlenecks, a single distribution strategy cannot exhibit the best performance in all cases.

*Equal contribution.

We observe that the above challenges come from a lack of separation between the *definition* of an RL algorithm and how it is *executed* by the system. For example, many RL systems allow users to define RL algorithms as a set of Python functions for agents, learners, and environments. The system then directly invokes the implementation of e.g., an agent's `act()` function to produce new actions for the environment. While this simplifies system implementation, it removes control from the system regarding how algorithmic components are parallelized or distributed at deployment time.

DNN training systems use intermediate representations (IRs), which are compiled to target devices for execution, to decouple DNN definition from execution [1,6,56]. Such approaches, however, assume a homogeneous training computation (forward/backpropagation over differentiable DNNs [2]), which can be expressed by a fixed set of computational operators over tensor types. In contrast, the space of RL algorithms exhibits more heterogeneity in terms of the computation performed by algorithmic components (agents, actors, learners, polices, environments, leaderboards), their exchanged data (observations, actions, policy updates) and communication patterns (one-to-one, one-to-many, all-reduce).

Our goal is to explore a new design for an RL training system that requires users to define an RL algorithm only once. At deployment, the system then supports (i) the execution of arbitrary parts of the RL computation on parallel devices (GPUs and CPUs); and (ii) the deployment of parts of the computation on distributed workers.

We describe **MSRL**, a distributed RL system that achieves this by decoupling the specification of a RL algorithm from its execution through the abstraction of a *fragmented dataflow graph* (FDG). Unlike dataflow approaches of DNN and data analytics systems, an FDG does not enforce a single uniform dataflow representation, which is challenging for diverse RL algorithms. Instead, it allows different components of an RL algorithm to have bespoke GPU or CPU implementations, chosen by the user at deployment time.

In summary, MSRL's design makes three contributions:

(1) Fragmented dataflow graphs (§3). From the RL algorithm implementation, MSRL constructs an FDG, which consists of independent *fragments*. Each fragment can have its own dataflow representation (e.g., DNN operators, CUDA, or Python) targeting GPUs or CPUs. MSRL then maps instances of fragments to devices at deployment time.

To obtain fragments, MSRL statically analyzes the RL algorithm implementation to group functions into fragments. By default, the boundaries between fragments are chosen based on the algorithmic components of the RL algorithm. Since fragments are deployed on different devices, MSRL synthesizes appropriate communication operators that allows fragments to exchange data.

(2) API with distribution policies (§4). Users specify an RL algorithm by implementing its algorithmic components as Python functions in a traditional way. The implementation makes no assumptions about how the algorithm will be executed: all runtime interactions between components are managed by calls to MSRL APIs. A separate *deployment configuration* defines the devices available for execution.

Since FDGs separate algorithm implementations from execution, MSRL can apply different *distribution policies* to govern how fragments are mapped to devices. MSRL supports distribution policies, which subsume the hard-coded distribution strategies of current RL systems: e.g., a policy can distribute multiple actors to scale environment interaction (like Acme [18]); distribute actors and move policy inference to learners (like SEED RL [8]); distribute both actors and learners (like Sebulba [16]); or represent the full RL training loop on a GPU (like WarpDrive [23] and Anakin [16]).

When a user changes the algorithm configuration, its hyper-parameters or deployment resources, they can also switch between distribution policy to maintain high training efficiency without having to change the RL algorithm implementation.

(3) Heterogeneous fragment execution (§5). For execution, MSRL deploys hardware-specific implementations of fragments on CPUs and GPUs. MSRL supports different fragment implementations: CPU implementations use regular (multi-process) Python code, and GPU implementations are generated as compiled computational graphs for DNN engines (e.g., MindSpore or TensorFlow) if a fragment is implemented using operators, or are implemented directly in CUDA.

MSRL optimizes co-located fragments on the same worker: it fuses data-parallel fragments for more efficient execution by batching data items (e.g., tensors) and using single-instruction-multiple-data (SIMD) execution.

We evaluate MSRL experimentally and show that MSRL's abstraction supports flexible training across different RL algorithm without compromising training performance compared to current hardcoded RL training systems: MSRL scales to 64 GPUs and outperforms the Ray distributed RL system [34] by up to 3×. By switching between distribution policies, MSRL can improve the training time of the PPO RL algorithm by up to 2.4× as hyper-parameters, network properties or hardware resources change.

2 Distributed Reinforcement Learning

Next we give background on RL algorithms (§2.1), discuss the requirements for RL training (§2.2), and survey the design space of existing RL systems (§2.3).

2.1 Reinforcement learning

Reinforcement learning (RL) solves a sequential decision-making problem in which an *agent* operates in an *environment*. The agent's goal is to learn a *policy* that maximizes the cumulative *reward* based on the feedback from the environment (see Fig. 1). RL training performs three steps: ❶ *policy inference*: an agent obtains an action by performing inference on a policy; ❷ *environment execution*: the environment executes the action, generating *trajectories* of $\langle state, reward \rangle$

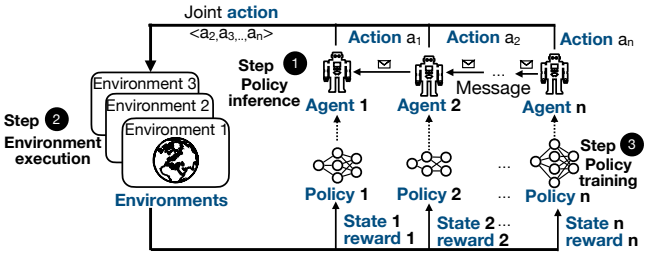

Fig. 1: RL training loop with multiple agents

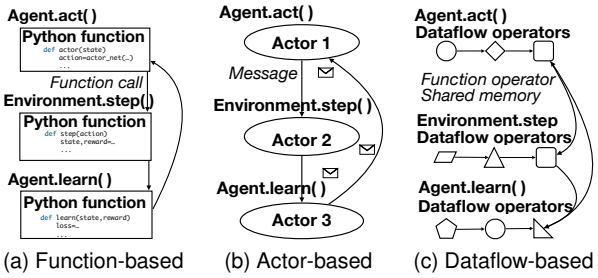

Fig. 2: Types of RL system designs

pairs; and ❸ *policy training*: the agent improves the policy by adapting it based on the reward.

RL algorithms are diverse in nature, falling into three categories: (1) *value-based* algorithms (e.g., DQN [33]) use a DNN to approximate a value function that predicts the expected return of actions. Agents then select actions based on these estimated values; (2) *policy-based* algorithms (e.g., Reinforce [55]) directly learn a parameterized policy – approximated by a DNN – for selecting actions without a value function. Agents use batched trajectories to train the policy by updating its parameters to maximize the reward; and (3) *actor–critic* algorithms (e.g., PPO [47], DDPG [27], A2C [32]) combine the two by learning a policy that selects actions and a value function that evaluates them.

Multi-agent reinforcement learning (MARL) employs multiple agents, each optimizing its own cumulative reward when interacting with the environment or other agents (see Fig. 1). A3C [32] executes agents asynchronously on separate environment instances; MAPPO [57] extends PPO to a multi-agent setting in which agents share a global parameterized policy.

2.2 Requirements for distributed RL systems

RL algorithms explore large spaces of actions, states and DNN parameters, which grow exponentially with the number of agents [37]. RL systems must thus exploit the parallelism of GPUs and scale computation to many worker nodes.

Due to the diverse computational patterns exhibited by different RL algorithms, there is no single strategy for parallelization and distribution that is optimal for all RL algorithms, e.g., in terms of both achieving the lowest iteration time and scaling to the most workers. Bottlenecks during training depend on the specific algorithm, the training workloads and the employed hardware resources: e.g., our experiments show that, for PPO [47], environment execution (❷) takes up to 98% of execution time; for MuZero [46], a large MARL algorithm with many agents, instead 97% of time is spent on policy inference and training (❶+❸).

Therefore, there are many proposals how to parallelize and distribute RL computation: e.g., in single-agent RL, environment execution (❷ in Fig. 1), policy inference and training (❶+❸) can be distributed across workers [8, 16, 16, 18, 34]; in MARL, agents can be distributed [25, 26, 34, 45] and exchange training state [29, 39]. Environment instances can execute in parallel [16, 32] or be distributed [7].

Instead of committing to one approach for parallelizing and distributing the RL computation, an RL system should provide the flexibility to change its execution approach based on the workload. This leads us to the following requirements:

(1) Execution abstraction. The system should have a flexible execution abstraction for parallelizing and distributing computation, unencumbered by how the algorithm is defined.

(2) Distribution strategies. The system should support multiple strategies for distributing RL computation. Users should be permitted to switch between strategies based on the training workload, without changes to the algorithm.

(3) Acceleration support. The system should exploit the parallelism of GPUs and CPUs, accelerating not just policy training and inference (❶+❸) but the full RL training loop, including environment execution (❷) [23].

(4) Algorithm abstraction. The system should expose familiar APIs to users for defining RL algorithms and their training loops, structured around algorithmic components [9, 13, 22], such as agents, actors, learners, policies, environments, etc.

2.3 Design space of existing RL systems

We analyze the design space of RL systems. Existing designs fit into three types (see Fig. 2):

(a) Function-based RL systems are the most common type. They express RL algorithms typically as Python functions, executed directly by workers (see Fig. 2a). The RL training loop is implemented through direct function calls. For example, Acme [18] and SEED RL [8] organize algorithms as actor/learner functions; RLGraph [45] uses a component abstraction, and users register Python callbacks to define functionality. Distributed execution is delegated to backend engines, e.g., TensorFlow [14], PyTorch [42], Ray [34].

(b) Actor-based RL systems execute algorithms as a set of (programming language) actors deployed on worker nodes (see Fig. 2b). For example, Ray [34] uses an actor model to define tasks, which are distributed among nodes using remote calls. Defining control flow in an actor model, however, is burdensome. To overcome this issue, RLlib [25] adds logically centralized control on top of Ray. Similarly, MALib [61] offers a higher level abstractions for population-based MARL algorithms (e.g., PSRO [35]) on Ray.

(c) Dataflow-based RL systems define algorithms through a

Type	System	(1) Execution	(2) Distribution	(3) Acceleration	(4) Algorithm
Function-based	SEED RL [8]	Python functions	environment only	DNNs only	actor/learner/env
	Acme [18]	Python classes			
	RLGraph [45]		delegated to backend		agent
Actor-based	Ray [34]	task (stateless) actor (stateful)	scheduler/RPC	DNNs only	Python functions with Ray API [34]
	RLlib [25]				
	MALib [61]				agent/actor/learner/env
Dataflow-based	Podracer [16]	JIT-compiled by JAX [12]	hardcoded	funcs/DNNs/envs	JAX [12] API
	RLlib Flow [26]	predefined dataflow operators	dataflow operators/ Ray tasks [34]	DNNs only	operator API
	WarpDrive [23]	GPU thread blocks	—	CUDA kernels	CUDA API
Fragmented dataflow	**MSRL**	heterogeneous fragments	any fragment	funcs/operators/ DNNs/envs	agent/actor/learner/env

Tab. 1: Design space of distributed RL systems

set of data-parallel operators, implemented by GPU kernels or distributed tasks (see Fig. 2c). Users must express the complete RL training loop using operators APIs. For example, Podracer [16] uses JAX [12] to compile vectorized Python to TPU kernels. RLlib Flow [26] provides Spark-like dataflow operators on top of Ray. WarpDrive [23] executes RL training loops implemented in CUDA using GPU thread blocks.

Tab. 1 considers how well these approaches satisfy the four requirements from §2.2:

(1) Execution abstraction. Function- and actor-based systems execute RL algorithms directly through implemented (Python) functions and user-defined language actors, respectively. This prevents systems from applying optimizations how RL algorithms are parallelized or distributed. In contrast, dataflow-based systems execute computation using operators [16, 26] or CUDA kernels [23]. This allows for execution optimizations, but algorithm implementations are restricted by the supported set of operators.

(2) Distribution strategies. Most function-based systems only support a hardcoded strategy, e.g., one that distributes actors to parallelize the environment execution (❶+❷ in Fig. 1) with a single learner. In actor-based systems, a scheduler assigns stateful actors and stateless tasks to workers, and users have no control over the distribution approach.

Similarly, existing dataflow-based systems only support fixed policies how dataflow operators are assigned to workers: *Anakin* [16] co-hosts an environment and an agent on each TPU core; *Sebulba* distributes the environment, learners and actors on different TPUs; and RLlib Flow [26] shards dataflow operators across distributed Ray actors.

(3) Acceleration support. Most RL systems only accelerate DNN policy inference and training (❶+❸). Some dataflow-based systems (e.g., Podracer [16] and WarpDrive [23]) also accelerate other parts of training, requiring bespoke dataflow implementations: e.g., Podracer accelerates environment execution (❷) on TPU cores; WarpDrive executes the entire RL training loop (❶–❸) on a single GPU using CUDA.

(4) Algorithm abstraction. Function-based RL systems provide intuitive actor/learner/env APIs. Actor-based RL systems exhibit harder-to-use low-level APIs for distributed components (e.g., Ray's `get`/`wait`/`remote` [34]) and must rely on high-level libraries (e.g., RLlib's `PolicyOptimizer` API [25]) to bridge the gap. Dataflow-based systems come with their own dataflow operators, requiring the rewriting of a complete RL training loop. For example, JAX [12] require users to express RL algorithms in terms of the `vmap` and `pmpa` operators for vectorization and single-program multiple-data (SPMD) parallelism, respectively.

We note that there is an opportunity to combine the usability of a function-based algorithmic abstraction, which allow users to express RL algorithms naturally using algorithmic components, with the acceleration potential of dataflow-based approaches. Such a design, however, requires a new execution abstraction, which also retains the flexibility of supporting different distribution strategies.

3 Fragmented Dataflow Graphs

We now describe the dataflow abstraction that we use to represent the heterogenous computation of RL algorithms and to map it to various devices for execution.

3.1 Overview

Our aim is to take an arbitrary RL training loop of a single- or multi-agent RL algorithm (Fig. 1) and translate it to a dataflow representation. The RL system can then use the dataflow representation to parallelize and distribute the computation across heterogeneous devices. We observe that RL training loops combine different types of computations: e.g., actors decide on an action to carry out based on inference results from the DNN policy, obtaining trajectories first; learners update the DNN policy using a DNN training algorithm; and environments execute steps in e.g., a physics simulator, returning trajectories based on the current simulation state.

Unlike existing dataflow models for DNN computation [1, 6, 19], this heterogeneity of computation makes it challenging to impose a single uniform dataflow model that prescribes a set of computational operators and a single data representation (e.g., tensors) between them. Instead, we adopt a *heteroge-*

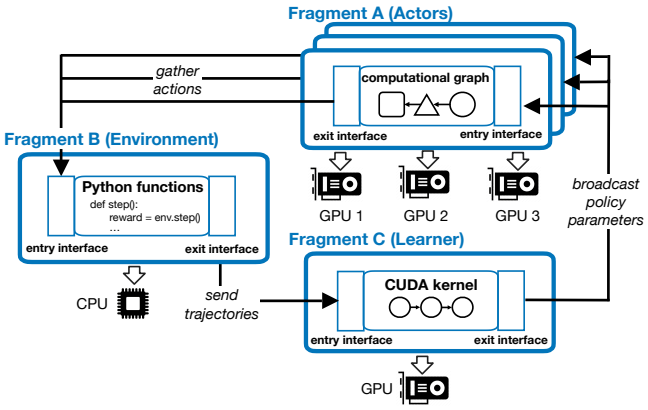

Fig. 3: Fragmented dataflow graph

neous dataflow model, in which independent dataflow representations for different algorithmic components of the RL training loop can be "stitched together" through well-defined interfaces. We refer to this dataflow model as a *fragmented dataflow graph* (FDG), shown in Fig. 3.

Fragments. Each node in an FDG is a potentially data-parallel *fragment*, which is implemented using a bespoke dataflow representation. For example, fragment A in Fig. 3 represents the action computation of an *actor* using the data-parallel operators of a DNN engine [1, 6, 19], performing model inference to decide on an action; fragment B implements the environment simulation directly as parallel Python code; and fragment C conducts the model training, which is implemented as CUDA kernels [11, 38].

Based on the fragment allocation, FDGs support the execution of RL computation on different devices. Each fragment is assigned to one or more devices: the DNN operator representation of fragment A allows it to be deployed on GPUs or CPUs; fragment B requires a Python interpreter with the `multiprocessing` library [10] on CPU cores; and instances of fragment C must run as CUDA kernels on GPUs.

In addition, it is possible to parallelize fragment execution by having multiple instances of a fragment and assigning each instance to a separate device. In Fig. 3, fragment A is replicated 3 times and executed by 3 GPU devices in parallel.

Communication. To form a connected FDG of the complete RL training loop, each fragment must support *entry* and *exit* interfaces, allowing them to exchange data: the entry interface receives data as a byte buffer, which is transformed into a fragment-specific representation (e.g., a tensor); and the exit interface requires a fragment to provide output, which is serialized for consumption by the next fragment.

The implementation of these interfaces depends on how the fragments are deployed: if two fragments are placed on different workers, the interface must use network communication to exchange data e.g., using an RPC protocol over Infiniband [48]; if two fragments are co-located on devices on the same worker, they can share data structures e.g., using inter-GPU communication links such as NVLink [40].

According to the communication method and distribution policy (§4.2), fragment interfaces may be *blocking*, which means that they only execute after all data has arrived, e.g., after a collective communication `AllReduce` round when aggregating DNN gradients. Alternatively, they can be *non-blocking*, which means that they execute continuously, e.g., allowing actors to interact with environments asynchronously.

3.2 Trade-offs with fragmented dataflow graphs

FDGs subsume execution strategies of existing RL systems. For example, an FDG may represent an actor and its environment as a single CPU-based fragment, and a learner as a GPU-based fragment, as proposed by Acme [18]. Alternatively, it may create a larger GPU fragment by moving the DNN policy to the learner, accelerating policy inference, as proposed by SEED RL [8]. An even larger fragment may contain the actor, learner, policy, and environment, executing the whole training loop on a single GPU, as proposed by WarpDrive [23] and Anakin [16].

More generally, FDGs expose two dimensions that impact execution performance:

Fragment granularity refers to the code size, which affects device utilization: a small fragment may underutilize a GPU, and a large one may exhaust GPU memory.

Fragment granularity also determines the ratio between computation and communication. The frequency and amount of data synchronization between fragments often limit scalability: coarser fragments require less synchronization with other fragments, which reduces communication overhead, but they remove opportunities for parallelism. For example, multiple fragments may exchange trajectories frequently at each step; alternatively, they may batch data from multiple steps and communicate only once in each episode.

Fragment co-location is the assignment of fragments to devices on the same worker. Co-locating fragments avoids network communication (e.g., Ethernet or InfiniBand) and instead uses more efficient intra-node communication (e.g., NVLink or PCIe). Whether two fragments can be co-located depends on the available resources on the worker, such as the number of available GPUs.

Choosing the right trade-off between fragment granularity and co-location is key to achieving good performance. In the next section, we describe how FDGs allow users to define an RL algorithm and select between different distribution policies, which expose these trade-offs.

4 Using MSRL

MSRL is our system that implements FDGs for parallel and distributed execution of RL algorithms based on distribution policies. We describe the APIs supported by MSRL for users to define RL algorithms (§4.1) and the distribution policies supported by MSRL to deploy FDGs (§4.2).

Type	API	Description
Component	`Agent, Actor, Learner, Trainer`	Abstract classes for components
	`Actor.act(...)`	Trajectory collection
	`Learner.learn(...)`	DNN policy training
	`Trainer.train(...)`	RL training loop
	`MSRL.agent_act(...)`	Invoke actor
	`MSRL.agent_learn(...)`	Invoke learner
	`MSRL.env_step(...)`	Execute environment
	`MSRL.env_reset()`	Reset environment
Interaction	`MSRL.replay_buffer_insert(...)`	Store trajectories in buffer
	`MSRL.replay_buffer_sample()`	Sample trajectories from buffer

Tab. 2: MSRL APIs

4.1 MSRL APIs

MSRL's APIs are designed to decouple the algorithm logic from its deployment, while supporting familiar algorithmic concepts (i.e., agents, actors, learners, trainers, and environments). As listed in Tab. 2, MSRL supports *component* and *interaction* APIs:

Component APIs specify an RL algorithm by defining algorithmic components derived from abstract classes. An `Agent` consists of actors and learners: actors collect trajectories in `Actor.act()` by invoking `MSRL.env_step()`; and learners implement the DNN update logic in `Learner.learn()`. A *trainer* constructs the RL training loop in `Trainer.train()`. It can use `MSRL.env_step()` to invoke the environment implementation and `MSRL.env_reset()` to reset the training episode.

Interaction APIs offer RL-specific functionality to algorithmic components. For example, an *actor* can store collected trajectories in a replay buffer using `MSRL.replay_buffer_insert()`, and a *learner* can sample from that replay buffer with `MSRL.replay_buffer_sample()`. This avoids direct invocations between components, which allows MSRL to distributed fragments transparently.

Alg. 1 shows a sample implementation of the multi-agent PPO (MAPPO) algorithm [57]. (For brevity, it omits the DNN policy definition.) The `MAPPOAgent` (line 1) defines the agent behavior: it interacts with the environment through `MAPPOActor` (line 6), and performs the policy training with `MAPPOLearner` (line 12). The agent collects trajectories (lines 8–9), and updates its DNN policy (lines 15–21).

`MAPPOTrainer` defines the RL training loop (line 23). At the start of each episode, it resets the environment (`MSRL.env_reset()`) and calls `MSRL.agent_act()` to place trajectories (line 28) in a replay buffer (line 10). The trainer invokes the learner through `MSRL.agent_learn()` (line 29).

To separate the algorithm's logic from its deployment, MSRL uses configurations, specified as Python dictionaries: an *algorithm configuration* instantiates the algorithmic components and their hyper-parameters (e.g., the number of agents and learning rates). In the MAPPO example (lines 30–38), the configuration requests 4 agents, each with 3 actor and 1 learner. Each actor interacts with 32 environments; and a *deployment configuration* defines (i) the resources (e.g., GPUs, CPUs, and worker nodes) and (ii) a *distribution policy*. In the example (lines 39–42), it deploys workers with 4 GPUs each, using the SingleLearnerCoarse distribution policy.

Algorithm 1: MAPPO algorithm in MSRL

```
1  class MAPPOAgent(Agent):
2    def act(self,state):
3      return self.actors.act(state)
4    def learn(self,sample):
5      return self.learner.learn(sample)
6  class MAPPOActor(Actor)
7    def act(state):
8      action = self.actor_net(state)
9      reward,new_state = MSRL.env_step(action)
10     MSRL.replay_buffer_insert(reward,new_state)
11     return reward,new_state
12 class MAPPOLearner(Learner):
13   def learn():
14     sample = MSRL.replay_buffer_sample()
15     action,reward,state,next_state = sample
16     last_pred = self.critic_net(next_state)
17     pred = self.critic_net(state)
18     r = discounted_reward(reward,last_pred,self.gamma)
19     adv = gae(reward,next_state,pred,last_pred,self.
           gamma)
20     for i in range(self.iter):
21       loss += self.mappo_net_train(action,state,adv,r)
22     return loss / self.iter
23 class MAPPOTrainer(Trainer):
24   def train(self,episode):
25     for i in range(episode):
26       state = MSRL.env_reset()
27       for j in range(self.duration):
28         reward,new_state = MSRL.agent_act(state)
29       loss = MSRL.agent_learn()
30 mappo_algorithm_config = {
31   'agent':{'num':4,'name':MAPPOAgent,
32            'actor':MAPPOActor,'learner':MAPPOLearner},
33   'actor':{'num':3,'name':MAPPOActor,
34            'policy':MAPPOActorNet,'env':True},
35   'learner':{'num':1,'name':MAPPOLearner,
36              'policy':[MAPPOCriticNet,MAPPONetTrain],
37              'params':{'gamma':0.9}},
38   'env':{'name':MPE,'num':32,'params':{'name':'MPE'}}}
39 mappo_deployment_config = {
40   'workers':[198.168.152.19, 198.168.152.20, [...],
41   'GPUs_per_worker':4},
42   'distribution_policy':'SingleLearnerCoarse'}
```

4.2 Distribution policies

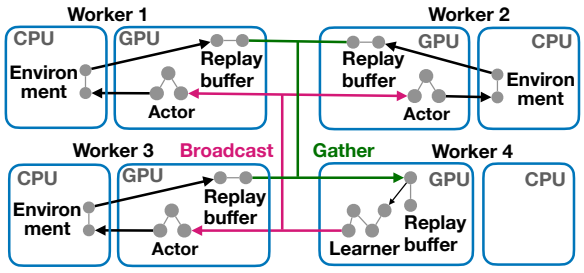
A *distribution policy* (DP) governs how MSRL distributes and parallelizes an RL algorithm by allocating, replicating and collocating fragments from the FDG to workers and devices.

In general, there exists no single DP that is optimal in all cases: the performance and applicability of a DP depends on the type of RL algorithm, the size and complexity of the DNN model, its hyper-parameters, the available cluster compute resources (i.e., CPUs and GPUs), and the network bandwidth. MSRL allows users to easily switch between DPs, either for the same RL algorithm or when using different algorithms. MSRL provides six DPs, which follow widely used hard-coded distribution strategies of existing RL systems.

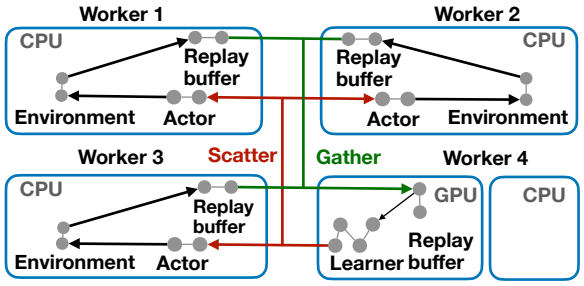
Next we give an overview of the support DPs and their trade-offs. Tab. 3 shows how three of the DPs deploy the fragments of an RL algorithm. (We list all DPs currently implemented by MSRL in Appendix A).

