The detailed scheduling process of Minos on the data plane is illustrated in Figure. 7. In Minos, our aim is to achieve per-flow scheduling, but the match-action pipeline in a programmable switch typically handles flows on a per-packet basis, lacking consideration for flow states. To enable flow interleaving, maintaining per-flow states becomes essential. In Minos, we address this challenge by utilizing registers within the programmable data plane to store the following flow states:

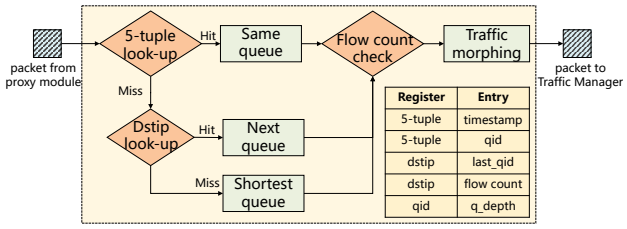

Figure 7: Schedule algorithm of Minos.

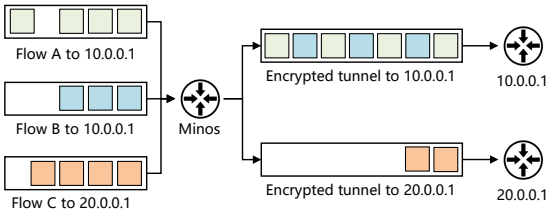

Figure 8: Example of multiple encrypted tunnels.

- **Timestamp**. The timestamp for a flow identified by the 5-tuple is stored in the corresponding entry. Upon packet ingress, Minos records the entry timestamp, signifying when the last packet from this flow entered the pipeline. Inactive flow entries are subject to expiration and removal from the register through the recirculation of dummy packets.
- **Queue ID**. The queue ID to which the flow is sent.
- **Flow count**. A Minos sender switch maintains multiple encrypted tunnels with multiple destination IPs, each representing a Minos receiver switch that performs decryption and de-obfuscation. We monitor the number of flows currently transmitting to each destination IP. Figure. 8 shows the scheduling of three flows. Flow A and B are sending to 10.0.0.1, so they will be mixed into an encrypted tunnel to 10.0.0.1. Flow C is sending to 20.0.0.1, so it will be sent into another encrypted tunnel. We assume that passive attackers will eavesdrop on each encrypted tunnel based on sender and receiver Minos switches' IP addresses. Recording flow numbers in each encrypted tunnel helps Minos decide whether traffic morphing is needed.
- The last assignment of the queue ID of each destination IP.

For each packet entering the pipeline, Minos first maps its 5-tuple into the timestamp register and performs a lookup in the queue ID register. If an entry exists, it means that previous packets of this flow have been sent into a specific queue so that the following packets should be sent through the same queue to avoid packet reordering. If no entry is found, it means

the packet is initializing a new flow. Then, the 5-tuple will be matched in the destination IP register. If an entry is found in the destination IP register, the flow will be assigned to the next queue based on the recorded queue ID. This new flow's queue ID will be the origin queue ID plus one. In this way, flows in the same encrypted tunnel will be evenly spread into different queues and scheduled in a round-robin manner, just like Flow A and B in Figure. 8. If the destination IP is not found, it means that we are building a new encrypted tunnel and no restrictions are applied to this flow. In this case, the flow will be sent into the shortest queue to balance queue length.

The flow count table keeps track of the number of flows sent to each destination to decide whether the Traffic Morphing Module should be activated. When the number of flows in an encrypted tunnel is very small, a mixture of these flows is insufficient to conceal their information effectively. Moreover, when only a few flows are active, the Schedule Module may encounter the problem of asymmetric flow interleaving, where one flow sends significantly more packets than others, resulting in consecutive packets from the same flow. This could potentially expose features from the aggregated flow to traffic analysis attackers. In such cases, the Traffic Morphing Module will perform dummy packet insertion to supplement packets for flow mixing. Besides, it will also conduct packet padding to further obfuscate flows. The flow count table is regularly checked to decide whether to invoke the Traffic Morphing Module to make sure sufficient protection is always in place. In the Schedule Module, we only track the target flows that require defenses, rather than recording every incoming flow. For detailed implementation, please refer to Section 7.1.

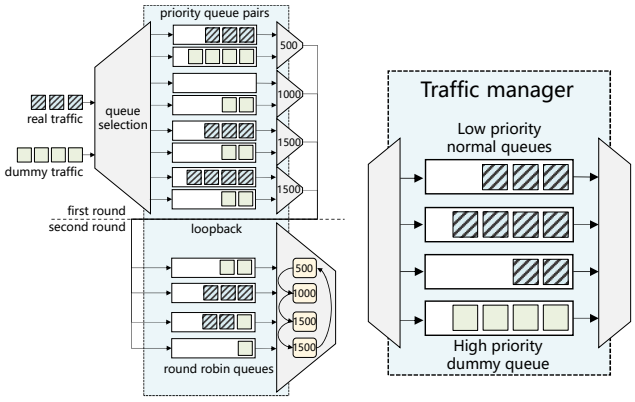
6 Traffic Morphing Module

The Traffic Morphing Module performs dummy packet insertion and packet padding to implement traffic morphing. In this section, we introduce how we implement the Dummy Module and the Padding Module in a lightweight manner.

6.1 Dummy Module

Although programmable switches cannot generate packets directly from the data plane, programmers can incorporate template packets into the pipeline. A typical workflow of this process is as follows. First, packet templates are sent by the switch CPU or through specific ports, marking every subsequent packet from that port as a dummy packet. Second, dummy packets are passed through the pipeline and essential functions are executed, e.g. updating registers. Third, after going through the ingress pipeline, dummy packets can either be sent into the egress pipeline or inserted into the recirculation port for another pass through the pipeline.

However, sending dummy packets in a pipeline is challenging, as they must be generated in advance and can not be sent



(a) Ditto Traffic Manager (b) Minos Traffic Manager

Figure 9: Different dummy packet scheduling methods.

on demand. In Minos, for instance, obfuscating a single flow within a tunnel requires the use of dummy packets. However, the inability to generate these packets instantaneously leads to unpredictable delays before a dummy packet can enter the pipeline. This limitation complicates the timely and seamless integration of dummy packets for effective obfuscation. Prior works [24, 28] have attempted to buffer dummy packets, but they cause significant bandwidth overhead.

In IMap [24], control plane programs generate dummy packets on the switch CPU, and recirculate them through the pipeline to accumulate speed. This approach handles dummy packet buffering by filling the pipeline entirely with dummy packets, enabling the generation of probe packets as needed. However, this approach introduces excessive dummy packets that would reduce overall throughput, contradicting our design goal of achieving a lightweight, line-rate defense model.

Another previous work, Ditto [28], conducts traffic morphing on the programmable data plane at the cost of high overhead. Ditto morphs traffic so that the sizes of packets sent out strictly adhere to a predefined pattern, e.g., [500,1000,1500,1500]. To achieve this, Ditto pads packets when their sizes are smaller than the intended size. Conversely, if the original packets are larger than the target size, Ditto uses dummy packets to simulate smaller ones. Consequently, a constant supply of dummy packets is required. As shown in Figure. 9a, Ditto uses hierarchical queues to buffer dummy packets, causing each packet to pass through the pipeline twice. In the first round, queues are organized by packet size (e.g., 500B). Real packets go to higher priority queues, while dummy packets fill lower priority ones. In the second round, packets are sorted by size and the traffic manager schedules them out in a round-robin manner to match the fixed pattern.

Previous studies fail to design a lightweight method to schedule dummy packets. In Minos, we design a priority-based dummy packet scheduling structure which utilizes priority queues in the Traffic Manager to approximate instant

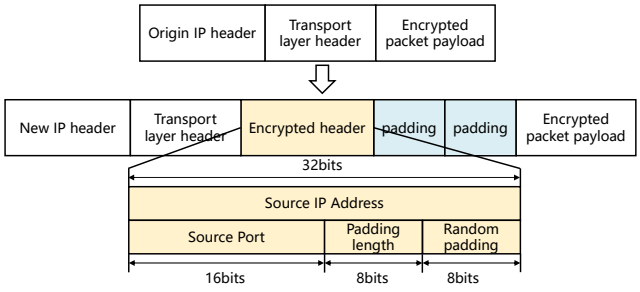


Figure 10: Minos packet format.

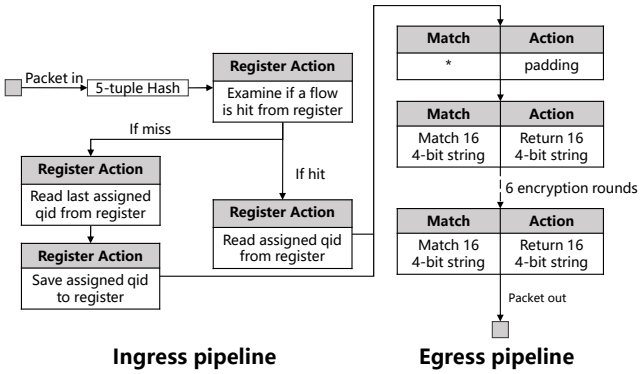

Figure 11: Minos flow table.

dummy packet insertion with strict priority queues. As Figure. 9b shows, in the Minos Traffic Manager, a set of queues for normal packets shares the same low priority, and a special dummy queue owns the highest priority. Normal packets are scheduled as Figure. 7 illustrates, and are sent in a round-robin manner. The dummy queue, while owning the highest priority, will be paused when it is not needed. Unfortunately, directly pausing and resuming queues is not a supported feature in P4 switches [40]. In Minos, we modify the queue state with the assistance of the control plane. Specifically, we send marker packets to the control plane at regular intervals to report the number of active flows. Then, according to the active flow number, the control plane decides the proper cycle lengths for periodically pausing and resuming queues. The control plane program adjusts the dummy packet rate as follows:

$$Dummy_rate = \left(\frac{1}{n} - d - i\right) * \frac{r}{R}, \tag{2}$$

where n is the number of rounds in the resume period, i is the interval between resume and pause periods, r is the output rate of the dummy queue, R is the current output rate of target flow, and d is a constant representing the delay of instructions between the control plane and the data plane. This approach allows us to efficiently blend normal packets with dummy packets at minimal cost, requiring only a single buffer queue in the Traffic Manager.

6.2 Padding Module

Besides dummy packets, packet padding is also necessary to hide packet length to defend against packet length attacks, such as PINGPONG [44]. In Minos, we apply random padding based on the average size of the original traffic. We can set different padding sizes according to different defensive needs, as discussed in Appendix A. The programmable switch pads packets by adding packet headers after regular packet headers. From the attackers' perspective, these headers are disguised as packet payload. As Figure. 10 shows, Minos adds multiple headers of different sizes after the transport layer header to realize dynamic padding. To de-obfuscate and remove these headers, the receiver Minos switch must be informed of the exact padding length.

Therefore, the padding length is also encrypted with the Proxy Module. A total of 64 bits will be encrypted and inserted after the transport layer header, including 32-bit source IP, 8-bit padding length, 16-bit source port, and 8-bit random padding. The padding size is calculated in the ingress pipeline and encrypted along with the source IP while padding headers are added in the egress pipeline. On the receiver switch, padding size and source IP will be decrypted in the ingress pipeline, so that extra headers can be stripped in the egress pipeline. Overall, the Proxy Module will bring a static 8 Bytes to each packet and the bandwidth overhead of the Padding Module depends on defense settings.

7 Hardware Prototype Evaluation

We implement a hardware prototype of Minos on two Barefoot Tofino1 switches with 32 × 100 Gbps ports. We use a traffic generator [4] to inject packets and record output traffic.

7.1 Implementation

The switch pipeline and flow tables are depicted in Figure. 11. Specifically, packets entering the ingress pipeline will first be hashed. Utilizing the inherent CRC32 hash function of the Tofino ASIC, the five-tuple of each flow is hashed into a unique flow identifier (ID). This flow ID subsequently serves as the key for storing flow-level information within the register. A Tofino1 switch offers 80 pages, each containing 1000 entries of 128b RAMs, which can be allocated for storing the flow-level information. These hardware resources enable Minos to manage over 10,000 concurrent flows. Nevertheless, as a gateway switch, the number of flows handled by Minos may exceed this capacity. It is important to note that Minos is designed to monitor only those flows that require defense, rather than monitoring the information of every single flow. Therefore, the register of Tofino does not affect the

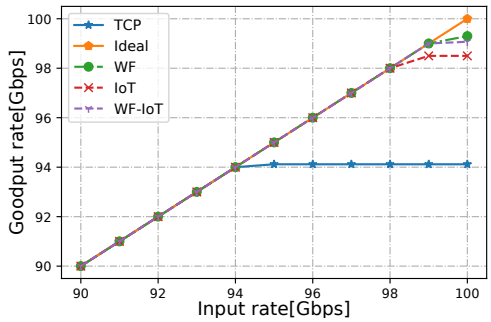

Figure 12: Throughput of Minos proxy module.

scalability of Minos. The dummy packets are injected from a specific port and assigned to the high priority queue. We use bfrt python scripts to pause and resume the dummy queue. In the egress pipeline, Minos first performs packet padding by adding packet headers. Then, in each encryption round, the original 64-bit string is segmented into 16 4-bit strings, and the match action table executes string-to-string mapping. Owing to the limitation of the number of stages, the maximum number of encryption rounds that can be performed is six.

Table 2 shows the utilization of each hardware resource. The Minos Proxy Module consumes only 6.15% of VLIWs and does not use any ALUs or TCAMs. Instead, it relies on 55.96% of SRAM to support match-action table-based encryption. Notably, many functions commonly deployed on P4 switches, such as Sketch [61] and Network Attack Detection [31], demand substantial ALU (>20%) or VLIW ($\approx$ 10%) resources but have low SRAM requirements. Therefore, Minos can coexist efficiently with these P4 programs. The receiving switch and the sending switch have the same hardware resource consumption because the same P4 program and the corresponding decryption flow tables need to be deployed.

7.2 Evaluation of the Proxy Module.

First, we evaluate the throughput of the Proxy Module. We send TCP packets of 128B at different rates to examine if Minos can perform line rate encryption and also evaluate the performance of the Proxy Module using realistic flows. The detailed construction of each dataset will be illustrated in section 7.6. In Figure. 12, the X-axis reflects the input rate of packets, and the Y-axis represents the actual output rate of real traffic without extra bytes brought by the Minos Proxy Module. The result proves that Minos is able to perform line rate source IP encryption in the case of realistic datasets. Minos reached an upper limit of 94 Gbps in the case of TCP streams because the packets in TCP streams are relatively small, which means that adding an 8-byte packet header has a greater impact and thus reduces the throughput. As Minos has a static 8-byte overhead per packet, the output ratio of real traffic will be higher if larger packets are sent.

Table 2: Hardware Resource utilization.

Module name	Stages	VLIWs	ALUs	TCAM	SRAM
Proxy module	10	6.15%	0%	0%	55.96%
Minos	12	7.81%	0%	0%	59.06%

Table 3: Arrival time of 1000th packet(s).

Origin	Limited output rate	Two flows	Three flows	Four flows
1	1.095861	1.102307	1.106605	1.108754

7.3 Evaluation of the Schedule Module.

We implement a simple scenario to evaluate the latency brought by the Schedule Module. In each flow, we send 1000 packets per second and record the arrival time of the 1000th packet. Then, we mix different numbers of flows to see if the flow mixture will bring extra latency overhead. In Minos, we record the current traffic rate and report to the control plane periodically to update port speed limitation, usually 99% of the current traffic rate. Otherwise, packets will not be cached in queues and will be sent out directly in the First-in-First-out manner. In this experiment, we set the output rate of the tested port at 90% of the current traffic rate to magnify the delay effect and evaluate the arrival time of 1000th packets of each flow.

As Table 3 shows, adding flow numbers only incurs less than 1% latency, which is insignificant compared to output rate limiting. The results show that Minos can handle multiple flows without incurring much delay. Therefore, we should keep track of the current traffic rate and synchronize it with the control plane frequently to reduce latency overhead.

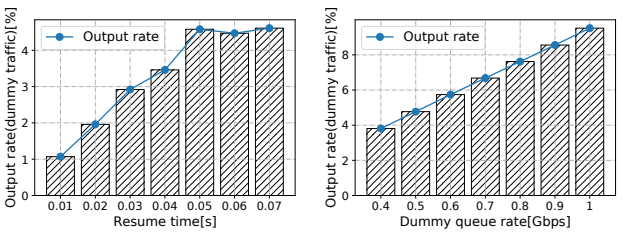
7.4 Evaluation of the Dummy Module

Minos enables real time dummy packet insertion by pausing and resuming priority queues. The control plane periodically pauses and resumes queues by altering queue status according to equation 2. We set the number of sending rounds n to 10 rounds per second and the output rate of normal queues to 1Gbps, and evaluate the impacts of resume interval i (X-Axis in 13a) and dummy queue output rate r (X-Axis in 13b) on dummy traffic rate.

When evaluating the impact of the interval between resume and pause dummy queue on output rate, we set the default output rate of the dummy queue to 0.1Gbps and alter interval lengths. As shown in Figure. 13a, the output rate of dummy packets increases as the interval increases and reaches its limit of about 4.5%. This is because we repeat each sending round 10 times per second, and each round lasts for 0.1 second. In this way, if we resume a queue for too long, the next resume instruction will come as soon as the previous pause instruction finishes, which means the queue will always be open.

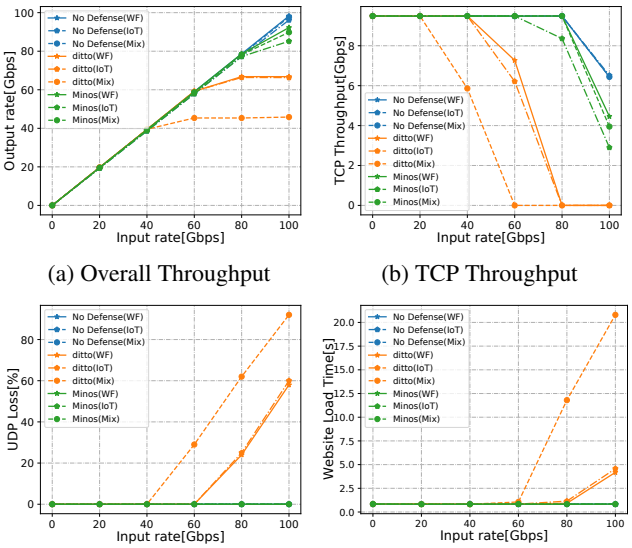
Table 4: Overhead of Minos

Flow type	arrival time of 500,000th packet(s)	Goodput rate(%)
Base	5	100%
One flow	5.02	95.3%
Multiple flows	5.12	99.2%



(a) Different intervals (b) Different output rates

Figure 13: Evaluation of the dummy module



(a) Overall Throughput (b) TCP Throughput

(c) UDP Packet Loss (d) Website Load Time

Figure 14: Evaluation results in comparison with Ditto.

In the evaluation of the impact of different dummy queue rates on output rate, we set the interval between resume and pause to 0.01 seconds. As shown in Figure. 13b, the output rate of dummy packets and the queue output rate exhibit an almost linear relationship, which means we can precisely control the output rate of dummy packets through the dummy queue output rate.

7.5 Overall Evaluation

At last, we evaluate Minos's overall latency overhead and bandwidth overhead of all three modules. We send packets of 1024B with 10,000 packets per second and evaluate Minos in both one-flow scenario and multiple-flow scenario. In the former case, we add 64B padding to each packet and insert dummy packets with 0.01s interval and 0.5Gbps output rate. When multiple flows are transmitting, we do not perform traffic morphing because flow interleaving is sufficient to defend against traffic analysis attacks.

Table 4 shows that Minos can perform with limited latency and bandwidth overhead. In the one-flow scenario, Minos reaches 95% goodput with little latency overhead. In the multiple-flow scenario, the goodput rate is close to 100% because we only add 8B of encryption header to each packet. The arrival time of the 500,000th packet experiences a slight delay of just around 2.4%. This delay is caused by the fact that the output rate of the tested port is limited to enable round-robin queues, as discussed in the evaluation of the Schedule Module.