DP-SingleLearnerCoarse replicates the actor and environment fragments but uses a single learner. The policy DNN is replicated across the actors and learner, which only requires coarse synchronization. This policy is therefore most suitable with

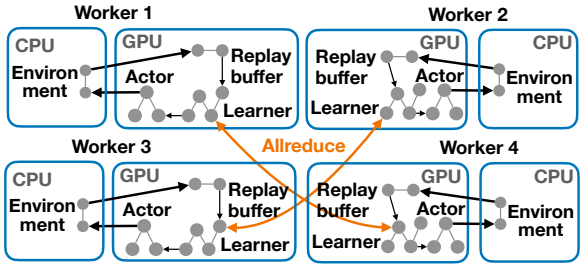
DP-SingleLearnerCoarse
replicate: *actor*,*env* split: *learner* e.g., Acme [18], Sebulba [16]



DP-SingleLearnerFine
replicate: fused *actor/env* split: *learner* e.g., SEED RL [8]



DP-MultiLearner
replicate: fused *actor/learner*, *env*



Tab. 3: Sample distribution policies with deployments

computationally-expensive environments that need scaling out, but small DNN models that can be synchronized in a batched fashion, e.g., Acme [18], Sebulba [16].

The MAPPO deployment in Alg. 1 uses DP-SingleLearnerCoarse: each agent is partitioned into 4 GPU fragments, i.e., 3 actors and 1 learner, and 3 CPU fragments for environments. Actor and environment fragments are collocated. This setting is replicated for each of the 4 MAPPO agents, as specified in the algorithm configuration.

In contrast, DP-SingleLearnerFine fuses the actor and environment into a single CPU fragment, and only deploys the learner on a GPU. Therefore it does not communicate policy parameters between workers, which is preferable for large DNN models with many parameters. Compared to the DP-SingleLearnerCoarse, it relies on fine-grained synchronization: training data is exchanged at each step, instead of being batched per episode. For good performance, DP-SingeLearnerFine therefore requires high bandwidth connectivity between workers, e.g., SEED RL [8].

DP-MultiLearner performs data-parallel training with multiple learners. This policy is necessary when the data generated from actors becomes too large for a single GPU, and e.g., DP-SingleLearnerCoarse cannot be used. However, it requires the tuning of hyper-parameters (e.g., the learning rate) to scale due to its reliance on data parallelism. Since workers only exchange information about the trained policy (e.g., aggregated DNN gradients), DP-MultiLearner is communication efficient, supporting fully decentralized MARL training [5, 43, 59, 62].

MSRL supports further policies: DP-GPUOnly fuses the RL training loop into a single GPU fragment and distributes it to multiple GPU devices. DP-Environments dedicates one or more workers for the execution of complex or compute-intensive environments (e.g., physics simulations). Finally, DP-Central introduces a separate fragment for a centralized component (e.g., policy pool [61] or parameter server [24]).

The choice of the best distribution policy depends on the algorithm's characteristics and available hardware resources: single-agent RL algorithms, such as PPO/A3C, exhibit the best performance under the DP-SingleLearnerCoarse policy, which distributes actors to speed up trajectory collection through data parallelism; multi-agent algorithms, such as MAPPO/MADDPG, require a DP-MultiLearner policy that distributes actors and learners separately from agents, thus parallelizing both trajectory collection and model training; a DP-GPUOnly policy can be used in a GPU environment to fuse the training loop and execute it entirely on GPUs, which offers the best performance.

Based on the hardware resources, bottlenecks shift between DPs: the DP-SingleLearnerFine policy exchanges data between actors/environments at a fine granularity by distributing inference/training to one GPU worker and environments across CPU workers. Despite the need for frequent communication, this policy is suitable in situations where GPUs are scarce; in contrast, the DP-SingleLearnerCoarse policy co-locates the GPU DNN inference with the environments, enabling the learner to gather batched training data. With enough GPUs, this policy accelerates trajectory collection.

5 MSRL Architecture

We describe MSRL's architecture, explaining how FDGs are generated (§5.1) and executed (§5.2).

MSRL follows a coordinator/worker design (see Fig. 4): a user submits the RL algorithm implementation to the *coordinator* ❶. The coordinator generates the fragments that constitute the FDG and dispatches them to the workers ❷. Each worker maintains one or more *execution backends* (e.g., a DNN engine, a CUDA job scheduler, a Python interpreter), each managing devices (e.g., GPUs or CPU cores). After receiving fragments, the worker optimizes them ❸ and submits them to a backend for execution ❹.

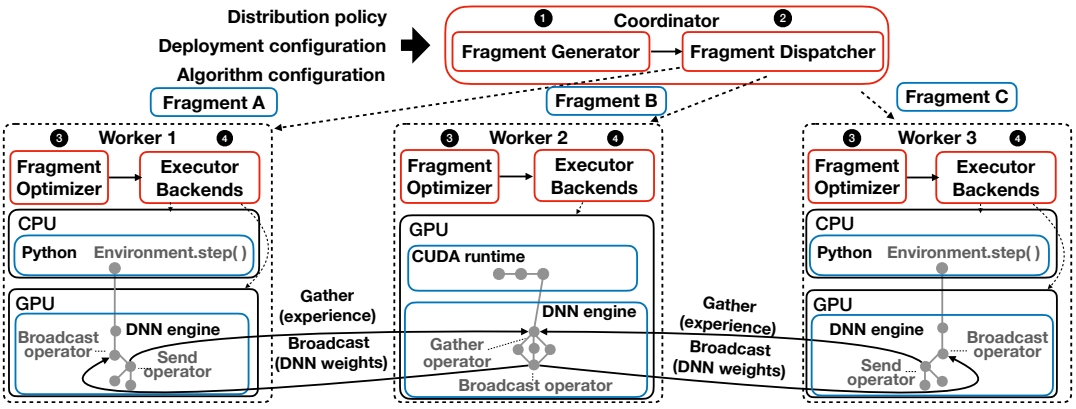


Fig. 4: Overview of the MSRL architecture

5.1 Generating FDGs

The coordinator has two components:

The **FDG Generator** partitions the RL algorithm according to the DP specified in the deployment configuration (§4.1). It splits the implementation at fragment boundaries and injects code for the interface implementations between fragments. The fragment logic is then emitted as part of a `run()` method in a generated `Fragment` class.

The partitioning of the RL algorithm into fragments uses the information associated with a DP. Each DP provides a set of rules about (1) how fragments are generated and (2) how they are distributed. The DP contains a *fragment template*, which associates each fragment with a Python class that has placeholders for class names, member functions, and other relevant elements. These placeholders instruct the Generator where to insert specific algorithm logic, such as actor computation, into the generated fragments. The DP also defines the communication operations required by the interfaces. To choose appropriate implementations, the DP refers to communication operations supported by backends (e.g., `comms.AllGather` [20] in a DNN engine). The DP also specifies which fragments are replicated into multiple instances for parallel execution, or co-located on the same worker.

When partitioning the RL training loop, the boundaries between fragments follow the algorithmic components (actors, learners, environments). The data to be transferred between fragments is defined in terms of the function signatures of the components. The partitioning is done on a dataflow representation of the RL algorithm: nodes in the dataflow graph are Python statements; edges represent the dataflow through variables. Therefore, edges at the boundary of algorithmic components describe fragment interfaces, and we refer to them as *boundary edges*. MSRL creates fragments by partitioning the dataflow graph at these boundary edges.

As an example, consider partitioning the MAPPO algorithm (Alg. 1) into actor and learner fragments, with the boundary between lines 28 and 29. Fig. 5a shows the simplified dataflow graph obtained after static analysis, with the input/output data of the components shown in red. Splitting the graph at these boundaries, partitions it into two fragments (see Fig. 5b), which communicate through the new interface obtained from the boundary edges (shown in red).

Algorithm 2 Generation of fragmented dataflow graphs

function generate_FDG (*alg*, *DP*):
1: *FDG* ← {}, *DFG* ← *generate_DFG(alg)*
2: *boundary_edges* ← *obtain_boundary_edges(DFG)*
3: *interfaces* ← *generate_interfaces(boundary_edges, DP)*
4: **for** *boundary* in *boundary_edges* **do**
5: *fragment_code* ← *build_fragment(alg, boundary)*
6: *fragment* ← *build_fragment(fragment_code, interfaces, DP)*
7: *FDG* ← *FDG* ∪ *fragment*
8: **return** FDG

Alg. 2 summarizes the FDG generation. The Generator takes the RL algorithm's abstract syntax tree (*alg*) and distribution policy *DP* as input (line 0) and constructs its dataflow graph (*DFG*) (line 1). Next, it locates the algorithmic components and determines the boundary edges from the DFG (line 2). Based on the information from the DP, it constructs the communication interfaces (line 3). For each boundary edge (line 4), it extracts the fragment code (line 5) and builds the fragment with its interface implementation (line 6). At the end, it returns the complete FDG (line 8).

The **Fragment Dispatcher** launches instances of execution backends on each worker according to the devices from the deployment configuration. It also sets up distributed communication, e.g., through MPI [30], as required by the fragment interfaces. Finally, it assigns fragments to devices based on the DP and sends the fragments to the workers.

5.2 Executing fragments

The workers use a set of *execution backends* to take the fragment code and run it. Some backends (e.g., a DNN engine) produce executable machine code for a given device (e.g., GPUs) by translating the fragment implementation into a computational graph, which enables code optimizations.

The communication between fragments is also handled by the execution backends. For example, a DNN engine

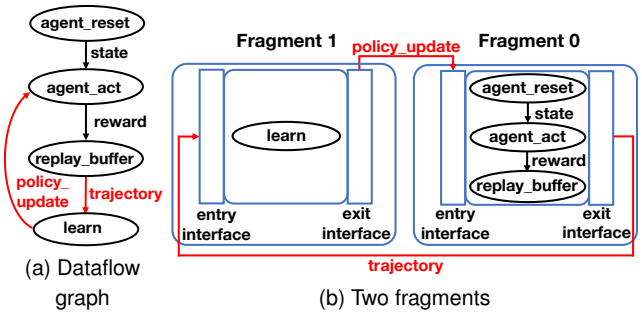

Fig. 5: Example of FDG generation for MAPPO

	MSRL	RLlib	WarpDrive
PPO	207	347 (+68%)	400 (+93%)
A3C	267	428 (+60%)	*n/a*

Tab. 4: Lines of code for the RL algorithm implementations

uses communication operators as part of its computational graph, automatically selecting suitable implementations (e.g., NCCL [39] for GPU collective communication).

Each worker has two components:

The **Fragment Optimizer** optimizes fragments that have been received for a given execution backend. To avoid the overhead of executing multiple instances of a replicated fragment, the optimizer attempts to *fuse* instances represented as computational graphs: it exploits the support of DNN engines to process data in a SIMD fashion by batching tensors from multiple fragment instances.

The Optimizer performs this transformation on the fragment's AST before submitting it to the DNN engine. It locates the AST nodes of tensors and merges their data. It then computes the new tensor shape to create a single tensor that can be processed by other data-parallel operators.

The **Executor backends** execute the fragments on a given target device: a DNN engine (MindSpore) executes computational graph on GPUs or CPUs; a CUDA job scheduler runs CUDA kernels on GPUs; a Python interpreter executes Python fragments on CPU cores; and a container scheduler can run arbitrary compute containers on CPU cores.

6 Evaluation

Our experimental evaluation answers the following questions: (i) what is the training performance that MSRL with FDGs achieves compared to existing RL systems with fixed execution strategies (§6.2)?; (ii) how does MSRL benefit from choosing different distribution policies (§6.3)?; and (iii) how well does MSRL scale in terms of the number of agents and the amount of training data (§6.4)?

6.1 Experimental set-up

Implementation. We implement MSRL in 11,700 lines of Python and C++ code. It uses CUDA 11.03, cuDNN 8.2.1, OpenMPI 4.0.3, and the MindSpore DNN framework 1.8.0 [19] as a GPU-based execution backend. The source code is available at https://github.com/mindspore-lab/mindrl.

Cluster	CPU cores *#nodes × #per node*	GPUs *#nodes × #per node*	Interconnects *intra-, inter-node*
Azure VMs NC24s_v2	Intel Xeon E5-2690 16×24, 448 GB	NVIDIA P100 16×4	PCIe 10 GbE
Local cluster	Intel Xeon 8160 4×96, 250 GB	NVIDIA V100 4×8	NVLink 100 Gbps IB

Tab. 5: Testbed configuration

MSRL uses the following distribution policies from Appendix A: DP-SingleLearnerCoarse; DP-SingleLearnerFine; DP-MultiLearner; DP-GPUOnly; and DP-Environments.

Baseline comparisons. For comparison, we use RLlib [34] of Ray V2.0, as a representative distributed RL system, and WarpDrive V1.6 [23], as a single-GPU system that accelerates the full RL training loop. Note that the implementations of RLlib Flow [26] and PodRacer [16] are unavailable.

RL algorithms. We focus on three popular algorithms: (1) *proximal policy optimization* (PPO) [47]; its multi-agent version, (2) *multi-agent PPO* (MAPPO) [57]; and (3) *asynchronous advantage actor-critic* (A3C) [31].

Tab. 4 compares the lines of code for the algorithm implementations. The RLLib and WarpDrive implementations require 68% and 93% more lines than MSRL, respectively, due to the hardcoded execution and distribution logic. This shows a benefit of MSRL's approach, which allows users to focus on the algorithm logic in their implementations.

For environments, we use two games (CartPole, HalfCheater) from the MuJoCo simulation engine [52], and two strategies (Spread, Tag) from the *multi-agent particle environment* (MPE) [28]. The policies use a 7-layer DNN.

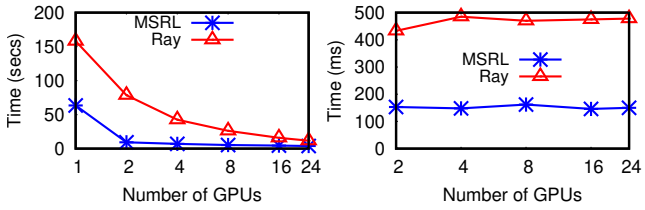
Testbeds. We conduct experiments on a *cloud* and a *local* cluster. The hardware details are given in Tab. 5: the cloud cluster has 16 VMs (with 64 GPUs); the local cluster has 4 nodes (with 32 GPUs). All nodes run Ubuntu Linux 20.04.

Metrics. For PPO, we measure (i) the training time to reach a given reward and (ii) the time per episode. For MAPPO, as the problem size increases with agents, we report (i) training time against the problem size and (ii) training throughput.

6.2 Performance with FDGs against baselines

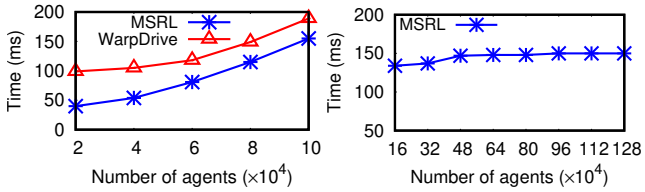
We investigate the performance impact that MSRL's FDG abstraction incurs compared to RL systems that only support hardcoded parallelization and distribution approaches.

Distributed training. We compare MSRL with DP-SingleLearnerCoarse to Ray [34] using PPO and A3C on the local cluster. For Ray, both algorithms are implemented using RLlib-Flow [26] and tuned based on RLlib's public PyTorch implementation [44]. DP-SingleLearnerCoarse is equivalent to the distribution approach implemented by RLlib-Flow's PPO and A3C implementations.



(a) Episode time vs. GPUs (PPO) (b) Episode time vs. GPUs (A3C)

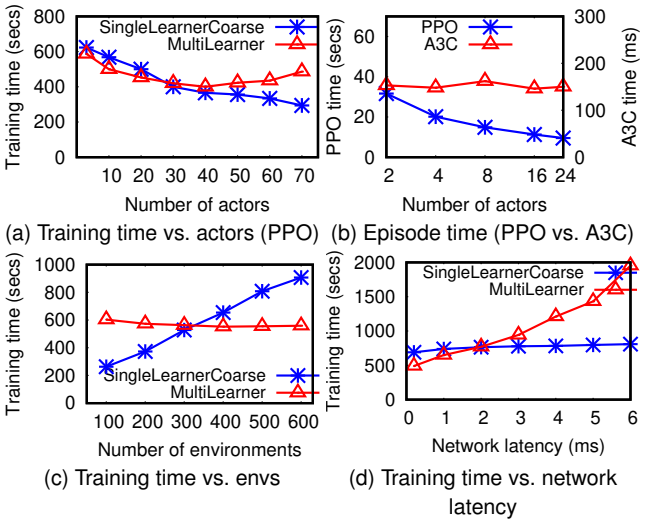
Fig. 6: Performance comparison with Ray



(a) Episode time vs. agents (1 GPU)

(b) Episode time vs. agents (n GPUs)

Fig. 7: Performance comparison with WarpDrive (PPO)



(a) Training time vs. actors (PPO) (b) Episode time (PPO vs. A3C)

(c) Training time vs. envs (d) Training time vs. network latency

Fig. 8: Impact of parameters on distribution policies

For PPO, we distribute 320 environments evenly among the actors, i.e., each actor interacts with $320/\#actors$ environments. A single learner trains the DNN. For A3C, one learner performs gradient optimization with gradients collected asynchronously from actors. Each actor interacts with one environment and computes gradients locally. We measure the time per episode, which is dominated by actor and environment execution. Since the DNN training/inference time is negligible, the fact that MSRL and Ray use different DNN frameworks (MindSpore vs. PyTorch) has low impact.

Fig. 6a shows the time per episode for PPO. MSRL's time with 1 GPU is 2.5× faster than Ray's, because Ray's CPU actor interacts with all environments sequentially. As the number of GPUs increases, both systems reduce episode time, because each actor interacts with fewer environments. With 24 GPUs, it takes 3.9 s for MSRL to execute an episode compared to 11.4 s for Ray (3× speed-up). When actors interact with multiple environments, MSRL combines DNN inference into one operation through FDG fusion, increasing GPU parallelism. It also uses fragments to execute environment steps in parallel by launching multiple processes.

Fig. 6b shows the time per episode for A3C. Both systems exhibit constant time with more GPUs, because the workload of each GPU executing an actor remains unchanged. MSRL executes actors 2.2× faster than Ray: since its distribution policy exploits customized asynchronous send/receive operations from the DL engine, it can avoid further data copies between GPUs and CPUs. In contrast, Ray must copy data to the CPU to communicate asynchronously.

In addition, MSRL generates the FDG that can be translated into a computational graph by the DL engine, enabling code optimizations and efficient execution. By leveraging code templates, MSRL generates optimized fragment code by directly manipulating the FDG AST.

GPU only training. Next, we use MSRL to deploy PPO with distribution policy DP-GPUOnly, which fuses the training loop into a single GPU fragment and replicates it for distributed execution. We use the *simple tag* MPE environment [28], which simulates a predator-prey game in which chaser agents are rewarded for catching runner agents. We train different numbers of agents, thus increasing the number of environments, on the local cluster and measure the training time per episode. We compare against WarpDrive [23], which performs single-GPU end-to-end RL training.

Fig. 7a shows the training time on 1 GPU. Compared to WarpDrive, MSRL is 1.2–2.5× faster when ranging from 20,000 to 100,000 agents. MSRL's DL engine (MindSpore) compiles fragments to computational graphs, exploiting more parallelization and optimization opportunities than WarpDrive's hand-crafted CUDA implementation.

While WarpDrive cannot scale to more than 1 GPU, Fig. 7b shows MSRL's performance when using up to 16 GPUs (each GPU trains 80,000 agents). Initially, training time increases from 138 ms to 150 ms due to the increased computation on a single worker (i.e., up to 640,000 agents). After that, training time is stable, and it is limited by communication bandwidth (InfiniBand, NVLink).

Conclusions: MSRL's FDG abstraction provides distribution policies for PPO and A3C that are tailored to their bottlenecks, e.g., enabling parallel environment execution and aggressively parallelizing GPU execution. Ray is limited by the distribution approach of its RLlib library; WarpDrive's manual CUDA implementation prevents it from exploiting more sophisticated compiler optimizations.

6.3 Trade-offs between distribution policies

Next, we explore the trade-offs between different distribution policies when changing RL algorithms and resources.

Actors. We measure PPO's training time with two distribution

policies, DP-SingleLearnerCoarse and DP-MultiLearner. We use a reward of 3,000 with 200 environments.

Fig. 8a shows the training time with 2 to 70 actors. DP-MultiLearner outperforms DP-SingleLearnerCoarse with fewer than 30 actors, but DP-SingleLearnerCoarse scales better after that, converging faster with more actors. Since DP-SingleLearnerCoarse only has 1 learner, its training batch size is fixed. Adding more actors therefore only distributes environment execution. In contrast, DP-MultiLearner fuses actors and learners into single fragments. With more actors, it also adds learners, reducing the batch size for each learner. This adds randomness to the training, affecting convergence [17].

Next, we compare two algorithms, PPO and A3C, under the same distribution policy DP-SingleLearnerCoarse.

Fig. 8b shows the time per episode for up to 24 actors. For PPO, the time decreases with the actor count; in contrast, A3C's time stays constant. Adding actors in PPO increases the parallelism of environment execution, thus reducing the workload per actor; for A3C, each actor only interacts with one environment, which makes its workload independent of the actor count. To reduce the episode time for A3C, a new distribution policy could be written that distributes the actor among multiple devices, combining data- or task-parallelism.

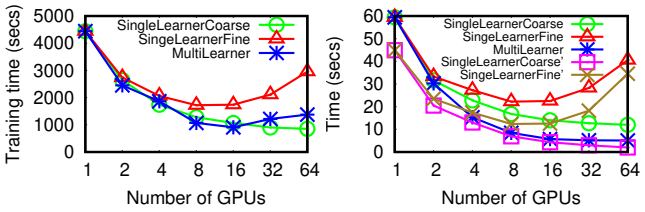
Environments. We explore how changing the number of environments affects the choice of distribution policy. When an agent interacts with more environments in parallel per episode, it trains with more data, improving training performance.

Fig. 8c shows the training time with 50 actors with 100–600 environments under DP-SingleLearnerCoarse and DP-MultiLearner. DP-MultiLearner scales better than DP-SingleLearnerCoarse with more than 320 environments: DP-SingleLearnerCoarse's training time increases with more environments, because its actors send trajectories to the learner, adding communication overhead; DP-MultiLearner only communicates gradients, having a fixed overhead.

Network latency. We examine the behavior of DP-SingleLearnerCoarse and DP-MultiLearner with PPO under different network latencies. We change network latency in our cloud cluster using the Linux traffic control (`tc`) tool from 0.2 ms to 6 ms. We use 400 environments and 50 actors.

As Fig. 8d shows, DP-MultiLearner is more sensitive to network latency than DP-SingleLearnerCoarse, and its training time increases with higher latency: since DP-MultiLearner uses Mindspore's data parallel model [19] to broadcast, aggregate and update gradients, it transmits many small tensors. This makes it a more suitable choice for cluster with low latency (< 2 ms); DP-SingleLearnerCoarse transmits the trajectory and DNN model weights as large tensors, performing data transmissions less frequently.

Cluster size. Finally, we study the performance of PPO under 3 distribution policies when increasing the GPU count: DP-SingleLearnerCoarse and DP-SingleLearnerFine use a single learner but apply different synchronization granularities; DP-MultiLearner scales to multiple learners using data-parallelism.



(a) Training time vs. GPUs (b) Episode time vs. GPUs

Fig. 9: Impact of GPU count on distribution polices

We use a constant 320 Mujoco HalfCheetah [4] environments.

Fig. 9a shows the training time in the cloud cluster to reach a reward of 4,000 with up to 64 GPUs; Fig. 9b reports the time per episode. With 64 GPUs, DP-SingleLearnerCoarse achieves the best speed-up in training time (5.3×). It maintains local copies of the DNN model at the actor and learner, and only actors send the batched states and rewards to the learner at the end of each episode (i.e., after 1,000 steps). This reduces the overhead with more GPUs compared to DP-SingleLearnerFine, whose actor fragments must communicate with the learner at each step.

DP-MultiLearner exhibits a different behavior: with 16 GPUs, it achieves better performance than either DP-SingleLearnerCoarse and DP-SingleLearnerFine, because it distributes policy training: it trains smaller trajectory batches on each GPU and aggregates the gradients from all GPUs. Instead, DP-SingleLearnerFine and DP-SingleLearnerCoarse gather all batches and train them using 1 learner.

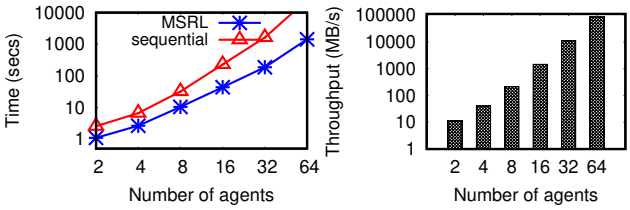
With more than 16 GPUs, DP-MultiLearner performs worse than DP-SingleLearnerCoarse: batches become smaller, making the gradient aggregation less efficient compared to training a large batch. Although DP-MultiLearner trains each episode faster than DP-SingleLearnerCoarse (see Fig. 9b), it requires more episodes to reach a similar reward value.

Note that DP-SingleLearnerCoarse and DP-SingleLearnerFine use the original PPO implementation with 1 learner [47], which limits scalability due to the centralized policy training (❸ in Fig. 1). To ignore this bottleneck in the algorithm, Fig. 9b also reports only the policy training time (labelled DP-SingleLearnerCoarse' and DP-SingeLearnerFine'). Now, MSRL scales better: when moving from 32 to 64 GPUs, performance increases by 25%.

Conclusions: As hyper-parameters, network properties or GPU counts change, the differences between distribution policies in terms of synchronization granularity and frequency of impact performance. MSRL's ability to allow users to switch between distribution policies at deployment time means that they can achieve the best performance in different scenarios without changing the algorithm implementation.