7.6 Comparison with SOTA work

We compare Minos with the state-of-the-art traffic morphing-based defense on programmable switches, as presented in Ditto [28]. Ditto is an end-to-end system that incorporates two Tofino switches, responsible for obfuscation and de-obfuscation respectively. To assess the performance of Minos and Ditto across various network conditions, we choose three datasets for our evaluation: Website Fingerprinting dataset (WF) [37], IoT Fingerprinting dataset (IoT) [36], and a mixture of both (Mix). We send background traffic ranging from 0 to 100Gbps with these datasets and conduct four experiments. Besides, we configure Minos to perform a 64B padding to each packet. Note that the Dummy Module is disabled because the evaluation involves transmitting multiple flows, and dummy packet insertion are unnecessary.

First, we assess the overall throughput of Minos and Ditto. Figure. 14a illustrates that Minos is capable of adapting to diverse scenarios, whereas Ditto's throughput is capped at 45Gbps when dealing with packets of more uniform sizes in the Mixed dataset. In the TCP throughput experiments, we send background traffic ranging from 0Gbps to 100Gbps along with a 10Gbps TCP flow. Figure. 14b reveals that the throughput of Ditto drops to near 0 when sending 80Gbps background traffic, whereas Minos maintains more than 8Gbps throughput at 80Gbps and approximately 4Gbps at 100Gbps. Additionally, we examine the performance of Minos and Ditto in terms of the UDP packet loss rate and the loading time of Google. The results show that Minos's performance is almost the same as the ideal case, with no significant impact on applications. However, Ditto can cause packet loss and website loading delays under high throughput conditions.

8 Use Case: Website Fingerprinting

In this section, we implement Minos to defend against Website Fingerprinting. We introduce our dataset, baseline attacks, and defenses in section 8.1 and introduce how we adapt Minos to defend WF attacks in section 8.2. At last, we evaluate Minos against baseline attacks and defenses.

8.1 Evaluation Setup

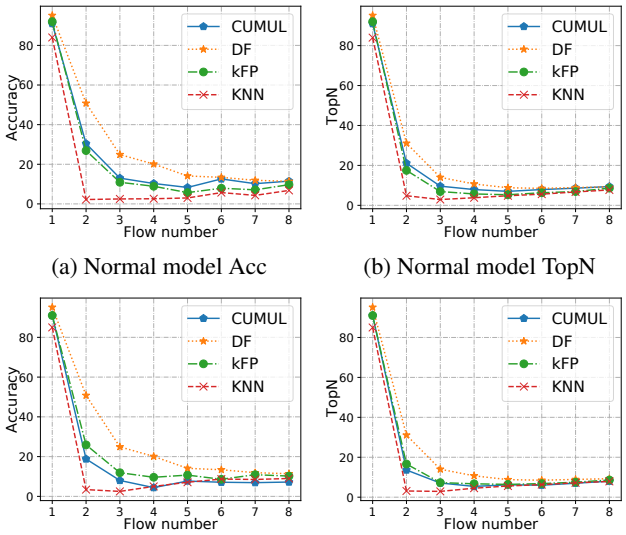
We request the parsed dataset with all meta-data including timestamps from [37]. The closed world dataset contains 900 websites, and 5,000 visits each. In our experiments, we select 300 websites and 100 traces each, 30,000 traces in total from the closed world dataset. Each trace acts as a real traffic trace and is sent to Minos according to its timestamp.

We evaluate Minos against four up-to-date Website Fingerprinting attacks: kNN [48], CUMUL [34], kFP [20], DF [42]. We use the simulation code provided by Gong et al. [18] and keep the suggested parameters from the original papers, but we change the maximum length of traces, which will be illustrated in section 8.3. As for defenses, we also adopt defenses provided by [18]: Tamaraw [10] and WTF-PAD [9]. The former is a heavyweight obfuscation defense, and the latter is a lightweight defense. We compare these two defenses to Minos on overhead and effectiveness.

8.2 Defense Design

Recall that in Minos, traffic morphing-based defense against Website Fingerprinting is only needed when we have a limited number of flows transmitting in an encrypted tunnel. When the number of transmitted flows is large, Minos performs flow-interleaving to obfuscate the flows. When the number of transmitted flows falls below a threshold, it supplements the defense with traffic morphing-based Website Fingerprinting defense. The exact threshold will be examined in section 8.3. In this section, we describe our lightweight defense mechanism.

Based on previous studies, the first few seconds of each trace leak the most useful features for website fingerprinting [20, 50]. [18] proposes FRONT, a defense that dedicates most of its bandwidth budget to obfuscate the trace front. FRONT samples a dynamic traffic window and sends packets based on Rayleigh Distribution, and uses four parameters to control this process. In Minos, we simplify this defense to two parameters: front window W and obfuscating parameter Ω. In the first W packets, we randomly insert dummy packets with a given probability Ω, and in the rest of the traffic, no dummy packets are inserted. To implement the above defense mechanism, we can use the estimated overhead budget and equation 2 to configure the dummy queue. To make this defense as lightweight as possible, we choose not to pad or delay packets and only insert dummy packets at a given possibility.



(a) Normal model Acc (b) Normal model TopN

(c) 5000 model Accuracy (d) 5000 model TopN

Figure 15: Evaluation of flow mixture

8.3 Evaluation

First, we evaluate the relationship between the flow number and the accuracy of attack models. The attacks are trained with the original recommended parameters, except for flow length. To avoid disturbance brought by flow aggregation, we train models at two fixed lengths: 5000 and 10000, and cut off input traffic traces to them. We apply two metrics to evaluate each attack model: the accuracy metric and the TopN metric. In both cases, we select the top N labels with the highest probability, where N equals the number of mixed flows. The accuracy metric evaluates if machine learning models return any right label of the original flows, while the latter metric evaluates how many labels are correct. Each correct label is counted as $1/N$ correct answer.

Figure. 15 shows our results. Figure. 15a and 15b show how metrics change with flow numbers. We can see that both evaluation metrics quickly decrease as the flow number n increases, and converge at n=5. When flow numbers are larger than 5, both metrics are lower than 20%, which is effective and able to defend against any attack models. As for the two graphs evaluating the top 5000 models, although different in exact numbers, the overall tendencies are the same, and also coverage at n=4 or 5. To conclude, mixing up flows can significantly obfuscate attackers with only a few flows. Based on this experiment, we set the threshold of enabling dummy packet insertion to 4, which decreases attackers' accuracy to lower than 20% without any extra overhead.

Then we evaluate our defense mechanism against other defenses. Here, we set the obfuscating parameter Ω to 0.6 and evaluate the defense effect of window sizes of 500 and 1000. The bandwidth overhead of each defense is shown in Table 6. Table 5 shows all evaluation results. We use accuracy, preci-

Table 5: **Defense performances**

Defense	**Accuracy**%				**Precision**%				**F1**			
	kNN	CUMUL	kFP	DF	kNN	CUMUL	kFP	DF	kNN	CUMUL	kFP	DF
No defense	84.62	91.47	91.68	96.9	83.46	90.72	91.56	96.75	0.831	0.9091	0.9147	0.9676

Minos-1000	7.38	38.73	32.66	6.67	8.49	52.61	38.31	6.7	0.06	0.38	0.28	0.045

Table 6: Overhead of each defense mechanism

Defense	Parameters	Overhead	
		Latency(%)	Bandwidth(%)
Tamaraw	ρ_{out} = 0.04,ρ_{in} = 0.012,L = 50	14.23	143.82
WTF-PAD	Normal rcv	0	60
Minos-500	$\Omega = 0.6$, window=500	0	6
Minos-1000	$\Omega = 0.6$, window=1000	0	12

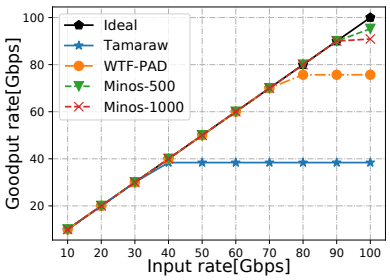

Figure 16: Throughput of each defense.

sion, and F1 score to evaluate defense performances. Without any defense, each attack model can achieve around 90% accuracy, and the DF model has the highest accuracy of 96.9%. Tamaraw decreases the accuracy of each attack to single digits at the cost of its high bandwidth overhead. On the other hand, lightweight defense WTF-PAD fails to defend against DF which still has more than 80% accuracy. In Minos, both defenses achieve less than 40% accuracy and 60% precision. With only one-third of the overhead of WTF-PAD, Minos achieves a satisfying defense effect. Besides, as a practical, lightweight defense mechanism, we are concerned about the actual throughput with each defense. As Figure. 16 shows, the previous defense schemes have lower output rates because of their high bandwidth overhead, even the lightweight defense model WTF-PAD reaches less than 80Gbps of real traffic. In Minos, we can achieve about 95Gbps throughput.

To sum up, although our simple and intuitive Website Fingerprinting defense cannot reduce the accuracy of Website Fingerprinting attacks to random guess, we believe it's acceptable because of its low overhead and high throughput. Besides, in more usual scenarios, we have more than four flows transmitting in one encrypted tunnel on the programmable switch, which can naturally decrease the accuracy of attackers to lower than 20% without any bandwidth overhead.

9 Conclusion

In this paper, we present Minos, a lightweight and scalable defense against traffic analysis attacks using programmable switches, providing both identity anonymity and traffic anonymity. Minos performs line rate packet header encryption with the Proxy Module and performs lightweight dummy packet insertion and packet padding with the Traffic Morphing module. Besides, Minos applies a dynamic flow scheduling algorithm to accommodate different network scenarios. Our evaluation shows that Minos can perform line rate packet encryption and flow scheduling at a low cost, and defend against Website Fingerprinting attacks with little overhead.

A Use case: IoT Fingerprinting

In this section, we adapt Minos to defend IoT Fingerprinting, which utilizes different features from Website Fingerprinting attacks. We apply public dataset from [36] and develop our defense against the state-of-the-art HomeMole [14] and ByteIoT [15]. All the experiments in this section are simulated in software. We evaluate the accuracy of both model against different padding sizes and dummy packet rates.

In Figure. 17a, we pad packets to different sizes to evaluate the impact of packet padding. The result shows that an average padding of 16 Bytes can reduce the accuracy of both attacks to 20%, with 98% goodput rate. On the contrary, inserting dummy packets is less effective. Figure. 17b shows the impact of inserting dummy packets with different rates, from adding 1 dummy packet for every 4 real packets (0.25), to adding 5 dummy packet for each real packet (5). The result shows that only with large amounts of dummy packets can we reduce the accuracy of ByteIoT to less than 40%.

That is because IoT Fingerprinting attacks utilizes packet length information with timing and directions, which makes packet padding more effective than dummy packet insertion based defense like [9]. For example, ByteIoT utilizes the frequency distribution of packet lengths, so that a large number of dummy packets has to be inserted to obfuscate the original frequency distribution. The results shows that different defense mechanisms are required to defense different traffic analysis attacks, and the adaptability of Minos can satisfy this need well.

GeneralSparse: Bridging the Gap in SpMM for Pruned Large Language Model Inference on GPUs

Abstract

The rapid growth of generative model parameters poses challenges in deployment, especially regarding weight storage and inference latency. The weight pruning is an effective technique to reduce the computational and memory overhead of Large Language Models (LLMs) while maintaining accuracy, which transforms the matmuls to Sparse Matrix Multiplication (SpMM) computation. However, the diverse pruning methods introduce varying sparsity patterns that challenge high-performance SpMM on GPUs. Existing solutions are limited with adaptability to these patterns, flexibility in handling different sparsity levels, and support for efficient optimizations.

In this work, we present GeneralSparse, a novel solution that bridges this gap by leveraging the abstraction of memory access and reduction spaces. GeneralSparse designs the process of dividing box to adapt dynamically to diverse pruning patterns and proposes hierarchical reduction algorithms tailored to GPU hierarchies. Through evaluations on pruned LLM weight matrices and the SuiteSparse collection, GeneralSparse achieves up to 20.82× speedup over cuSPARSE libraries. At end-to-end inference time on LLMs, GeneralSparse achieves up to 2.33× speedup over counterparts.

1 Introduction

Generative models, particularly Large Language Models (LLMs), have achieved remarkable success in various natural language processing tasks [4, 35], such as machine translation [4, 37], text summarizing [50, 51], etc. However, with the rapid growth of the parameter size, it becomes increasingly challenging to efficiently deploy these models. On one hand, their weights could be too large to be placed on GPUs. On the other hand, LLMs usually cause very high inference latency even using multiple GPUs as large amounts of computation and memory access are required [27, 31, 39].

The weight pruning methods [12, 15, 43] have been demonstrated to be effective in reducing memory usage and computations for model inference while retaining good accuracy. There are plenty of pruning algorithms focused on accelerating tensor operations such as matrix-matrix multiplications, which form **Sparse Matrix Multiplication (SpMM)** computation. Different pruning methods remove elements from different positions in the weight matrix, resulting in varying sparsity patterns in the matrix. However, because of the diversity of pruned matrix sparsity patterns, and the close association between pruned matrix sparsity and the SpMM performance, it is unrealistic to find a one-fits-all method to achieve high performance for all pruned weight matrices.

Many studies focus on improving the performance of SpMM on GPUs in the past decades from artificial designs, auto-tuners, and domain-specific compiler technologies. Artificial design methods [16, 22, 23] rely on human expertise to design optimization techniques. Traditional auto-tuners [9, 28, 46] are designed to select the most appropriate methods for a given sparse matrix from a set of artificial candidate methods. Compilers technologies [6, 13, 26] generate the specific computation codes for each given input.

Table 1: Comparison with state-of-the-art works on GPUs.

Work		Adaptability		Support
		Sparsity Pattern①	Sparsity Level②	SpMM Auto-Implement
Artificial Designs	ASpT [23] Sputnik [16] SparTA [53]	✘	✘	✘
Traditional Auto-tuners	Xin et al. [46] DgSPARSE [9] EC-SpMM [28]	✔	✘	✘
Compiler Technologies	TVM [6]	✘	✘	✘
	AlphaSparse [13] TACO [26]	✔	✘	✘
Intelligent Auto-tuner	GeneralSparse	✔	✔	✔

① **Sparsity Pattern** means the position distribution of non-zero elements.
② **Sparsity Level** means the percentage of zero elements in sparse matrix.

Despite extensive efforts to improve the SpMM performance, limitations remain evident in current research across three aspects of program design methodology (Table 1). Detailed explanation as follows:

*Guangming Tan is the corresponding author: tgm@ict.ac.cn
†These authors contributed equally to this work.

Limitation1 in Sparsity Pattern: The adaptability to matrices with diverse sparsity patterns using different pruning methods of LLMs. Artificial design methods usually use fixed memory access optimization strategies for a specific type of sparsity pattern. ASpT [23] uses column sorting for sparse matrix with localized dense features. Sputnik [16] is proposed for sparse matrix with little variation in row length. SparTA [53] is applied for sparse matrix with structured pruning. However, each method targets specific application scenarios, lacking adaptability to sparsity patterns resulting from various pruning methods (Figure 4).

Limitation2 in Sparsity Level: The adaptability between efficient reduction algorithms and varied pruned sparsity levels at different depth layers of LLMs. For maintaining model accuracy, the weight matrices of different depth layers in LLMs are usually pruned to different sparsity levels (e.g, 70% at the bottom and top layers, 90% at intermediate layers) [2, 38, 49], while matrices of different sparsity levels require corresponding efficient reduction methods in SpMM. In auto-tuners, Xin et al. [46] and EC-SpMM [28] use thread sequential reduction for all sparse matrices. DgSPARSE [9] designs two reduction algorithms, but it also ignores the interaction between reduction algorithms and sparsity levels.

Limitation3 in SpMM Automatic Implementation: The support of automatic code implementations to cover diverse optimizations. Recent works [9, 23–25, 47] implement the SpMM program as the predefined complete program templates, required a significant amount of human time and effort to design. Current compiler technologies works, such as TVM [6] and AlphaSparse [13], do not support SpMM, utilized for dense tensor operations and SpMV respectively. TACO [8] generates the program for sparse tensor algebra operations on CPU, which is not specifically optimized for GPU. Currently, there is still a lack of research for automatically generating high-performance SpMM programs on GPUs.

To address the above three limitations, we abstract the memory access to dividing box strategies for dynamically adapting to diverse sparsity patterns of pruned matrix and form the **memory access space**. It employs a multi-level **reduction space** aligned with GPU hierarchies, enabling efficient handling of varying sparsity levels. Additionally, an **automated kernel generator** generates SpMM kernels for specific sparse matrices, reducing manual effort for implementing the program. These innovations collectively overcome the constraints of existing methods for GPU-based SpMM computation.

In this work, we present GeneralSparse to address the challenges of efficient SpMM for pruned LLMs on GPUs. The key contributions of this work are summarized as follows:

- GeneralSparse proposes the memory access space (§3.2) and reduction space (§3.3), which allows for efficient handling of diverse sparse matrix patterns and sparsity levels.
- GeneralSparse designs a cost model (§3.4) and implements an efficient code generator (§3.5), which saves the time of program development for diverse pruned methods.
- GeneralSparse demonstrates up to 20.82× speedup over existing SpMM libraries on pruned weight matrices of LLMs and the SuiteSparse collection, and achieves up to 2.33× speedup over counterparts on inference time of LLMs.

2 Background and Motivation

2.1 Generative Model Inference

Inference performance hotspot of LLMs. Figure 1a depicts the typical decoder architecture of a single layer in LLMs. Within the decoder layer, there are four primary matrix multiplications (matmuls): QKV Projection, Output Projection, MLP1, and MLP2. The inference performance of LLMs is significantly constrained by these four matmuls. Related works [1] and our experiments reveal that these matmuls account for about 80% of the end-to-end execution time. Although the pruning method (magnitude [20]) has been applied to network weights and matmuls have been replaced with the SpMM computation (implemented via cuSPARSE library), Figure 1b shows SpMM still remains the performance bottleneck **(about 70%)** and has room for further optimization.

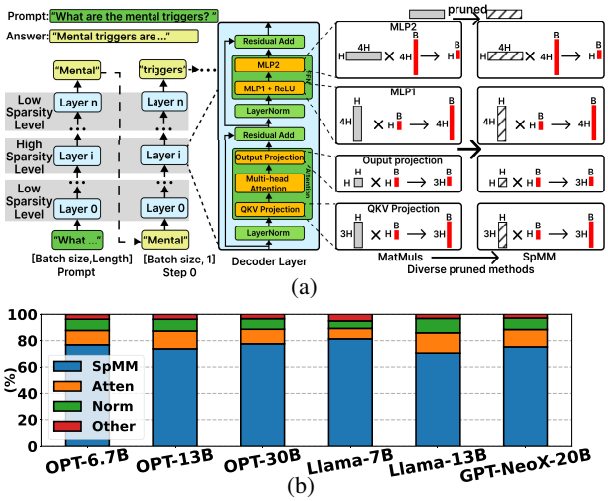

Figure 1: (a) Network architecture of LLMs. The **H** and **B** mean the hidden dimension and inference batch size. (b) The time proportion of inference occupied by different kernels in the pruned model at 8 batch size.

Diverse sparsity patterns by different pruning methods. Many pruning methods have been proposed for LLMs, which are usually classified into structured [5, 7] and unstructured pruning [20, 40]. In practice, unstructured pruning typically retains better accuracy than more restrictive structured pruning [15, 18, 21]. Our approach is applicable to both types, with a primary focus on unstructured pruning. Besides, we give the examples of two well-known unstructured pruning methods, random [3] and magnitude [20]. Random prunes values randomly and results in a uniform non-zero element distribution per row, while magnitude prunes values with smaller absolute

values of matrix weight and leads to an unpredictable and irregular distribution. Sparsity patterns caused by these two pruning methods result in performance fluctuation in Figure 4.

Varied sparsity levels across layers at different depths in LLMs. Current works [2, 38, 49] observe that layers at different depths have different sensitivities to parameter pruning. To maintain accuracy, the sparsity level of pruning varies with the layer depth. For example in Figure 1a, the bottom and top layers show higher sensitivities (low sparsity level), while the intermediate layers have lower sensitivities (high sparsity level) [38]. This variance in sparsity level across layers poses additional challenges for efficient SpMM computation, as different sparsity levels demand corresponding tailored optimization strategies.