6.4 Scalability

Finally, we investigate how MSRL's design scales with the number of deployed agents for a MARL algorithm and of environments, thus increasing training data. We want to validate



(a) Training time per episode (b) Training throughput

Fig. 10: Scalability with agent count (MAPPO)

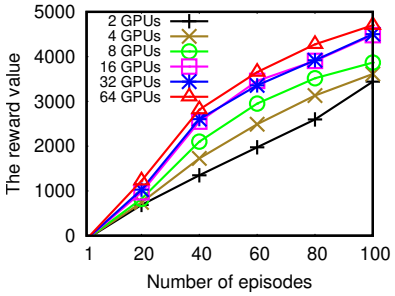


Fig. 11: Statistical efficiency with environment count (PPO)

if MSRL's approach introduces scalability bottlenecks.

Agents. We use MAPPO with the MPE *simple spread* environment [28], in which n agents learn to cover n landmarks while avoiding collisions. Agents must also process global observations on how far the closest agent is to each landmark. This results in $O(n^3)$ observations with n agents, quickly growing in computational cost and GPU memory usage [28]. We deploy on the cloud cluster using DP-Environments: each GPU trains 1 agent, and 1 worker executes all environments.

Fig. 10a shows the training time per episode for up to 64 GPUs against a sequential baseline (1 GPU). Due to its cubic complexity, the time increases both for the baseline and MSRL. With distributed training, MSRL's time grows more slowly than the baseline: with 32 agents, MSRL improves performance by 58×; with 64 agents, the baseline exhausts GPU memory, while MSRL trains one episode in 23.8 mins.

Fig. 10b compares the throughput with different agent numbers. Throughput is measured as the amount of data trained per second (in MB/s). Adding more agents (i.e., GPUs) significantly improves throughput, and the margin becomes larger with more GPUs: the throughput with 64 agents is over 7,600× higher than with 2 agents, as multiple GPUs train agents in parallel, processing more observations per GPU.

Environments. We observe the effect of more environments on statistical efficiency, i.e., the episodes needed to reach a given reward. We use 10 environments per CPU, adding more workers in the cloud cluster using DP-SingleLearnerCoarse.

Fig. 11 shows the reward along with the number of episodes for different environment counts. More environments lead to a higher reward: as more CPUs execute environments, the larger use of trajectories per episode yields a higher reward.

Conclusions: FDGs do not deteriorate scalability. MSRL scales to a large number of data-intensive agents, handling the increase in communication between fragments without bottlenecks. A larger amount of data generated by more environments also improves the statistical efficiency of training.

7 Related Work

DNN compilation. XLA [56] is a domain-specific compiler that accelerates the linear algebra of DNN models. JAX [12] uses just-in-time (JIT) compilation to transform vectorized Python programs to GPU or TPU code. TVM [6] is an automated end-to-end optimizing compiler for DNN training. These approaches focus on DNN training and inference workloads with regular computation/communication patterns. In contrast, RL algorithms exhibit more complex control and data flow in their training loops.

DNN auto-parallelization. Alpa [60] and Unity [53] automatically parallelize and distribute DNN training using data/operator/pipeline parallelism. They search for effective distributed execution plans using dynamic or integer linear programming. In future work, we want to explore the use of optimization techniques to generate an optimal distribution policy for a given RL algorithm. Since an FDG has more heterogeneity than DNN dataflows, the search space is substantially larger and based on more complex cost models.

Dataflow and actor systems. Spark [58] and Naiad [36] express programs as dataflow graphs, sharding data across workers. They provide high-level APIs to express computation as a single homogeneous dataflow. In contrast, FDGs allow different dataflow models to be integrated into a single distributed computation, as governed by distribution policies.

Ray [34] offers a general actor-based platform for distributed computing. To support RL algorithms, it uses domain-specific libraries (RLlib/RayFlow [25, 26]) that hardcode distribution strategies, preventing it from switching strategies based on e.g., hardware properties. Instead, MSRL proposes FDG, a higher-level abstraction for parallelizing and distributing RL training loops, which decouples RL algorithms from their execution through explicit distribution policies.

8 Conclusions

While DNN systems have mature dataflow abstractions that improve execution performance, similar abstractions for RL systems have been under-explored. We described MSRL, a system that supports the flexible parallelization and distribution of RL algorithms using *fragmented dataflow graph*. Accounting for the heterogeneous nature of RL training loops, MSRL separates the algorithm from its execution by using *distribution policies* that allocate dataflow fragments to GPUs and CPUs. Our experiments showed how distribution policies generalize existing RL systems without overhead.

A Supported Distribution Policies

Distribution policy	Deployment	Description
[DP-SingleLearnerCoarse] replicate: (*actor*, *env*) split: (*learner*) e.g., Acme [18], Sebulba [16]		DP-SingleLearnerCoarse replicates the actor and environment fragments: W1–W3 co-locate 1 GPU fragment with an actor for DNN policy inference and 1 CPU fragment for the environment execution. A single GPU fragment with a learner performs policy training (W4), gathering batched training data, training the policy and broadcasting updates.
[DP-SingeLearnerFine] replicate: fused *actor/env* split: *learner* e.g., SEED RL [8]		DP-SingleLearnerFine fuses the actor and environment into 1 fragment (W1–W3) but handles policy inference at the learner (W4), i.e., actors do not contain DNNs. W4 executes policy inference and training in 1 GPU fragment; W1–3 only have CPU fragments. W4 scatters actions to W1–W3 and gathers data for policy training.
[DP-MultiLearner] replicate: fused *actor/learner*, *env*		DP-MultiLearner performs data-parallel training with multiple learners, supporting fully decentralised MARL training [5,43,59,62]. DP-MultiLearner co-locates 2 fragments: a GPU fragment that fuses the actor and learner, accelerating policy inference, training and replay buffer management, and a CPU fragment for environment execution.
[DP-GPUOnly] replicate: fused *actor/learner/env*		DP-GPUOnly fuses the training loop into 1 GPU fragment. To enable communication among GPU fragments, DP-GPUOnly uses `Allreduce` operators compiled into the computational graph with NCCL2 [39]. DP-GPUOnly is a distributed implementation of the single-node systems (e.g., WarpDrive [23]).
[DP-Environments] replicate: fused *actor/learner* split: *env* e.g., MALib [61]		DP-Environments has a dedicated worker for environment execution. W1 has CPU fragments to execute environment instances on multiple CPU cores; W2–W4 fuse the actor and learner to accelerate policy inference and training. W1 gathers the inferred actions and scatters the states and rewards.
[DP-Central] replicate: fused *actor/learner*, *env* split: *param server/policy pool*		DP-Central supports a central *policy pool* [61] or *parameter server* [24] on a separate worker (W1). W2–W4 co-locate GPU fragments for policy inference and training and CPU fragments for environment execution.

Beware of Fragmentation: Scheduling GPU-Sharing Workloads with Fragmentation Gradient Descent

Abstract

Large tech companies are piling up a massive number of GPUs in their server fleets to run diverse machine learning (ML) workloads. However, these expensive devices often suffer from significant underutilization. To tackle this issue, GPU sharing techniques have been developed to enable multiple ML tasks to run on a single GPU. Nevertheless, our analysis of Alibaba production traces reveals that allocating partial GPUs can result in severe *GPU fragmentation* in large clusters, leaving hundreds of GPUs unable to be allocated. Existing resource packing algorithms fall short in addressing this problem, as GPU sharing mandates a new scheduling formulation beyond the classic bin packing.

In this paper, we propose a novel measure of fragmentation to statistically quantify the extent of GPU fragmentation caused by different sources. Building upon this measure, we propose to schedule GPU-sharing workloads towards the direction of *the steepest descent of fragmentation*, an approach we call *Fragmentation Gradient Descent* (FGD). Intuitively, FGD packs tasks to minimize the growth of GPU fragmentation, thereby achieving the maximum GPU allocation rate. We have implemented FGD as a new scheduler in Kubernetes and evaluated its performance using production traces on an emulated cluster comprising more than 6,200 GPUs. Compared to the existing packing-based schedulers, FGD reduces unallocated GPUs by up to 49%, resulting in the utilization of additional 290 GPUs.

1 Introduction

Graphics Processing Units (GPUs) are widely deployed in production clusters to accelerate machine learning (ML) tasks for a plethora of AI applications [14, 16, 17, 21, 31, 39]. Compared to CPUs and other resources, GPUs are considerably more expensive but often underutilized in production clusters, with the reported utilization rates ranging from 25% to below 50% [16, 19, 22, 31].

The primary reason for low GPU utilization is that a large number of ML tasks, mostly inference, cannot fully utilize the capacities of modern GPUs, which have seen exponential performance improvements in recent years. This trend is expected to continue in the foreseeable future [36]. To address this issue, GPU sharing techniques have been developed to enable multiple ML tasks to safely run on a single GPU with guaranteed isolation, where each task is allocated *partial resources* by means of virtualization [9, 13, 27, 33, 35] or the Multi-Instance-GPU (MIG) feature supported in NVIDIA's Ampere architecture [3].

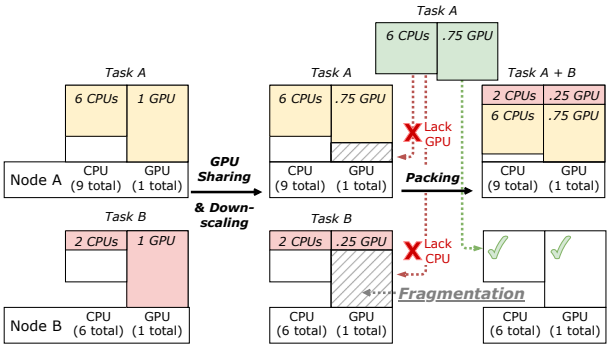

Figure 1: The allocation of partial GPUs results in fragmentation, which can be addressed with packing.

However, simply enabling GPU sharing does not necessarily lead to high utilization. In many cases, allocating partial GPUs results in *fragmentation*, preventing the remaining GPU resources from being allocated. Figure 1 illustrates this problem in a toy example. Consider a cluster of two nodes A and B with ⟨9 CPUs, 1 GPU⟩ and ⟨6 CPUs, 1 GPU⟩, respectively. There are two tasks A and B running on the two nodes, each demanding ⟨6 CPUs, 0.75 GPU⟩ and ⟨2 CPUs, 0.25 GPU⟩, respectively. Without GPU sharing, both tasks are allocated an entire GPU even though they cannot fully utilize it (Figure 1, left). This problem can be addressed by allocating partial GPUs, using the GPU sharing technique (Figure 1, middle). Now supposing another instance of task A arrives, it cannot run on either node even though the cluster has sufficient aggregate GPU resources ($0.25 + 0.75 = 1$ GPU).

GPU fragmentation has been widely observed in our production clusters that support GPU sharing. Figure 2 shows a 7-day trace collected from a 1280-GPU cluster. On average, the aggregate GPU allocations account for 77.6% of the total

*Equal contributions.

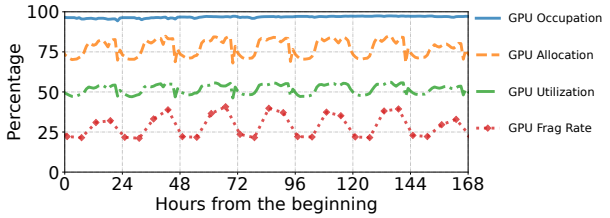

Figure 2: A 7-day trace from a large GPU-sharing cluster. GPU occupation measures the number of GPU devices that are not fully idle; GPU allocation measures the total amount of allocated GPU resources; GPU utilization refers to the proportion of actual GPU resources used by tasks; GPU frag rate is the percentage of unallocated GPU resources that become unusable due to fragmentation (defined in §3.2).

capacity (orange dashed line). These allocations, many being partial GPUs, are distributed across almost all GPU devices (blue solid line), turning 21–42% of the unallocated GPU resources into fragments (red dotted line) that cannot be utilized by the current workload. In general, higher allocations result in more severe fragmentation. In our operational experience, complaints about scheduling failures usually surge in rush hours, although the cluster still has sufficient aggregate idle GPUs, indicating severe fragmentation.

An effective approach to addressing fragmentation is to perform *packing*. Returning to the previous example, the scheduler can instead pack the two original tasks to node A, thereby leaving the entire node B to the new instance of task A (Figure 1, right). A large body of work formulates workload scheduling as a multi-dimensional bin packing problem, in which tasks and nodes are respectively modeled as balls and bins with sizes in multiple resource dimensions, and the goal is to pack balls to the fewest number of bins. Many heuristics have been proposed to schedule cluster workloads, such as best-fit [11, 21, 24, 30], vector alignment scoring [8, 23, 24], and "GPU Packing" [31, 33].

However, our experiments show that none of these heuristics work well in scheduling GPU-sharing workloads (§6). The fundamental reason, we believe, is that the problem is *intrinsically different* from the classic bin packing when a node has multiple GPUs. Consider two natural bin packing formulations. The first is to model a server's multiple GPUs as one large device with the aggregate capacity. This formulation pools together all unallocated GPUs, and the fragments on individual GPUs become irrelevant, which is not the case in reality. Alternatively, one can treat a server's multiple GPUs as different "resource dimensions". Yet, unlike other resources such as CPU and memory, these GPUs are not independent but *interchangeable* for a task that can run on any of them, mandating a new formulation beyond classic bin packing.

In this paper, we develop a novel fragmentation-aware scheduling approach for GPU-sharing workloads. Central to our approach is a new analytical framework that quantifies statistically the degree of GPU fragmentation in a cluster. Given a task, we identify the GPUs on each node that cannot be used to run the task (e.g., lacking sufficient GPU or other resources). These GPUs are *fragmented* from the view of that task as none of their remaining resources can be utilized. Now, consider the *target workload*, which consists of a set of tasks that are of interest (e.g., ML inference and training). We quantify the degree of GPU fragmentation as *the expected number of GPUs that cannot be allocated to a task which is randomly sampled from the target workload*. Intuitively, it measures the expected GPU resources that cannot be utilized by the target workload. We can further break down the fragmentation analysis into different causes, such as the node having insufficient or stranded GPUs, or the mismatch between the workload and the node spec. This analysis provides more insights for the operator to reason about the cluster state (§3).

Based on the GPU fragmentation analysis, we propose a simple, yet effective heuristic to schedule workloads towards the direction of *the steepest descent of fragmentation*, which we call Fragmentation Gradient Descent or FGD. For each GPU task submitted, FGD chooses a node and the available GPU(s) on it to run the task so that the growth of GPU fragmentation caused by this decision is minimized (§4). By doing so, FGD can minimize GPU fragmentation, saving a large amount of expensive resources for more workloads.

We have implemented FGD as a new scheduler in Kubernetes [1] (§5) and evaluated its performance with production and synthesized workload traces on an emulated cluster consisting of more than 1,200 nodes and 6,200 GPUs (§6). FGD consistently outperforms existing packing-based scheduling algorithms in various settings: it reduces the unallocated GPUs by up to 49%, allowing 290 GPUs to be utilized in a large production cluster. Our implementation, including the scheduler and the emulator[1], as well as the trace data[2] used in the evaluation, are available as open-source software.

2 Background and Motivation

In this section, we briefly introduce the GPU sharing technique and illustrate the resulted fragmentation problem through production trace analysis. We discuss the unique scheduling challenge brought by GPU sharing that invalidates the classic bin packing formulation.

2.1 GPU Sharing

Underutilized GPUs. GPU underutilization has been widely observed in production clusters that run diverse ML workloads. Many tech companies report the low GPU utilization averaging between 25% to below 50% [16, 19, 22, 31], which has become a thorny pain point in reducing the total cost of ownership of large GPU clusters.

[1] https://github.com/hkust-adsl/kubernetes-scheduler-simulator
[2] https://github.com/alibaba/clusterdata

There are multiple factors that contribute to the low GPU utilization. Most importantly, thanks to the exponential improvement of GPU performance in recent years, many ML tasks, especially inference, cannot saturate the compute capacity of a modern GPU. Taking the latest A100 GPU as an example, the peak inference speed of a ResNet50 [15] model reaches over 36k images per second [36], far exceeding the usual throughput requirement of an object detection application. In fact, even for training tasks, increasing evidences show that many of them cannot fully utilize a GPU [5, 6, 28, 31, 33, 34, 37].

GPU Sharing. GPU sharing techniques have recently been developed to enable multiple tasks to run on a single GPU with guaranteed performance isolation, where each task is allocated a partial GPU. In production systems, GPU sharing can be implemented at three levels.

1) Framework-level: This approach adds new dynamic scaling mechanisms and sharing primitives to the existing ML frameworks (e.g., TensorFlow, PyTorch, JAX) to allocate each task the exact amount of required GPU memory and compute units [6, 33, 34, 37]. The benefit of this approach is that it can achieve fine-grained sharing between tasks by leveraging their semantics information (e.g., training accuracy and loss), which is available to the framework. On the other hand, it requires users to switch to the modified framework to enable GPU sharing – not all users are willing to do so.

2) Device runtime-level: This approach uses the API remoting technique to implement GPU sharing and virtualization [9, 13, 27, 28, 32]. It deploys a GPU manager on each host. The manager intercepts compute- and memory-related runtime APIs (e.g., `cuLaunchKernel` and `cuMemAlloc` in CUDA Library) to keep track of the compute and memory resources requested by each task. A task's memory allocation request is accepted only when the its allocation is within the specified limit. The manager also controls kernel scheduling to enforce the specified allocation of compute capacity by time-multiplexing the device's compute units between tasks (e.g., a task with 0.1 GPUs is guaranteed to receive at least 10% of GPU time). This approach requires no framework changes or user cooperation.

3) Hardware-assisted: Starting with Ampere architecture, NVIDIA GPUs support the Multi-Instance GPU (MIG) feature. MIG can partition a GPU into as many as seven separate instances [3]. Compared with the software approaches, MIG provides the strongest isolation guarantee as each GPU instance has dedicated resources for compute, memory, and memory bandwidth. On the downside, MIG only supports resource sharing at a coarse granularity and is available exclusively to A100, A30, and H100 GPUs at the moment.

Production Deployment in Our Clusters. At Alibaba, we have developed our own GPU sharing solution based on CUDA Runtime API interception and deployed it in production clusters that run a mixture of training and inference tasks. A task can have one or multiple instances, each running in a container and requesting multiple resources such as CPUs, memory, and GPUs. We observe the GPU requests to be either a partial GPU or full GPU(s), but rarely the combination of both (e.g., 1.5 or 2.3 GPUs). In our implementation, the minimum GPU allocation unit is 0.01 GPUs, in which a task instance is allocated 1% of the GPU memory and *at least* 1% of the GPU time.[3] Tasks and their instances are orchestrated using a customized Kubernetes system [1] with many new features tailored to the production needs. In the following discussions, unless otherwise specified, *we do not differentiate between tasks and instances* as their meanings are usually clear from the context.

2.2 The Prevalence of GPU Fragmentation

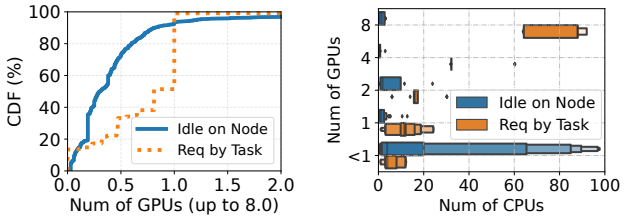
Operational Experience. GPU sharing greatly reduces the number of allocated GPUs for a workload, allowing more tasks to run in a cluster than before. However, as we consolidate more workloads, an increasing number of users complained about the long task wait time or even scheduling failures due to the timeout of pending tasks, although they still have sufficient GPU quotas to spare. In many clusters, the GPU allocation rate can reach 85–90% maximum, leaving hundreds of GPUs unable to utilize. In some extreme cases, pending tasks start to build up when the GPU allocation rate reaches above 80%. All these indicate heavy fragmentation.

Trace Analysis. We perform trace analysis to confirm the fragmentation problem, which occurs when a GPU has *insufficient resources* or becomes *stranded* as the host runs out of the other resources, such as CPU and memory. We choose a highly crowded ML cluster H consisting of 1.2k nodes with over 6.2k GPUs and 107k CPU cores. After scheduling over 7.6k tasks, the GPU (CPU) allocation ratio reaches 92% (75%), which is among the highest in all clusters. At this point, cluster H is fully packed and cannot accommodate new tasks despite having a total of 500 GPUs unallocated, causing a significant resource waste. Figure 3a depicts the distributions of unallocated GPUs on each node and the requested GPUs of each pending task. Around 92% of nodes have < 1 GPU left unallocated (blue solid line), whilst 49% of the pending tasks request ≥ 1 GPU (orange dashed line). Figure 3b gives the boxen plot of the nodes' unallocated CPUs and the tasks' requested CPUs, grouped by their GPU resources. Among the nodes with ≥ 1 unallocated GPU, over 75% have ≤ 10 CPUs left (blue boxes), which are *insufficient* to allocate to most tasks (orange boxes), leaving the unallocated GPUs stranded.

2.3 Inapplicable Bin Packing Formulation

While fragmentation is not a novel problem in cluster management, GPU fragmentation is noteworthy because it (1)

[3] In our system, a task instance can opportunistically use more GPU time if the computing capacity of the said GPU is not exhausted by the other tasks.



(a) CDF of idle and requested GPUs. (b) Boxen of idle and requested CPUs.

Figure 3: Illustration of GPU fragmentation in a fully packed cluster H. (a) Most nodes have insufficient GPUs. (b) Nodes with abundant GPUs are usually in short of CPUs.

inherently differs from other resource fragmentation problem and (2) is aggravated by partial-GPU allocation (Figure 1).

GPU Fragmentation Cannot be Handled Similarly as Other Resources. Fragmentation is a common problem in resource allocation. Taking file allocation as an example, when the disk has no enough contiguous space to store a file, the fragmentation occurs [4], and the solution is to chunk the file into blocks for non-contiguous allocation. However, GPU allocation must be *contiguous*: Consider a task requesting one full GPU, it is not possible to allocate it two partial GPUs (e.g., 0.3 GPUs + 0.7 GPUs).

Partial-GPU Allocation Invalidates Bin Packing Formulation. Bin packing is known effective to address the fragmentation problem [23, 24]. In the standard formulation, tasks and nodes are respectively modeled as balls and bins of sizes in $\mathbb{R}^d$, where d is the number of concerned resources, such as CPU, memory, and GPU. The goal is to pack balls to as fewest bins as possible. However, unless a node has a single GPU, this formulation does not apply to GPU-sharing tasks, which we illustrate through two formulation attempts.

Attempt-1: Treating Multiple GPUs as a Unified Logical Device. This formulation pools together all the available GPU resources of a node into a large logical GPU, leading to a node resource vector such as $\langle 16\text{ CPUs}, 24\text{ GiB memory}, 1.3\text{ GPUs}\rangle$. However, this formulation is problematic as it ignores the *allocation boundary* of physical GPUs, making it unable to differentiate the fragmentation state on each individual device. For example, consider a 2-GPU node with the remaining capacity of 0.4 GPUs and 0.9 GPUs. For a task that requests one full GPU, although in total the node has 1.3 GPUs, neither of its two GPUs has sufficient capacity to run the task, to which both GPUs are fragmented.

Attempt-2: Treating Each GPU as an Independent Resource Dimension. An alternative formulation is to model each GPU on a node as an independent resource dimension, just like CPU and memory. This formulation is also problematic as GPUs are *interchangeable* as long as they have sufficient capacity to run a task. Returning to the previous example and assuming that the node has 16 CPU cores and 24 GiB memory available, its resource vector is $\langle 16\text{ CPUs}, 24\text{ GiB memory}, 0.4\text{ GPUs}, 0.9\text{ GPUs}\rangle$. For a task that requests 2 cores, 8 GiB memory, and 0.3 GPUs, it can run on the node with any of the two GPUs. The task hence has two interchangeable demand vectors $\langle 2\text{ CPUs}, 8\text{ GiB memory}, 0.3\text{ GPUs}, 0\text{ GPUs}\rangle$ or $\langle 2\text{ CPUs}, 8\text{ GiB memory}, 0\text{ GPUs}, 0.3\text{ GPUs}\rangle$. This invalidates the classic bin packing formulation as the balls are now "deformable" and can transform to various sizes.

To summarize, we stress that the inapplicability of bin packing formulation stems from the contiguous GPU allocation requirement and the partial-GPU allocation practice, in which each GPU has its own allocation boundary (Attempt 1) but is also interchangeable to one another (Attempt 2). Through extensive experiments in §6, we will show that none of the existing packing heuristics, including best-fit [11, 21, 24, 30], vector alignment scoring [8, 23, 24], and "GPU Packing" [31, 33], work well in scheduling GPU sharing workload.

3 The Fragmentation Measure

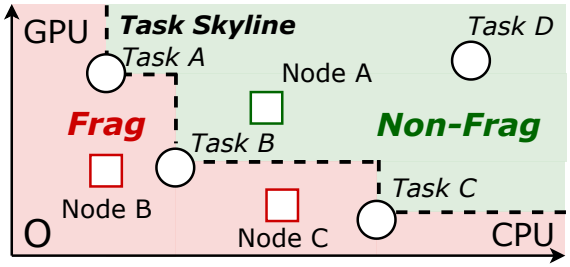
"You keep using that word. I do not think it means what you think it means." — Inigo Montoya, *The Princess Bride*

While the term fragmentation has been frequently mentioned in the existing cluster scheduling works [8, 11, 29, 30, 33, 34, 39, 40], its formal definition and quantitative measure remain unclear. In this section, we answer *what fragmentation is and how can it be measured*. We start with a conventional measure defined in absolute terms and discuss its ineffectiveness (§3.1). We next present a new measure that statistically quantifies the fragmentation degree in a cluster (§3.2). We show in case studies that the new measure can help operators better reason about the cluster state (§3.3).