2.2 SpMM

SpMM (Sparse Matrix Multiplication) multiplies an $M \times K$ sparse matrix A and an $K \times N$ dense matrix B to output a $M \times N$ dense matrix C (i.e., C = AB). Figure 2 shows the SpMM computation process, where using the CSR format to store sparse matrix. In SpMM, there are two key factors that affect performance on GPUs. ***One aspect*** **is how to distribute three loops ($M/N/K$ dimension) of sparse and dense matrix to GPU process units for parallel memory access.** Especially sparse matrices have diverse non-zero element distributions and a specially designed storage format, which leads to load unbalance and irregular memory access latency. ***The other aspect*** **is how to accumulate (reduce) intermediate results with reduction dependencies of K-dimension.** The number of reduction results varies with different sparsity levels of sparse matrix, which affects the computation efficiency of GPU process units. Many fine-grained analyses [9, 28] on SpMM suggest that diverse optimization strategies for distinct sparse matrices are necessary to achieve high performance on GPUs.

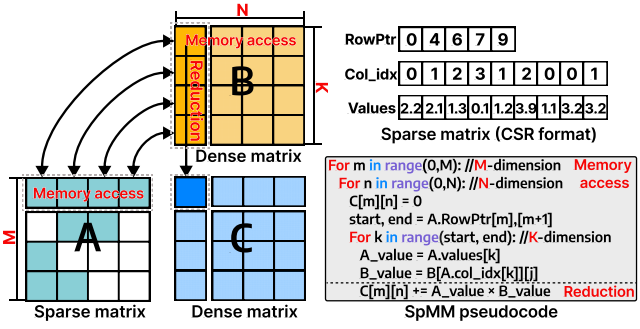

Figure 2: SpMM computation and pseudocode.

2.3 Motivation

The motivation of GeneralSparse comes from two observations, which separately show its necessity and feasibility.

Observation1. Parallel memory access strategies can be abstracted as the process of dividing boxes for diverse sparsity patterns. The parallel memory access strategies are to distribute regions of sparse and dense matrix to parallel process units on GPUs, which can be abstracted as the process of dividing boxes. Sparse and dense matrices are divided consecutively at the block/warp/thread level. Then, dividing strategies of sparse and dense matrices are integrated to form the memory access strategy (e.g., Sputnik [16] in Figure 3). However, existing SpMM methods on GPUs usually use the fixed parallel memory access strategy for all sparse matrices.

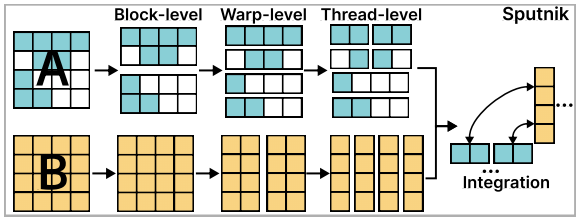

Figure 3: Parallel memory access strategies are abstracted as the process of dividing box at the block/warp/thread-level.

Based on the above observation, the **memory access space** can be constructed, where the sparse matrix is adaptively and fine-grained divided for diverse sparsity patterns, and the dense matrix is regularly divided by column. Finally, different division strategies of sparse and dense matrices are integrated. The memory access space covers enormous and fine-grained box division strategies, which makes it challenging to implement this vast space. As shown in Figure 4, the performance of methods varies across different weight matrices, and new strategies in memory access space achieve higher performance.

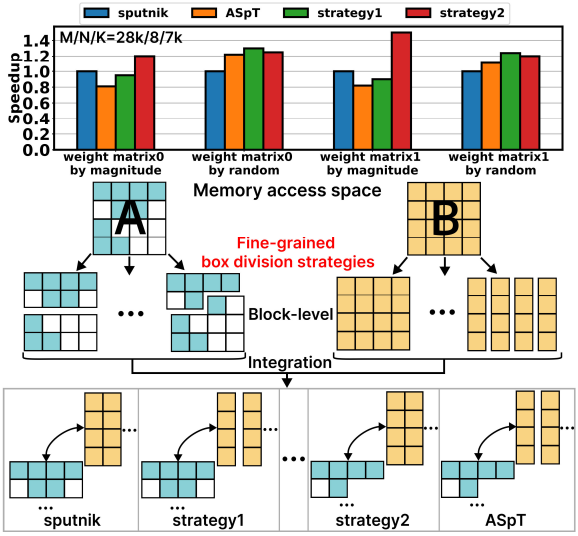

Figure 4: Memory access space is composed of fine-grained box division strategies of the sparse and dense matrix. For simplicity, warp/thread-level is not shown here.

Observation2. Multi-level reduction algorithms can be used in combination for varied sparsity levels in LLMs. The current methods usually use a thread to sequentially reduce the results, while it limits the GPU parallel computation

efficiency, especially in cases of low sparsity levels. As illustrated in Figure 5, we also use the warp-level instruction to reduce results, and the performance of two reduction algorithms varies with sparsity levels, indicating a single reduction algorithm cannot achieve optimal performance in all cases.

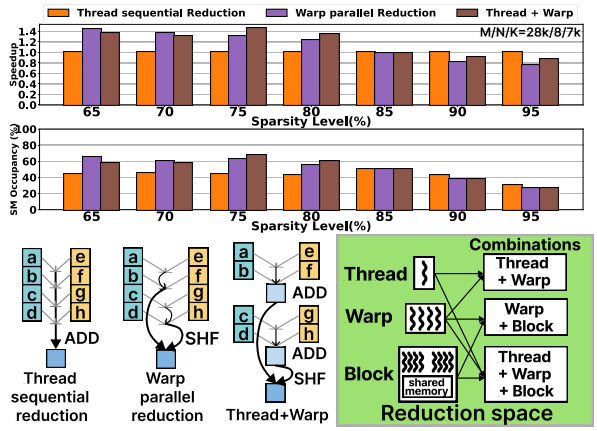

Figure 5: Performance comparison between reduction algorithms, and the reduction space based on GPU hierarchy.

Due to the performance effect between sparsity levels and reduction algorithms, a hierarchical **reduction space** is required to adapt to different matrix sparsity levels based on GPU hierarchy. Furthermore, the reduction algorithms can also be used **in combination of multi-levels thread/warp/block on GPU** (e.g., Thread+Warp in Figure 5), which is challenging to implement these flexible combinations of reduction algorithms. Therefore, there is a need to explore and design efficient reduction strategies that can dynamically select or combine reduction algorithms to fully utilize hardware resources.

3 GeneralSparse Design

3.1 Overview

We propose GeneralSparse, which automatically designs and implements high-performance SpMM programs on GPUs, as illustrated in Figure 6. It consists of four parts: the memory access space, the reduction space, the cost model, and the code generator. The pruned sparse matrix and dense matrix are initially processed within the memory access space. Subsequently, reduction algorithms are selected and applied in the reduction space. Through the cost model for the optimal solution, the code generator generates the SpMM program.

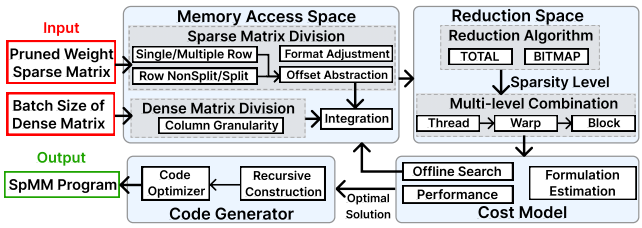

Figure 6: Overview of GeneralSparse.

3.2 Memory Access Space

The memory access space covers fine-grained division strategies of sparse and dense matrix, representing that distributing sparse and dense matrix to process units for parallel memory access. In some cases, we use the concept of **worker** to represent parallel process units (thread/warp/block) on GPUs.

In memory access space, we design an orthogonal division of sparse matrices (row-based and split-based) and a column-based division of dense matrices. Then, we use offset abstraction for sparse matrix division and perform format adjustments. This allows for adaptive handling of diverse sparsity patterns and integration of sparse and dense matrix.

Design rationales for row-based and split-based. For improving the performance, there are two design rationales: reducing memory access latency and improving GPU efficiency. For reducing memory access latency, row-based reduces row index accesses, while split-based reduces non-zero subscript accesses. For GPU parallelism, if non-zeros concentrate in a few columns per row, multi-row row-based processing improves efficiency by enabling simultaneous column access. If non-zero counts vary greatly across rows, split-based achieves better load balancing.

Orthogonal dimension in sparse matrix division (allocation). In sparse matrix allocation, we design two orthogonal dimensions, including row-based and split-based dimensions as depicted in Figure 7a. Row-based dimension is considered from the perspective of GPU processing units, divided into `single/multiple-row`. Split-based dimension is considered from the matrix perspective, divided into `row-nonsplit/split`.

Single/multiple-row dimension means non-zero elements of single/multiple rows in the sparse matrix are processed by a worker. `Single-row` is beneficial when the matrix rows have distinct characteristics and require individual processing. For example, in matrices with highly irregular row-wise non-zero element distributions, processing one row at a time can simplify the data handling and computation process. `Multiple-row` takes advantage of the parallel processing capabilities of GPUs. When there is a certain similarity or correlation among adjacent rows, processing multiple rows together can significantly reduce the overhead of data fetching and processing, thereby improving the overall efficiency.

Row-nonsplit/split dimension means whether a row of the sparse matrix is split and processed by different workers. In `row-nonsplit`, each row of the sparse matrix is kept intact during processing. This ensures that the internal structure of each row is preserved, which can simplify memory access patterns and reduce the complexity of data management. It is useful for matrices with a relatively uniform row-wise structure. The `row-split` means dividing each row of the sparse matrix into smaller segments. This allows for more fine-grained processing, especially for matrices with highly irregular row structures. By splitting the rows, it becomes

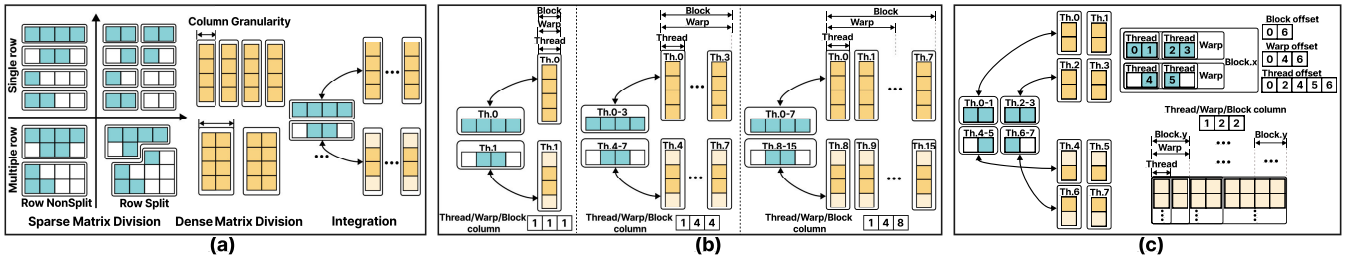

Figure 7: (a) Division of sparse matrix and dense matrix, and integration in SpMM computation. (b) Integration between sparse and dense matrices using thread, warp, and block hierarchies. (Assume each warp/block has 4/8 threads). (c) Offset abstraction for sparse matrix division, along with integration.

possible to better balance the workload among different processing units, resulting in improved performance.

Dense matrix division (allocation). The dense matrix allocation mode pertains to the organization of dense matrices. The dense matrix is distributed to workers with a uniform pattern of data block in column granularity, because computations between columns are independently parallel. An important aspect is the adjustable column granularity of allocation. The number of columns grouped for a particular allocation unit can be changed. For example in Figure 7a, we respectively group 1 and 2 columns into a single allocation unit. By adjusting this grouping of columns, we can optimize the memory access patterns and data transfer operations.

Integration between sparse and dense matrix. Integration of Figure 7a illustrates the column-based relationship between sparse and dense matrices. The arrow indicates the mapping between data blocks of the sparse matrix and those of the dense matrix. In Figure 7b, the dense matrix is divided into 1 column for thread (`thread column = 1`) and each thread processes one row of sparse matrix. When adjacent consecutive threads process different columns of dense matrix (`warp/block column > 1`), threads load the same non-zero elements in sparse matrix but different columns of dense matrix, which forms the `thread-groups` (e.g., Th.0-3 and Th.4-7 in middle of Figure 7b). It achieves data reuse in sparse matrix and coalesced access in dense matrix. When adjacent consecutive warps/blocks process the same non-zero elements in sparse matrix, it also forms `warp/block-groups`.

Offset abstraction of adaptable division in sparse matrix. We use a hierarchical approach with `thread/warp/block offset` for sparse matrix division, which is aligned with `column-based` integration in dense matrix. In Figure 7c, dense matrix is distributed with `Block.y` and two consecutive threads process different columns (e.g., thread-groups of Th.0-1). Sparse matrix is distributed with `Block.x`, cooperated with `Block.y` of dense matrix. Besides, sparse matrix is allocated with thread-groups by single-row and row-split at thread-level, and allocated with warps by single-row and row-nonsplit at warp-level (etc. in block-level). `Thread offset` indicates the starting position of processing non-zeros range by thread-groups (e.g., 0 and 2 of Th.0-1 and Th.2-3). `Warp/Block offset` indicates the starting position of warps/blocks.

Design factors of offset abstraction. When designing the abstract representation of GPU allocation for sparse matrices, two crucial factors need to be taken into account. ***First***, it should comprehensively cover the orthogonal allocation dimensions of the sparse matrix (including single/multiple-rows and row-split/nonsplit) to adapt to different structures and optimize memory access. Regarding covering the orthogonal allocation dimensions, offsets can clearly locate the positions of different rows or row segments, effectively implementing data processing under different strategies. ***Second***, it must align with the integration of the dense matrix. The change of `warp/block column` affects the number of threads in the thread-group, as shown in Figure 7c. So, the `thread offset` is based on thread-groups, not individual threads. `Warp/block` offset is also based on warp/block-groups, if the adjacent warps/blocks process the same non-zero elements in the sparse matrix.

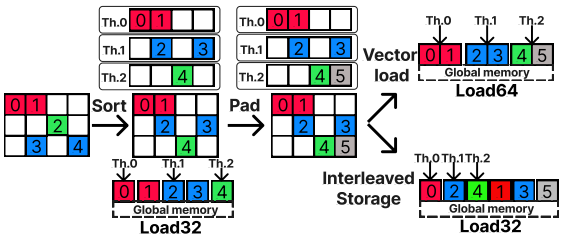

Figure 8: Format adjustments of sparse matrix with thread allocation for access.

Format adjustment is centered around optimizing the memory access layouts of sparse matrices, which encompasses several crucial operations in Figure 8. `Sort` is employed to reorder the elements, leading to more regular and predictable memory access patterns. `Pad` ensures proper data alignment, especially considering the alignment requirements of the hardware. `Interleaved storage` stores data in a way that enables multiple elements to be loaded in a single coalesced memory access. Besides, **vector instruction** is utilized for memory access. For dense matrices, they allow simultaneous loading of multiple columns, maximizing memory bandwidth utilization and enhancing data throughput. For sparse matrices, adjacent threads can also load data in a coalesced manner, minimizing redundant memory accesses in Figure 8.

Workflow of memory access space. Based on our abstraction of the memory access, ***first***, the columns of dense matrix are divided three times (`block/warp/thread column`), determining the threads number in `thread-groups` of sparse matrix. ***Second***, the non-zero elements of sparse matrix are divided three times. The non-zero elements are divided into different blocks (`block offset`). The non-zero elements within the blocks are further divided into warps (`warp offset`) and threads (`thread offset`). ***Third***, format adjustment and vector instructions are employed to fine-tune the memory access.

3.3 Reduction Space

Reduction space represents the reduction (accumulation) algorithms of intermediate results. We design reduction space from two aspects. ***First***, **reduction algorithms can be used in combination, with consideration of the pruning sparsity levels and the GPU hierarchy.** The thread-level reduction can use fine-grained parallelism and is suitable for higher sparsity levels, while warp/block-levels can handle more data and suitable for lower sparsity levels. The reduction algorithms can be used in combination for diverse pruning sparsity levels. ***Second***, **reduction algorithms need to be aligned with the memory access space, especially irregular sparse matrix allocation.** The memory access space determines data organization and access in memory, so the allocation of sparse and dense matrices affects the reduction method choice.

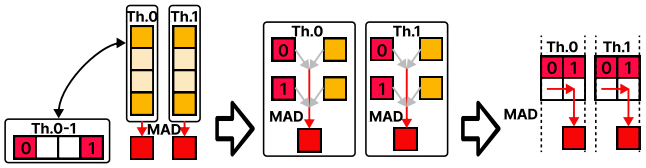

Figure 9: Simplified illustration of reduction methods.

Simplify figure expression of the reduction algorithm. To describe reduction algorithms more clearly, we show the example in Figure 9. It depicts that two threads (Th.0 and Th.1) use Multiply-Add (MAD) operations to reduce the results of two adjacent columns corresponding with the same row. The elements of the dense matrix are removed for clarity.

Reduction algorithms are designed from GPU hierarchy, and aligned with single/multiple-row dimension. We design reduction algorithms from three-levels of GPU, and propose `TOTAL` and `BITMAP` algorithms which are aligned with `single/multiple-row` dimension. For single-row dimension, each row can be independently processed by a thread or a small set of threads. So it leads to a relatively simple and faster `TOTAL` algorithm. For multiple-row dimension, it enables the distribution of non-zero elements across rows, thereby achieving better load balancing among the processing units. However, it incurs additional overhead, because `BITMAP` algorithm must handle reductions that span across rows, necessitating the determination of element row membership.

TOTAL Reduction Algorithm. We introduce the `TOTAL` algorithm from three-levels of GPU corresponding with single-row dimension. Figure 10(a) shows that `THREAD_TOTAL` uses the MAD operation and registers to sequentially reduce the results of non-zero elements within the same row. Figure 10(c) shows that `WARP_TOTAL` uses the warp-level shuffle instruction and registers to reduce results processed by a warp. Figure 10(e) shows that `BLOCK_TOTAL` uses MUL and ADD instructions on block-level shared memory to reduce results.

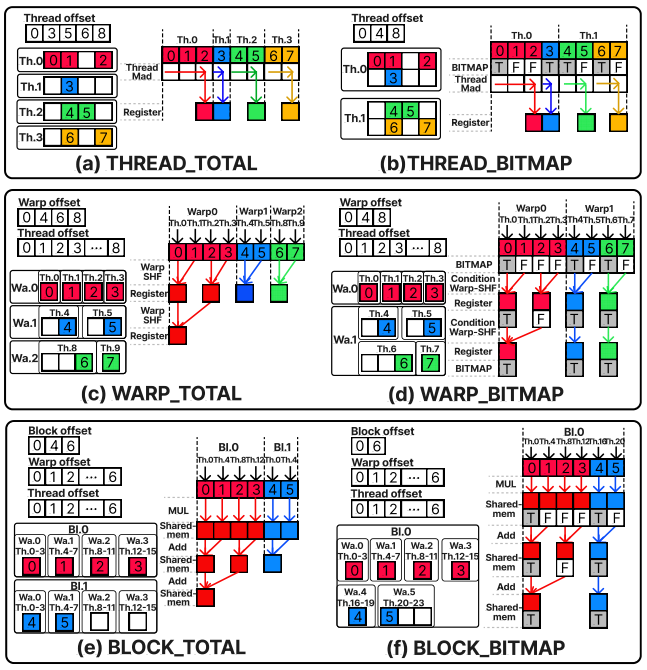

Figure 10: TOTAL and BITMAP reduction example. Thread to warp/block level are suitable for sparsity from high to low.

BITMAP Reduction Algorithm. We propose the `BITMAP` algorithm from three-levels of GPU corresponding with multiple-row dimension. It uses the data structure of a BITMAP to judge whether the non-zero elements span rows. Each binary bit of BITMAP represents a non-zero element, `T` represents the starting position of the row, and `F` represents the positions within the row. Figure 10(b) shows that `THREAD_BITMAP` uses the BITMAP to determine whether a thread continues accumulating the current result. If the next step crosses rows, the result will be written back directly. In warp/block level (Figure 10(d,f)), multiple threads perform reduction in parallel, detailed in Algorithm 1.