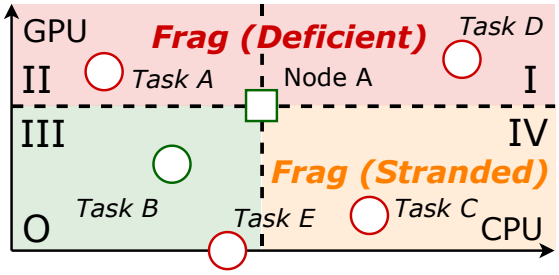
3.1 Fragmentation in Absolute Terms

Basic Assumption. In general, *whether a node has fragmented resources depends on the target workload*. For example, a node with 0.6 GPUs is considered fragmented by a task that requests one full GPU, but not by the one that demands 0.5 GPUs. In this paper, we assume that the target workload, which contains a set of tasks with popularity (e.g., number of instances) following a certain distribution, is known to the cluster. This is reasonable as production ML workloads consist of a large number of recurring tasks [31]. We also assume that each task can request either a partial GPU or full GPU(s), but not both, as mentioned in §2.1.

An Absolute Fragmentation Measure. Although not formally defined, it is commonly accepted that a node is fragmented *if its remaining resources cannot be allocated to run any tasks* in the target workload. In this definition, fragmentation is measured in absolute terms: regardless of task scheduling, the fragmented resources cannot be utilized anyway and are inevitably wasted.



(a) Absolute fragmentation defined by task skyline is defective.



(b) Statistical fragmentation in expectation of randomly sampled tasks.

Figure 4: Fragmentation definition in the example cluster with nodes of various unallocated resources (squares) and tasks of various requested resources (circles).

Figure 4a gives a pictorial illustration. For simplicity, we only consider CPU and GPU resources in a two-dimensional plane. A task is depicted as a circle (ball) with x- and y-coordinates being the requested CPUs and GPUs, respectively. Similarly, a node is depicted as a box (bin) with the two coordinates being the unallocated CPUs and GPUs. In case that a node has multiple GPUs, we map their unallocated capacity (a vector) to a scalar number as follows. Let f be the number of *fully-unallocated GPUs* and p the *maximum unallocated partial GPU*. We map the vector of unallocated GPUs to a scalar $u = f + p$.[4] For example, a 4-GPU node with an unallocated capacity of $\langle 1, 1, 0.5, 0.25 \rangle$ is considered having $u = 2.5$ unallocated GPUs. Under this mapping, a node has sufficient GPUs to run a task that requests g GPUs *if and only if* $u \geq g$, provided that the task requests either a partial GPU or full GPU(s), i.e., $g \in [0,1) \cup \mathbb{Z}^+$.

With nodes and tasks depicted in the resource plane, we see that a node has sufficient GPUs and CPUs to run a task if it is located above and on the right of the task (e.g., node A and task B). We call this region the *non-fragmentation region* of the task. Taking the union of the non-fragmentation regions of all tasks gives the non-fragmentation region of the target workload (the green area in Figure 4a). It encompasses all tasks, with the "innermost" ones (e.g., tasks A, B, and C) located on the region's border which we call the *skyline* [38]. The area below the skyline is the *fragmentation region*, within which a node cannot run any task due to insufficient resources and is thus fragmented (e.g., nodes B and C).

[4]The mapping is not unique. For example, alternatively one can map the capacity vector to $u = \max\{f, p\}$, which serves the same purpose.

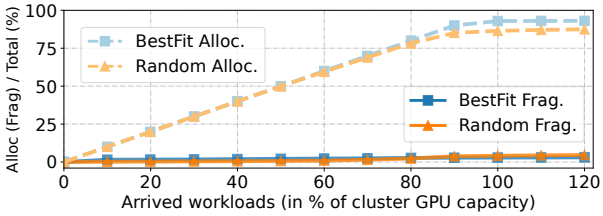


Figure 5: Trace-driven emulations with two scheduling policies (details in §6.1). The x-axis is the cumulative GPU demands of arrived tasks, divided by the total cluster capacity. Fragmentation in absolute terms (lower-right corner) stays at a low level ($< 5\%$) throughout the allocation of arrival workloads, failing to provide useful feedback to the scheduler.

The Inefficiency of the Absolute Measure. Under the absolute measure, resource fragmentation is identified in a rather biased manner. Whether a node is fragmented solely depends on if it has sufficient resources to run a task that is located on the skyline (i.e., the skyline task), whereas the other tasks are irrelevant. Yet, skyline tasks can rarely represent the entire workload. Compared with the other tasks, they request fewer CPUs and/or GPUs, and usually have a small population. In our clusters, only 0.06% of instances belong to the skyline tasks. On average, a skyline task requests $\langle$3.2 CPUs, 0.07 GPUs$\rangle$, as opposed to the average demand of $\langle$9.4 CPUs, 0.9 GPUs$\rangle$. As a result, even if a node has a small amount of resources that cannot be allocated to run the majority of the tasks in the target workload, it may still be considered non-fragmented as long as it can run a tiny skyline task.

For the reasons above, the absolute fragmentation measure cannot be used as a good metric to guide task scheduling. To see this, we run trace-driven emulations with two different scheduling policies (details in §6.1) and depict in Figure 5 the fragmented and allocated GPUs in percentage of the total capacity. The fragmentation measure stays at a low level ($< 5\%$) throughout the process regardless of the scheduling logic and its placement decisions, failing to provide useful feedback to the scheduler. Increased fragmentation is only observed when the cluster starts crowded, by which it is too late for the scheduler to take actions. In fact, even when the cluster becomes fully packed (i.e., the allocation curve flattens when the cumulative GPU demands reach over 100% of the cluster capacity), over 50% of unallocated GPUs are still deemed non-fragmented under the absolute measure.

3.2 A Statistical Fragmentation Measure

We believe a good fragmentation measure should not be defined against a small subset of tasks, but a joint calibration of the entire workload. We hence use a *statistical measure* to quantify the degree of fragmentation. Formally, let M be the target workload in which each task m has popularity p_m.

Without loss of generality, we assume normalized popularity where $\sum_{m \in M} p_m = 1$. Given a node n, $F_n(M)$ denotes the GPU fragmentation measured by workload M, and $F_n(m)$ is the fragmentation measured by a certain task m in the workload. We define the node-level measure as the weighted sum of the task-level, i.e.,

$$F_n(M) = \sum_{m \in M} p_m F_n(m). \quad (1)$$

One can interpret Eqn. (1) as *the expected fragmentation* measured by a task that is *randomly sampled* from the target workload. We next describe how $F_n(m)$ can be computed.

Pictorial Interpretation. From the view of a task, it considers a GPU of a node being fragmented if it cannot be allocated to the task. As a pictorial interpretation, we refer to Figure 4b and consider node A. In case that the node has multiple GPUs, we map their unallocated capacity (a vector) to a scalar representation following the approach described in §3.1. We partition the resource plane into four quadrants with node A at the origin. The node has insufficient resources to run any of the tasks that are located in Quadrants I, II, and IV, among which those in Q-I are in short of CPUs and GPUs (e.g., task D), Q-II in short of GPUs (e.g., task A), and Q-IV in short of CPUs (e.g., task C). From the point of these tasks, the unallocated GPUs are all fragmented, as they either have insufficient capacity (Q-I and Q-II) or become *stranded* due to the lack of CPU resource on the node (Q-IV).

Things become a bit more complex when it comes to Q-III. While the node has sufficient resources to run a task in that quadrant, not every unallocated GPU has enough capacity. For example, on a 4-GPU node with an unallocated capacity of $\langle 1, 1, 0.5, 0.25 \rangle$, the two partial GPUs cannot be assigned to a task that requests 2 GPU, even though the node has sufficient GPU resources. In this case, the two partial GPUs should be counted as being fragmented for the task. More generally, given a task in Q-III, we check each unallocated GPU, and those with insufficient capacity are considered fragmented.

In addition to the four quadrants, tasks can also locate on the x-axis if they request no GPU resource (e.g., task E). For these tasks, all the unallocated GPUs are considered fragmented as none of them can be utilized.

Formal Description. We now give a formal description of the computation of $F_n(m)$, where we consider only GPU and CPU resources. That being said, the fragmentation measure can be easily generalized to a high-dimensional space with more resources such as memory and network.

We start with a few notations. Given a node n with G_n GPUs, denote by $R_n = \langle R_n^{\text{CPU}}, R_{n,1}^{\text{GPU}}, \cdots, R_{n,G_n}^{\text{GPU}} \rangle$ the unallocated resource vector, where $0 \le R_{n,g}^{\text{GPU}} \le 1$ for all GPU g. Let R_n^{GPU} be the scalar representation of the unallocated GPU vector, which is defined as the number of fully unallocated GPUs plus the maximum partial GPU ($u = f + p$ in §3.1), i.e., $R_n^{\text{GPU}} = \sum_g \lfloor R_{n,g}^{\text{GPU}} \rfloor + \max_g (R_{n,g}^{\text{GPU}} - \lfloor R_{n,g}^{\text{GPU}} \rfloor)$. For each task m, denote by $D_m = \langle D_m^{\text{CPU}}, D_m^{\text{GPU}} \rangle$ the resource demand vector, where $D_m^{\text{GPU}} \in [0, 1) \cup \mathbb{Z}^+$. We compute $F_n(m)$ in the following three cases.

Case-1 (Q-I, Q-II, and Q-IV): Task m cannot run on node n due to the lack of CPU or GPU resources, i.e., $D_m^{\text{CPU}} > R_n^{\text{CPU}}$ or $D_m^{\text{GPU}} > R_n^{\text{GPU}}$. In this case, all the unallocated GPUs are considered as fragments by task m. We have

$$F_n(m) = \sum_{1 \le g \le G_n} R_{n,g}^{\text{GPU}}. \quad (2)$$

Case-2 (Q-III): Task m can run on node m and has a GPU request, i.e., $D_m^{\text{CPU}} \le R_n^{\text{CPU}}$ and $0 < D_m^{\text{GPU}} \le R_n^{\text{GPU}}$. In this case, we check each unallocated GPU and those with insufficient capacity are identified as fragment in the view of task m. Note that if m requests one or more GPUs, all partial GPUs cannot be allocated and are hence fragmented. We have

$$F_n(m) = \sum_{1 \le g \le G_n} R_{n,g}^{\text{GPU}} \mathbb{1}(R_{n,g}^{\text{GPU}} < \min\{D_m^{\text{GPU}}, 1\}), \quad (3)$$

where $\mathbb{1}(\cdot)$ is an indicator function that returns 1 if the given condition holds, and 0 otherwise.

Case-3 (x-axis): Task m requests no GPU, i.e., $D_m^{\text{GPU}} = 0$. In this case, all the unallocated GPUs are deemed fragments by task m, as none of them can be utilized. We have $F_n(m)$ computed the same way as in Eqn. (2).

In essence, $F_n(m)$ measures the amount of available GPUs on node n that cannot be allocated to task m. Taking the expectation of $F_n(m)$ with respect to the popularity distribution of tasks (see Eqn. (1)), we obtain $F_n(M)$, which measures the unallocated GPU resources on node n that are *expected to be fragmented* (hence wasted) from the viewpoints of the entire workload M.

Fragmentation Rate. Once $F_n(M)$ is obtained, we compute the node's *fragmentation rate* as the ratio between the amount of fragmented GPUs and the unallocated GPUs, i.e.,

$$f_n(M) = \frac{F_n(M)}{\sum_{1 \le g \le G_n} R_{n,g}^{\text{GPU}}}. \quad (4)$$

Intuitively, Eqn. (4) measures the severity of GPU fragmentation on a node.

Cluster-Level Fragmentation Measure. Given a cluster N and the target workload M, the cluster-level GPU fragmentation, denoted by $F_N(M)$, is the aggregate fragmentation of all nodes n in N, i.e.,

$$F_N(M) = \sum_{n \in N} F_n(M). \quad (5)$$

Normalizing $F_N(M)$ by the unallocated GPUs in the cluster gives the fragmentation rate of the cluster, i.e.,

$$f_N(M) = \frac{F_N(M)}{\sum_{n \in N} \sum_{1 \le g \le G_n} R_{n,g}^{\text{GPU}}}. \quad (6)$$

(c) Frag rate among various nodes. (d) Stranded frag rate among nodes.

Figure 6: Distribution of node fragmentation and CPU-to-GPU ratio of node and task in the fully packed cluster *H*.

3.3 Fragmentation Analysis in Action

The fragmentation measure described above can help operators better reason about the cluster state. To demonstrate its practical utility, we perform fragmentation analysis in various production clusters.

High Fragmentation Blocks Further Allocation. We reexamine a production cluster *H* previously described in §2.2. For each node, we measure its GPU fragmentation rate (Eqn. (4)) and depict the distribution in Figure 6a (red dash-dotted line). We observe that 25% of the nodes have GPUs fully allocated and are free of fragmentation, while the other 75% nodes measure over 99% fragmentation rate. This explains why the cluster cannot run any tasks even if it still has a capacity of 500 unallocated GPUs.

Breakdown Analysis of the Fragmentation Causes. Using the quadrant interpretation descried in §3.2, we can break down the fragmentation of a node into different causes: (1) having insufficient CPUs and GPUs to run tasks in Q-I (Figure 4b); (2) having insufficient GPUs to run tasks in Q-II, some GPU-sharing tasks in Q-III, and tasks that request different types of GPUs (not shown in Figure 4b); (3) having insufficient CPUs to run tasks in Q-IV (stranded GPUs); (4) running non-GPU tasks (x-axis) on a GPU node.

Figure 6a attributes the fragmentation rate to different causes and depicts their distributions. We see that the high fragmentation is primarily caused by the node lacking sufficient CPU and GPU resources (green dashed line), followed by lacking GPUs only (orange dotted line). This suggests that in cluster *H*, the allocation of CPUs and GPUs are relatively balanced. But still, a small number of nodes (4.6%) attribute stranded GPUs as the dominant factor (over 80%) of fragmentation (blue solid line).

Impact of CPU-to-GPU Ratio. In our analysis, we are interested in knowing which nodes are more likely to become fragmented and find the CPU-to-GPU ratio a good indicator. Figure 6b compares the CPU-to-GPU ratio of the node specs and the task requests. On one hand, 65% nodes (tasks) have (request) $\leq$ 16 CPUs per GPU, for which it is a good match between the node specs and workload demands. On the other hand, the cluster workload also contains 13% non-GPU tasks (with an infinite CPU-to-GPU ratio), and they account for 23% of all CPU requests. The existence of non-GPU tasks renders nodes with low CPU-to-GPU ratios more likely to become fragmented, especially with stranded GPUs.

Figure 6c correlates the fragmentation rate with the node's CPU-to-GPU ratio. Among the nodes with CPU-to-GPU ratio $\leq$ 16, 80% of them measure high fragmentation rate over 98% (dark red lines near the bottom). This proportion drops to only 47% when it comes to the nodes with 52 CPUs per GPU (light blue lines in the center). As for the fragmentation caused by stranded GPUs, Figure 6d shows that they are more commonly observed on the low-CPU nodes (e.g., 8 or 12 CPUs per GPU). We therefore recommend adding more high-CPU nodes to the cluster for reduced fragmentation and improved utilization.

Fragmentation in a Less-Crowded Cluster. Fragmentation is not a unique problem to fully packed clusters. Referring back to Figure 2, we measured the the cluster-wide fragmentation rate (Eqn. (5)) between 21% and 42% in a 1280-GPU cluster in a normal (off-peak) period with 77.6% average GPU allocation rate. Breakdown analysis further shows that 60% of the fragmentation was caused by GPU shortage. This highlights the importance of reducing fragmentation by packing existing GPU tasks, even in periods where the cluster is less crowded. Additionally, non-GPU tasks contributed only 13% to fragmentation in this cluster.

Running CPU Workloads in GPU Clusters. Our fragmentation analysis has also identified a pathological case. We have observed in a large cluster *B* consisting of 6.4k GPUs and 750k CPU cores, there were 84% of tasks requesting no GPU, resulting in many pending GPU tasks when the GPU and CPU allocation ratios reached only 80% and 86%, respectively. This led to the waste of 1.2k GPUs, with 95% of them considered being stranded. The main cause of this issue was *the lack of CPU reservation on GPU nodes* when scheduling non-GPU tasks. To address this problem, we recommend migrating non-GPU tasks to CPU nodes or even CPU clusters in order to decrease fragmentation and improve resource utilization. However, implementing this solution requires coordination and collaboration in areas such as scheduling, quota design, admission control, and capacity planning.

4 Fragmentation Gradient Descent

The fragmentation measure not only helps operators reason about the cluster state, but can also be used to guide task scheduling. In this section, we present the Fragmentation Gra-

dient Descent (FGD) algorithm that schedules tasks towards the direction of the steepest descent of fragmentation (§4.2), thereby achieving the maximum GPU allocation rate. We start with a description of the scheduling problem (§4.1).

4.1 Online Task Scheduling

We consider a GPU cluster managed by a container orchestration system such as Kubernetes [1] and Borg [30], in which tasks are submitted as pods and maintained in a queue. In its simplest form, tasks are scheduled in a first-come-first-served (FCFS) manner. For each task pod, the scheduler finds the best node and, if necessary, GPU(s) for it to run on. If no node can be assigned, the pod remains unscheduled and is pending for another scheduling attempt (e.g., placed to the end of the queue after a certain timeout). This formulates an *online scheduling problem*, in which tasks are revealed sequentially to the scheduler for placement decision making.

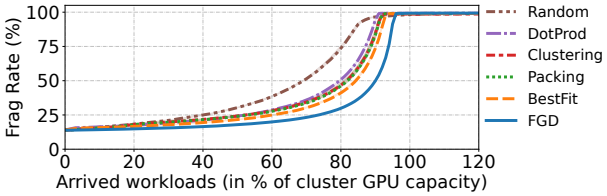
Fragmentation as a Metric. Each time a pod is assigned to a node, the remaining resources decrease, moving the node closer to the origin in the resource plane (Figure 4b). As a result, the fragmentation region (Q-I, Q-II, and Q-IV) expands and the fragmentation rate grows. Figure 7a depicts the growing fragmentation rate as the arriving tasks are scheduled under different policies in our trace-driven emulations (details in §6.1). Compared with the absolute measure (§3.1), the fragmentation rate is more sensitive to the placement decision and can be used as an indicator of the scheduling quality: higher fragmentation rate suggests a poorer scheduling decision.

Unlike the fragmentation rate, the fragmentation amount has no clear trend of growing or decreasing, as shown in Figure 7b. This is because by Eqn. (5), it is the product of the fragmentation rate and the unallocated GPUs – whilst the former grows as more tasks are scheduled, the latter decreases. Also note that the fragmentation starts with 13% of the total GPU capacity – all attributed to non-GPU tasks – but ends up at different degrees under different policies when the cluster is fully packed. At that point, all unallocated GPUs are fragmented (100% fragmentation rate in Figure 7a).

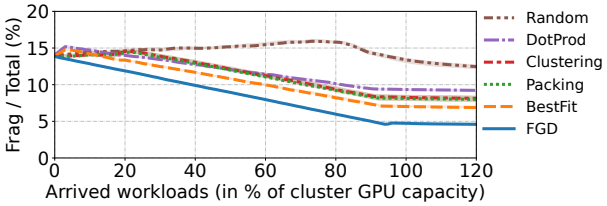
4.2 FGD Algorithm

Key Insight. From the previous discussions, we see that an effective approach to minimizing fragmentation is to *suppress the growth of fragmentation rate as much as possible*. This can be achieved by scheduling tasks towards the steepest descent of fragmentation, a heuristic called Fragmentation Gradient Descent or FGD.

Algorithm Description. Algorithm 1 formalizes the description of FGD scheduling. Given a task (pod) to schedule, the scheduler first filters out all the unavailable nodes with insufficient resources or unsatisfied placement constraints (lines 3–4), such as the lack of requested GPU types. The scheduler



(a) Fragmentation rate grows to 100% as more resources are allocated.



(b) Percentage of fragmented GPUs to total resources under our measure. It reveals the differences between various strategies from the early stage.

Figure 7: FGD pursues the lowest fragmentation among various policies in scheduling production workloads (more results under the same experiment settings are shown in Figure 9).

then *hypothetically* assigns the task to each node and calculates the increment (can be negative) of fragmentation that would be caused by each assignment. In case a task requests a partial GPU, the hypothetical assignment needs to try each GPU as well (line 6). Note that the hypothetical assignment can be performed *in parallel* for acceleration (lines 2–7). The scheduler finally assigns the task to the node (and the GPU) that causes the minimum increment of fragmentation (line 9).

Complexity and Scalability. FGD has a low computational complexity and scales to a large cluster. For a cluster with N nodes, the score of each node can be evaluated *in parallel* (Algorithm 1 line 2) and the scheduler simply selects the minimum. Besides, the scale of M is also limited since it only represents the number of *distinct* task resource requirements (e.g., 80 among 7.6k tasks). In our evaluation (§6), each scheduling decision can be made in *hundreds of milliseconds* on a cluster of $N = 1.2k$ nodes.

A Running Example. To better illustrate the scheduling process of FGD, we refer to Figure 8 for a running example. Consider a node with $\langle 0.5, 1\rangle$ unallocated GPUs. The target workload has three tasks with equal popularity, each requesting 0.3 GPUs (task-A), 0.5 GPUs (task-B) , and 0.7 GPUs (task-C). Originally, only GPU-A is considered fragmented (by task-C only). It thus measures the fragmentation of $0.5 \times 1/3 = 1/6$ GPUs. Assume that task-A arrives first. Assigning it to GPU-A increases the fragmentation to 0.2 GPUs whereas assigning it to GPU-B results in no increase. FGD hence assigns task-A to GPU-B, leaving the node with $\langle 0.5, 0.7\rangle$ unallocated GPUs. Next for task-B, FGD assigns it to GPU-A, reducing the fragmentation to 0. In comparison, assigning it to GPU-B would increase the fragmentation by 0.2 GPUs. Finally for task-C, it has no choice but to run on GPU-B, the only GPU with the sufficient capacity.

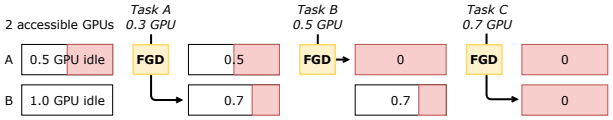


Figure 8: A running example of FGD scheduling. The target workload contains three tasks with equal popularity.

Algorithm 1: Task scheduling of FGD

Input : Cluster N, incoming task m, target workload M
Output : Assigned node n^*

Initialize node score set $\mathcal{S} \leftarrow \varnothing$, and output $n^* \leftarrow \varnothing$.
parallel for *node* $n \in N$ **do**
  if *Insufficient resources* $\|$ *constraints not met* **then**
    Return ▷ Filter out unavailable nodes
  $n^- \leftarrow \text{AssignTaskToNode}(m,n)$ ▷ Hypothetically
  $\Delta \leftarrow F_{n^-}(M) - F_n(M)$ ▷ Fragmentation increment
  $\mathcal{S} \leftarrow \mathcal{S} \cup (n,\Delta)$
if $\mathcal{S} \neq \varnothing$ **then**
  $n^* \leftarrow \arg\min_{n \in \mathcal{S}} \Delta$ ▷ pick the node with the least Δ.

As FGD considers both the resource availability and task distribution, it exhibits distinct behavior compared to other scheduling algorithms. Back to the provided example, for task-A scheduling, the best-fit (and similar bin packing policies) would prioritize GPU-A (0.5 GPUs idle) over GPU-B (1 GPU idle), whereas for task-B scheduling, the worst-fit (and other load-balancing policies) would choose GPU-B (0.7 GPUs idle) over GPU-A (0.5 GPUs idle). These policy preferences diverge from the scheduling choices made by FGD.

5 System Implementation

We have implemented a prototype scheduling system on top of Kubernetes v1.25.0 [1] in over 10k lines of Go codes. Our system consists of two main components: a standalone scheduler and an event-driven emulator.

A Standalone Scheduler. Kubernetes provides a pluggable architecture called the *scheduling framework* [2] for developers to implement a customized scheduler. Following this standard approach, we have implemented FGD and many other scheduling policies as individual score plugins. The scheduler listens for task creation events from the Kubernetes API server and maintains a queue to cache submitted tasks which are scheduled on a first-come-first-served basis.

Also, to enable fine-grained GPU allocation, which is not supported by native Kubernetes, we have implemented a *GPU-sharing* plugin to manage GPU resources. It filters out nodes with insufficient GPUs or mismatched GPU types, assigns tasks to the node with the *highest* scheduling score, and keeps track of the allocatable GPU resources on each node.

Event-Driven Emulator. The event-driven emulator interacts with the API server to manage the creation and deletion of nodes and tasks. It supports two modes: *high-fidelity simulation*, which can receive production traces as input and simulate the scheduling process in a large cluster consisting of tens of thousands of GPUs within a few hours; and *real deployment*, which can take over a production cluster with valid certificates and create task pods on real nodes. The goal of our system is to study the packing efficiency and resource fragmentation of different scheduling policies, which are critical in large clusters. Although it is not possible to perform experiments on real clusters with thousands of nodes, we use the *high-fidelity simulation* mode in our evaluation. This mode uses real traces as input and simulates task placements and resource allocations based on the scheduling logic, which yields the same scheduling results as real deployment.

6 Evaluation

In this section, we conduct extensive experiments to demonstrate the effectiveness of our scheduling policy FGD. We first compare FGD with several state-of-the-art mechanisms in scheduling production workloads (§6.2). Further, we examine the generality of FGD in various scenarios, covering a variety of traces featured by GPU-sharing (§6.3), multi-GPU (§6.4), GPU-type-constrained (§6.5), and non-GPU tasks (§6.6).