Multi-level combination of reduction algorithms can be used on GPU for diverse sparsity levels, which are aligned with row-split/nonsplit dimension. The reduction algorithms of three-levels can be used in combination from thread to warp/block. In row-nonsplit dimension, only a single processing pass is required to reduce all values within a row. This is because the entire row is processed intact, and the reduction can be finished straightforwardly. Conversely, in row-split dimension, the reduction values of the row are divided into several segments, so an extra step of reduction

Algorithm 1 Parallel BITMAP Reduction Algorithm

Require: Array *Result* of length L, $BITMAP$ of length L.
$n = \lfloor \log_2(L) \rfloor$, $step = 1$, $BITMAP_{init} = BITMAP$
for $i = 0$ to n **do**
  $step = step \times 2$
  for $j = 0$ to $L - 1 - step$ **in parallel do**
    if $BITMAP[j + step] = F$ **then**
      $Result[j] = Result[j] + Result[j + step]$
      $BITMAP[j + step] = BITMAP[j] \vee BITMAP[j + step]$
    end if
  end for
end for
for $i = 0$ to $L - 1$ **in parallel do**
  if $BITMAP_{init}[i] = T$ **then**
    return $Result[i]$
  end if
end for

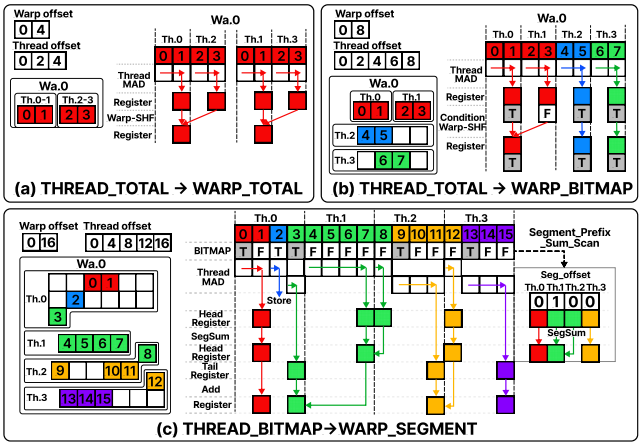

Figure 11: Multi-level combination examples of reduction.

becomes necessary to consolidate these segments. For example, after an initial reduction at a low-level (e.g., thread-level), further reductions at a high-level (e.g., warp-level) are needed.

Low-level TOTAL to High-level TOTAL. In Figure 11(a), it shows the example of `THREAD_TOTAL` and `WARP_TOTAL`. Thread-level allocation is in `single-row` and `row-split` dimension, which corresponds with the `THREAD_TOTAL` to reduce results, and needs further warp-level reduction. Warp-level allocation is in `single-row` and `row-nonsplit` dimension, which corresponds with `WARP_TOTAL`, and does not need further block-level reduction.

Low-level TOTAL to High-level BITMAP. In Figure 11(b), it shows the example of `THREAD_TOTAL` and `WARP_BITMAP`. Thread-level allocation is in `single-row` and `row-split dimension`, which corresponds with `THREAD_TOTAL` to reduce results, and needs further warp-level reduction. Warp-level allocation is in `multiple-row` and `row-nonsplit`, which corresponds with the `WARP_BITMAP`, and does not need further block-level reduction.

Low-level BITMAP to High-level SEGMENT. `SEGMENT` algorithm (Algorithm 2) is proposed to process the remaining intermediate results of low-level `BITMAP`. In Figure 11(c), `THREAD_BITMAP` produces two intermediate results: the remaining result of the non-zero elements of the previous row and the head part of the non-zero elements of the next row, which need to further reduced by `WARP_SEGMENT`. `WARP_SEGMENT` algorithm uses `Seg_offset` to perform reduction in head part, then adds the head and tail results together.

Algorithm 2 Parallel SEGMENT Reduction Algorithm

Require: Array $HeadRegister$ of length T, Array $TailRegister$ of length T, $BITMAP$ of length L.
$n = L/T$
Seg_offset = Segment_Prefix_Sum_Scan($BITMAP$)
for $i = 0$ to $T - 1$ **in parallel do**
  $HeadRegister[i]$ = SegSum($HeadRegister$[i:i+Seg_offset[i]])
  $Result[i] = HeadRegister[i] + TailRegister[i]$
end for
return *$Result$

Function Segment_Prefix_Sum_Scan(*$BITMAP$):
  malloc(*Seg_offset, T)
  for $i = 0$ to $T - 1$ **in parallel do**
    Seg_offset[i] = False
    for $j = 0$ to $n - 1$ **do**
      Seg_offset[i] = Seg_offset[i] $\vee$ BITMAP[$i \times n + j$]
    end for
    Seg_offset[i] = 1 - Seg_offset[i]
  end for
  Cumu_sum(*Seg_offset) // Accumulate the positions with
  // consecutive values of 1 to the first position
  return *Seg_offset
End Function

Rule-based selections of reduction algorithms considering sparsity levels and sparse matrix allocation. The selection process is structured into three hierarchical layers in Figure 12 and each layer has the judge of `single-row` and `row-split` dimension of sparse matrix allocation. The `*offset range` is calculated by `*offset[i+1] - *offset[i]`. When the weight matrix is pruned at the high sparsity level, we set the `thread offset range` ≥ 2, so a thread reduction algorithm is applied. Conversely, when the pruned weight matrix at the low sparsity level, we set the `thread offset range` < 2, so it skips to warp/block-level, and warp/block reduction algorithms are utilized.

3.4 Cost Model

Workflow of GeneralSparse. Based on our abstraction of the memory access and reduction space, ***first***, the sparse matrix and dense matrix are consecutively divided and integrated at block/warp/thread levels for distinct sparsity patterns. ***Second***, the reduction algorithm is selected based on the rules, considered from sparsity levels. ***Third***, through offline traversal search and the cost model for performance estimation, the optimal solution is selected.

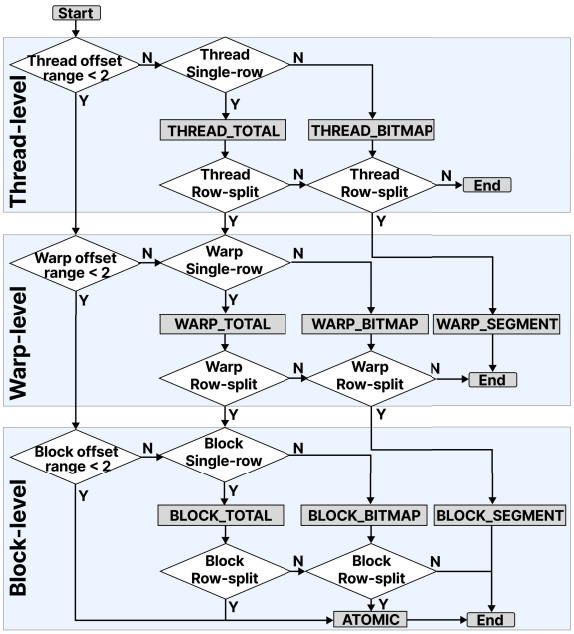

Figure 12: Rule-based selections of reduction algorithms from GPU structures. The `offset` is set by sparsity levels.

Problem definition. Based on the workflow of GeneralSparse, the SpMM computation on GPUs can be expressed as a combinatorial problem of divisions (partitions). Consider NNZ non-zero elements of $M \times K$ sparse matrix and N columns of dense matrix that are divided into several groups. We summarize a variety of division strategies and each division (memory access) strategy incurs a specific cost c. Each division strategy is with its post-processing (reduction) cost d. The objective is to select a combination of division and post-processing strategies that minimizes the total cost of division and post-processing costs $c+d$.

Cost estimation for division and reduction strategies. We collect the sparse characteristics of the sparse matrix (e.g., the average number of non-zeros per row), the column number of dense matrix and etc, as input, and fit the cost estimation using linear regression. The cost functions include the following aspects. `Division (memory access) cost` (c_{ij}): Estimated based on workload distribution between parallel computation units. `Post-processing (reduction) cost` (d_{ij}): Estimated based on the number and type of arithmetic operations, including read and write operations of reduction results. The goal is to minimize the total cost:

$$\min_{i\in I, j\in J} \quad x_{ij}(c_{ij}+d_{ij}) \tag{1}$$

subject to:

$$x_{ij} = 0, \quad \text{if exceeding hardware limitations} \tag{2}$$

Offline search solution for optimal strategy. We solve this problem offline by a traversal search. ***First***, we generate the valid strategy combinations for dense and sparse matrices, and calculate costs for each combination, factoring in division and post-processing costs. ***Second***, identify the combination with the minimum cost as the optimal strategy. The offline search for the cost is lightweight compared with long-time running inference services, because the optimal strategy can be reused in the network of LLM.

Table 2: Variable Definitions

Variable	Type	Description
x_{ij}	Binary	1 if the division strategy i of dense matrix and j of sparse matrix is selected; 0 otherwise.
c_{ij}	Real	Division cost associated with the ij-th division strategy.
d_{ij}	Real	Post-processing (reduction) cost associated with the ij-th division strategy.

Cost model explanation. For designing, our cost model is a linear regression model, to estimate the running performance of a specific matrix under a specific combination of strategies. For training, we use the characteristics of the sparse matrix (e.g., row numbers, column numbers, average non-zero elements per row and etc.) as the input for linear regression. We then use this model to fit the actual running performance of the sparse matrices in the training-set and the accuracy rate is approximately 90%. For dependency, there are different linear regression formulas for each specific memory access/reduction algorithm to estimate the actual running performance. Therefore, each formula of cost model depends on the specific memory access/reduction algorithm. Based on the estimated cost, we select the optimal memory access strategy and reduction combination for each sparse matrix.

3.5 Code Generator

The code-generator needs to generate executable code based on the memory access and reduction space. The kernel implementation includes recursive construction of the parallel loop and code optimizer.

Recursive construction algorithm. The SpMM kernel is decomposed into multiple levels of parallelism, recursively from block to warp and thread as shown in Figure 13. At the highest level, the SpMM kernel initiates the block-level parallelism and performs block reduction algorithms (if needed). Then move down to the warp and thread level. Each thread operates on a division of the data. The `Thread Action` involves vector loading of elements from the sparse matrix and dense matrix, reusing sparse data of thread-groups. Finally, the thread reduction is performed using either the `THREAD_TOTAL/BITMAP` algorithm, depending on the sparse allocation.

Code Optimizer. An important consideration of code optimizer is the memory access of `offset`, which is used to determine the address range of non-zero elements in sparse matrix. However, `offset` may exhibit certain computational patterns in Table 3, so we can replace `offset` access with computational code. For instance, if the values follow a linear

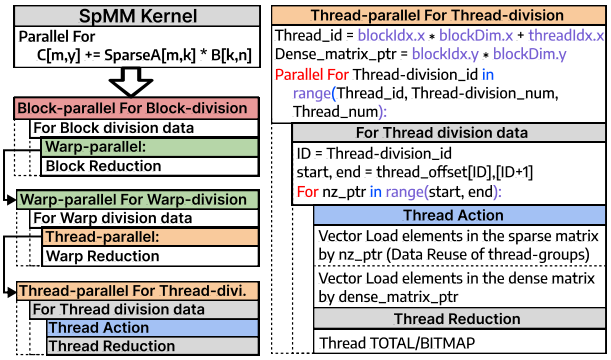

Figure 13: Kernel skeleton of code generator.

progression (fixed intervals n), instead of directly accessing the values, a mathematical formula ($n \times ID$) can be used to calculate the address. This approach reduces the memory access overhead and can enhance the overall efficiency of the SpMM implementation.

Table 3: Patterns of the offset values, where the memory access can be replaced with the computational code.

Method	Description	Offset Example
Linear	Compress indices with linear patterns into expressions	[0,5,10,...] → 5×ID ①
Branch	Compress indices with only k values into if statements	[0,5,8] → 0 if ID=0; 5 if ID=1; 8 if ID=2
Cyclicity	Periodically retain one complete cycle and the cycle size	[0,1,6,7,...] → 6×(ID/2)+ID%2
Quasilinear	Fit a linear function to transform data reads into linear calculations plus residuals	[3,8,13,...] → 5×ID +3

① start, end = thread_offset[ID],[ID+1] → start, end = 5×ID, 5×(ID+1) in Figure 13.

4 Evaluation

4.1 Experimental Setup

We evaluate the performance of GeneralSparse from two aspects: kernel-level and model-level evaluation. Mixed precisions (FP16/32) are supported. The platform is the NVIDIA Tesla A100, based on the Ampere architecture. The CUDA environment is version 12.1.

4.2 Kernel Performance

Dataset of matrices. The sparse matrix datasets are from two aspects. ***First***, the pruned weight matrix of LLM is across different shapes, corresponding to the matmuls within the OPT-30B and OPT-66B models [52]. ***Second***, to demonstrate that our method is applicable to various sparsity patterns, we evaluate 1168 matrices from SuiteSparse collection [11], which source from real-world problems in various scenarios, including scientific computing, graph processing, etc.

Baselines. We compare GeneralSparse with various methods targeting SpMM optimization:

(1) Library: (i) CuSPARSE (v12.1) [30], which inputs sparse matrices in CSR format and offers three parameter choices, with the best result chosen.

(2) Artificial designs and auto-tuners: (i) ASpT [23], which uses column sorting and adaptive tiling to partition sparse matrices. (ii) Sputnik [16], a well-designed sparse library for matrices in DL. (iii) DgSPARSE [9], as the auto-tuner, offers eight algorithm choices, with the best result chosen. (iv) Flash-LLM [45], which uses tensor core to accelerate sparse weight matrices in DL. (v) SparTA [53], which supports structured sparsity on tensor core. (vi) TC-GNN [44], which fits the sparse GNN workload on dense TCs. (vii) DTC-SpMM [14], which is tailored to harness TCs.

(3) Sparse compiler technologies: (i) TACO [26], which supports the code generation of SpMM with the default schedule. (ii) SparseTIR [48], which provides a sparse tensor compilation abstraction.

Furthermore, SpMM in LLMs is the half-precision computation and only partial methods support half-precision. So on pruned matrices of LLMs, SpMM is compared on these partial methods. For the remaining methods, the comparison is conducted on SuiteSparse matrix using single-precision.

Achieved performance on pruned weight matrix. To verify the performance superiority of our method under different sparsity levels and pruning methods, we employ two representative pruning methods (Magnitude and Random) and two sparsity levels (70/90%). Figure 14 presents the kernel performance (in TFLOPs) of GeneralSparse compared to the state-of-the-art methods. GeneralSparse consistently outperforms other methods.

(1) Notably, GeneralSparse achieves the average speedup of 17.15/19.14/20.82× at 8/32/64 batch size over cuSPARSE.

(2) GeneralSparse achieves performance improvements of average 1.84/1.57/1.30× at 8 batch size on A100 over Sputnik, sparTA and Flash-LLM (2.24/1.37/1.31× at 32 and 3.37/1.27/1.38× at 64 batch size). Other methods do not support half-precision computation on GPU.

(3) GeneralSparse achieves the average speedup of 1.21/1.34 /1.33× at 8/32/64 batch size over SparseTIR. TACO does not support half-precision on GPU.

Speedup on pruned methods and sparsity levels. Table 4 shows GeneralSparse outperforms other methods in different pruned methods and sparsity levels. The results also show that sparTA outperforms sputnik in random pruning (70%), while sputnik outperforms sparTA in magnitude pruning (90%). This is because random pruning leads to the low variance of the non-zero elements number per row and 70% sparsity level is relatively dense, which is more suitable for SparTA based on tensor-core operations. While GeneralSparse consistently outperforms other methods, because other methods are unable to adaptively adjust to different sparse pruning patterns.

Speedup on unstructured and structured pruned weight matrix. As pruning methods are usually divided into two

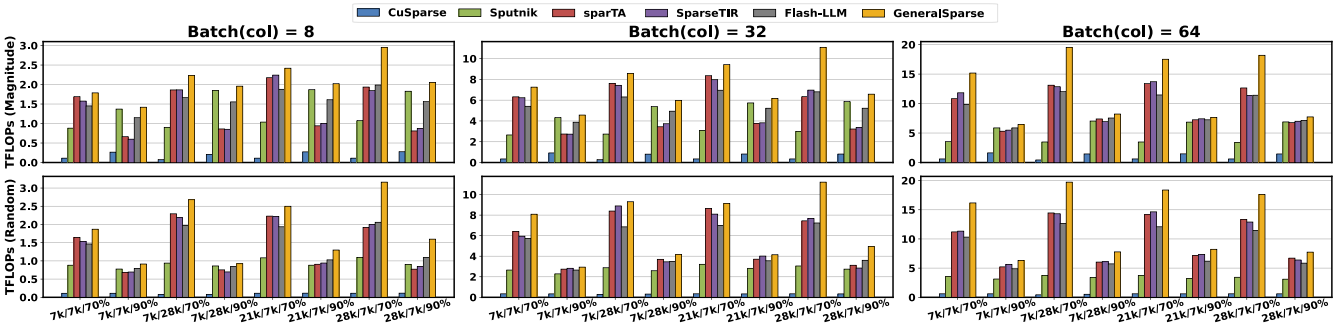

Figure 14: Kernel performance on weight matrices of different shapes using Magnitude and Random pruning.

Table 4: The average speedup of GeneralSparse over other methods on the weight matrices in Figure 14.

Methods	Pruned methods	col=8		col=32	
		70%	90%	70%	90%
CuSPARSE	Magnitude	23.71×	7.40×	27.99×	7.01×
	Random	26.13×	11.35×	29.29×	12.31×
Sputnik	Magnitude	2.39×	1.07×	3.15×	1.09×
	Random	2.54×	1.37×	3.20×	1.54×
SparTA	Magnitude	1.22×	2.27×	1.28×	1.77×
	Random	1.27×	1.51×	1.23×	1.22×
Flash-LLM	Magnitude	1.33×	1.26×	1.42×	1.21×
	Random	1.36×	1.24×	1.41×	1.21×

categories [5, 7]: structured pruning and unstructured pruning. We use different sizes of the pruning area to demonstrate the difference between the unstructured pruning method and the structured pruning method. The size of the pruned area in structured pruning is larger compared with unstructured pruning. Table 5 presents the kernel performance of GeneralSparse compared to the other methods.

The results indicate that GeneralSparse outperforms the cuSPARSE and Sputnik methods under various pruning granularities. However, it is inferior to SparTA, Flash-LLM, TC-GNN and DTC-SpMM in the case of a pruning granularity of (8, 8) and 70%. This is because when the pruning granularity is relatively large and relatively dense, it is more favorable for the structured computation of tensor-core. This indicates that our method is more suitable for unstructured pruning, but it also has a speedup for higher sparsity in structured pruning.

Achieved performance on SuiteSparse matrix. To validate that our method is applicable to a wider variety of sparse matrix characteristics, we conduct tests on the SuiteSparse matrix collection and use single-precision for floating-point values. Figure 15 illustrates the performance of 1168 matrices across various libraries and systems. The achieved performance is represented in a scatter plot, where the horizontal axis denotes the number of non-zero elements in the matrices, and the vertical axis measures performance in TFLOPS. The results demonstrate that GeneralSparse consistently outperforms other methods across the majority of the matrices analyzed. We can observe that:

(1) Notably, GeneralSparse achieves the average speedup of 6.39/4.38/7.46× over cuSPARSE at 8/32/64 batch size.

Table 5: The average speedup of GeneralSparse over other methods using random pruning on weight matrix.

Methods	Pruned size	col=8		col=32	
		70%	90%	70%	90%
CuSPARSE	(1,1)	26.13×	11.35×	29.29×	12.31×
	(4,4)	27.08×	13.33×	30.35×	12.37×
	(8,8)	27.10×	14.01×	31.37×	12.45×
Sputnik	(1,1)	2.54×	1.37×	3.20×	1.54×
	(4,4)	2.60×	1.45×	3.27×	1.56×
	(8,8)	2.61×	1.47×	3.28×	1.57×
SparTA	(1,1)	1.27×	1.51×	1.23×	1.22×
	(4,4)	1.12×	1.26×	1.11×	1.18×
	(8,8)	0.97×	1.02×	0.89×	0.93×
Flash-LLM	(1,1)	1.36×	1.24×	1.41×	1.21×
	(4,4)	1.22×	1.20×	1.31×	1.12×
	(8,8)	1.05×	1.15×	0.98×	1.04×
TC-GNN	(1,1)	1.41×	1.32×	1.46×	1.22×
	(4,4)	1.32×	1.25×	1.35×	1.16×
	(8,8)	1.07×	1.19×	0.98×	1.01×
DTC-SpMM	(1,1)	1.23×	1.20×	1.21×	1.32×
	(4,4)	1.11×	1.18×	1.09×	1.10×
	(8,8)	0.95×	1.02×	0.88×	0.95×

(2) GeneralSparse achieves performance improvements of average 2.32/1.37/N.A.× on A100 over Sputnik, DgSPARSE, and ASpT at 8 (1.22/1.20/7.69× at 32 and 1.29/1.23/2.15× at 64) batch size.