6.1 Methodology

Baselines. We compare FGD with five state-of-the-art heuristic policies for scheduling GPU workloads:

1. Best-fit (BestFit) [11,21,24] assigns tasks to the node with the least remaining resources, computed as the weighted sum of all resource dimensions.
2. Dot-product (DotProd) [8, 23, 24] allocates tasks to the node with the smallest dot-product value between the node's remaining resources and the task demands.
3. GPU Packing (Packing) [31] prioritizes task assignment to occupied GPUs, followed by idle GPUs on occupied nodes, and finally to fully idle nodes. The intuition is to reserve available resources for multi-GPUs tasks.
4. GPU Clustering (Clustering) [33] packs the tasks of the same GPU request together (GPU-sharing tasks are packed together). It avoids heterogeneous distribution of task resource requirements on the same node.
5. Random-fit (Random) distributes the task randomly to any node that meets the requirements for load balancing.

Since most of the policies above provide no native support of GPU-sharing workloads, we made some simple extensions as follows: 1) GPU resources of multi-GPU nodes are summed up as one dimension; 2) GPU-sharing tasks scheduled to a node are placed on the available GPU with the least remaining resources (i.e., BestFit); 3) multi-resource vectors are normalized by the maximum node capacity in the cluster.

GPU Request per Task	0	(0, 1)	1	2	4	8
Task Population (%)	13.3	37.8	48.0	0.2	0.2	0.5
Total GPU Reqs. (%)	0	28.5	64.2	0.5	1.0	5.8

Table 1: Distribution of tasks in the traces of cluster H.

Monte-Carlo Workload Inflation and Metrics. To assess the cluster's ability to accommodate workload under a given scheduling policy, we employ the Monte-Carlo *workload inflation* approach [29]. Specifically, we repeatedly submit tasks to the cluster for scheduling until they no longer fit. The tasks are randomly sampled from the traces with replacement [12], along with their resource requests and scheduling constraints. We repeatedly conduct each experiment 10 times and report the average and standard deviation of the key metric—the percentage of unallocated GPUs in the cluster when cumulative GPU requests reach 100% of the cluster capacity[5].

6.2 Allocation of Original Production Traces

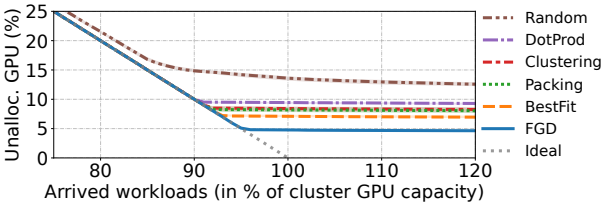
To evaluate the performance of different scheduling policies, we emulate the scheduling of over 8k tasks on the heterogeneous cluster H (§2.2) with 6.2k GPUs. As shown in Table 1, the majority tasks are the 1-GPU and GPU-sharing ones. Despite the small population of 8-GPU tasks, they still occupy a non-negligible portion in terms of requested GPUs (5.8%).

FGD Saves More Unallocatable GPUs. Figure 9a illustrates how the unallocated GPUs in the cluster decrease as tasks arrive under different scheduling policies. Ideally, the arrived tasks should be scheduled successfully until all GPUs are allocated (gray dotted line). However, in practice, the fragmentation rate also increases with the allocation of arrived tasks (Figure 7a). After a certain point when the fragmentation rate reaches 100%, all unallocated GPUs become fragmented and the allocation rate plateaus at a certain level, depending on the used scheduling policy (e.g., DotProd at 90%). Compared to classic scheduling policies, FGD achieves the highest allocation rate and reduces wasted GPUs by 33–49%, which translates to the additional allocation of 150–290 GPUs.

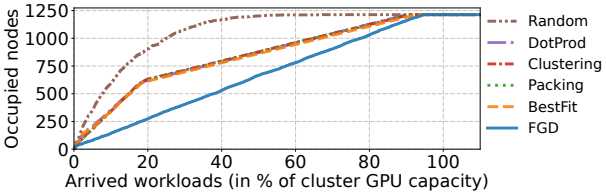
FGD Occupies Fewer Nodes in Scheduling. Figure 9b shows how the number of nodes that have at least one task running (occupied nodes) grows during the scheduling process under different policies. We observe that FGD packs tasks onto nodes whenever possible, leading to the fewest occupied nodes among all policies. Especially in early stages when the GPU allocation rate is 20%, FGD requires 55–70% fewer nodes to host all the tasks compared to other policies. As a result, FGD can enable significant savings in energy consumption (on premises) or operational cost (on clouds).

FGD Schedules More GPU-Sharing and One-GPU Tasks.

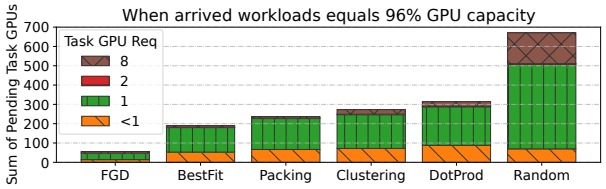
[5] Although a slight decrease in unallocated GPUs may still occur thereafter (thanks to few tiny tasks), the cluster is oversubscribed and rejects the majority of incoming tasks; this is not a desirable state to be considered in our metric.



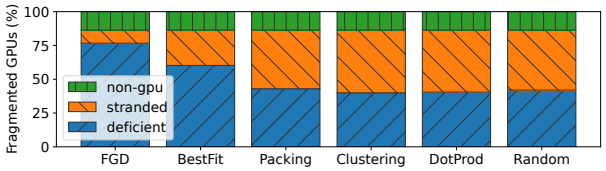
(a) The percentage of unallocated GPUs given arriving workloads.



(b) The number of GPU nodes occupied during the scheduling.



(c) GPU requests of failed tasks when the cluster is almost full (i.e., cumulative GPU requests reach 96% of the cluster capacity).



(d) The breakdown of GPU fragmentation into three causes.

Figure 9: Performance comparison of FGD and various scheduling policies. FGD outperforms all baselines with fewer unallocated GPUs and failed tasks.

Figure 9c depicts the distribution of GPU requests of unscheduled tasks under different policies when the cluster is almost full (i.e., the cumulative GPU requests of arrived tasks reach 96% of the cluster capacity). Except for Random, all policies schedule multi-GPUs tasks well. Compared to classic policies, FGD schedules up to 5.9× GPU-sharing tasks and 6.6× one-GPU tasks while reserving multi-GPU slots.

Early Detection of Fragmentation. Being able to detect fragmentation early on is the key to improving the GPU allocation rate. Referring back to Figure 7a, we see that FGD consistently achieves the lowest fragmentation rate among all policies, indicating better scheduling quality. As tasks arrives, the advantage of FGD becomes larger. When the cumulative requests grow to 90% of the total capacity, although most policies can still successfully schedule tasks, FGD outperforms alternative policies with 24–44% lower fragmentation rate. Figure 9d further decomposes the fragmented GPUs generated by each scheduling policy. It shows that $< 10\%$ of the fragmented GPUs by FGD come from stranded resources,

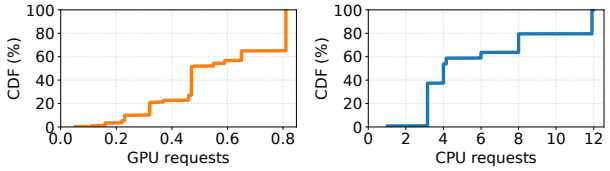


Figure 10: Distribution of resource requests of GPU-sharing tasks in cluster *H*.

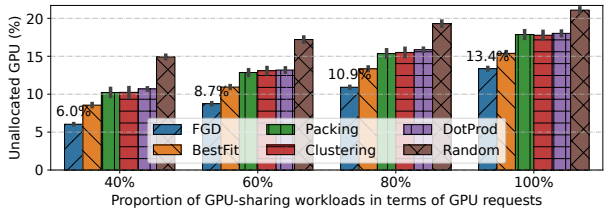

Figure 11: Scheduling results when the traces contain a varying number of GPU-sharing tasks. Y-axis shows the percentage of unallocated GPUs when the overall GPU requests of the arrived tasks reach 100% of the cluster's GPU capacity (same for the following figures).

which is 63–79% fewer than other policies. This confirms that reducing the amount of stranded resources provides better packing efficiency, which is in line with Borg's insights [30].

6.3 Allocation of More GPU-Sharing Tasks

GPU-sharing techniques enable finer-grained resource allocation. For GPU-sharing tasks, their resource requests are typically based on the actual usage of model execution. Figure 10 depicts the CDF of resource requests of GPU-sharing tasks. We observe that around 35% of GPU-sharing tasks request 0.8 GPUs, while no more than 5% tasks request less than 0.2 GPUs. This indicates that fractional GPUs (i.e., GPUs with partial resources allocated), after scheduling 0.8-GPU tasks, will mostly become fragmented. Nonetheless, there are still many packing combinations of tasks that can effectively maximize the use of shared GPUs. For example, 0.32-GPU tasks and 0.65-GPU tasks account for nearly 10% tasks, respectively—they can be placed together to reduce fragmentation.

FGD Tailors Resources for GPU-Sharing Tasks. To evaluate the impact of GPU-sharing tasks on scheduling, we construct different experimental settings based on production traces (§6.2), increasing the proportion of GPU-sharing tasks while keeping their resource requests in line with the original distribution. Fragmented GPUs increase as the proportion of GPU-sharing tasks rises (Figure 11). FGD considers the chances that remaining resources after packing can be utilized and tailors proper resources for subsequent tasks (Figure 8). It outperforms the other policies in all cases; even when the cluster has only GPU-sharing tasks, FGD reduces the unallocated resources of 125–290 GPUs.

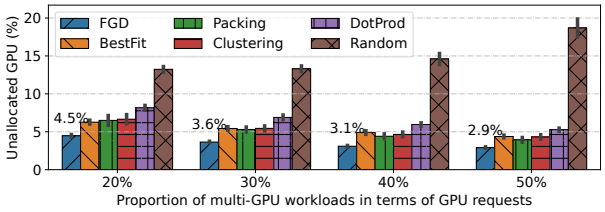

Figure 12: Various proportions of multi-GPU tasks.

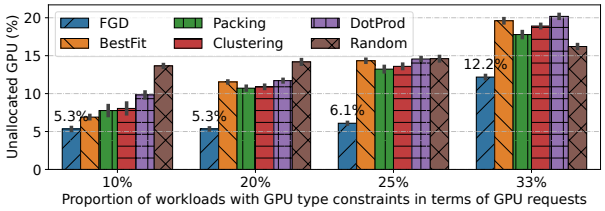

Figure 13: Proportions of task with GPU-type constraint.

6.4 Allocation of More Multi-GPUs Tasks

To better understand the scheduling impact of multi-GPUs tasks, we artificially adds more of them to the input workload, increasing their GPU requests from 20% to 50% of the overall demands. Figure 12 shows the scheduling results given by different policies. We observe that all policies except Random perform well when the workloads contain more multi-GPUs tasks. The reasons are two-fold: (1) As the population of multi-GPUs tasks increases, the scheduling impact caused by GPU-sharing tasks becomes less significant, making the classic multi-resource bin packing algorithms more effective. (2) Reserving multi-GPUs slot is desirable due to the presence of multi-GPU tasks. Compared to other scheduling policies, FGD avoids stranded resources and judiciously reserves GPU cards on nodes, reducing unallocated GPUs by 26–45% even when the multi-GPU tasks account for 50% of GPU requests.

6.5 Allocation of Tasks with GPU Constraints

In previous experiments, we have mainly considered fragmentation caused by *mismatches of resources*. Yet, production tasks also have placement constraints of desired GPU type. They typically request high-end GPUs for better performance; models are sometimes optimized for a specific generation of GPU. In our clusters, around 33% of GPU tasks have specified desired GPU types, while the rest can run on any GPUs. Heterogeneous GPUs in a cluster are often unevenly distributed, posing a challenge to resource scheduling.

Figure 13 shows the performance of different policies with varying numbers of tasks that specify GPU-type constraints. Classic heuristic policies only consider the alignment of resource demands, which is likely to cause severe fragmentation. In comparison, FGD reduces 32–40% of fragmented GPUs when tasks with GPU-type constraints account for 33% of the total GPU requests. FGD selectively reserves popular GPUs to avoid fragmentation caused by mismatches of GPU types.

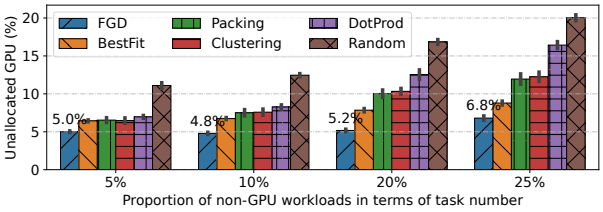

Figure 14: Various proportions of non-GPU tasks.

6.6 Allocation of More Non-GPU Tasks

In GPU clusters, there are often many tasks that request no GPU but other resources, such as CPU, memory, and disk. Examples include parameter servers and data processing tasks. These non-GPU tasks are usually not resource-intensive. Yet, if scheduled unwisely, they may cause some GPUs to become stranded. To evaluate their impact to scheduling, we vary the number of non-GPU tasks and compare the performance of different scheduling policies in Figure 14. FGD consistently maintains the unallocated GPUs at a low level, demonstrating its strong capability of avoiding stranded resources when making scheduling decisions. In fact, as the proportion of non-GPU tasks increases from 5% to 20%, fragmented GPUs caused by FGD increase by $< 3\%$ while other policies increase fragmentation by 18–45%.

7 Discussion

Scheduler Independence of Fragmentation Metrics. Our proposed fragmentation metric quantifies how fragmented the current cluster is considering only the next incoming task. This narrow focus ensures *scheduler independence*. Specifically, if we consider two or more incoming tasks, each node would need to determine the likelihood that the first task has consumed its resources when assessing the fragmentation measured by the second task. This determination would involve the scheduling policy. In contrast, our one-step fragmentation metric determines if a node is fragmented based solely on whether its remaining resources can be fully utilized by the next task, agnostic to the scheduler or other nodes.

Combining with Other Heuristics. Guided by the one-step fragmentation metric, schedulers may perform suboptimally in early stages when the cluster has abundant resources and little fragmentation is observed. However, the fragmentation-guided scheduling heuristic can be combined with other heuristics to navigate this initial period. For example, the scheduler could fall back to a best-fit approach if no increase in fragmentation is detected.

8 Related Work

Resource Fragmentation. Many research works address resource fragmentation in clusters [8,29,30,39,40]. For example, Tetris [8] shows that fair schedulers usually result in fragmented resources and delayed job completion, and proposes to combine them with an alignment-based policy. Borg [30] uses a hybrid scoring model to reduce the amount of stranded resources. HiveD [39] eliminates external fragmentation across multiple tenants by constructing virtual clusters. However, these works do not give a formal definition of fragmentation. We propose a statistical measure to quantify the degree of resource fragmentation and use it to guide task scheduling.

Multi-Resource Bin Packing. Resource allocation is often formulated as a multi-dimensional bin packing problem, which has been extensively studied [24]. Many heuristic policies, such as best-fit, vector alignment scoring (dot-product), are proven effective with high packing efficiency for scheduling big data analytics workloads [8] and virtual machines consolidation [11, 23]. However, it can be observed from our experiments that they do not work well in GPU sharing scenarios. Our work advocates resource allocation from the perspective of mitigating fragmentation, which can further reduce wasted resources.

GPU Cluster Scheduling. Recent works on GPU scheduling concern various objectives, such as cluster utilization [21, 32–34, 37, 40], job completion time [10, 18, 25, 26], job performance [22], and fairness [7, 20]. Although some research efforts (e.g., Gandiva [33], Salus [37], AntMan [34], TGS [32]) exploit GPU sharing techniques to improve resource *utilization*, they do not address GPU fragmentation. Our work complements them by reducing fragmentation and improving the GPU allocation rate.

9 Conclusion

In this paper, we have identified the significant fragmentation problem caused by GPU-sharing workloads that are increasingly deployed in production clusters. To address this problem, we have proposed a novel metric to statistically quantify the degree of GPU fragmentation caused by various sources. Based on this measure, we have proposed a simple, yet effective scheduling approach, named Fragmentation Gradient Descent (FGD), that schedules tasks towards the direction of the steepest descent of GPU fragmentation. Large-scale trace-driven emulations show that FGD substantially achieves higher GPU allocation rate compared to existing packing-based heuristics, saving hundreds of GPUs.

Abstract

Iterative relational algebra (RA kernels in a fixed-point loop) enables bottom-up logic programming languages such as Datalog. Such declarative languages are attractive targets for high-performance implementations of relational data analytics in fields such as graph mining, program analysis, and social-media analytics. Language-level constructs are implemented via high-performance relational algebra primitives (e.g., projections, reorderings, and joins). Such primitives would appear a natural target for GPUs, obtaining high throughput on large datasets. However, state-of-the-art Datalog engines are still CPU-based, scaling best between 8–16 threads. While much has explored *standalone* RA operations on the GPU, relatively less work focuses on *iterative* RA, which exposes new challenges (e.g., deduplication and memory management). In this short paper, we present a GPU-based hash-join implementation, leveraging (a) a novel open-addressing-based hash table implementation, (b) operator fusing to optimize memory access and (c) two variant implementations of deduplication. To evaluate our work, we implement transitive closure using our hash-join-based CUDA library and compared its performance against cuDF (GPU-based) and Soufflé (CPU-based). We show favorable results against both, with gains up to 10.8× against cuDF and 3.9× against Soufflé.

1 Introduction

High-performance iterative relational algebra (RA) has the potential to automatically extract massive data-parallelism from applications built on top of bottom-up logic programming languages such as Datalog [2, 6, 9, 21, 38]. Datalog is a *declarative* logic programming language that has been applied to a wide variety of applications such as big-data analytics [17], graph mining [26, 33], and program analysis [5, 34]. The goal of declarative languages is for a user to provide a few understandable and compact rules that define a solution while the language automatically extracts an operational approach for computing the solution. Standard bottom-up Datalog solvers do just this: rules are implemented via standard RA operations and combined into kernels that infer new facts from discovered facts in a fixed-point loop.

Modern Datalog applications scale to extreme input-relation sizes (billions of rows/facts, tens of gigabytes of data), and thus highly parallel implementations are increasingly valuable. Unfortunately, however, modern CPU-based Datalog implementations have hit scalability walls due to their use of locking shared-memory data-structures—in our experiments, scalability for Soufflé (a best-in-class solver) peaks at roughly 16 threads. By contrast, modern GPUs offer (tens of) thousands of data-threads of computation in their high-throughput SIMD architecture. While there has been a plethora of work discussing implementation of standalone joins [20, 24, 30–32, 36] on the GPU, not much work tackles the problem of iterative joins, especially in the context of the modern GPU architectures. Iterative joins, fused with other relational operations such as union and projection, needed in the context of Datalog engines, add extra layers of complexity such as having to deal with low-level memory management, performing deduplication and mantainance for index data structures.

In this paper, we present key innovations which have allowed us to build scalable GPU-based implementations of Datalog-style declarative programs. Specifically, we implement the classic Datalog problem of finding all reachable paths (i.e., transitive closure) of a graph—a simple case of feature extraction. This problem entails implementing joins along with other RA operations like union and projection iteratively in a fixed-point loop. With this work, we make an important first step towards developing a complete GPU based datalog engine. Specifically, we make the following novel contributions to literature:

1. Developed a high-performance GPU-based hash table tailored to relational data; the hash table is used to accomplish binary hash joins between relations.
2. Implemented RA-operation fusion (e.g. join and projection) to improve memory and computation footprint.
3. Implemented deduplication using two techniques (a) sort

and unique (using thrust [4]), and (b) merge (two sorted lists) and unique. Both, key in facilitating iterative RA.

4. Evaluated our performance by comparing it against state of art openMP-based implementation, Soufflé and a cuDF implementation. We outperform both for almost all graphs and achieve speedups up to 3.9× over Soufflé and up to 10.8× over cuDF.

2 Related Work and Background

RA on GPUs Previous efforts in parallelizing RA have mostly focused on stand-alone implementations of select few RA primitives, such as join. Join is the most complex primitive to implement as its output size is not known in advance and depends on the characteristics of the input data and relations must be sorted, or stored in an index, for efficient joins to be possible. The most common algorithms for implementing joins are hash-joins and merge-sort join [3]. These algorithms have been extensively studied for shared memory systems, being parallelized for both GPUs [16, 19, 20, 24, 30–32, 36] and multi-core CPUs using openMP [23]. MPI-based distributed join operations have also shown promise in several recent studies [10, 13, 14, 25, 26]. However, unlike distributed join implementations, most extant GPU-based implementations do not maintain an order in their relations [39]. This poses a problem in some iterated relational algebra algorithms (such as transitive closure computation) as they require the join results to be sorted. If join results are sorted by default, we can avoid costly operations like sorting the entire result at each iteration of the algorithm, which impacts the overall performance of all iterations and compounds across the fixed-point loop. Additionally, off-the-shelf Python libraries also provide RA primitives to perform iterated join operations [35], but using the predefined methods does not allow fusing RA operations and creates memory overhead storing all intermediate results during iterated RA operations.

Datalog and iterated RA In Datalog, rules can be provided to define relations (tables) in terms of others. The following Datalog program inductively defines the transitive closure, T, of an input graph G using two rules: $T(x,y)$:– $G(x,y)$. and $T(x,z)$:– $T(x,y), G(y,z)$. The first rule represents a base case that says: every x-to-y edge in G implies an immediate x-to-y path in T. The second rule says: every x-to-y path in T that can be extended with a y-to-z edge in G, implies an extended x-to-z path. The second rule is recursive and must be iterated repeatedly until stabilizing at a value for T that is consistent with all rules.

The first rule can be implemented by inserting every element of G into T, a simple copy or union operation. The second rule can be implemented by iteration of a kernel function, composed of several RA operations, iterated to a least-fixed-point. One iteration of this function would join T on its second column with G on its first column, yielding all triples (x,y,z) where (x,y) can be drawn from T and (y,z) can be drawn from G. Projection to the set of unique (x,z) tuples, removing the middle column (as a graph, this is removing the intermediate vertex in the discovered path), and unioning this set of tuples with those in T completes one iteration of the second rule. The output (newly discovered facts) acts as the input for the following iteration, and the process continues till all reachable paths are discovered (see Figure 1).

3 Standalone Join

We first implement a standalone join operation between two input relations. A low-level programming model such as CUDA allows us to control the memory hierarchy and fuse operations together. We create a static hash table on the input relation and then use a hash-join-based approach to join the relations.

Representation We have developed a novel GPU-based hash table from scratch to meet requirements pertinent to our system. We extend the hash-join-based approach to support the relational data type specific to our application (2-ary column). This is done by implementing an efficient hash table that effectively supports search and can be easily linearized to a compact 1D array (required for deduplication)– both essential in implementing iterative joins.

To facilitate seamless hash-joins between relations, we use the entries of the join column of every relation as the key of the hash table. In particular, the join column of a relation is used as the *key*, which *maps* to a set of values (corresponding to the non-join column values). For example, for a relation that is hashed on the first column, with tuples $(1,2)$, $(1,3)$, and $(1,4)$ the key corresponds to 1 and the set of values would correspond to $2,3,4$. Note that, our hash-table uses only the join column as the key for hashing– making it easy to facilitate fast look-ups, needed for joins. Furthermore, to simplify our development (targeting graph analytic applications), we assume all base values are 32 bits wide.

All hash tables must support collision resolution. Two popular schemes include separate chaining and open addressing. However, GPUs face intrinsic difficulties in dealing with linked data, and we instead use an open-addressing-based hash table consisting of a fixed-size buffer. In our design, collision resolution is accomplished via linear probing, which (in our experiments) shows better cache performance than quadratic and double-hashing techniques. Our implementation uses the `Murmur3` hash, a popular implementation that performs well on open-source benchmarks [22]. The hash is calculated using a combination of bit shifts, multiplications, and XOR operations. We obtain a hash-table build rate of 4 billion keys per second for a string graph and 400 million keys per sec for a random graph (see Sec. 5 for more details).

In an open-addressing-based hash table, the load factor measures a table's sparsity, Load factor$(\alpha) = size(input)/size(hashTableSize) \leq 1$. Intuitively, a lower load will yield fewer collisions (and thus higher performance) [11]. In experiments, we use load factors 0.1 and 0.4 to pre-allocate our hash table as the nearest (larger) power of two (called *hashTableSize*); this permits us to replace the more expensive modulo operation in our hash function with an efficient binary AND operation. We create the hash table as a strided array of structures (*Entity*) with 32-bit integers *Key* and *Value* as fields. The hash table is initialized with a sentinel value (-1) to indicate an empty value. While doing bulk insertions in the hash table, CUDA threads search for the index of each tuple they are assigned, using the hash function. If the position is available (i.e., -1), we insert the tuple in the hash table using CUDA's atomic compare-and-swap operation (*atomicCAS*). If the position is already occupied, we search for the next available position using linear probing. In CUDA, if each thread only operates on one element of the input array, it can lead to problems if the input is larger than the number of available threads. To address this, we use a *grid-stride loop*, which allows a single thread to traverse multiple elements of the input array by incrementing its index by a stride value that is determined by the grid size and block size. Each CUDA thread performs build hash table computation on one grid size ($blockDim.x * gridDim.x$) at a time to provide maximum memory coalescing.

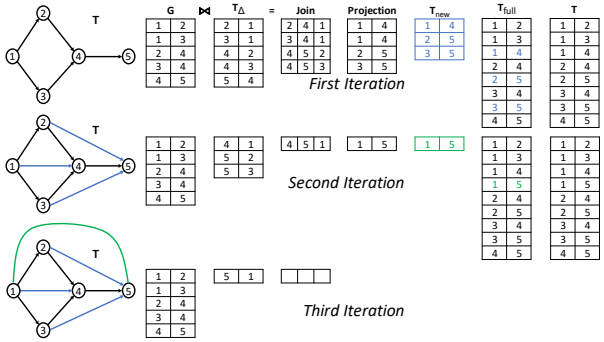

Figure 1: An example of the iterated joins on transitive closure computation of a graph

Hash-Join Phases We perform a join operation to get the join result of the hash table and input relation of *Entity* structure element with two 32-bit integers (*Key* and *Value* as structure members). We use two passes to compute the join result. These two passes are carried out by two CUDA kernels. First, we initialize an array (*offset*) with the size equal to the input relation. In the first phase, each CUDA threads searches for a total of n keys of the input relation in the hash table where n is the size of one grid($blockDim.x * gridDim.x$). If it finds a matching key in the hashtable, it increases the counter of the *offset* array for that input element. Thus, we calculate the number of matches for each key of the input relation using this CUDA kernel. We use thrust library's *reduce* and *exclusive_scan* APIs with device execution policy to get the total amount of matches and the exclusive prefix sum of the *offset* array. As the *offset* array reveals the size of the matches for each key of the input relation, the second pass inserts the joined columns to the join result array using another CUDA kernel. In the second pass, we do not insert the join column to fuse the join and projection operation in one kernel invocation. Both of these kernels use offset-based calculation without using any atomic operations or barrier synchronization, which are computationally costly. On top of that, our kernels use grid-stride loops to distribute the workload equally to the available CUDA threads. It also eliminates the branch divergence problem, where some CUDA threads could have more workloads than others.