(3) GeneralSparse achieves the average speedup of 10.60/4.97/2.73× on A100 over TACO at 8/32/64 batch size. A primary factor is that TACO's design is not tailored for GPUs.

Speedup on SuiteSparse matrix. To illustrate the comparison between methods, we present the speedup ratio for the matrices in Table 6. The results demonstrate that there is a speedup effect compared to the other three methods across different columns for most matrices and experiences slowdown only for a small fraction of the matrices. This is because the current optimization method of the cost model we are using fails to cover finer-grained strategy selections. The best speedup effect is achieved where col = 8. This is because when col is relatively large, the proportion of computation increases compared with memory access, so the impact of memory access and reduction adjustments on GPU decreases.

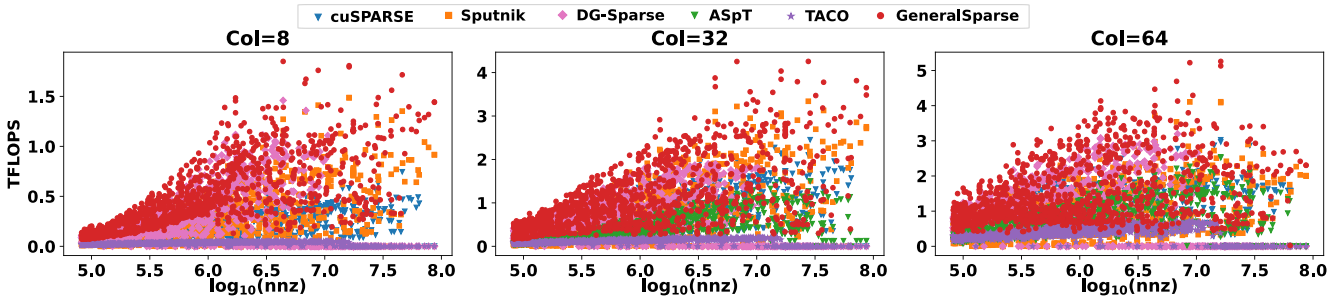

Figure 15: Kernel Performance on SuiteSparse matrix.

Table 6: The speedup of GeneralSparse over other methods. The percentage represents the portion of matrices from suitesparse matrices. (N.A., ASpT is not applicable to col=8).

Col	Speedup	cuSPARSE	Sputnik	DgSparse	ASpT

4.3 Kernel Analysis

The kernel analysis primarily focuses on comparing GeneralSparse with two representative methods, Sputnik [16] and SparTA [53], to investigate the root causes of performance improvement from various perspectives. Additionally, ablation experiments are performed to evaluate our proposed method.

GeneralSparse achieves speedup compared to Sputnik by improving SM utilization. The profiling metrics for the matrix are presented in Figure 16. Notably, *Active warps per SM* of each matrix increases significantly. Sputnik uses a fixed GPU allocation to assign the row of sparse matrix to different thread blocks, leading to load unbalance. SparTA's SM utilization is not listed because it uses tensor cores, making the comparison meaningless. GeneralSparse uses *offset* abstraction to achieve flexible GPU allocation of memory access and improve the parallelism. In addition, reduction methods, such as warp-level reduction, also improve the SM utilization.

GeneralSparse achieves speedup compared to SparTA by improving memory access efficiency. The profiling metrics for the matrix are presented in Figure 17. Notably, the *Memory Bandwidth* and *L1/TEX Cache Throughput* of each matrix increases significantly. The distinction in memory utilization is reflected in the reduction methods. SparTA converts the matrix into a format that is suitable for processing by

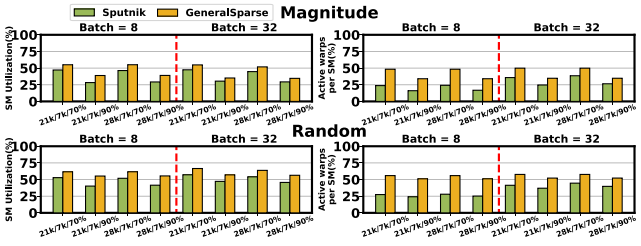

Figure 16: Profiling metrics compared with Sputnik.

the tensor-core and further performs reduction sequentially. GeneralSparse performs multi-level reduction on the GPU in the reduction method, alleviating the pressure of memory write-back to global memory. It saves the number of redundant write-back operations, improves L1 cache utilization, and thus increases memory bandwidth. Although the computing power of the tensor-core is stronger than that of the cuda-core, the performance bottleneck is limited by the memory access rather than the computing power.

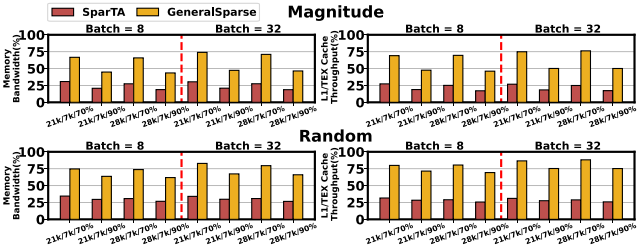

Figure 17: Profiling metrics compared with SparTA.

Performance gain breakdown. We breakdown the performance gain in Figure 18 brought by GeneralSparse on suitesparse matrix. Due to the diverse sparse characteristics of matrices, the key points for improving performance vary on different matrices. *GeneralSparse (base)* means using the fixed GPU allocation (one thread block per row of sparse matrix) and thread sequential reduction. *Op1* represents the flexible GPU allocation with format adjustments. *Op2* represents using the multi-level reduction methods. *Op1* mainly improves the performance on *magnitude* (*90%*) matrices, because they have a large variance in non-zero elements per row. *Op2* mainly improves the performance on *70%* matrices, because they have a relatively large number of non-zero elements per row. *GeneralSparse (base + op1 + op2)* achieves the best performance among them.

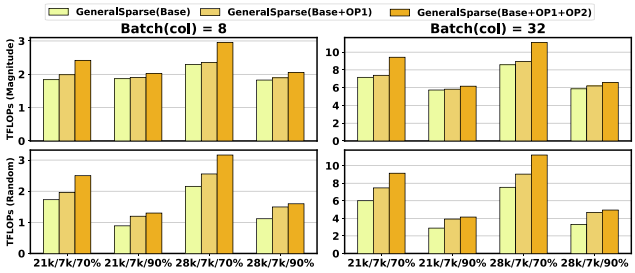

Figure 18: Performance gain breakdown of GeneralSparse.

Achieved performance on additional GPU hardware. We also test the performance improvements of the pruned weight matrices at 8 batch size on NVIDIA V100 in Figure 19.

(1) Notably, GeneralSparse achieves the average speedup of 16.08× at 8 batch size over cuSPARSE.

(2) GeneralSparse achieves performance improvements of average 1.73/1.55/1.28× at 8 batch size on V100 over Sputnik, sparTA and Flash-LLM.

(3) GeneralSparse achieves the average speedup of 15.98× at 8 batch size over SparseTIR.

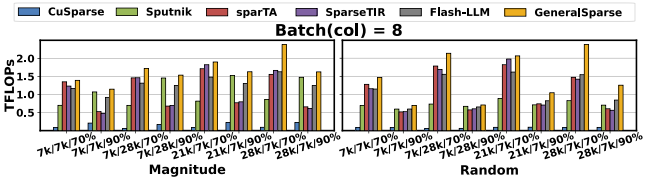

Figure 19: Kernel performance on weight matrices using Magnitude and Random on NVIDIA V100.

4.4 Model Evaluation

Settings and Baselines. We integrate the kernels, generated by GeneralSparse, into FasterTransformer [31] by providing a set of C++ APIs, which enables high-efficiency distributed inference with sparsified weight matrices. GeneralSparse can also be easily integrated into other deep learning frameworks through library calls with APIs. We compare GeneralSparse with various methods by end-to-end performance:

(1) Dense computation: (i) CUBLAS [33], which is included as a baseline to compare the performance gains to standard dense implementations of LLM inference.

(2) Sparse counterparts: (i) CuSPARSE, which is the sparse library. (ii) Flash-LLM, which is also integrated into FasterTransformer.

Dataset of models. We benchmark the end-to-end inference latency on OPT-30B/66B [52] and Llama-7B/13B/65B [41], Llama-3.1-8B/70B [19]. For all experiments, the input prompt sequence length is 64, and the output/generated sequence length is 512. We utilize the magnitude pruning [29] method, and use 70% sparsity level at the bottom and top layers, and 90% sparsity level at the intermediate layers.

To demonstrate that the pruned model maintains comparable performance to the original model, we evaluate the accuracy of the pruned versions of OPT-30B/66B [52] on the BoolQ task of SuperGLUE [42] by lm-evaluation-harness benchmark [17]. Specifically, the accuracy for OPT-30B decreases from 69.69% to 67.20%, while OPT-60B's accuracy declines from 70.46% to 68.01%.

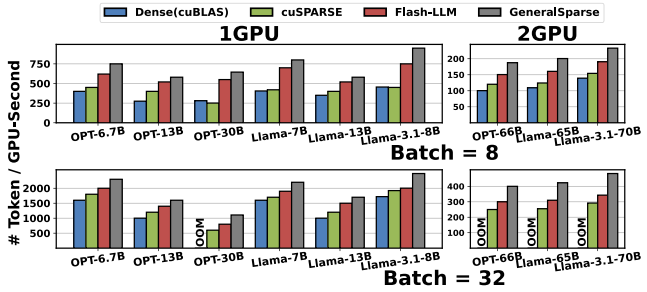

Figure 20: End-to-end model throughput.

Metric. We use the metric of `tokens per GPU-second` to represent normalized inference throughput, accounting for both inference time and hardware cost (i.e., the number of GPUs used), which is calculated by the formula: $N_{token}/\sum_{i=1}^{N_{gpu}} T_i$. N_{token} means the number of tokens generated, whereas N_{gpu} and T_i mean the GPU number and the time spent on the i'th GPU for execution. (OOM, out-of-memory).

Speedups on models. OPT-60B, Llama-65B and Llama-3.1-70B models are evaluated on two A100 GPUs in a tensor parallel manner. Other smaller models are evaluated on a single GPU. From the results, we observe that:

(1) Notably, GeneralSparse achieves the average speedup of 2.33/1.58× over Dense(cuBLAS) at 8/32 batch size.

(2) GeneralSparse achieves performance improvements of average 1.50/1.20× at 8 batch size, 1.48/1.23× at 32 batch size over cuSPARSE/FlashLLM.

OPT-30B, OPT-66B and Llama-65B models exceed the GPU memory limit (OOM, out-of-memory) when batch size is 32. However, the weights after sparse pruning reduce the memory usage, enabling the normal inference process. Besides, under the OPT-30B model (batch size = 8), the inference time of cuSPARSE is even worse than that of the dense implementation, because in some sparse patterns the performance of cuSPARSE is worse than its dense implementation.

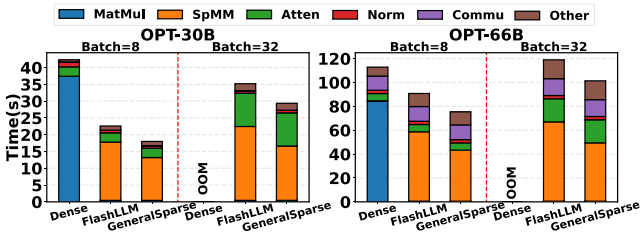

Figure 21: Time breakdown compared with other methods.

4.5 Model Analysis

OPT-30B. For figuring out why GeneralSparse can achieve better performance, we conduct the end-to-end breakdowns using the NSight System [32]. The inference time is shown in Figure 21. GeneralSparse can achieve lower inference latency mainly because we replace the dense MatMul with the more efficient SpMM. Besides, the time of MatMul, SpMM, and attention all increase with the increase in batch size. Compared with cuSPARSE and Flash-LLM, however, due to the performance improvement of SpMM, we decrease the inference time of the end-to-end model.

OPT-66B. To verify the proportion of our matrix time on multiple GPUs, we further analyze the inference time of OPT-60B across 2-GPUs. The OPT-60B runs on two GPUs in a tensor parallel manner, where the weight matrices are split and distributed to 2 GPUs. We conduct the time breakdown of end-to-end inference for OPT-66B as shown in Figure 21. Compared with a single GPU, there is additional communication overhead, but the performance bottleneck is still the MatMul part. It also verifies that our kernel speedup and tensor parallel can be effectively integrated. In detail, the acceleratio ratio in the prefill and decoding stages is 1.21/1.45 times and 1.52/1.63 times higher than FlashLLM/Dense at 8 batch size.

4.6 Search Analysis

Offline search analysis. The number of search iterations depends on the number of valid strategy combinations and the matrix characteristics. The search ranges about 30-50 iterations and 10-30 seconds in our search, achieving 90% of the best performance (hundreds search and about 15 minutes). For performance impact of different strategies, the difference in performance between different strategies for different matrices varies, with some matrices having a performance gap of three times that of different strategies, while others fluctuate by about ten percent.

Code generation and compilation time cost. For code generation time cost, it takes about a few seconds on small matrices, and one or two minutes on large matrices. During the offline search, the generated code has already been compiled for each matrix. At runtime, one can directly call the customized library for each matrix, similar to calling a sparse matrix multiplication library. We measure the compilation time for each matrix, which is only a few seconds. For the entire model compilation time, it takes only a few minutes for smaller models like Llama-7B, and for larger models such as Llama-65B, it takes around ten-odd minutes.

5 Related Work and Discussion

Our work draws inspiration from and contributes to several key research directions:

SpMM optimization. SpMM is a fundamental operation in sparse computation, with prior works such as cuSPARSE [34] and TACO [26] providing essential support for sparse matrix operations. However, these approaches often lack flexibility and fail to fully leverage GPU architectures for diverse sparsity patterns. Recent methods, such as Sputnik [16] and ASpT [23], have focused on optimizing SpMM for specific sparsity configurations, while SparTA [53] and Flash-LLM [45] utilize GPU tensor cores for structured sparsity acceleration. Despite their improvements, these methods often remain limited in adaptability to diverse sparsity patterns. GeneralSparse addresses these limitations by introducing an adaptable solution and automated code generation.

Pruning techniques for neural networks. Pruning methods are usually classified into unstructured pruning [20, 40] to structured sparsity [5, 7], which have been widely adopted to reduce the computational and memory demands of neural networks. In practice, unstructured pruning achieves higher accuracy retention [15, 18, 21] compared with structured pruning. GeneralSparse is designed to handle both categories, providing consistent performance gains across varying sparsity levels and patterns.

Large language model acceleration. Accelerating LLMs has become a critical research focus due to their growing computational demands. Existing efforts, such as FasterTransformer [31], DeepSpeed [36], and FlashAttention [10], have optimized various components of LLM inference, including attention mechanisms and scheduling strategies. By integrating seamlessly with existing LLM acceleration frameworks, GeneralSparse enhances the overall efficiency of sparsified LLM inference.

Discussion. This work represents a convergence of advancements in sparse computation, pruning methods, and GPU optimization, delivering a **vertical solution** that aligns with ongoing developments in LLM acceleration and sparse computation. By bridging the gap between adaptability and performance, GeneralSparse sets a new benchmark for high-performance sparse computation on GPUs.

6 Conclusion

We present GeneralSparse, a novel solution for designing SpMM programs on GPUs, addressing key challenges in performance bottlenecks in LLM inference considering diverse pruning patterns and sparsity levels. By introducing a unified abstraction of memory access and reduction spaces, flexible GPU allocation, and automated kernel generation. Extensive evaluations demonstrate its adaptability across pruned weight matrices and real-world datasets. Our code is available on https://github.com/Wangyaoyuu/GeneralSparse.

Abstract

End-to-end deep neural networks' (DNNs) training performance depends not only on the time spent in training the model weights but also on the time spent in loading and preprocessing the training data. Recent advances in GPU hardware have made training substantially faster. As a result, the bottleneck has shifted to the CPU-based input pipeline. This pipeline must fetch and transform each sample through multiple stages before it can be consumed by the GPU.

Prior works accelerate preprocessing by caching intermediate results across epochs, but suffer from several key limitations: (1) They cache either in memory or in storage, but are unable to leverage both together. (2) They can cache the output of a stage only if it can entirely fit in the cache, which is a severe limitation for larger datasets. (3) They can cache the output of *only* one of the stages which could be suboptimal.

We thus introduce Hybrid Cache (HyCache), a runtime that enables the caching of subsets of preprocessed data from multiple intermediate steps on *both* memory and storage. HyCache possesses the ability to partially cache the outputs of a stage across both memory and storage. HyCache deploys integer linear programming (ILP) to automatically determine the best caching strategies across the memory and the storage by finding an optimal trade-off between recomputation and caching. Importantly, it does so *without* any manual intervention. HyCache outperforms state-of-the-art prior approaches, delivering a raw pipeline throughput improvement ranging in speedups from 1.11× to 10.1× over a variety of pipelines.

1 Introduction

Deep Neural Networks (DNNs) have emerged as a transformative force in the field of machine learning, revolutionising how we process, understand, and make decisions from complex data. Their importance lies in their ability to learn intricate patterns, hierarchies, and representations automatically from data. Their success has driven advances across diverse domains such as computer vision [17, 25, 41, 48], natural language processing [15, 49], healthcare [3], and autonomous systems [22].

DNN training typically proceeds over multiple epochs, each representing a complete pass over the training dataset. To achieve high accuracy and generalisation, the model often requires multiple such passes over large-scale, high-quality datasets [11, 50]. However, these raw datasets—e.g., JPEG images or text files—are not directly consumable by the model and must first be transformed into structured tensors.

The **input preprocessing pipeline** handles the transformation of the raw dataset into structured tensors, which are finally consumed by the training pipeline. The pipeline performs a series of operations, such as image decoding, colour-space conversion, normalisation, data-type casting, and random augmentations, to prepare data batches for the accelerator [36]. These steps are essential for maintaining model accuracy and training stability. Their exact composition varies by model and task. As training progresses through epochs, each sample repeatedly passes through this pipeline, making it a critical component of end-to-end training performance. Generally, input preprocessing is managed by the CPU while the GPU performs training.

Today, accelerators like GPUs have dramatically improved the throughput of model training [40]. Meanwhile, dataset sizes continue to grow exponentially [20]. This places a significant pressure on the CPU-based preprocessing pipeline. Consequently, preprocessing is now often the critical path, stalling training and wasting valuable GPU cycles [23, 33].

Studies show that preprocessing delays can dominate training time: up to 65% of epoch time can be spent in the preprocessing pipeline [33]. Google reported that 62% of training pipelines stall for at least 1 ms *per epoch* due to input pipeline delays, and 16% stall for more than 100 ms [26] per epoch. At any given time, up to 10% of jobs wait on preprocessing and end-to-end training can spend as much as 65% of epoch time on data preprocessing alone [33].

Alleviating input preprocessing pipeline bottlenecks: A widely used strategy to mitigate preprocessing pipeline stalls is to cache the output of expensive preprocessing stages so that

*Work done as a student at the Indian Institute of Science.

they can be reused across epochs. Existing frameworks like *tf.data* [34] offer built-in support for in-memory and on-disk caching. However, these mechanisms rely on users to manually specify which pipeline stages to cache.

Recent systems have proposed automated and profile-guided caching strategies [14, 20, 26, 30]. These systems address a key limitation of OS-level caches—such as LRU—which perform poorly under the random access patterns caused by input shuffling across epochs [33]. Instead, they use offline profiling to identify preprocessing steps that are both compute-intensive and have a small data size footprint, making them ideal candidates for caching. For example, PRESTO [20] and Cachew [14] selectively cache such steps to reduce preprocessing latency.

However, these techniques face an important tradeoff: intermediate outputs, such as decoded RGB images, can be significantly larger than the raw dataset. As a result, even if a step is computationally expensive, caching its output may be infeasible due to memory or storage budget. Thus, any effective caching strategy must balance the cost of recomputation against the space required to store intermediate results.

Limitations of prior caching approaches: While prior works demonstrate the value of caching in DNN input pipelines, they remain limited in flexibility and adaptability. Most existing techniques suffer from four key shortcomings:

(1) They adopt an all-or-nothing approach—a pipeline stage is cached only if its entire output fits within the available memory or storage. If not, caching is disabled entirely, even though partial caching could still reduce recomputation costs.

(2) They treat memory and storage as disjoint caching tiers, using either memory or storage for caching but never coordinating the two. This separation prevents optimal combined use of system resources.

(3) If both memory and storage are used for caching, prior work restricts caching to the same pipeline step in both memory and storage. This limits the flexibility to exploit the differing performance characteristics of each tier.

(4) These works lack any mechanism to estimate or reserve working memory, which is needed for tasks like batching, data queuing, or threading. As a result, they risk overcommitting memory when allocating space for the cache, potentially causing stalls or out-of-memory errors.

These design simplifications ease implementation, but they miss significant opportunities for improving cache efficiency, particularly in modern training environments that provide sufficient DRAM and storage bandwidth.

Hybrid Caching (HyCache): We propose HyCache, which is designed to overcome the limitations of existing caching approaches by enabling partial, exclusive and coordinated caching across both memory and storage. It enables:

(1) HyCache supports **partial caching** of intermediate outputs. Rather than requiring an entire stage's output to fit in memory or storage, it allows arbitrary subsets of tensors to be cached. This enables reuse even under tight resource budgets.

(2) HyCache ensures **exclusive caching** across memory and storage. The intermediate outputs cached in both do not overlap. This avoids duplication, maximises overall capacity utilisation, and simplifies cache management.

(3) HyCache uses a **coordinated caching policy** to decide not only which tensors to cache, but also from which pipeline step and whether in memory or storage. It may place outputs of different preprocessing steps in memory and storage depending on their compute intensity and size.

(4) HyCache automatically estimates the **working memory requirements** of the input pipeline—accounting for batching, threading, and buffer management—and only allocates the remaining DRAM for caching. This prevents out-of-memory errors without burdening the user to tune cache sizes manually.

To realise its hybrid caching strategy, HyCache first profiles the input preprocessing pipeline to estimate the compute cost saved by caching in memory or storage and the output size of each step. It then formulates an integer linear program (ILP) to determine the optimal caching plan under given memory and storage budgets. The ILP balances the cost of recomputation against the latency and footprint of storing intermediate outputs, selecting both which steps to cache and where to cache them. The selected tensors are then placed into memory or storage according to this plan.

At runtime, HyCache supports seamless ingestion of intermediate tensors regardless of their origin—some may be fetched from DRAM, others from SSD, and the rest recomputed as needed. It guarantees correctness and ordering across these mixed sources, enabling fine-grained reuse without interrupting pipeline execution.

To avoid memory overcommitment, HyCache estimates the working memory required for pipeline operation—accounting for batching, threading, and buffer usage—and reserves only the remaining memory for caching. This prevents OOM errors and eliminates the need for manual tuning. Finally, HyCache exposes a simple, user-facing API that abstracts the cache management logic, enabling drop-in integration into existing training pipelines.

Summary: HyCache (1) Enables partial and coordinated caching across memory and storage, allowing different stages to be cached in different tiers. (2) Uses profiling and ILP to select what to cache and where, optimising for latency and resource constraints. (3) Supports ingestion of mixed cached and uncached tensors while preserving pipeline correctness. (4) Automatically adjusts cache sizes based on working memory needs and exposes simple APIs for easy integration.

2 Background

The input preprocessing pipeline can be characterised as a three-stage extract, transform, load (ETL) process. It applies transformations to the input data, such as permuting and filtering data to extract a subset of the relevant features and create input tensors to be used for training. Since the input data is usually stored on a CPU-attached storage device,

the transformation operations are performed on the CPU. Depending on the type of transformation, they may require significant computation. It may also generate outputs that exceed the input size. Finally, the third stage loads the data onto the GPU for training. Models are iteratively trained for several epochs for accuracy. Due to the large size of the dataset generated from transformations, it is not possible to keep all processed data in GPU memory for training. Thus, the preprocessing is repeated to generate tensors for each epoch.

The input pipeline is typically decoupled from the training on the GPU. Ideally, the input pipeline should continuously feed data to the GPU. Decoupling works effectively when the GPU computation time per batch equals or exceeds the latency to ETL the input data batch. With the GPU computational throughput increasing over time, the training time has decreased, making input pipelines a potential bottleneck. Prior works [26, 33] have shown that DNN training is now often I/O bound, bottlenecked by fetching the data from storage, or CPU-bound, bottlenecked by computation on the data items.

To provide further insights into the ETL process, consider the raw input for an image classification model. The raw input might be a protocol buffer containing a JPEG-encoded image, and the input pipeline must convert the raw input into a dense three-dimensional array of floating-point values corresponding to the RGB values of each pixel. During this process, the input pipeline needs to extract and decode the JPEG, then apply extra transformations like affine transformations and changes in colour space to augment the training data. Some of the input transformations lead to a significant increase in data size that exceeds available space even in large server-class CPU configurations. Further, given the slow access time to the storage devices, it is not always beneficial to cache the transformed tensors; recomputing them may be faster than accessing the cached tensors.

Preprocessing steps can be classified into two: ① **Offline (deterministic) steps**: always produce the same output for a given input, like JPEG decode, fixed resize, channel-wise normalisation. These steps can be computed once and cached across epochs. ② **Online (stochastic) steps**: which introduces randomness in each epoch, like random crops/flips, colour jitter. Hence, caching them either wastes space or defeats their randomness. We focus on caching offline steps, where outputs are repeatable and caching is feasible.

3 Opportunities for improving caching

In this section, we quantify the performance headroom for DNN input preprocessing pipelines and identify key opportunities for a partial, exclusive and coordinated caching strategy across memory and storage.

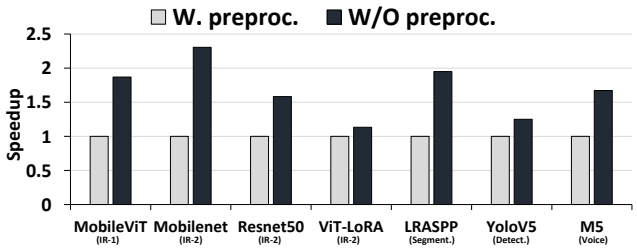

Figure 1: Headroom analysis for preprocessing pipelines.

3.1 Measuring headroom for improvement

We quantify the performance headroom available in end-to-end DNN training pipelines by eliminating preprocessing stalls. To do so, we measure two latencies: the baseline latency where input is fetched and preprocessed on demand before training, and the ideal latency with no preprocessing stalls.

To emulate the no-stall ideal scenario, we preload ~16K fully preprocessed tensors into CPU DRAM and measure the training time over these in-memory batches. This setup effectively removes all preprocessing stalls. [1] We then compare this against the baseline latency, where raw data is fetched and preprocessed for every batch. The difference between the two latencies quantifies the upper bound on speedup achievable by eliminating preprocessing stalls.

Figure 1 shows this headroom across various models (see Table 3 for model-pipeline details). Each model has two bars: one for the default case with preprocessing (W. preproc.') and one for the no-stall case (W/O preproc.'). The ratio between them reflects the speedup from removing preprocessing delays, ranging from 1.13× to 2.3× depending on the model.

3.2 Analyzing key limitations of prior works

All-or-nothing caching: Frameworks like TensorFlow offer APIs (e.g., `tf.data.Dataset.cache`) to cache the output of a specific pipeline step—provided the entire output fits in memory or storage. Users must manually select which step to cache, balancing the cost of recomputation against retrieval. Recent systems automate this decision by profiling the pipeline to identify a single "optimal" step for caching [14, 20].

While simple, this approach is sub-optimal. Many preprocessing steps, such as JPEG decoding, significantly inflate data volume [33], making their outputs too large to fully cache in. These steps are thus excluded from caching, even when partially caching their outputs could improve performance. An ideal caching framework should support *partial caching*—storing only a subset of intermediate tensors.

Caching either in memory or storage: Prior works focus on caching either in memory [26, 33] or in storage [20], but do not coordinate both. This separation can lead to inefficiencies.

[1] This emulation is valid because per-batch preprocessing and training latencies remain the same across samples, so the DRAM-resident subset accurately reflects a no-stall pipeline.

For example, data cached in storage may still be fetched into DRAM via the OS page cache, duplicating cached content across both. To fully utilise system resources, caching decisions should be coordinated across memory and storage, with exclusive contents in each.

Difference in memory and storage latency: Memory and storage differ significantly in both latency and capacity. A preprocessing step that is expensive to recompute may benefit from being cached in memory but not in storage, where access latency could outweigh recomputation. Prior works cache the same pipeline step in both tiers, ignoring the difference in latencies of memory and storage. A better approach would select different steps for memory and storage based on a comparison of recompute and access costs.

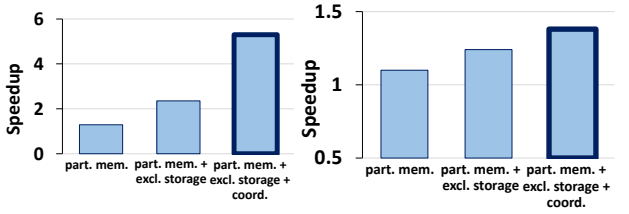
Variable working memory requirements: Different pipelines demand different amounts of working memory for batching, buffer management, and parallel fetching. In our study across six pipelines, we observed working memory usage ranging from 16–77 GB. This requirement also varies with dataset characteristics and the number of fetcher processes. Manually estimating this budget is error-prone; overprovisioning leads to poor cache utilisation, while underprovisioning risks out-of-memory failures. However, prior works require users to manually specify cache size, without accounting for dynamic working memory needs, limiting usability in real-world deployments.

Summary. An ideal caching framework should address these limitations by: ① Supporting partial caching of intermediate outputs instead of requiring all-or-nothing decisions; ② Coordinating memory and storage while avoiding redundant copies; ③ Allowing different preprocessing steps to be cached in memory and storage based on latency–cost trade-offs; ④ Automatically sizing the cache after reserving sufficient working memory for pipeline execution.

3.3 Quantifying opportunities for better caching strategies

We evaluated three different caching schemes on two representative DNN training pipelines (voice recognition and object detection) to quantify the potential benefits of a coordinated memory and storage caching strategy. We used the C2 configuration as described in Table 5. The first strategy allows partial caching of the output of a pipeline step only in memory (`'part. mem.'` in short). The optimal step to cache for a given available memory capacity is decided by an ILP solver (detailed Section 5), which considers the fraction of the output of the steps that can be cached in the available memory.

The second strategy additionally caches data in storage (here, SSD), denoted by `'part. mem + excl. storage'` in short. This policy ensures that the contents of the cache in memory and SSD are *exclusive*. However, the output of the *same* intermediate step is cached partly in memory until the available memory is fully utilised. The remaining tensors are cached in storage until storage capacity is exhausted. The remaining tensors are recomputed.



(a) **Voice recognition pipeline** (b) **Object detection pipeline**

Figure 2: Speedup of voice recognition and object detection pipeline across different caching policies (speedup is relative to the baseline).

Finally, the third configuration improves it further by allowing the caching of outputs of *different steps* in memory and storage (`part. mem. + excl. storage + coord.`). This coordinated strategy uses an ILP and access latency profiling to decide which step to cache in memory and storage.

Figure 2 shows the performances of these different caching policies for two representative DNN input pipelines: voice recognition and object detection. The performance of the caching policies is measured as the speedup over in-memory caching that disallows partial caching, as in prior work. We observe that enabling partial caching in memory improves performance by 28% and 10% for the voice and detection pipelines, respectively. Allowing partial caching cumulatively across memory and storage, such that cache contents in memory and storage are mutually exclusive, improves performance further to 2.35× and 24%. Finally, allowing different steps to be cached in memory and storage improves performance by 5.3× and 38%. These experiments suggest that a caching strategy that allows partial caching of multiple steps across memory and storage can significantly improve the performance of the input preprocessing pipelines.

3.4 Caching vs. re-computing trade-offs

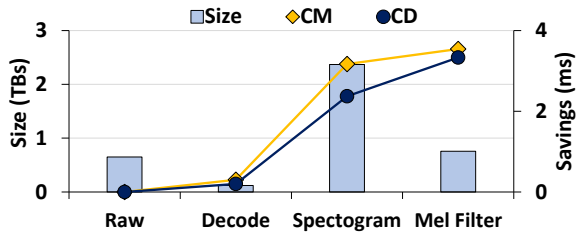
The next question is which pipeline steps to cache in memory and which to cache in storage. The decision depends on three factors: ① the available capacity in each tier, ② the latency of fetching data from that tier, and ③ how that latency compares with the cost of recomputation. To evaluate this trade-off, we run an empirical experiment on a small subset of the dataset.

We define two metrics : C_{M_i} and C_{D_i}, shown in equation 1.

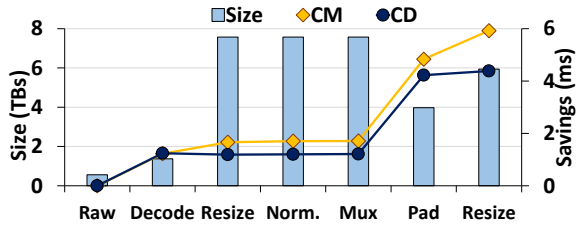
$$C_{M_i} = t_{M_{raw}} - t_{M_i}, \quad C_{D_i} = t_{D_{raw}} - t_{D_i} \tag{1}$$

$t_{M_{raw}}$ and $t_{D_{raw}}$ are the times (in ms) to fetch and preprocess the *raw* tensor from the memory and storage, respectively. [2] Similarly, t_{M_i} and t_{D_i} are the times (in ms) to fetch and preprocess the tensor cached after step i in memory and

[2] "Raw" refers to the original dataset sample without any preprocessing.



(a) **Voice pipeline**



(b) **Detection pipeline**

Figure 3: Savings and Storage vs Pipeline steps. The left y-axis shows the intermediate tensor sizes. The right y-axis is the unit savings(ms) per tensor in memory(C_{M_i}) or storage (C_{D_i}).

storage. Hence, C_{M_i} and C_{D_i} are the times *saved* by employing a caching strategy in memory and storage, respectively.

Figure 3 shows the trends of C_{Mi} and C_{Di} metrics across the preprocessing steps of voice recognition and object detection pipelines (subgraphs). Here, we report the measurement for a *single* tensor without loss of generality. The x-axis lists the preprocessing steps of these pipelines. The height of each bar captures the tensor output size of the given step (lower is better, primary y-axis). The two lines represent the (cumulative) latency savings *per tensor* in ms (secondary y-axis) from caching in memory and storage.

Note C_{M_i} is generally higher than C_{D_i}. As expected, the time savings from caching in memory are higher than caching in storage. The step with the lowest memory or storage footprint, i.e., the height of the bars, can potentially be cached well within a limited budget. However, one should also ensure that caching maximises the time saved on recomputation, i.e., where the saving curve for C_{M_i} (or C_{D_i}) rises steeply. For example, in detection shown in Figure 3(b), 'Pad' generates smaller tensors than 'Mux', yet its compute time is higher. Caching Pad, therefore, needs less capacity but yields substantial time savings. For the voice pipeline shown in Figure 3(a), 'Spectrogram' gives the largest time savings but also the largest tensors. 'Mel Filter' offers nearly the same savings while requiring far less space, making it a better candidate. Here, the most beneficial step to cache depends on the interaction of multiple factors, including available cache size, time to fetch data from the cache, and computation time.

3.5 Offline and online preprocessing steps

Pipelines	Online time %	#online steps
Recognition on ImageNet	7%	1
CubePP	18%	1
Voice recognition, object detection, image recognition and segmentation	0%	None

Table 1: Time spent on online steps across different preprocessing pipelines.

Thus far, we have discussed the steps to cache and how to cache them. An important note is that we cache **only offline steps**. Offline steps are deterministic and idempotent, so their outputs can be cached without altering training. Online steps add stochastic augmentations; caching them would eliminate this randomness and harm augmentation quality. As shown in Table 1, among the six pipelines we study, only image recognition on ImageNet [13] and CubePP [12] contain a single online step, and even then offline steps still account for 82% to 100% of the total preprocessing time.

Step	Action	Type	% time
Raw	Read JPEG	Offline	48%
Decode	JPEG to RGB tensor	Offline	9%
Resize	Scale to 224×224	Offline	26%
Normalise	Convert, channel normalise	Offline	10%
Flip	Random horizontal flip	**Online**	7%

Table 2: Preprocessing steps of image recognition pipeline.

Breakdown of image recognition pipeline: The pipeline comprises four offline steps—raw read, decode, resize, and normalise—and one online step, flip. The offline steps consume 93% of preprocessing time, making them ideal caching targets. The lone online step is left uncached to preserve randomness. As offline steps dominate the runtime, an effective caching policy can concentrate solely on them. This approach preserves data-augmentation randomness—and thus training quality—while still delivering near-maximal caching benefit.

4 HyCache: Key Ideas and Design Principles

Guided by the limitations outlined in Section 3.2, HyCache is designed to accelerate the input preprocessing pipeline by maximising memory and storage utilisation while minimising user effort. The design has following four key contributions:
1. Partial caching of intermediate outputs: HyCache supports partial caching, allowing any fraction of a pipeline stage's outputs to be cached in memory or storage. This relaxes the all-or-nothing constraint of prior systems and enables effective reuse even under limited capacity. Multiple stages can also be partially cached depending on resource availability.

2. Exclusive caching across memory and storage: To avoid duplication, HyCache guarantees that the memory and storage caches contain mutually exclusive data. Each cached tensor is placed in exactly one tier, ensuring efficient and non-redundant use of available hardware.

3. Coordinated tier-aware caching decisions: HyCache uses a profile-guided ILP formulation to determine which steps are best cached in memory versus storage, based on recomputation cost, output size, and access latency. Different steps can be cached in each tier, and the system automatically constructs an optimized pipeline that ingests tensors from memory, storage, or raw data as needed.

4. Automatic estimation of working memory: HyCache analyzes the runtime memory demands of preprocessing—such as batching, buffering, and fetcher overhead—and reserves only the remaining capacity for caching. This eliminates the need for manual tuning while ensuring stability and high resource utilisation. To create an automated framework HyCache does:

(1) Cost-Benefit profiling: Each step in the input pipeline is profiled with just a few sample batches to evaluate the relative merits of caching its tensors in memory and storage.

(2) Identifying the optimal steps to cache: The framework then identifies the optimal step for caching, guided by the memory and storage budgets and the computed cost-benefit ratios using an ILP solver. This approach allows HyCache to scale across different hardware configurations.

(3) Optimised pipeline generation: HyCache finally generates an optimised pipeline that is capable of sourcing tensors from various levels of the input pipeline, utilising both memory and storage resources efficiently.

(4) Working memory size estimation: It calculates the amount of working memory required for executing preprocessing tasks and reserves the rest for caching tensors.

5 Design and Implementation of HyCache

In this section, we describe the implementation details of HyCache. The input to HyCache consists of: (1) a user-defined preprocessing pipeline, (2) the raw dataset of N training samples, (3) a memory budget M, and (4) a storage budget D. Users may also annotate specific steps in the pipeline as "online-only," indicating they should not be cached.

Given these inputs, HyCache produces an optimised pipeline that fetches data from memory, storage, or raw input depending on availability. It also configures and populates memory and storage caches. Figure 4 provides an overview of the components involved, which we describe below.

Annotator and Step Filter: The first step in HyCache is identifying which pipeline stages are worth considering for caching. HyCache analyses the preprocessing pipeline to determine the input/output dimensions of each step. When a sequence of consecutive steps—e.g., S_k, S_{k+1}, S_{k+2}—produces intermediate tensors of identical size, only the final step (S_{k+2}) is considered for caching. The rationale is that since intermediate outputs do not change in size across these steps, caching earlier steps would offer no additional space-related tradeoffs.

To implement this logic, HyCache executes each step in isolation over a sample training batch and records the size of the output tensor. It then identifies sequences of steps with identical output sizes, retaining only the last step of each sequence. These are annotated as `filter_steps`, and they comprise the set of steps to be evaluated for caching. In Figure 4, these steps are highlighted in orange (e.g., `filtered_steps` $= S_2, S_3, S_5$). For example, if S_1 and S_2 produce outputs of the same size, only S_2 is retained for evaluation.