4 Iterated Joins on the GPU

Implementing iterated joins requires the allocation of extra buffers to materialize intermediate results. Additionally, these intermediate results must be deduplicated between each RA iteration to ensure tractability. In this section, we demonstrate our approach to efficient iterated joins, using transitive closure as an illustrative example; our techniques generalize to other problems using finite-domain Datalog.

Transitive closure: Transitive closure is operationalized as iterated joins between a monotonically-growing set of transitive edges, T, and an extensional database of edges, G. With each iteration, new paths of increasing lengths are discovered (monotonically extending T) until all reachable paths are found and execution terminates. In practice, efficient implementations of Datalog employ semi-naïve evaluation [1], tracking a *frontier* of new facts rather than all-yet-seen facts. This is implemented by distinguishing multiple run-time tables for each syntactic relation: T_Δ, T_{full}, and T_{new}. T_Δ tracks the most-recently-discovered (last iteration's) transitive edges in T—T_Δ is merged into T_{full} after each iteration. Facts discovered during the *current* iteration are accumulated into T_{new}, which is swapped into T_Δ between iterations.

Figure 1 visualizes the execution of transitive closure on a line graph consisting of five nodes. As a preparatory step before the first iteration, T_Δ is populated by G. The first iteration joins G and T_Δ, yielding four (intermediate) triples. This is followed by projection of the join column, which results in a duplicate edge $(1,4)$. We deduplicate by sorting the results and applying consecutive deduplication (Thrust's unique, which required a preceding stable sort) to produce unique inferred paths in T_{new}. As a data-structure invariant, tuples are sorted (using the natural lexicographic sort): this enables merging T_{new} into T using a *single* scan of T_{new}. Next, we union the merged relation and generate the union result in T_{full}. This graph is visualized in the middle left side of Figure 1, where blue edges indicate the new unique paths found from the first iteration. We update the graph relation T_Δ with T_{new} for the next iteration. We continue this iterated join operations until we cannot find any new path or the size of T does not change after the deduplication of the merged relation.

Algorithm 1 formalizes our implementation of transitive closure in CUDA. This algorithm uses a combination of library functions illustrating the cruxes of Datalog on the GPU: joins (boxed in blue), union (orange), deduplication (green), and clearing (red). We begin by establishing the initial invariants: building an initial *result* by sorting G, and copying G into T_Δ. Next, we iterate until we reach a fixed-point; at the end of each iteration we compare the number facts in the next T with the number in the current T—when no new facts are added, the algorithm terminates at a fixed-point.

Join operation in transitive closure The join operation uses the single hash-join operation in a fixed-point iteration described in Section 3. We create the hash table (R in Algorithm 1) only once and repeatedly use it in the iterated hash join. The relation T_Δ is initialized with input relation G. The two-pass approach (Sec. 3) calculates the join result size (*joinOffset*) for each record of T_Δ and then inserts the join result in the *joinResult* array. Our algorithm fuses the join and projection operations together and thus reduces time and memory consumption for the iterated join (by up to 5%). This optimization is novel from an iterated join on the GPU perspective.

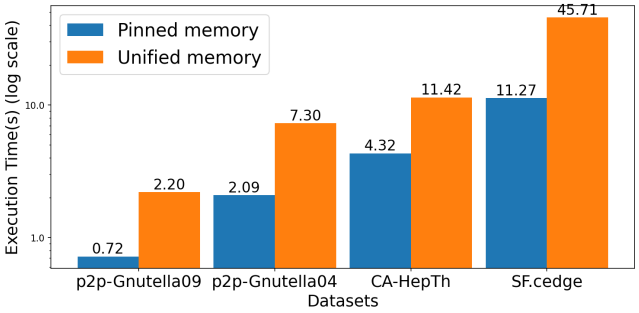

Figure 2: Time comparison between CUDA's pinned memory and unified memory model for hash join based TC computation. (log-scale for Y-axis)

Deduplication of the join result and merged result We use the key insight that some relational data can be permanently maintained in sorted order while some cannot and use this information to implement two kinds of deduplication techniques. Duplicate tuples are generated in two segments; after the join and projection operation and after the union operation. We use thrust library's *sort* and *unique* API to remove duplicates from the join result. The *sort* API first sorts the join results, and then the *unique* API removes the consecutive duplicate elements from the array. To deduplicate the union result, we initialize the *result* array with the input graph G and sort it. To remove duplicates from the union result ($result \cup T_\Delta$), we merge the sorted arrays ($result$, T_Δ). Then we apply the thrust's *unique* API to remove the consecutive duplicates from the merged result. This merging step eliminates the requirement of sorting the large *result* array before applying the deduplication process.

Memory management The CUDA programming model provides four memory allocation schemes: pageable memory, pinned memory, mapped memory, and unified memory [7]. Pageable memory involves two transfers: from host pageable memory to temporary pinned memory on the host, and then to device memory. Pinned memory initializes data on the host's pinned memory, requiring only one transfer to send it to device memory [18]. Mapped memory maps pinned memory in the device address space, avoiding host-to-device memory copying but increasing program processing time. Unified memory creates a managed memory pool for accessing data from both host and device using the same address, but introduces supplementary operations for memory management. For both the single join operations (Sec. 3) and iterated join operations (Sec. 4), we utilize the CUDA pinned memory model. We keep only two arrays (input relation and the final result) in the host memory, and all intermediate buffers are kept in the device memory without any need for data transfer

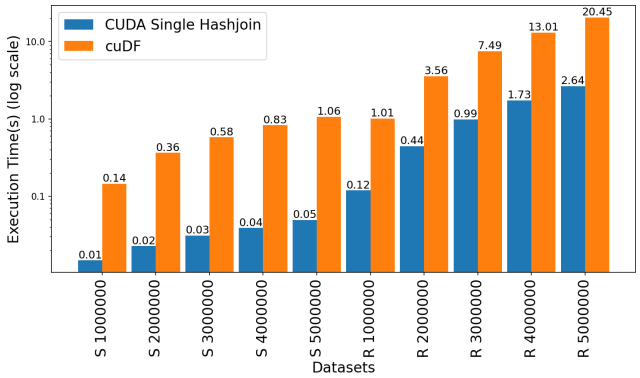

Figure 3: Time comparison between single join operation using CUDA and cuDF. R indicates Random, and S indicates String graph. (log-scale for Y-axis)

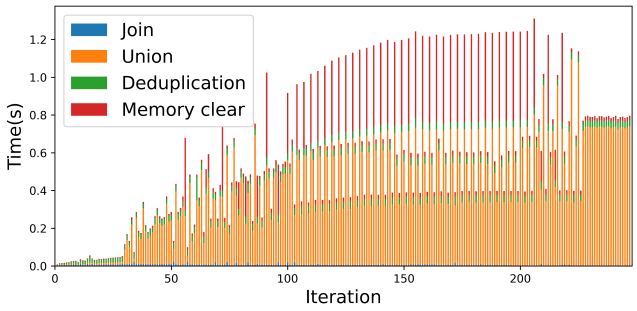

Figure 4: Our time breakdown for *fe_ocean* graph (CUDA outperforms Soufflé by 3.9×)

between the host and device memory for intermediate results. We ensure the implementations have no memory leakage using *cuda-memcheck* and *compute-sanitizer* API provided by CUDA library.

5 Evaluation

We perform a series of experiments to evaluate the performance of our iterative hash-based join implementation. We begin by evaluating the performance tradeoffs offered by using different memory management schemes of CUDA. Following which, we study the performance of a hash-join in isolation, comparing it against state-of-art join implementation of the cuDF library – part of NVIDIA's rapids framework that uses NVIDIA CUDA programming model for GPU parallelism [12, 15, 37]. Finally, we evaluate the performance of our iterative joins, by computing the transitive closure of a range of graphs. We compare our performance against Souffle, a state of art openMP-based library for performing iterated joins, and our cuDF-based implementation.

Experiment platform and datasets We conduct our experiments on the ThetaGPU supercomputer of Argonne National lab [27]. It has 24 NVIDIA DGX A100 nodes with eight NVIDIA A100 Tensor Core GPUs per node. Each node features two AMD EPYC 7742 processors with 3.31GHz clock speed and a total of 128 cores.

cuDF package was installed on a Python conda environment, and we developed our code using CUDA version 11.4. We use Souffle version 2.3 with 128 threads in ThetaGPU. As cuDF and our CUDA experiments use only one GPU device (single-gpu benchmark) we use a single GPU node from ThetaGPU. The single GPU node has 108 multiprocessors on device (SM) and we use $3,456$ (32×108) blocks per grid and 512 threads per block for each of the CUDA kernels.

To evaluate the experiments, we use real-world and synthetic graph datasets from the Stanford large network dataset collection, SuiteSparse matrix collection, and road network real datasets collection [8,28,29]. Table 1 shows all our graphs used along with performance results.

Memory optimization We evaluated the pinned memory, and unified memory as memory allocation schemes for transitive closure computation for several real-world graphs mentioned in Table 1 [7]. Figure 2 shows the time comparison between these two memory allocation schemes for directed and undirected graphs. We observe 2.6× to 4.1× speedup for transitive closure computation using the pinned memory over the unified memory model. However, we see that the unified memory model can handle graphs with larger TC size (e.g. dataset $p2p-Gnutella31$ from Table 1) without getting a run time error (out of memory error) as unified memory can oversubscribe the GPU global memory since CUDA version 8. Therefore, the graph $p2p-Gnutella31$, which has a higher workload per iteration overflows the GPU global memory (with pinned memory). For a single GPU-based implementation, this is an expected result.

Single hash-join performance To benchmark the single hash-join implementation (described in Sec. 3), we use two types of synthetic datasets; random graphs (numbers in the range of 0 to 32,767) and string graphs (e.g. $(1 \rightarrow 2), (2 \rightarrow 3), (3 \rightarrow 4)$). Both types of graphs have edges between 1 million to 5 million. Figure 3 shows the time performance comparison between cuDF and our standalone join.

For a random synthetic graph, we can build a hash table at a rate of 400 million keys per second. For the string graph, the build rate goes up to 4 billion keys per second. These two graph types invoke the two ends of the performance spectrum, with the random graph leading to tons of inefficient matches (worst case) and the string graph leading to perfectly aligned matches (best case). We observe up to 21× speedup for single hash-join computation for the string graph using our CUDA-based implementation over the cuDF join implementation. We notice that the increase in speedup is directly related to the size of the input relation for string graphs. For the random graph, we see 7.6× to 8.4× speedup using the CUDA-based

Table 1: Transitive closure performance using Hashjoin based CUDA, Souffle, and cuDF implementation. CUDA implementation uses 3,456 blocks and 512 threads per block. The Soufflé implementation uses 128 threads. Type *U* and *D* indicate undirected and directed graphs.

implementation over the cuDF based implementation.

Iterated hash-join We compare our iterated hash-join-based transitive closure computation with state-of-the-art Souffle and Nvidia's cuDF library in Table 1. The benchmark results are based on multiple runs (at least 10), with the average being reported. The variance between runs was negligible (maximum standard deviation is <1%). For 15 out of 19 graphs, our CUDA-based implementation outperforms Souffle's implementation (128 threads). For the graph with the largest TC (*fe_ocean*, 1.6 billion edges), we observe a speedup of 3.9× over Souffle. We observe a speedup of 10.8× over cuDF implementation. Moreover, the cuDF implementation gets out of memory error several times where the CUDA based implementation is able to compute the transitive closure of those graphs using the same experimental setup. Additionally, we fused the projection operation with join operation in CUDA implementation, which is not possible in cuDF-based implementation. Thus, it shows both time and space performance enhancement of our iterated hash-join-based transitive closure computation. To better understand the time consumption for each of the individual operations (mainly join, union, deduplication, and memory clear) at the iteration level, we break down the operations at the granular level. One such granular benchmark is shown in Figure 4. We notice that the deduplication and union operation takes more time than the other operations. Also, as the number of join results is smaller in the first few iterations, it takes significantly less time in those iterations. For the graph (*usroads*), where we under-perform compared to souffle, our hypothesis is that we are not saturating the GPU as this graph has an increasing number of iterations (606) and less work per iteration.

6 Conclusion

We explored the issues for iterated operations such as inefficient operation fusion, GPU memory management, and facts deduplication while implementing the RA primitives which are necessary for developing Datalog applications. Our system is limited to a single GPU, and thus there are inherent scaling walls dictated by available VRAM on the GPU–by contrast, the largest unified nodes offer orders-of-magnitude more available RAM, supporting larger graphs. We view this work as a step towards multi-GPU joins across a cluster to develop a scalable backend for Datalog.

7 Acknowledgements

This work was funded in part by NSF RII Track-4 award 2132013, NSF collaborative research award 2217036, and NSF collaborative research award 2221811. We are thankful to the ALCF's Director's Discretionary (DD) program for providing us with compute hours to run our experiments on the ThetaGPU supercomputer located at the Argonne National Laboratory.

VectorVisor: A Binary Translation Scheme for Throughput-Oriented GPU Acceleration

Samuel Ginzburg Mohammad Shahrad[†] Michael J. Freedman

Princeton University [†]*University of British Columbia*

Abstract

Beyond conventional graphics applications, general-purpose GPU acceleration has had significant impact on machine learning and scientific computing workloads. Yet, it has failed to see widespread use for server-side applications, which we argue is because GPU programming models offer a level of abstraction that is either too low-level (e.g., OpenCL, CUDA) or too high-level (e.g., TensorFlow, Halide), depending on the language. Not all applications fit into either category, resulting in lost opportunities for GPU acceleration.

We introduce VectorVisor, a vectorized binary translator that enables new opportunities for GPU acceleration by introducing a novel programming model for GPUs. With VectorVisor, many copies of the same server-side application are run concurrently on the GPU, where VectorVisor mimics the abstractions provided by CPU threads. To achieve this goal, we demonstrate how to (i) provide cross-platform support for system calls and recursion using continuations and (ii) make full use of the excess register file capacity and high memory bandwidth of GPUs. We then demonstrate that our binary translator is able to transparently accelerate certain classes of compute-bound workloads, gaining significant improvements in throughput-per-dollar of up to 2.9× compared to Intel x86-64 VMs in the cloud, and in some cases match the throughput-per-dollar of native CUDA baselines.

1 Introduction

Server-side GPU acceleration has become ubiquitous, with all major cloud providers offering virtual machine instances with attached GPUs. GPU workloads such as graphics and machine learning have found widespread adoption due to the superior throughput-per-dollar that GPUs offer.

Typical approaches to accelerating these workloads on GPUs use domain-specific programming languages (DSLs). DSLs for GPUs heavily restrict which abstractions can be used by developers to write applications, and in particular forces them to use parallel abstractions. For example, machine learning programming systems such as TensorFlow [24] require users to specify programs as a series of operations performed on n-dimensional arrays. Approaches to extracting parallelism on GPUs for graphical workloads such as Halide [73] enforce more extreme restrictions such as requiring developers to express image operations as pure mathematical functions, defining the value of each function at each point. Other DSLs targeting batch dataflow workloads require developers to express their program using built-in parallel functions, which impose additional restrictions on application logic [75].

Developers who cannot express their application logic using these restricted abstractions are stuck manually rewriting applications in OpenCL or CUDA, which expose a low-level programming interface. Complex programs that use large pre-existing libraries, or where extracting parallelism is difficult, can be time-consuming to write and require drastic modifications to run using GPUs.

In this paper, we explore the feasibility of an alternative programming model for GPUs—where we take existing single-threaded programs and execute many copies of them using GPU threads. Each GPU thread corresponds to an emulated CPU thread, running a single instance of the program. Unlike prior approaches [37] which utilize interpretation, we translate the input program to native GPU code, substantially boosting performance while enabling a wider variety of target languages and runtimes. Unlike OpenCL or CUDA programs, we provide support for system calls and a CPU-like flat memory model. While less efficient than manual translation, this approach substantially reduces the barrier to accelerating throughput-oriented workloads using GPUs, ultimately improving the throughput and cost efficiency of applications that would otherwise run on CPUs.

Many applications written to run on CPUs are single-threaded programs, often implemented using high-level programming languages with large imported libraries. Without modification, these applications do not map cleanly to existing GPU programming models (e.g., those using language-level parallel functions such as in TensorFlow or Halide). Instead, these workloads process requests independently, with

no inter-request synchronization or communication. Examples of these workloads include cryptographic operations, image manipulation, and compression. These workloads are generally amenable to GPU acceleration [60, 67, 73], but are frequently run on CPUs instead.

Effectively enabling this programming model requires one to overcome several technical challenges in dealing with the substantial differences between GPUs and CPUs. These differences include how programs are executed—e.g., in which programs are run to completion without preemption—as well as a lack of support in GPUs for system calls. Further, failing to take differences in GPU memory hierarchies into account can result in an order of magnitude decrease in read and write performance. Prior approaches to running unmodified programs on GPUs suffer from poor performance due to the overheads of interpretation [37] as well as compatibility issues such as the lack of support for system calls [45].

To explore this unique programming model for GPUs, we built VectorVisor—a system which utilizes a vectorizing binary translator for GPUs. VectorVisor is designed to accelerate existing and unmodified programs that are designed to run on CPUs but can benefit from GPU acceleration. Target programs are automatically translated to run on GPUs efficiently, eliminating the need for complex manual translation. In particular, VectorVisor uses WebAssembly [54] as the intermediate binary format, which enables secure, fast, and efficient compilation for a wide range of applications.

We overcome the differences in program execution and memory hierarchy by translating WebAssembly programs to run directly on the GPU as opposed to using interpretation. We show that the remaining differences between CPUs and GPUs can be bridged with a combination of three techniques:

Continuations: CUDA and OpenCL do not provide support for preempting running applications in addition to lacking support for system calls. Without preemption, we cannot dispatch system calls, making it impossible to run complex and unmodified programs. To bypass this issue, we implement *continuations* for OpenCL C. Continuations are language-level primitives that allow us to save the program state at arbitrary locations, and then resume execution at a later time. Doing so allows us to pause and resume running GPU kernels, and to provide support for system calls. We also benefit from the portability of our approach—enabling VectorVisor to be run with multiple GPU vendors (e.g., NVIDIA, AMD).

WebAssembly: WebAssembly (WASM) binaries are designed with performance, portability, and security in mind. Many popular languages can compile to WASM (e.g., Rust, Go, C, C++, AssemblyScript, and more), making it an ideal intermediate format. WASM binaries are designed with runtime JIT compilation in mind, persisting vital information not present in x86 binaries. WASM semantics provide VectorVisor with memory alignment information, register allocation hints, type-checks on operations, and language-enforced structured control-flow. We heavily utilize this information to deal with challenges such as efficiently making use of the substantially larger per-thread [14] register space on GPUs—which is crucial for maximizing performance. Other important performance optimizations are also enabled through this compile-time information.

Memory Interleaving: GPUs organize threads in *warps*, or groups of threads. Each thread in a warp has a numerical index, and threads with adjacent indices must access adjacent bytes for optimal performance—so that memory accesses can be coalesced together. Coalesced memory accesses enable GPUs to maximize memory bandwidth usage at the cost of a more complex programming model. To bridge the differences between the GPU and CPU memory hierarchies, we automatically interleave the memory of each virtual machine running on the GPU to transparently coalesce all memory accesses.

We demonstrate VectorVisor's capabilities to accelerate several unmodified, third-party applications which use popular open-source libraries. We then evaluate VectorVisor's efficacy using nine benchmarks with throughput-per-dollar as our primary metric. Selected benchmarks include multiple classes of workloads, some of which reflect ideal applications of VectorVisor, with others reflecting the limitations of our programming model. Comparisons against native x86-64 and WebAssembly versions of each benchmark are provided, showing that VectorVisor can achieve superior throughput-per-dollar. We also provide native CUDA versions of two benchmarks to evaluate the efficacy of our translation. Our paper makes the following contributions:

1. We introduce a novel cross-platform approach to running lightweight virtual machines using GPUs, where VMs securely execute native code to maximize performance and support multiple high-level languages.

2. We show that support for system calls can be efficiently provided using continuations in addition to supporting recursion and indirect calls in OpenCL.

3. We demonstrate that we can emulate a flat memory model using an efficient memory interleave, enabling existing programs to leverage the high memory bandwidth of GPUs.

4. We explore the implications of batch size, latency, and throughput on VectorVisor's programming model and discuss which categories of workloads are optimal for it.

5. We discuss the limitations of our system and optimal GPU configurations for it.

2 Motivation and Challenges

The past several years have shown a large increase in the availability of cloud accessible GPUs. GPUs that cost thousands of dollars are now available at affordable prices per hour. Developers can quickly test if accelerating their program using

a GPU is cost-effective without large up-front investments in GPU hardware. However, despite having strong parallel processing power and cloud availability, GPUs are not often used for running high concurrency server-side applications.

Translating programs originally intended to execute on CPUs to run on GPUs is difficult due to the substantial differences between the execution models and memory hierarchies. Today's approaches to tackling these issues either require strong language-level restrictions with unintuitive stumbling blocks for developers, or slower automated approaches such as interpretation [37].

2.1 Execution Model Differences

Taking advantage of the throughput that GPUs offer requires using a different execution model than CPUs offer. GPUs feature restrictions on both the application runtimes and control flow that limit the set of possible workloads.

Runtime Limitations: CUDA and OpenCL are the two most popular compute APIs available for GPUs, and they share a near identical programming model. Programs that run on GPUs (GPU kernels) are submitted and execute until completion without preemption. High-level languages targeting general-purpose GPU programming such as CUDA C++ and OpenCL C feature restrictions on the usage of standard libraries, recursion, indirect function calls, variable length arrays, virtual functions, and templates [12, 16]. Support for other common features such as system calls and preemption are absent, further restricting the set of programs that can run.

Divergence: Unlike CPUs, which allow for different hardware threads to execute different instructions, GPUs organize threads into groups of threads (warps). Each warp shares a program counter, so all threads execute the same instruction on each clock cycle. Support for conditional branching is provided by executing no-ops for threads that have diverged, while the remaining threads block on threads executing the conditional branch. This results in the serialized execution of branches. Programs with substantial divergence are not able to efficiently use GPU resources as a result [33, 43, 51].

2.2 Memory Hierarchy Differences

GPUs and CPUs handle memory accesses differently due to the different design constraints imposed upon the hardware. CPUs optimize for reduced memory latency for all threads of execution, so they feature large cache sizes to minimize accesses to main memory. In contrast, GPUs seek to maximize memory bandwidth. GPUs can achieve $3\times$ the memory bandwidth of a comparable CPU [5, 8]. While GPUs can achieve higher memory bandwidth, memory latency on a given GPU can be up to $2.75\times$ worse than a comparable CPU [61, 66]. These differences in the memory hierarchy between GPUs and CPUs have two key implications for developers:

Register Space: At a high level, the memory hierarchies of CPUs and GPUs are similar, with both devices featuring registers, data caches, and byte-addressable memory. However, GPUs feature substantially larger register files. Each thread on recent NVIDIA GPUs can have a maximum of 255 32-bit register values [12] (just under 1 KiB of storage). In contrast, the x86-64 instruction set architecture has 16 64-bit general purpose registers (128 bytes of storage). Additionally, GPUs typically feature far more threads of execution than CPUs, further magnifying the difference. *Making use of this extra space is critical to maximizing performance on GPUs* [36, 70].

Memory Accesses: Rules regarding efficient memory access patterns are different for GPUs. GPUs require that programs perform *coalesced memory accesses*. Similar to CPUs, locality of memory accesses allows reads and writes to be cached, and is required to get optimal performance. However, GPU kernels must also ensure the locality of memory accesses across threads. Threads in a GPU warp are numerically indexed, and adjacent threads must access adjacent bytes of memory as a general rule. Otherwise, memory accesses within a warp can be serialized. Without proper memory coalescing GPU memory bandwidth can be cut by up to $32\times$ [12].

In addition to performance drops, GPUs can have stricter memory access policies than CPUs. Ideally, memory accesses are naturally aligned—meaning N byte accesses must be N-bytes aligned. Unaligned accesses cause running GPU kernels to fault on NVIDIA GPUs [12], causing programs that would have run correctly on a CPU to crash on a GPU.

3 System Design

In this section we introduce VectorVisor [1], a vectorizing binary translator for GPUs designed to leverage the implicit parallelism provided by our programming model. Our approach enables us to run many instances of unmodified programs on the GPU concurrently, making it far easier to utilize the substantial parallelism that GPUs offer.

We first describe our programming model in depth, where we explain how developers can leverage VectorVisor to accelerate programs. We characterize a set of ideal workloads for VectorVisor and explore the limitations of our programming model. Following this, we provide a high-level overview of VectorVisor's primary system components. To enable our simple and easy to use programming model, VectorVisor automates data transfer to and from the GPU. We illustrate this by showing the life cycle of a request processed by VectorVisor. Lastly, we provide an example of a short program, and how we transform it to run on the GPU.

3.1 Programming Model, Target Workloads

In contrast to OpenCL or CUDA, VectorVisor mimics the abstractions provided by CPU threads, treating each individual GPU thread as a small virtual machine. Each VM operates on a statically allocated chunk of memory, fully isolated from

[1] https://github.com/SamGinzburg/VectorVisor

other VMs. This memory model does not support inter-VM communication, and thus prevents deadlocking. Many copies of the same program are mapped to GPU threads, which then operate on distinct inputs.

This approach to parallelism for GPUs enables developers to run complex and *unmodified* single-threaded programs originally written for the CPU. Developers can leverage GPU acceleration without learning complex programming models or rethinking the logical structure of their programs.

VectorVisor is designed to function with unmodified workloads, but not all programs are equally amenable to acceleration using our programming model. Data parallel, latency-insensitive, and compute-bound 'serverless-like' workloads are ideal targets for GPU acceleration using VectorVisor. For a subset of these workloads, correct manual translation can be difficult without domain-specific knowledge—and those workloads represent an ideal use-case for VectorVisor. Suitable workloads share a number of characteristics:

High Execution Volume: VectorVisor relies on running many instances of the same program concurrently, instead of accelerating a single execution. Therefore, the more instances packed on the GPU, the higher the cost efficiency. Naturally, the latency QoS of the application should be able to afford the added batching latency prior to execution.

Application Limitations: VectorVisor runs unmodified programs where possible, but some abstractions are expensive to emulate on GPUs. Recursion and indirect calls reduce application performance due to how we implement them (explained further in Section 3.3).

Navigating tradeoffs between application concurrency and heap size are key to maximizing performance when using VectorVisor. We experimentally found in our evaluation that running 4096-6144 VMs with a heap size of 3-4 MiB proved optimal for our selected workloads. However, it is possible to run VectorVisor with varying degrees of concurrency—adjusting for different heap sizes.

Lastly, floating point differences between CPUs and GPUs can result in different outputs for applications [11, 37, 65], depending on the specific application and compiler.

Low Divergence: Ideal workloads should minimize program divergence in order to fully utilize the superior throughput and memory bandwidth that GPUs can offer.

Data Transfer Overheads: VectorVisor automates data transfer to and from the GPU; however, the overhead involved can be a substantial fraction of end-to-end request time. Maintaining a high ratio of GPU compute to input and output size is ideal for maximizing VM throughput.

3.2 Design Overview

VectorVisor consists of two key components, the binary translator (compiler) and the vectorized virtual machine monitor (VMM). We show an overview of VectorVisor in Figure 1, showing the role of each component as well as the life cycle of an incoming request to the system. Requests are first queued externally to VectorVisor, before being batched by the VMM, and submitted to the VMs running on the GPU—which are blocked on a system call awaiting input. We provide a pre-configured web server that automatically handles all data transfer to the VMM. After executing a batch of requests, responses are returned via another system call, and then back to the web server. This approach enables VectorVisor to be used as a drop-in replacement for existing systems, without the need for developers to manually batch incoming requests.

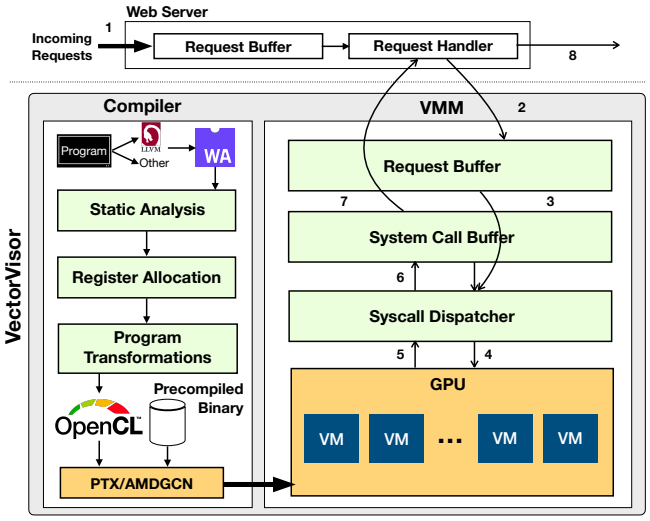

Figure 1: *System Overview*.

Binary translation is a separate process, occurring before applications run. Programs are compiled from any language targeting LLVM [64] (e.g., Rust, C, C++) into WebAssembly, our intermediate binary format. We then compile WebAssembly to OpenCL C. Targeting OpenCL C enables VectorVisor to support multiple GPU vendors. This approach allows us to run existing programs without the need to worry about complex language semantics—we only need to concern ourselves with WebAssembly semantics which are far simpler than alternatives such as LLVM IR and directly compiling high-level languages. LLVM IR places minimal restrictions on control flow structures, and can represent programs that are impossible for any GPU to run. WebAssembly only provides structured control flow by design, ensuring that programs can always be translated to run on the GPU [54]. Alternative approaches that directly compile high-level languages to run using GPUs require substantial engineering effort, and can run into compatibility issues [37].

Our system design features a number of novel contributions that we employ to bridge the substantial differences that exist between GPUs and CPUs described in Section 2. Our contributions succeed in bridging most of the gaps in capabilities between CPU and GPU runtimes. Recursive and indirect functions limit performance for some workloads but do not limit our functionality or correctness.

```
;; // Pseudocode in C:
;; int main(void) {
;;   // fd 1 == stdout
;;   char text[] = "ABCD\n";
;;   return write(1, text, strlen(text));
;; }
(module
  (import "wasi_unstable" "fd_write"
  (func $fd_write (param i32 i32 i32 i32) (result i32
      )))
  (memory (;0;) 1)
  (export "memory" (memory 0))
  (export "_start" (func $_start))
  (func $_start (result i32)
      i32.const 1  ;; stdout
      i32.const 0  ;; iovec ptr
      i32.const 2  ;; entries
      i32.const 24 ;; out bytes
      call $fd_write
  )
  (data (i32.const 0) "\10\00\00\00\02\00\00\00")
  (data (i32.const 8) "\12\00\00\00\02\00\00\00ABCD")
)
```

Figure 2: *WebAssembly Example*. We show an example of a simple program which makes a single system call.

3.3 Compiler

VectorVisor uses a binary translator (compiler) to translate input programs such that they can run on the GPU. The role of the compiler is to automate away the difficulties involved in writing programs for the GPU that are outlined in Section 2. We explore a set of techniques for enabling the execution of unmodified programs, which we demonstrate using a simple example of an input program.

3.3.1 Compiling WebAssembly

WebAssembly (WASM) [54], is a low-level language designed for performance, size, portability, and security. WASM binaries differ significantly from x86-64 binaries, as they are designed to be recompiled before runtime, retaining significant compilation information that can be used. Using WASM as an intermediate format simultaneously allows us to avoid dealing with the complex semantics of higher-level languages (e.g., Rust, C, C++) while also improving the performance of VectorVisor. We make use of this information in three places within our compiler:

1. Register Allocation: Recent NVIDIA GPUs have up to 255 32-bit registers per thread [12], providing roughly 8× the amount of storage per CPU thread ignoring vector registers. Traditional x86-64 binaries target CPUs with only 16 64-bit general purpose registers. Static analysis could conceivably be used to place stack allocations in x86-64 binaries into GPU registers, but WebAssembly provides a more convenient solution. In contrast to x86-64 binaries, WASM is a stack-based virtual machine and does not explicitly allocate registers [54]. Instead, values are placed either onto the stack or into local variables. Figure 2 shows an example WebAssembly program, which places four integers onto the stack. During compilation, we are able to store these values directly into variables which the backend GPU compiler (OpenCL C compiler) can then place into GPU registers. This approach allows the OpenCL C compiler to place values into registers that an x86-64 compiler would have placed on the stack.

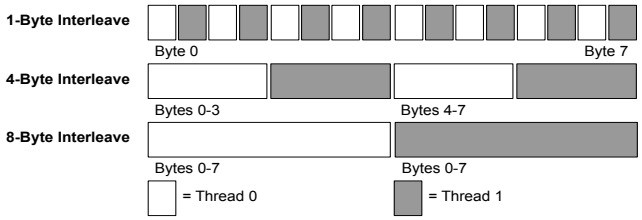

Figure 3: *Memory Interleaving* Examples of 1, 4, and 8-byte interleavings for a system with 2 threads are shown.

2. Runtime support: Most programs require some degree of modification to run on GPUs. Memory allocation, locking primitives, and threading primitives make assumptions about the underlying system that are false on GPUs. However, many such modifications are already performed by WebAssembly compilers. WASM binaries not only provide substantial compilation information, but also a "batteries-included" set of runtime modifications. Compilers targeting WebAssembly typically compile programs with a modified standard library with the necessary modifications already made.

3. Memory Alignment: Misaligned accesses cause running programs to crash when run using NVIDIA GPUs [12]. Handling misaligned accesses can be done at runtime by performing multiple aligned reads, but doing so introduces runtime overhead. Emitting optimized code for aligned accesses substantially boosts application performance. WASM binaries contain alignment information (e.g., the `align` attribute) that we can use to optimize reads and writes. However, the align attribute is only a hint, and as per the WASM specification, programs are expected to run correctly even with incorrectly specified alignments [54]. In practice, WASM binaries compiled by LLVM always contain the correct alignment information. By restricting the set of programs that we run to those compiled by LLVM, we can leverage these compilation hints safely to improve the performance of VectorVisor. VectorVisor supports running programs with and without this optimization using compiler-flags.

3.3.2 Memory Interleaving

GPUs have strict memory access rules to obtain optimal performance. As described in Section 2.2, GPU kernels must coalesce memory accesses to maximize memory bandwidth. Doing so requires developers to interleave objects in memory, such that adjacent threads access adjacent bytes, breaking the abstraction of a flat memory model. Other aspects of the flat memory model, such as process (or VM) memory isolation are also absent on GPUs by design.

VectorVisor provides the abstraction of a flat memory model to developers, automatically interleaving the address space of underlying virtual machines (threads) on the GPU

```
__kernel  void wasm_entry(...) {
  // Set up the stack, heap, buffers, ...
  do {
    /* call the next func/continuation */
    switch (*entry_point) {
      case 0:
        ___start(...);
        break;
      default:
        return;
    }
  // Check if we are done executing
  } while(*sfp!=0 && *syscall_number==-2);
}
```

Figure 4: The *trampoline* function serves as the entry point to each GPU kernel.

to provide both performance and security. This approach allows existing programs to run, while also extracting the full performance benefits of a GPU—assuming that running VMs exhibit similar memory access patterns. Randomized memory access patterns or significant program divergence can reduce memory bandwidth. Figure 3 shows how memory is interleaved across VMs in VectorVisor. Memory is organized into *cells* of contiguous bytes. Cell addresses are computed using the following pointer arithmetic (C operator precedence):

$$cell\_addr = (\frac{offset}{ileave}) \times (num\_vms \times ileave) + (vm\_idx \times ileave) + mem\_base$$

Where the interleave (*ileave*) represents the byte-width of the interleaving (e.g., 1, 4 or 8), the *offset* is the zero-indexed WebAssembly address, and *mem_base* is the base address of the allocated chunk of memory. Memory accesses are rewritten to operate on cells, with misaligned and larger (e.g., 8, 16-byte value) accesses requiring multiple operations. Our approach enables us to support 1, 4, and 8-byte interleavings, with larger interleavings typically achieving superior memory bandwidth.

WASM memory is represented as a zero-indexed linear array of bytes with pointers in the range of 0–2^{32}-1 and does not expose virtual addresses to running VMs. The relative addressing model WASM uses enables the compiler to control the virtual addresses of all memory reads and writes. Our cell address computation prevents VMs from computing cell adresses which belong to other VMs— preventing out-of-bounds accesses from corrupting or leaking data and providing memory isolation by construction.

3.3.3 GPU Preemption

Section 2.1 described the limitations of GPU programming models such as OpenCL and CUDA. Common features of programs such as system calls, recursion, and indirect calls vary in support—with system calls being absent from both OpenCL and CUDA. To fully mimic the execution environment provided by a CPU in VectorVisor, we support all three features. Implementing these features within OpenCL C requires us to provide support for preempting running programs. We provide support for preemption in VectorVisor by extending OpenCL C with support for continuations. Continuations provide the abstraction of being able to pause and resume programs at arbitrary points. To maximize the performance of VectorVisor, we leverage several compiler optimizations to reduce the overhead they introduce.

```
# 'c' is the called continuation
def example_fn(c, ...):
# context restore handler
switch (context):
  case 0:
    goto resume0;
  case n:
    goto resume_N;
  default:
    # Direct call, start from the top
# Indirect function call
switch(func_ptr):
  case 0:
    return c(example_fn, 0, resume0, ...)
    resume0:
  case n:
    return c(example_fn, 1, resume1, ...)
    resume1:
  default:
    trap;
# Optimized calls can be issued directly
call_example_func(...)
# Standard function call
return c(example_fn, 2, resume2, ...)
resume2:
# Recursive function call]
# In this case example_fn == 3
return c(example_fn, 3, resume3, ...)
resume3:
# System call
# These functions return control to the VMM
return c(example_fn, 4, resume4, ...)
resume4:
```

Figure 5: *Transformed Program* Pseudocode example of how different types function calls are implemented.

Continuations. Continuation-Passing Style [81] (CPS) is a relatively uncommon programming style where functions take in an additional parameter (the continuation), and instead of returning a value call the provided continuation with the return value. CPS with trampolining [27] is similar to standard CPS, with the difference being that function calls return continuations instead of just calling the provided continuation. A control operator (trampoline function), is used to repeatedly call the returned continuations. Figure 4 shows the trampoline function used in VectorVisor, which is the main entry point to each running GPU kernel. Implementing CPS with trampolines in this manner enables VectorVisor to preempt running GPU kernels at arbitrary locations—although we only return control to the CPU when either every VM is finished executing or when every VM is blocked on a system call. In Figure 5 we see that the only difference between recursive, indirect, and standard calls is the returned continuation (which encapsulates the program control state). This approach makes it easy to bypass OpenCL C language-level restrictions and provide support for recursive and indirect calls.

Compiler Optimizations. Naively implementing CPS with trampolines enables support for system calls and recursion

with large runtime overheads. To obtain better performance, VectorVisor performs static analysis to minimize the size of saved program contexts. We apply liveness analysis in addition to leveraging WASM type and control flow information to enable (1) incremental context saving, (2) loop-invariant code motion, and (3) WebAssembly-specific optimizations.

Liveness is associated with local usage inside WASM stack frames, and we insert all context save and restore operations around control flow instructions (e.g., `block`, `loop`, `br`, `br_if`, and `end`) and function (or system) calls. Runtime taint tracking is used to further enhance our liveness estimates.

Stack frame contexts are saved incrementally—only saving values written to since the previous context save operation. Liveness estimates are used to minimize context sizes in addition to only restoring live values when resuming continuations or unwinding stack frames. Loops without recursive or indirect calls can be further optimized—with context saving and restoring operations hoisted out of the loop. WASM function type signatures are used to translate amenable indirect calls into direct calls by filtering possible indirect call targets.

3.3.4 Profile-Guided Optimization

Minimizing the overhead of translating recursive and indirect calls is key to running complex applications. Compiler optimizations eliminate much of the overhead in the common-case. Edge cases, such as heavy usage of indirect and recursive calls in a tight loop remain a challenge. While recursion often cannot be eliminated without restructuring programs, indirect calls are easier to remove [25, 34]. Most indirect calls in high-level languages have only one target—with on average 73.5% of indirect call sites in Java programs being monomorphic [59]. Despite aggressive monomorphization in the Rust compiler [26], up to 37% of the most popular Rust libraries reduce code size by not removing optimizable indirect calls where possible [85]. Up to 98% of indirect calls in Java programs can be optimized out entirely [59].

We package a separate tool for instrumenting binaries, to implement profile-guided optimization for VectorVisor. Each program is instrumented and run using sample inputs representative of the overall workload. Using profiler data, we replace all indirect calls with less than 15 seen call targets with direct calls. To avoid emitting indirect calls to handle unseen targets, we instead emit panic handlers which check for valid targets.

3.3.5 Soundness

VectorVisor performs a 1-to-1 translation for all operations in input WebAssembly programs (e.g., stack operations, memory access, arithmetic, control flow). Limitations on the soundness of our approach come from (1) Compilation to WebAssembly and (2) Optimizations.

Most common workloads can be recompiled to WebAssembly without problems, but programs which rely on specific x86 instructions (e.g., 80-bit floats), language implementation details (e.g., undefined and implementation defined behavior), and complex language runtimes with unimplemented features (e.g., Go) can experience correctness issues.

Compiler-flags and tools (e.g., `wasm-snip`) are used to replace panic-related functions with `unreachable` statements. Unrecoverable errors can be expensive to handle, and in most cases replacing them with program aborts has no impact on correctness. Profile-guided optimization (PGO) can reduce indirect call counts, significantly improving performance in some cases. Our implementation of PGO only includes function calls we observe as potential targets at indirect call sites, aborting on unseen call targets. In practice, the indirect call targets we observed did not vary significantly with user-input beyond what we observed during profiling.

3.4 VMM

VectorVisor's VMM handles all data transfer between the running VMs on the GPU and CPU, as well as executing all system calls. The VMM greatly simplifies the use of VectorVisor by developers, avoiding the need to manage data transfer manually or to batch incoming requests.

Support for dispatching system calls is provided through the WebAssembly System Interface (WASI). We implement two custom WASI system calls—which are used to create a serverless-like event handler API for running VMs. Other implemented calls are primarily used to initialize language runtimes (e.g., reading environmental variables), support random number generation, serve as synchronization barriers (e.g., block on a subset of VMs), and perform simple IO (e.g., error logging).

Incoming requests are buffered using the request buffer, while system calls use an alternate buffer, as shown in Figure 1. Double buffering adds some overhead, but enables VectorVisor to overlap expensive network IO with on-GPU execution time. Sufficiently compute-intensive workloads prevent workloads from bottlenecking on the VMM, which can process thousands of VMs per-CPU. VectorVisor supports using pinned memory transfers with multiple GPU vendors (e.g., NVIDIA, AMD) to further optimize data transfer speeds—with vendor-specific optimizations [1, 4].

4 Evaluation

In this section, we present an evaluation of VectorVisor. First, we discuss the efficiency of (1) our memory interleaving and (2) system call implementation. Second, we explore a variety of modified and unmodified workloads to better understand the tradeoff space of our novel approach to accelerating programs. In several cases we show that we obtain superior throughput-per-dollar against x86 CPUs. Breakdowns of the end-to-end latencies of each benchmark are provided as well to explain our results. Finally, we evaluate the efficiency of our translation against handwritten CUDA baselines.

Instance Name	CPU	GPU	Cost/Hr
g4ad.xlarge	Intel Cascade Lake	AMD Radeon Pro V520	$0.3785
g4dn.xlarge	Intel Cascade Lake	NVIDIA T4	$0.526
g4dn.2xlarge	Intel Cascade Lake	NVIDIA T4	$0.752
g5.xlarge	AMD EPYC 7002	NVIDIA A10G	$1.006
g5.2xlarge	AMD EPYC 7002	NVIDIA A10G	$1.212
c5.xlarge	Intel Cascade Lake	N/A	$0.17
c5a.xlarge	AMD EPYC 7002	N/A	$0.154

Table 1: *Hardware Configurations.* Prices as of 1/5/2023.

4.1 Methodology

Testbed. We evaluated VectorVisor using Amazon Web Services (AWS). Five different VM types were used to compare against x86-64 baselines, and an additional two larger instances types were used to compare VectorVisor against CUDA baselines. We provisioned three VMs with attached GPUs (g4ad.xlarge, g4dn.xlarge, g5.xlarge), each with 4 vCPUs and 16 GiB of memory. Two additional compute-optimized VMs were used for evaluating CPU performance (c5.xlarge, c5a.xlarge), each with 8 GiB of memory and 4 vCPUs. Lastly, we used a single invoker VM (c5.8xlarge) for sending requests. These instances were used to obtain the results in Figures 8 and 9. Double extra large (2xl) instances have 2× the memory and CPU of smaller (xlarge) instances. These instances were used (in addition to xlarge instances) to evaluate handwritten CUDA programs. CUDA results which use 2xl instances can be found in Table 4. All VMs are allocated in `us-east-1`, in the same availability zone. Benchmarks are evaluated end-to-end over the network with IO and system overheads included in all measurements.

Some hardware configurations could not be evaluated due to AMD-specific bugs. AMD v520 GPUs, which are the only cloud-available AMD GPU on AWS, are unsupported in ROCm [21, 23] resulting in runtime crashes. Two benchmarks (Strings-Go and Strings-AScript) are built with WebAssembly-focused runtimes and do not have evaluated x86-64 configurations. Detailed results for all system configurations can be found in Tables 5 and 6 (Appendix).

Table 1 shows the hardware each VM has attached. NVIDIA configurations use the latest CUDA 12 backend, while AMD GPUs use ROCm 5.4.0 with the latest AMDGPU-Pro driver. For our GPU instances, we do not run any fraction of our workload on the available CPU cores to focus on evaluating GPU performance using VectorVisor. Undoubtedly, a hybrid CPU/GPU deployment would be more cost-efficient. We leave the exploration of heterogeneous deployments to future work. VectorVisor runs each benchmark using a 4- or 8-byte memory interleaving.

Workloads. Workloads are run using a cross-platform 'serverless-like' event-loop. Figures 11, 12, and 13 (Appendix) demonstrate how programs are written to run using our event-loop with x86-64, WASM, and VectorVisor. Our benchmarks evaluate VectorVisor using 'as-is' open-source library code in addition to optimized code written to run more efficiently. We explore the translation of lightweight (e.g., Rust) and complex language runtimes featuring garbage collection such as Go using TinyGo [22], and AssemblyScript [19]—a TypeScript-like language. Our x86-64 baselines are compiled at -O3 with SIMD enabled. Two benchmarks (Blur-Bmp, PHash-Modified) were manually rewritten to run natively using NVIDIA CUDA APIs to explore the efficiency of our translation. Table 2 shows each benchmark, its category, whether it features code that runs inefficiently in our system, whether we had to modify the imported library, batch sizes, and the total number of downloads on crates.io, a public repository for Rust libraries [10]. Benchmarks are run for 10 minutes to compute the average throughput (RPS).

Example Functions. Perceptual hashing is widely used in industry, such as by Facebook [6, 7], to cross-reference a given image against a database of images. We evaluate an open-source implementation of Blockhash—a variation on existing perceptual hashing algorithms [9, 90]. To further evaluate the efficiency of our translation, we also evaluate a modified blockhash library that we optimized to run more efficiently using VectorVisor. Additionally, we evaluate a bill generator which generates PDFs containing a set of purchased items formatted with a default template. Both benchmarks use mock data to simulate realistic workloads, with the hashing benchmark using 200×200 randomly generated images and the bill generation benchmark using 25 randomly generated item names and prices with an attached image.

Microbenchmarks. We evaluate a set of common microbenchmarks, including image processing workloads (e.g., Gaussian image blur), cryptography (e.g., password-based key derivation functions such as Scrypt and Pbkdf2), string compression (LZ4), histogram computation (Histogram), and string processing (e.g., stop word filtering and hashtag extraction). Our image processing, histogram, and cryptographic benchmarks operate on realistic, synthetic, and random inputs. We use the same parameters as Cisco type 8 passwords [20] for Pbkdf2 and Litecoin parameters for Scrypt [15]. To simulate realistic workloads, the compression and string benchmarks use as input a public dataset of tweets [41].

Baseline comparison. For our evaluation, we use two different baselines as points of comparison. First, for each of our benchmarks we compile them to WebAssembly (WASM), optimize them using `wasm-snip` and `wasm-opt` [17, 91], and execute them using Wasmtime [18] (a popular WASM JIT compiler). VectorVisor takes in the same WASM binary as an input. Second, for each of our benchmarks we compile and run them natively on an x86-64 CPU. This is the default choice for many developers who choose to run applications in the cloud, as most programs target x86-64. Each CPU benchmark is evaluated with multiple threads executing in parallel—proportional to the number of cores available.

Table 2: Details of evaluated benchmarks. We count benchmarks as containing recursive or indirect calls only if they execute those calls in the critical path of the application. All-Time crates.io download counts are as of 1/5/2023. 'M' and 'A' represent memory and arithmetically intensive benchmarks respectively. 'D' represents benchmarks with substantial divergence. 'Alg' represents benchmarks with significant algorithmic differences. *Bill-PDF uses a no-op system call as a barrier to mitigate heavy program divergence, but does not modify imported libraries.

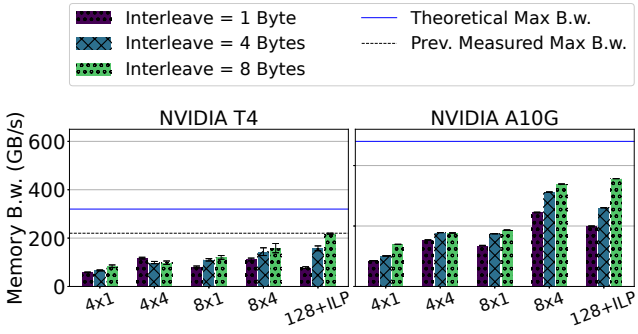

Figure 6: GPU `memcpy` bandwidth (Bytes copied×unroll #)

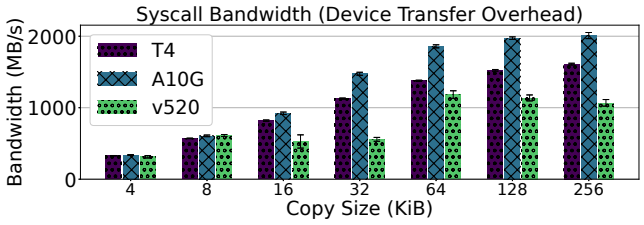

Figure 7: System call host-to-GPU PCIe transfer bandwidth.