Profiler The profiler evaluates the cost–benefit tradeoff of caching each `filter_step` in memory or storage. For each step $S_i \in$ `filtered_steps`, the profiler computes the expected benefit of caching its output in memory (C_{M_i}) or storage (C_{D_i}), as defined in Equation 1. It also records the average output tensor size Sz_i. While output sizes are typically deterministic, some steps may depend on input characteristics, so Sz_i is averaged over samples.

Profiling is conducted during the first epoch and proceeds until 1% of the dataset is processed. This threshold has been shown to provide a representative view of the overall dataset [26]. Since profiling spans multiple batches, HyCache averages the measurements to account for batch-to-batch variability. This process incurs minimal overhead (Section 7.5).

Tuning number of fetchers Pipeline throughput improves with additional fetchers, but at the cost of higher memory usage. Each fetcher is a separate process responsible for loading and preprocessing data, and increasing the number of fetchers reduces latency but consumes more working memory, thereby reducing the cacheable memory capacity.

To strike the right balance, HyCache performs a binary search over the number of fetchers during the profiling phase. It measures the throughput of preprocessed batch creation for each configuration. The search upper bound is the number of available CPU cores, and the search converges at the point where adding fetchers no longer improves throughput. It identifies the optimal number of fetchers F_i for the pipeline, ensuring efficient data ingestion without overcommitting memory.

ILP solver: At the core of HyCache is an ILP solver, which identifies the optimal steps for caching in the memory and storage based on the profiling. The solver uses the cost savings, C_{Mi} and C_{Di}, and the tensor sizes after each filter_step (Sz_i).The goal is to identify the optimal caching steps in memory (S_{optM}) and storage (S_{optD}), as well as the number of tensors to cache for these steps (N_{optM} and N_{optD}).

The optimal caching policy is formulated using Equations 2 to 5. S_{optM}, S_{optD} is the solution that maximizes the sum in Equation 5, using the constraints in Equations 2 through 4.

$$\sum N_{M_i} Sz_i \le M, \quad \sum N_{D_i} Sz_i \le D \tag{2}$$

$$N_{optM} = \sum N_{M_i}, \quad N_{optD} = \sum N_{D_i} \tag{3}$$

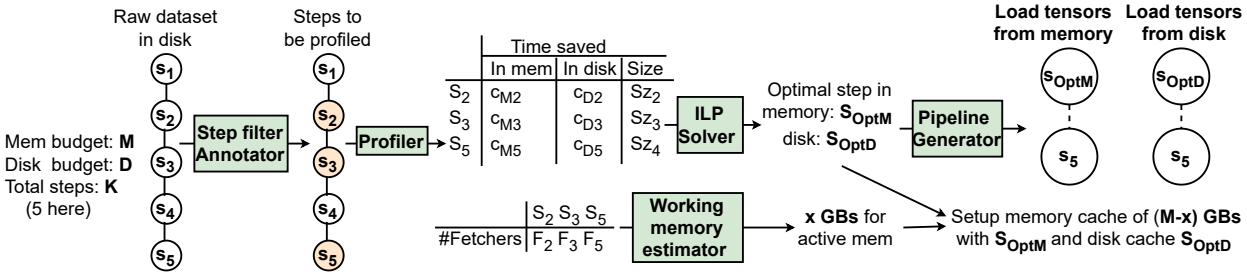


Figure 4: Overview of HyCache.

$$N_{optM} + N_{optD} \leq N \tag{4}$$

$$maximize \sum N_{M_i} C_{M_i} + \sum N_{D_i} C_{D_i} \tag{5}$$

Equation 2 ensures that the cumulative size of tensors at any step remains within the memory and storage budget. Equation 3 defines N_{optM} and N_{optD}, as mentioned previously. Equation 4 constrains the total number of tensors cached jointly in the memory and storage, never to exceed the number of elements in the dataset. It also allows for *partial* caching in both storage and memory, as the number of total tensors cached may be less than or equal to the total elements (N).

Jointly optimising the cache stores of the memory and storage allows convergence into a solution that accounts for the access latency of SSD while deciding what to cache in memory, i.e., a global maxima solution, as opposed to locally maximising the utility of the memory cache in isolation.

HyCache uses a *coordinated* caching policy across memory and storage that ensures the exclusivity of tensors stored in each store. The memory and storage caches are created sequentially, keeping track of cached data items such that tensors cached in memory and storage do not overlap. Equation 4 ensures that, collectively, the memory and storage caches encompass a part of or the entire dataset (i.e, all elements N). The ILP solver finally returns the optimal step(s) for storage (S_{optD}) and the number of tensors to be cached (N_{optD}). Recall from Section 3.4 that C_{M_i} and C_{D_i} represent the recomputation latency saved by caching a tensor in memory and storage, respectively. Note that C_{M_i} and C_{D_i} are measured in the profiling phase. The equation 5 finds the values of N_{M_i} and N_{D_i} that maximizes the saving of recomputation cost.

Figure 4 pictorially depicts the working of key components of HyCache, including the ILP solver. The solver is also capable of identifying and recommending multiple optimal steps for storage caching, along with the number of tensors to cache from each. This capability is helpful when the cache size (e.g., storage cache) is big enough to accommodate outputs of more than one intermediate step.

Working memory size estimation: The size of the working memory directly influences the amount of memory available for caching (Section 3.2). Manually calculating the memory available for caching introduces complexity and is prone to mistakes. If the working memory size is underestimated, then it can lead to an out-of-memory error during preprocessing. Its overestimation leads to memory under-utilisation since the cache size could be set to a lower number than necessary. HyCache alleviates this requirement by dynamically determining the required working memory for a given pipeline, hardware configuration, and dataset, using Equation 6.

$$\begin{aligned} working_mem = (max(Sz_i) \times bs \times prefetch_depth) \\ + (mem_per_fetcher \times max(F_i)) + metadata \end{aligned} \tag{6}$$

The equation incorporates the following: First, it considers the maximum size of intermediate tensors (Sz_i), batch size (bs), and $prefetch_depth$. The $prefetch_depth$ factor is for the number of fully preprocessed batches that can be kept in memory waiting to be transferred to the GPU for training. It is set to two by default. Typically, a batch is processed by parallel threads. Second, the memory requirement of a fetcher is multiplied by the maximum of F_i to ensure sufficient working memory for any possible number of fetchers. Finally, some space is also reserved for Python's metadata, e.g., a list of all files, which is easily determined empirically.

Pipeline creation and cache population: HyCache automatically creates multiple pipelines to ingest data samples at different stages of preprocessing in the pipeline as chosen by the ILP solver. Specifically, HyCache generates one pipeline for each different stage of preprocessing whose output the ILP solver decides to cache. For example, in Figure 4, HyCache creates two pipelines – one ingesting tensors from S_{optM} and another from S_{optD}. Further, since HyCache allows the partial output of different stages of pipelines, it is also possible that the output of none of the steps is fully cached in either of the cache stores. In such cases, HyCache employs an additional pipeline to process the raw data samples.

Allowing data to be ingested from different steps and sources (e.g., memory, SSD) requires modification to a regular pipeline. HyCache annotates the preprocessing pipeline code to automatically insert conditional execution by using *if then else* conditions. For instance, if the output from the last step of a series of steps is fully cached, there is no need to execute all the intermediate steps in the series. In addition, HyCache can conditionally preprocess until a step for fetching partially preprocessed tensors from a cached source.

HyCache populates the memory and storage caches with tensors from the output of pipeline stages, S_{optM} and S_{optD},

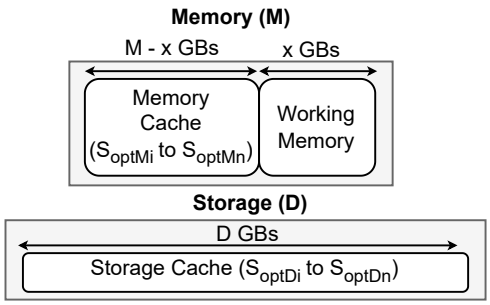

Figure 5: Overview of data placement in memory and storage.

as chosen by the ILP solver, and populates the caches during the execution of the first epoch (epoch 0). HyCache maintains directories that map each sample to the location where it is cached, which is just the filename for a raw sample. HyCache also sets the number of fetchers for different pipelines. For example, it sets the number of fetchers for S_{optD} as determined by the profiler to fetch data from the storage.

The profiler may choose to cache outputs of multiple steps in memory and/or storage if the available capacity permits. Thus, S_{optM} and S_{optD} can be a set of steps rather than a single step.HyCache creates a coordinated cache fetch and preprocessing pipelines for each of the steps in S_{optM} and S_{optD}. HyCache coordinates multiple pipelines to continuously supply a stream of batches from both cached and recomputed preprocessing steps automatically. While HyCache creates multiple internal pipelines, it presents a single pipeline iterator to the user. This abstraction ensures that users can seamlessly harness HyCache without code modifications.

Figure 5 shows the final allocation of both memory and storage resources by HyCache. The total memory budget M is split into two parts: x GB for working memory and $M-x$ GB for the in-memory cache, which is populated with the optimal in-memory steps $S_{\text{Opt}M_i}$ through $S_{\text{Opt}M_n}$. Simultaneously, the storage cache is populated with the optimal on-storage steps $S_{\text{Opt}D_i}$ through $S_{\text{Opt}D_n}$.

Training: With HyCache, the training remains unaffected. HyCache's improvements are solely limited to the input preprocessing pipeline. The data is immediately ready for training on any computational device after batch generation by the pipeline. HyCache further extends support for multi-GPU environments, where the CPU manages the input pipeline while facilitating concurrent training across several GPUs.

6 Ease of deploying HyCache

```
from hcLib import BasePipeline, HyCache                    1
class ImageRecognition(BasePipeline):                      2
    def defineGraph(self):                                 3
    ...                                                    4
    # Define the preprocessing steps here                  5
    ...                                                    6
# Include other arguments here too.                        7
HyCachePipeline = HyCache(ImageRecognition, M=100%,
    D=500, dataset_path="/path/to/dataset")                9
iterator = HyCachePipeline.build()                         10
# Initialize your model                                    11
model = models.resnet50().cuda()                           12
for batch in iterator:                                     13
    train_model(model, batch)                              14
```

Listing 1: Using `hcLib` library for an input pipeline.

In this section, we show how a user can leverage HyCache. Its key functionalities are encapsulated in a library that we name `hcLib`. A key benefit of using HyCache is that it needs minimal changes to a regular model training process. Listing 1 shows how a user can interface with our library. The user needs to first import `BasePipeline` as usual and then `HyCache` classes from the library `hcLib` (line 1). `BasePipeline` is a wrapper class over `nvidia.dali.Pipeline` object that internally enables profiling and other required changes to support our programming paradigm.

The user-defined preprocessing class must inherit this class instead of the original `nvidia.dali.Pipeline` (lines 2-6). Then, to finally enable pipeline optimisations and get the iterator, the user has to initialise an object of `HyCache` with the Pipeline class (lines 8-9). This object initialisation requires arguments such as the total memory budget (note, not the cache size), storage budget, batch size, dataset path, or list of dataset files, etc. Other important arguments include `storage_cloc`, which is the location of the storage cache, `world_size`, which should be used in case of distributed training, and `cache_steps`, which is an integer to indicate consideration for caching only up to a given step. If this argument is not provided, it is assumed that all the steps are offline and can be considered for caching. It is also important to note that the allowed budgets for memory and SSD are never exceeded. However, the value provided by the user cannot be smaller than the expected active memory size. Also, the user should expect an out-of-memory error if the memory budget exceeds the available free memory in the system.

To get the iterator for continually yielding batches, the user has to call the `build()` method on the returned object (line 10). Next, as in a regular training script, the user initialises their training model (line 12). We show an example of creating a `resnet50` model, with GPU training enabled using the `.cuda()` method. There is no constraint on using the GPU for training. Any other accelerator, even the CPU, can be used. However, the user needs to consider the memory bloat of the model in case the CPU is used. Finally, the user can use regular loop-yielding style calls to the iterator to get batches and do further training on the model (lines 13-14).

7 Evaluation

We present the performance evaluation of HyCache on a single server setup. We empirically assess the efficiency of Hycache's caching policies against prior works and the baseline. We then quantify improvements in end-to-end training jobs.

7.1 Methodology

Pipeline	Dataset	Model
Image Recognition-1 (IR-1) [47]	OpenImagesV5 (561GB) [24, 29]	MobileViT-BS16 [32]
Image Recognition-2 (IR-2) [13]	Imagenet-22K *(650GB) [19]	MobileNetV3-BS16 [18] ResNet50-BS16 [17] ViT-LoRA-BS3584 [52]
CubePP [20]	CubePP-JPG *(550GB) [12]	–
Segmentation [44]	Imagenet-22K *(650GB) [19]	LRASPP-BS16 [18, 37]
Object Detection [45]	OpenImagesV5 (561GB) [24, 29]	YoloV5-BS16 [39, 42]
Voice Recognition [20, 46]	FMA *(650GB) [5]	M5-BS12 [10]

Table 3: Pipeline characteristics and configurations. '*' indicates the dataset was reduced or augmented.

Workloads: Our evaluation spans six distinct preprocessing pipelines, listed in Table 3, covering a range of ML tasks including object detection, image recognition, voice recognition, and segmentation. Each pipeline is paired with a dataset and a downstream DNN model used for training.

Note that multiple models may share the same preprocessing pipeline and dataset. For example, MobileNet, ResNet50, and ViT-LoRA all use the same ImageNet-22K dataset and pipeline. However, the degree of preprocessing bottleneck experienced by each model can differ significantly depending on its architectural complexity and computational intensity.

All DNN models are sourced from the TorchVision library [1, 31] or implemented using `torch.nn` [35]. Table 3 also includes the batch sizes used in both end-to-end training and preprocessing-only evaluations. These batch sizes represent the largest configurations that could fit on a single GPU under data-parallel training.

Datasets marked with '*' have been reduced or augmented to fit within our 2 TB storage limit (see Table 4), ensuring sufficient space for storage-based caching.

Since our primary goal is to accelerate the input preprocessing pipeline, we focus first on how HyCache improves preprocessing throughput, independent of the model's training speed. Later in this section, we evaluate the end-to-end impact of HyCache on overall training time, including both preprocessing and model execution.

Experimental setup: Our evaluation platform is listed in Table 4. We show the performance of HyCache on various configurations, listed in Table 5, derived from this base platform. We design these configurations based on the available VM setups on Google Cloud Platform [9]. For example, for an A100 GPU with 40 GBs of memory, 85 GBs of CPU memory, and 12 vCPUs on the CPU are available for a single VM instance, and this ratio is consistent across their A100 offerings. We mention the evaluation configuration used for each experiment explicitly and mention any changes in the evaluation setup in their respective subsection. By default, for all experiments, we use the configuration C2 unless otherwise mentioned. Note that each vCPU is mapped to a separate physical core. In short, we do not oversubscribe the cores.

CPU	AMD EPYC 7313 16-Core @ 64× 3GHz
DRAM	512GB DDR4
SSD	2TB Samsung 980 PRO
Software	Python-3.10, Nvidia DALI v2.1

Table 4: Configuration of the evaluation platform.

Config	vCPUs	Memory	SSD Size
C1	12	85GB	250GB
C2	24	170GB	500GB
C3	24	170GB	1000GB
C4	48	340GB	500GB
C5	48	340GB	1000GB

Table 5: Configurations used for evaluation

Training environment and parameters: We implement HyCache atop Nvidia DALI [7]. We use Python 3.10 and DALI-v2.1.0 to create this library. Although we use PyTorch for model training, the `hcLib` library is agnostic to the model framework used. For end-to-end training, we use Pytorch's distributed data-parallel training [38] to allow training on multiple GPUs. For all experiments, the number of threads processing a batch is set to the number of cores available (e.g., 12 for 12 cores/vCPUs). The number of fetchers for HyCache is set to the ideal number of fetchers determined by its profiler. Related works do not have the ability to choose the number of fetchers automatically. Thus, while evaluating them, we set the number of fetchers to the number of available CPU cores.

Comparison with other caching policies: We measure our performance against two works that also optimise the input pipeline, MinIO [33] and PRESTO [20]. MinIO caches random data items as they are fetched from storage to populate the memory cache. Once the cache capacity is reached, MinIO does not evict any items in the cache. Instead, the requests to other data items fetch them directly from the storage. PRESTO decides the ideal step to cache in the storage, based on profiling. We also implemented PRESTO in DALI [7] to compare with our solution, where we choose the best step to cache that can *completely* fit in the given storage budget. If PRESTO does not have a step that can fit in the storage, it uses the raw dataset.

7.2 Performance of input pipelines

Figure 6 shows the normalised performance of HyCache and its competitors across various input pipelines. Since we

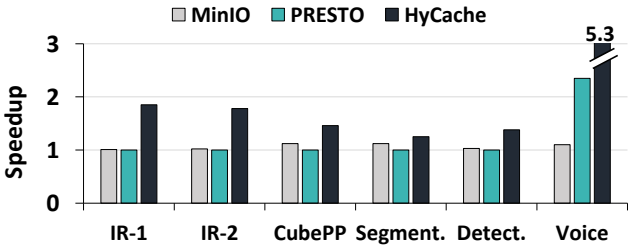

Figure 6: Performance of different caching policies.

Pipeline	MinIO	PRESTO	HyCache
IR-1	Fixed Pagecache Memory + Raw	OS Managed Memory + Raw	5M + 3D + Raw
IR-2			2M + 2D + Raw
CubePP-JPG			2M + 3M + 2D + Raw
Segmentation			3M + 3D + Raw
Detection			6M + 5D + Raw
Voice		OS Managed Memory + Step 1D	3M + 1D + 3D

Table 6: Strategies used for evaluation in section-7.1

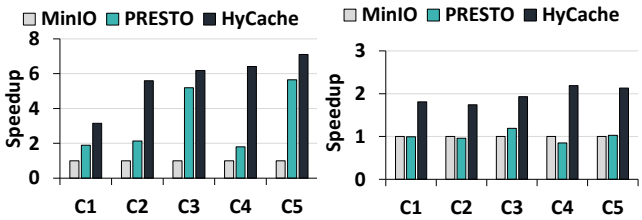
focus on improving input processing pipelines while leaving the training unchanged, we isolate the performance of the pipelines by measuring the number of samples preprocessed by each pipeline under various platforms, MinIO, PRESTO, and HyCache. The heights of each bar are normalised over the number of samples processed under the traditional OS page cache (higher is better). MinIO speeds up pipelines by up to 12% (average, 7%) [3] PRESTO significantly speeds up the voice pipeline as it could fit the output of the optimal intermediate step in its storage cache, but not for other pipelines.

We observe a speedup in the range of 1.11×-5.3× over MinIO, and 1.24×-2.26× over PRESTO. The improvements were the largest for the voice pipeline – through the coordinated caching in memory and storage, HyCache was able to save more than 80% of the compute time. The image processing pipelines (IR-1 and IR-2) save 58% and 42% of recomputing time and speed up by 1.84× and 1.74×, respectively, over MinIO. PRESTO can significantly outperform MinIO only for the voice pipeline through caching in storage.

Table 6 summarises the caching strategies employed by various platforms. MinIO does not cache the outputs of intermediate preprocessing steps. Instead, it focuses on caching raw datasets via the OS's page cache, optimising I/O for unprocessed samples. PRESTO supports caching intermediate outputs in storage, enabling the reuse of either raw or preprocessed samples by loading them into the OS page cache.

In contrast, HyCache offers significantly more flexible and

[3]The authors of MinIO [33] reported up to 50% speedup (Figure 13(a)). Our setup uses 3× faster SSD than the one used in the original paper [33]. This reduced the scope for MinIO's speedup.



(a) **Voice Pipeline** (b) **IR-2 pipeline**

Figure 7: Performance across different hardware configs.

fine-grained caching capabilities. It can cache the outputs of any intermediate step or the raw dataset itself. Moreover, HyCache supports caching different preprocessing stages in memory and storage independently. It can even cache outputs from multiple distinct steps within the same tier—either memory or storage—depending on available resources and recomputation tradeoffs.

In Table 6, nM' denotes that the output of the n^{th} intermediate step is cached in memory, while kD' indicates that the k^{th} step's output is cached in storage. Entries marked 'Raw' means raw dataset is cached directly in memory or storage.

This table highlights HyCache's versatility in leveraging both memory and storage to reduce preprocessing costs. For instance, in the voice pipeline, HyCache caches the output of the 3$^{\text{rd}}$ step in both memory and storage, and also caches the 1$^{\text{st}}$ step's output in storage. This coordinated strategy improves resource utilisation and minimises recomputation.