4.2 System Performance

4.2.1 Copy Efficiency

Memory Bandwidth. To demonstrate that our memory interleaving can efficiently utilize the high memory bandwidth of GPUs, we evaluate five different `memcpy` implementations which vary copy size (bytes copied per-loop iteration) and loop unroll count. For each configuration we copy 1 MiB of data (using volatile memory accesses to bypass caching effects) from one array in memory to another non-aliased array. Each benchmark is run 50 times, with a heap size of 3 MiB with 4096 (on T4) or 6144 (on A10G) VMs running concurrently. Figure 6 shows that VectorVisor can achieve close to 100% of the experimentally derived maximum memory bandwidth of the T4 [61] and 74% of the theoretical memory bandwidth of the A10G [5]. We can see that larger interleaves, loop unrolling, and instruction level parallelism (ILP) [88] all have substantial impacts on memory bandwidth. VectorVisor leverages the `memory.copy` and `memory.fill` WASM intrinsics to insert optimized copy and fill functions into programs.

Syscall Performance. System calls provide a simple, familiar abstraction for developers to transfer inputs to and from a GPU. However, performing per-VM system calls incurs high data transfer overheads for smaller inputs. To evaluate our system call implementation, we copy inputs to and from the GPU, using batch sizes of 2048 (v520), 4096 (T4), and 6144 (A10G). Figure 7 shows the bandwidth for our VMM excluding network IO. Native CUDA transfer speeds peak at 6.3 GB/s for the T4 and 12.9 GB/s for the A10G—for a single large transfer. Despite high batching overheads, VectorVisor obtains ∼25% of the max possible bandwidth for fine-grained transfers of 256 KiB per-request using the T4. VectorVisor additionally supports overlapping data transfers with running GPU programs to avoid bottlenecks on VMM overhead.

4.2.2 Throughput

We evaluate VectorVisor's throughput against native x86-64 and WebAssembly baselines—with x86-64 being our primary baseline. WebAssembly numbers show the potential for heterogeneous deployments of VectorVisor in addition to showing the overhead of using WebAssembly. Figure 8 shows the best throughput for each configuration that we evaluated in terms of requests per second (RPS). AMD-specific issues, detailed in Section 4.1, prevent some configurations from being evaluated. Detailed throughput results for all system configurations can be found in Table 5 (Appendix).

VectorVisor outperforms x86 and WebAssembly for all but one benchmark (LZ4). We see high variation in throughput for each benchmark across our configurations. Device architecture (e.g., Turing vs. Ampere vs. RDNA 1), memory interleave size, backend compiler optimizations, and program characteristics have outsized impacts on performance. To evaluate the impact of program characteristics such as recursive and indirect function calls, we make use of profile-guided optimization (PGO) to remove indirect calls. Table 3 shows that we can remove all indirect calls from our benchmarks, reducing unoptimized function calls by up to 3430×. Removing all indirect calls and inlining functions where possible obtains mixed results. Bill-PDF improves in throughput by 1.3×, while other benchmarks are 10-20× *slower*. Function inlining caused by removing indirect calls can result in expensive register spilling. Counterintuitively, not removing indirect calls can improve throughput despite the context saving overhead.

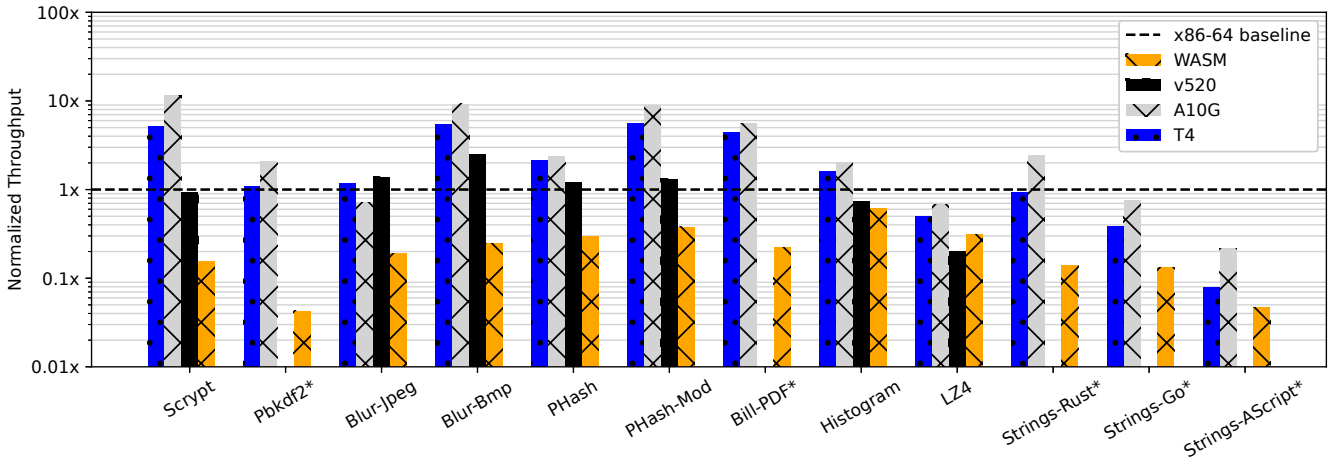

Figure 8: Normalized throughput (average RPS of each benchmark). Results are normalized to the x86-64 baseline for each benchmark except for Strings-Go and Strings-AScript, which are normalized to the x86-64 baseline of Strings-Rust instead. *Benchmarks without an AMD v520 result.

	Scrypt	Pbkdf2	Blur-Jpeg	Blur-Bmp	PHash	PHash-Modified	Bill-PDF	Histogram	LZ4	Strings	Strings-Go	Strings-AssemblyScript
# Total Slowcalls	52062	4828	4023	1416	11460	1410	285632	4117086	804807	43941	2172120	137212574
# Total Slowcalls w/PGO	206	1211	206	213	7844	206	2023	206	206	43744	2990690	143397289
# Indirect Calls	1	5228	162007	2	207031	1	211656	1	1	2	2869093	820142
# Indirect Calls w/PGO	0	0	0	0	0	0	0	0	0	0	0	0

Table 3: *Profile-Guided Optimization Results.* Cumulative indirect and unoptimized call counts for 200 invocations of each instrumented WASM function. These benchmarks were run locally using a 16-core, 64 GB RAM machine running Ubuntu 18.04.

Complex runtimes such as Go and AssemblyScript have significantly higher overhead than Rust on x86-64 WASM baselines (on average 0.41× the throughput of the Rust baseline for Strings-Go using the T4). Runtime support for garbage collection, reflection, and compiler design choices in TinyGo/AssemblyScript all contribute to the observed overheads.

4.2.3 Throughput-per-dollar

Throughput as a metric is insufficient to evaluate VectorVisor. Improving throughput for data parallel workloads by allocating more resources (VMs) represents the status quo. Instead, we show that VectorVisor can achieve greater *efficiency*—improving throughput using fewer resources. Measuring efficiency requires normalizing performance across both CPUs and GPUs, which we accomplish using throughput-per-dollar. It is computed by dividing the requests-per-second (RPS) by the cost of each respective instance per-hour using on-demand pricing in `us-east-1`. On-demand prices are used as a conservative measure of the cost benefits of VectorVisor. Spot instance pricing can be cheaper, further improving the throughput-per-dollar of GPU (T4) instances vs CPU (Intel) instances by 1.49× (reported as of 1/5/2023).

Figure 9 shows the best throughput-per-dollar results for each configuration. Detailed throughput-per-dollar results for all system configurations can be found in Table 6 (Appendix). VectorVisor outperforms x86 instances for four benchmarks (Scrypt, Blur-Bmp, PHash-Modified, Bill-PDF), and on all but two benchmarks versus WebAssembly. Throughput-per-dollar results are overall lower than our throughput results in Section 4.2.2. Leveraging GPU acceleration requires substantial throughput improvements to offset the high cost of GPU hardware (e.g., 3.42× for the T4 vs. AMD x86-64 CPUs). Bottlenecks on application-level divergence (e.g., Strings) and data transfer overheads (e.g., LZ4 and Histogram) result in lower throughput and throughput-per-dollar results.

In three out of the four benchmarks where VectorVisor surpasses our x86-64 baselines, the T4 outperforms the A10G, even though it belongs to an earlier generation of GPUs (e.g., Turing vs. Ampere). Despite differences in GPU hardware, the best predictor of superior throughput-per-dollar with VectorVisor is the ratio of the global memory size (e.g., the number of VMs that can fit) to cost. Compared to the A10G and v520, the T4 packs 27.5% and 43% more VMs-per-dollar respectively. Workloads such as Scrypt, which leverage hardware differences like the larger memory bandwidth of the A10G, can break this trend.

4.2.4 Latency

VectorVisor runs many instances of a program in parallel, improving total throughput, but not latency. Batches of requests have higher on-device execution times than x86-64, ranging from 84-1040× longer using the T4—limiting usage to non-latency sensitive applications.

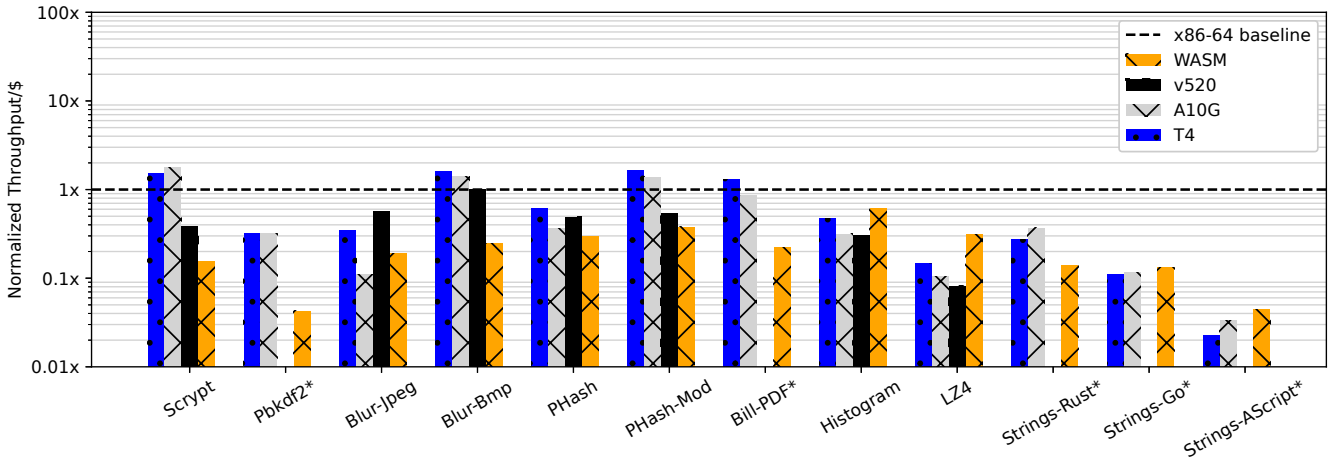

Figure 9: *Benchmark Throughput-per-Dollar.* Results are normalized to the x86-64 baseline for each benchmark except for Strings-Go and Strings-AScript, which are normalized to the x86-64 baseline of Strings-Rust instead. *Benchmarks without an AMD v520 result.

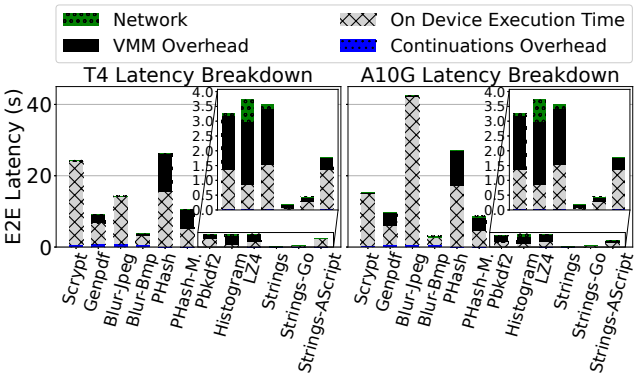

Figure 10: Per-benchmark latency breakdown of execution time, VMM overhead (e.g., syscall overhead), continuations overhead (e.g., context saving/restoring), and network IO. Breakdowns correspond to the best performing configurations with PGO disabled from Table 5.

4.3 Latency breakdown

Figure 10 shows the end-to-end (E2E) latency breakdown for each benchmark. Batch sizes, which impact request latency, can be found in Table 2. On-device execution time dominates the E2E latency for most benchmarks, with the histogram benchmark being the exception. We see that supporting preemption using continuations has low overhead, varying between <1% (PHash-Modified) and 19% (Blur-Bmp) of the on-device execution time. Similarly, by overlapping compute with VMM and network IO VectorVisor significantly reduces related overheads. Benchmarks with a low operational intensity (Ops/Byte) (e.g., Histogram, LZ4) which cannot overlap on-device execution time with batch formation as efficiently are more likely to bottleneck on VMM or network IO.

GPU	Platform	Instance Name	Benchmark	Throughput	Throughput/$
NVIDIA T4	VectorVisor	g4dn.xlarge	Blur-Bmp	804.83	1530.10
NVIDIA A10G	VectorVisor	g5.xlarge	Blur-Bmp	1365.84	1357.69
NVIDIA T4	VectorVisor	g4dn.xlarge	PHash-Modified	384.32	730.65
NVIDIA A10G	VectorVisor	g5.xlarge	PHash-Modified	608.02	604.40
NVIDIA T4	CUDA	g4dn.xlarge	Blur-Bmp	576.28	1095.59
NVIDIA T4	CUDA	g4dn.2xlarge	Blur-Bmp	1118.95	1487.96
NVIDIA A10G	CUDA	g5.xlarge	Blur-Bmp	652.96	649.06
NVIDIA A10G	CUDA	g5.2xlarge	Blur-Bmp	1250.33	1031.62
NVIDIA T4	CUDA	g4dn.xlarge	PHash-Modified	408.85	777.27
NVIDIA T4	CUDA	g4dn.2xlarge	PHash-Modified	821.15	1091.95
NVIDIA A10G	CUDA	g5.xlarge	PHash-Modified	462.27	459.52
NVIDIA A10G	CUDA	g5.2xlarge	PHash-Modified	896.35	739.56

Table 4: Performance of handwritten CUDA benchmarks.

4.3.1 CUDA Comparison

Leveraging GPU acceleration typically involves manually breaking down a program into fine-grained tasks which can be parallelized—speeding up individual invocations of a function. In contrast, VectorVisor runs many instances of the same program in parallel, improving throughput but not latency. To evaluate the efficiency of our translation, we manually rewrote two benchmarks (Blur-Bmp and PHash-Modified) using CUDA. CUDA baselines incur additional CPU overhead from increased kernel launch overheads and running a fraction of the workload on the CPU. To fairly evaluate these baselines, we benchmark them using both xlarge and 2xlarge instances with additional CPUs (Table 1).

We see in Table 4 that VectorVisor slightly outperforms a handwritten CUDA Gaussian blur function, and obtains 67% of the throughput-per-dollar of our CUDA PHash function. PHash-Modified has higher VMM overhead than Blur-Bmp (35% vs 12% of the E2E latency) which affects overall efficiency.

5 Discussion

Workload Characterization. Identifying ideal workloads for VectorVisor is key to improving the cost efficiency of real

applications. Ideal workloads minimize divergent execution, recursion, indirect calls, and are compute-bound. Future work can incorporate model-based approaches [79] to identifying acceleration opportunities for VectorVisor.

Evaluation Limitations. We use both throughput and throughput-per-dollar as evaluation metrics. Throughput-per-dollar is a powerful metric that enables us to compare the end-to-end *efficiency* of VectorVisor, which considers system complexities as well as the capital and operational cost implications of running throughput-oriented workloads. Cloud providers allow customers to insure themselves against high variation in hardware pricing [62, 63], providing a steady baseline cost (at a premium). On-premises hardware configurations can be less expensive over long periods of time, for those willing to pay higher up-front costs. Despite shortcomings, cost-based efficiency metrics provide tangible baselines.

System Call Implementations. Providing support for system calls using continuations was key to running realistic workloads using VectorVisor. Systems such as GPUfs, GPUnet, and Berkeley Borph [76–78, 82, 86] instead provide support using a more performant RPC-like interface using vendor-specific APIs or custom drivers. RPC-style interfaces rely on the ability to perform concurrent and consistent CPU–GPU memory accesses. OpenCL 2.0 *in theory* enables this with fine-grained buffer SVM [3, 53]. In practice, support for fine-grained SVM is mixed—with NVIDIA OpenCL 3.0 not supporting the API and AMD providing partial support [2]. Continuations provide a cross-platform and reasonably performant approach to supporting system call support for GPUs.

6 Related Work

Continuations. Continuations are often used by compilers to support complex control flow operations such as exceptions and preemption [27, 28, 30, 71, 84]. VectorVisor uses continuations to efficiently provide support for preemption and complex control flow on GPUs.

GPU Preemption. GPU kernel preemption can be supported through compiler-based approaches that partition (or slice) programs into chunks [29, 35, 39, 89, 93, 94], or with hardware/driver support [13, 68, 83, 86].

High-Level GPU Languages. CUDA or OpenCL require developers to write programs using low level abstractions. High level language approaches [2, 31, 44, 48, 52, 55, 57, 72, 92] make it easier to accelerate existing programs by reusing existing codebases. Common language features such as dynamic memory allocation, garbage collection, reflection, and recursion are often absent. Unlike VectorVisor, code often must be rewritten to explicitly leverage parallel APIs.

Domain-Specific GPU Systems and Languages. Programming languages designed for domain-specific workloads (DSLs) [24, 38, 40, 46, 58, 73–75, 80] can offer substantially improved performance over general-purpose programming languages. DSLs obtain superior performance through language restrictions, forcing developers to express programs using specific syntax or function calls. While DSLs can efficiently accelerate specific workloads, they trade off performance for programmability—e.g., many workloads cannot be expressed using restrictive DSLs. Similar to DSLs, domain-specific systems can significantly improve performance for throughput-oriented workloads [32, 42, 56, 87]. Domain-specific systems vectorize common workloads (e.g., image processing, machine learning, database operations) using handwritten GPU kernels. Other systems manually vectorize functions from (non GPU-specific) DSLs (i.e. SQL) [50, 51, 69].

Vectorized Program Translation. Systems that abstract a SIMT or SIMD lane as a VM often target restricted use-cases (e.g., fuzz testing) [37, 45, 47, 49]. VectorVisor's design and implementation notably differ from prior work, offering superior GPU language, runtime, and hardware support.

7 Conclusion

VectorVisor is a research prototype which demonstrates that applications originally written for CPUs can be directly run on GPUs without significant modifications. Not only is such GPU execution possible, but it can in fact yield superior throughput-per-dollar versus compute-optimized x86-64 CPUs in the cloud.

Binary translation for GPUs is an exciting and predominantly unexplored area of research, with many potential applications. VectorVisor shows the viability of our new approach to parallelism, opening up the area to future research.

Table 6: *Benchmark Throughput-per-Dollar.* Values correspond to the average RPS of each benchmark normalized to instance cost. Bold values correspond to the best throughput-per-dollar.

A.2 Rust Example

```rust
#[macro_use]
extern crate lazy_static;
// Import existing open-source libraries!
use pdf_writer::*;
use pdf_writer::types::{ActionType, AnnotationType, BorderType};
use std::fs::File;
use std::io::Write;
use std::time::Instant;
// Import our custom 'serverless' runtime. We use this in our x86 and WASM benchmarks as well.
// WASM benchmarks run the same binary that VectorVisor does!
use wasm_serverless_invoke::wasm_handler::*;
use wasm_serverless_invoke::wasm_handler::WasmHandler;
use wasm_serverless_invoke::wasm_handler::SerializationFormat::MsgPack;
use serde::Deserialize;
use serde::Serialize;
// Image and compression libraries
use image::{ColorType, GenericImageView, ImageFormat};
use miniz_oxide::deflate::{compress_to_vec_zlib, CompressionLevel};
// Include a sample template image for our PDF footer
lazy_static! {
    static ref EMBED_IMAGE: &'static [u8] = include_bytes!("test.png");
}
// Syntactic sugar for (de)serializing JSON/MsgPack inputs
#[derive(Debug, Deserialize)]
struct FuncInput {
    name: String,
    purchases: Vec<String>,
    price: Vec<f64>, // Typically prices should not be encoded as floats, we do this for simplicity.
}
#[derive(Debug, Deserialize)]
struct BatchInput {
    inputs: Vec<FuncInput>
}
#[derive(Debug, Serialize)]
struct FuncResponse {
    resp: Vec<u8>
}
#[derive(Debug, Serialize)]
struct BatchFuncResponse {
    resp: Vec<FuncResponse>
}
#[inline(never)]
fn makePdf(event: FuncInput) -> Vec<u8> {
    // Perform PDF formatting, image manipulation, and compression to generate a valid PDF
}
fn batch_genpdf(inputs: BatchInput) -> BatchFuncResponse {
    let mut results = vec![];
    for input in inputs.inputs {
        results.push(FuncResponse { resp: makePdf(input) });
        // Bill-PDF is the only benchmark to use system calls as synchronization barriers
        unsafe { vectorvisor_barrier() }; // We can wait on arbitrary subsets of VMs (unlike OpenCL barrier(...))
    }
    return BatchFuncResponse{ resp: results };
}
fn main() {
    // Specify input format type and buffer sizes
    let handler = WasmHandler::new(&batch_genpdf);
    // Starts the event-loop and encapsulates serverless_invoke/serverless_response
    handler.run_with_format(1024*512, MsgPack);
}
```

Figure 11: *Bill-PDF*. This benchmark performs PDF processing, image manipulation, and compression.

A.3 Golang Example

```go
package main;

// define our system call interface
// #include "serverless.c"
import "C"
import (
    // Import JSON + string manipulation libraries
    "github.com/json-iterator/tinygo"
    "unsafe"
    "strings"
)

//go:generate go run github.com/json-iterator/tinygo/gen
type Payload struct {
    Tweets  []string `json:"tweets"`
}
//go:generate go run github.com/json-iterator/tinygo/gen
type Response struct {
    Tokenized  [][]string
    Hashtags   [][]string
}
// Go doesn't provide Map/Filter for us, so we use our own implementation
func Map[T, U any](ts []T, f func(T) U) []U {
    ...
}
func Filter(vs []string, f func(string) bool) []string {
    ...
}
func main() {
    json := jsoniter.CreateJsonAdapter(Payload_json{}, Response_json{})
    // Use this as a set, track all stopwords
    stopwordSet := make(map[string]bool)
    for _, word := range stopWords {
        stopwordSet[word] = true
    }
    input_buf := make([]byte, 1024*450) // buffer for raw inputs from VectorVisor
    for { // serverless_invoke is the system call used for transferring inputs from the host (CPU) to the GPU
        in_size := C.serverless_invoke((*C.char)(unsafe.Pointer(&input_buf[0])), 1024*450)
        if in_size == 0 { // if in_size == 0, then this VM is blocked off and has no input for this batch
            fakeaddr := uintptr(0x0) // serverless_response copies inputs from the GPU back to the CPU.
            C.serverless_response((*C.char)(unsafe.Pointer(fakeaddr)), 0)
            continue
        }
        var input Payload;
        json.Unmarshal(input_buf[0:in_size], &input);
        // First tokenize each tweet []string --> [][]string
        ...
        // Now process each tweet, filtering out stop words
        ...
        // Get the hashtags, we will add them as we see them
        var tags = make([][]string, 0)
        ...
        var response Response;  // create a JSON response and return it!
        response.Tokenized = tokenized;
        response.Hashtags = tags;
        bytes, _ := json.Marshal(response);
        C.serverless_response((*C.char)(unsafe.Pointer(&bytes[0])), (C.uint)(len(bytes)))
    }
}
```

Figure 12: *Strings-Go*. Tokenize some input tweets and return the hashtags. TinyGo (https://tinygo.org/docs/reference/lang-support/) provides us with a conservative mark and sweep garbage collector, limited runtime reflection and goroutine support.

A.4 AssemblyScript Example

```
import { Console, FileSystem, Descriptor } from "as-wasi/assembly"; // Import needed syscalls
import { JSON, JSONEncoder } from "assemblyscript-json/assembly"; // Import a JSON encoder/decoder
import { listen } from "./env"; // Import our event-driven runtime
import { stopWords, initSet, getSet } from "./stop"; // Import a dataset of stopwords
function abort(message: usize, fileName: usize, line: u32, column: u32): void {
    unreachable() // needed for the AssemblyScript runtime
}
initSet(); // init our set of "stop words"
let set: Set<string> = getSet();

// TypeScript-like syntax for GPU programing!
function process_tweets(input: JSON.Obj): Uint8Array | null {
    let tweets: JSON.Arr | null = input.getArr("tweets");
    if (tweets != null) {
        let strTweets: string[] = tweets._arr.map<string>((val: JSON.Value): string => val.toString());
        // Split each tweet (tokenize)
        let tokenize: string[][] = strTweets.map<string[]>((val: string): string[] => val.split("␣"));
        // Remove empty values and stop words
        let filtered: string[][] = tokenize.map<string[]>((arr: string[]): string[] =>
                                    arr.filter((word: string): bool => {
                                            if (set.has(word)) {
                                                return false;
                                            } else {
                                                return true;
                                            }
                                        }));
        // Get the array of hashtags for each tweet
        let hashtags: string[][] = filtered.map<string[]>((tweet: string[]): string[] =>
                                    tweet.filter((word: string): bool => {
                                        if (word.charAt(0) == '#' && word.charAt(1) != "") {
                                            return true;
                                        } else {
                                            return false;
                                        }
                                    }));
        let encoder = new JSONEncoder(); // encode a JSON response
        encoder.pushArray("tokenized");
        for (let tweet_idx = 0; tweet_idx < filtered.length; tweet_idx++) {
            ...
        }
        encoder.popArray();
        encoder.pushArray("hashtags");
        for (let tweet_idx = 0; tweet_idx < hashtags.length; tweet_idx++) {
            ...
        }
        encoder.popArray();
        let json: Uint8Array = encoder.serialize();
        return json;
    }
    // else we failed somehow...
    return null;
}
listen(1024*512, process_tweets); // Starts the event-loop and encapsulates serverless_invoke/serverless_response
```

Figure 13: *Strings-AssemblyScript*. Same as Strings+Strings-Go, but with different syntax. Support for incremental garbage collection is provided.