In summary, HyCache enables adaptable, multi-tier caching policies that exploit the full capacity of available memory and storage to accelerate input pipelines.

7.3 Performance scaling and Adaptability

A key advantage of HyCache is its ability to automatically configure cache sizes and determine the number of fetcher threads, in contrast to prior approaches that require manual tuning. In this section, we empirically demonstrate HyCache's adaptability to varying hardware configurations.

We evaluate the performance of HyCache against PRESTO and MinIO across five different system setups, listed in Table 5. Figures 7(a) and 7(b) show the normalized throughput of the three platforms for two representative pipelines: Voice and Image Recognition-2 (IR-2). On the x-axis, we vary the hardware configurations, while the y-axis reports throughput normalized to MinIO (higher is better).

Across all configurations, HyCache consistently outperforms both baselines. For the voice pipeline, HyCache achieves 3.14× to 7.10× speedup over MinIO and 1.2× to 3.5× over PRESTO. For the IR-2 pipeline, it provides 1.73× to 2.13× improvement over MinIO and 1.61× to 2.57× over PRESTO.

Further analysis reveals that for the voice pipeline, both PRESTO and HyCache choose to cache the output of the same step (step 3). However, HyCache outperforms PRESTO

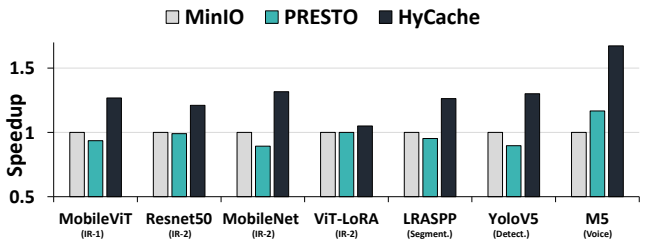


Figure 8: Improvement in end-to-end training throughput.

due to its coordinated use of memory and storage, which PRESTO lacks. In configurations like C4, HyCache's support for partial caching gives it a significant edge, allowing it to utilize constrained resources more effectively.

We observe similar trends in the IR-2 pipeline. In some configurations, HyCache gains from its partial caching strategy, while in others, its ability to split caching across memory and storage proves more beneficial.

7.4 End to End Training

Thus far, we have focused on evaluating preprocessing pipelines in isolation. In this section, we quantify the impact of HyCache on full end-to-end training jobs, including model training on the GPU. The models and corresponding batch sizes used in these experiments are listed in Table 3.

Figure 8 presents the normalized end-to-end training performance for each model. Unlike prior graphs, which were pipeline-centric, this figure reports model-specific speedups. As shown in Table 3, multiple models may share the same preprocessing pipeline—e.g., MobileNet and ResNet both use the IR-2 pipeline for image recognition. To clarify this, we annotate the associated pipeline below each model name on the x-axis.

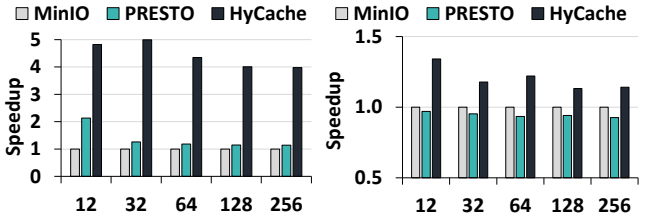
This experiment uses configuration C4 from Table 4. We observe that HyCache delivers speedups ranging from *1.05*× to *1.67*× over MinIO, and from *1.05*× to *1.47*× over PRESTO. These gains depend on both the preprocessing bottleneck and the GPU training load of the model.

For instance, ViT-LoRA—based on the `vit_base_patch16_224` architecture is the most compute-heavy model in our evaluation, and achieves a more modest *1.05*× speedup.

Because DNN models are computationally intensive, improvements in the input pipeline only impact a portion of the total training time. Nonetheless, HyCache achieves up to *1.67*× end-to-end speedup without any GPU-level training optimisations. Notably, we do not apply techniques such as mixed-precision training (e.g., Apex [6]), which could further shift the performance bottleneck toward input preprocessing, potentially increasing the benefits of HyCache.

Pipeline	Profile(s)	Epoch(s)	Over head %	Batch size
IR-1	427	7016	6.1	48MB
IR-2	273	2093	13.0	135MB
CubePP-JPG	496	2794	17.8	152MB
Segmentation	648	3567	18.2	192MB
Detection	700	10075	6.9	64MB
Voice	204	8150	2.5	43MB

Table 7: Profiling overhead as a percentage of a vanilla epoch.



(a) **Voice Pipeline** (b) **Detection pipeline**

Figure 9: Performance of pipelines across different batch sizes.

7.5 Profiling Overhead

HyCache profiles 1% dataset to find out the output size of each of the intermediate steps of a pipeline. It also profiles the runtimes of each step of a pipeline. The ILP solver uses these for choosing a caching strategy. We report the profiling overheads in Table 7. We report the time needed for profiling in seconds, the time needed to preprocess samples for an epoch. We report the batch size in MB. The profiling overhead ranges from 2.5% to 18.2% of the preprocessing time of *one* epoch (i.e, one pass over the dataset). The profiling is done *only* during the first epoch, while a typical training job runs for hundreds of epochs. Thus, it adds little overhead to the overall preprocessing pipeline. Note that the profiling overheads vary across pipelines based on the number of steps in the pipeline. The higher the number of steps, the larger the profiling overheads. Further, a larger batch size (bytes) increases overheads as larger amounts of raw data must be accessed during profiling.

7.6 Sensitivity to Varying Batch Sizes

The batch size used for model training is a hyperparameter. This section highlights that our framework is able to adapt to varying batch sizes and offers consistently high performance across different sizes compared to prior work. Figure 9 shows the normalised performance of the two representative pipelines under varying batch sizes for the three frameworks. As before, the throughputs are normalised to those under MinIO. We notice that across batch sizes, HyCache outperforms other platforms. This shows that HyCache is able to adapt well to

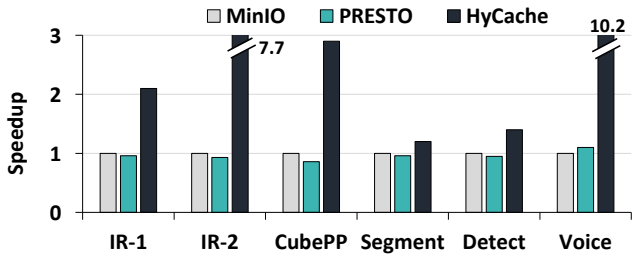


Figure 10: Throughput with remotely connected storage.

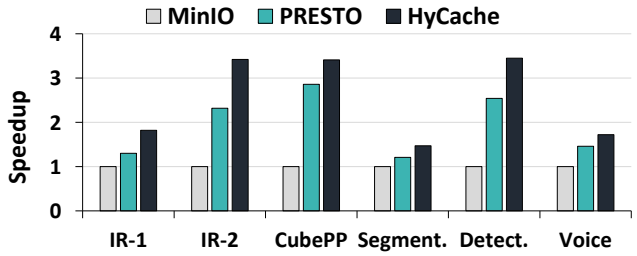

Figure 11: Pipeline throughputs for small datasets

different batch sizes. We also notice that increasing batch size often reduces the speedups for HyCache. Larger batch sizes necessitate larger working memory for computation and, thus, smaller memory caches. This, in turn, limits HyCache's ability to leverage caches for limiting recomputation.

7.7 Implications of Remote Storage

Finally, we evaluate the implications of keeping the raw dataset in a remote NFS file server [2] This emulates the scenario where the dataset is remotely located in a cloud storage. Fetching raw data from a remote server introduces network latency and potential bandwidth constraints into the data ingestion process, making it worthwhile to evaluate it separately.

For this experiment, we use configuration C4 from Table 5. Figure 10 shows the performance of PRESTO and HyCache relative to MinIO. We observe a speedup in the approximate range of 1.11× - 10.1× over MinIO, and 1.19× - 9.28× over PRESTO. The IR-2 and voice pipeline witness substantial speedups with HyCache over the other two because they have a solution that completely fits in the available storage and memory budget. In contrast, the other two suffer a significant drop in performance since they have to rely on the NFS throughput. The maximum available throughput on this device is 64.8 MiB/s, which we tested using the `fio` [4] utility. In summary, HyCache is able to perform well across a wide variety of settings and configurations – a treatment to HyCache's ability to automatically adapt to varying deployment scenarios.

7.8 Analyzing PRESTO's usefulness

One would notice that PRESTO [20] is generally ineffective in speeding up preprocessing pipelines, except for the voice

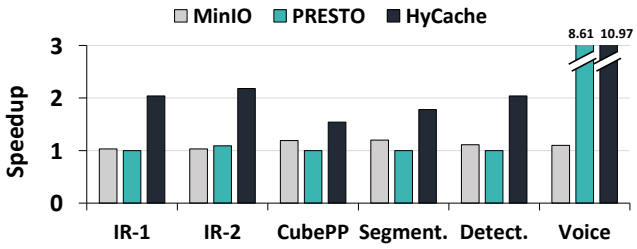

Figure 12: Pipeline throughput for C5 configuration.

pipeline. The efficacy of PRESTO is limited by its inability to partially cache the output of an intermediate step and its inability to harness both memory and storage for coordinated caching, unlike HyCache. We found that PRESTO is useful only when used with small datasets such that the output of all or most of the intermediate steps could fit well in its cache budget. The original paper used datasets as small as 250MBs, up to 146GBs. However, small datasets are contrary to current trends of using ever larger dataset sizes. In our evaluation, we use datasets that exceed at least 550GBs.

To demonstrate PRESTO's efficacy for smaller datasets, we limited the preprocessing pipelines to use only 100 GB of the dataset but allocated 1650GB storage cache. Figure 11 shows the performance of different pipelines under MinIO, PRESTO, and HyCache, normalised to MinIO. For smaller datasets, PRESTO provides a more significant speedup of 1.21×-2.86× over MinIO. HyCache performs 1.3× better on average over PRESTO in this setting as well, demonstrating its adaptability to varying system configurations.

Finally, while Figure 6 reported performance under configuration C2, we further evaluate the effectiveness of different caching mechanisms under configuration C5, which features a larger SSD, as shown in Figure 12.

Despite the increased storage capacity, a 1000 GB SSD was still insufficient to fully cache intermediate outputs for four of the six pipelines. Among the successful cases, the Voice pipeline achieved the optimal caching configuration and delivered a speedup of 8.61×, while the IR-2 pipeline showed a modest improvement of 1.09×.

In summary, PRESTO provides performance gains only in limited scenarios, typically when the pipeline fits entirely within the storage budget. In contrast, HyCache continues to improve performance even under tighter resource constraints due to its support for partial and coordinated caching.

7.9 HyCache in distributed environment

In this subsection, we will discuss how HyCache can be extended in a distributed environment. The current implementation of HyCache uses a single node to demonstrate its key ideas. However, its design can seamlessly operate in distributed environments where data is partitioned across multiple

machines. In homogeneous clusters—where hardware configurations are identical and data is evenly distributed—the profiler and ILP solver can be run once, and the resulting cache plan applied uniformly across all nodes. In contrast, heterogeneous clusters with varying hardware or skewed data distributions can run HyCache independently on each machine, allowing each node to tailor its caching strategy to local workload and resource characteristics. Since the profiler relies only on the underlying hardware and the pipeline, HyCache in a distributed setting does not require any coordination across nodes and can seamlessly generate distributed plans.

8 Related Works

Distributed training: FastFlow [43] automatically offloads input pipeline preprocessing to remote CPUs, aided by lightweight profiling. Meta [51] discusses preprocessing bottlenecks causing stalls in their Deep Learning Recommendation Models(DLRMs). Cachew [14] is a fully managed service for ML data processing that dynamically scales distributed resources to avoid stalls in training jobs. Cachew's autocaching policy fails when materialized tensors are too large to fit in memory or disk. Nectar [16] focuses on automating the management of data and computation across their cluster of many-node servers. Our work is orthogonal to Nectar and our caching strategies can be used as a basis for cache creation. Quiver [28] boosts DNN training efficiency with transparent data reuse, flexible cache hits, and job-aware allocation. The distributed cache that is shared across multiple users and training jobs can use our caching policy coupled with their hash-based addressing to boost training performance.

Random Augmentations: Several recent works have explored techniques for optimizing DNN training pipelines through caching randomly augmented datasets, i.e., cache creation, coupled with cache management or replacement. Data Echoing [8] t reuses intermediate outputs from earlier pipeline stages to reclaim idle accelerator capacity for faster training when reading data over a network. Data subsampling [27] utilizes subsampled versions of training data for augmentation, reducing computation and memory requirements while maintaining performance. Revamper [30] reuses partially augmented samples within specific stages of the pipeline to speed up training. While these works focus on speeding up random augmentation, we focus on offline/deterministic preprocessing steps that has reuse. Caching random steps can affect training accuracy and convergence. However, HyCache does not modify the output of a pipeline and has no impact on accuracy.

Caching Policies and single node training: MinIO [33] reduces the amount of disk I/O (fetch stalls) in single-server training. While saving disk I/O can be useful, our analysis shows that saving computation by using cached tensors proves to be more advantageous than caching raw data in memory. Cachew [14] also considers caching intermediate step on the memory or optionally to the disk, an all-or-nothing policy that may fail. Plumber [26] uses `tf.data.Dataset.cache` to greedily cache a pre-processed `Dataset` into memory or storage. Greedily choosing a step to fully fit against HyCache partial caching does not perform well, as shown in Figure 2.

Accelerator-assisted preprocessing: DALI allows offloading pre-processing to the GPU. However, it may cause interference with the training or inference task itself [33], and limit available GPU memory for training itself. Similarly, SMOL [21] also presents a system that offloads preprocessing to an accelerator, by pipelining preprocessing of image-based data and model training on the GPU while controlling accuracy convergence.

9 Conclusion

We present HyCache, a novel hybrid caching mechanism designed to accelerate DNN training pipelines. It leverages both memory and storage for caching, orchestrating the usage of these resources automatically, showing a significantly reduced data preprocessing time, thereby addressing the bottleneck in DNN training input pipelines. HyCache can achieve substantial performance improvements, with gains ranging from 1.11× to 5.3× over traditional preprocessing pipelines.

Abstract

KOALA is a benchmark suite aimed at performance-oriented research targeting the Unix and Linux shell. It combines a systematic collection of diverse shell programs collected from tasks found out in the wild, various real inputs to these programs facilitating small and large deployments, extensive analysis and characterization aiding their understanding, and additional infrastructure and tooling aimed at usability and reproducibility in systems research. The KOALA benchmarks perform a variety of common shell tasks; they combine all major language features of the POSIX shell; they use a variety of POSIX, GNU Coreutils, and third-party components; and they operate on inputs of varying size and composition—available on both permanent archival storage and scalable cloud storage. Applying KOALA to four systems aimed at accelerating shell programs offers a broader perspective on their trade-offs, generalizes their key results, and contributes to a better understanding of these systems.

1 Introduction

Shell programming is as prevalent as ever. It consistently ranks among the top ten programming languages, with a recent popularity increase that dwarfs those of established languages such as C and Python [32]. These trends are mirrored by recent academic activity on the shell aimed at accelerating shell programs through parallelization [50, 72, 85], distribution [66, 75], and other forms of scale-out [34, 52, 54, 74].

Unfortunately, research on the shell is often held back by the absence of an established benchmark suite—a systematic collection of representative, diverse, and well-studied programs released as a reusable artifact. Consider the difficulties that the Shark authors faced in evaluating the performance benefits of its program transformations [14]:

> *To our knowledge, there does not exist a set of shell language benchmarks. We present preliminary results on a handful of microbenchmarks that we wrote ourselves.*

The absence of such a suite decelerates research on the shell, as authors waste time searching for new benchmarks. It also eschews core scientific principles, such as replicability and reproducibility, and hinders fair comparison, as different systems are compared against different baselines. It creates additional and unnecessary work, as it forces researchers to hand-roll their own benchmarks. Finally, it limits the impact of otherwise sound and widely applicable techniques, due to the lack of supporting evidence.

The KOALA benchmarks: This paper presents KOALA, a benchmark suite aimed at performance-oriented research targeting the Unix and Linux shell. KOALA combines a collection of diverse, real-world, POSIX shell programs; realistic inputs of varying size; extensive analysis and characterization of these benchmarks; and additional infrastructure for packaging, automation, and reporting aimed at reusability and reproducibility. Its goal is to enable and support research on shell-script performance optimization, as well as broader systems research within the context of the shell—*e.g.*, CI/CD, analytics, automation, *etc.* (see §2–3).

The KOALA benchmarks are sourced from multiple time periods and perform a wide variety of tasks typically found in the shell—including log analysis, data processing, system administration, bioinformatics, software building, and continuous integration and deployment. They combine all major language features of the POSIX shell; use a variety of POSIX, GNU Coreutils, and third-party commands; and operate on inputs of varying size and composition—available via both permanent archival storage and scalable cloud storage for rapid access. Additional automation aims at setting up KOALA across a variety of environments, confirming input and output correctness, and reporting on several execution characteristics. This additional automation is structured to maximize usability, configurability, replicability, and reproducibility.

Extensive analysis of the KOALA suite reveals that it covers the full range of features of the POSIX shell; represents these features in proportions that align with real-world shell scripts; captures a wide range of script sizes, complexities, and styles—reflecting the shell's diverse use cases; and exhibits a variety

of runtime characteristics—from compute- to memory- to I/O-intensive and short-lived to long-running computations.

Contributions: In summary, this paper contributes:

- **A collection of benchmark programs:** A systematic and diverse collection of real-world programs representative of tasks commonly found in the context of the shell and combining a variety of computational domains, language features, and shell components.
- **Permanent and scalable storage of varying inputs:** A set of real-world inputs stressing these benchmarks as well as smaller inputs aimed at immediate results, both stored on highly available and scalable cloud storage backed up by permanently available archival storage.
- **Tooling and automation for reuse:** Additional infrastructure offering tooling, automation, and configurability for executing these benchmarks on a variety of environments, confirming input and output correctness, and reporting on their observed characteristics.
- **Characterization and implications:** Extensive analysis and characterization of these benchmark programs and their inputs over several dimensions, and application of the entire suite on four prior optimization systems and tools targeting the shell.

Availability: The full set of benchmarks, their inputs, and infrastructure for automation, containerization, and reporting are all available as an MIT-licensed open-source repository.

https://kben.sh

2 Example & Motivation

KOALA targets the systematic evaluation of shell-related systems and tools—for example: Shark [14], a system for accelerating shell script execution using syntactic transformations; GNU `parallel` [59], a command-line utility for parallelizing shell pipelines; *hS* [52], a system speculatively re-ordering the execution of shell programs; and PASH [50], a just-in-time shell-script parallelization system.

Available options and the pains of characterization: The authors of these systems currently have a limited set of options for characterizing their performance benefits.

Microbenchmarks—small, isolated code fragments—are necessary for zooming into key trade-offs, stressing particular behaviors, and highlighting system limits—and are often handwritten to meet these goals [14, 48, 50, 75, 85]. Such synthetic workloads differ significantly from ones seen in practice. Microbenchmarks don't admit generalizable conclusions or holistic evaluations of complex systems.

Standards tests [33, 78] offer a thorough evaluation of shell behavior—*e.g.*, that pipelines take precedence over redirections in their constituent commands. The POSIX test suite is one example [78]. They focus on behavioral equivalence against a specification, not judging the performance of real workloads. Lacking the size and features of workloads seen in practice, they offer little insight into how optimization systems affect real programs.

Open-source code repositories are ripe targets for longitudinal studies—*e.g.*, understanding a community's use of certain shell features [22, 71]. Leaving scraping and parsing challenges aside, these programs typically lack inputs, setup scripts, explicit dependency declaration, and portable constructs—often consisting of noisy, low-quality, or even incomplete programs. Ad hoc collections are also not well understood by the community or the authors themselves, who risk accidentally skewing results due to these challenges.

User or developer study corpora are primarily focused on understanding developer patterns [21, 69]. Due to time constraints and the need to control for confounding factors, user study corpora broadly optimize for program characteristics that do not necessarily support generalization to the diversity of size, shape, and complexity of real-world programs.

Requirements and goals: The aforementioned options available to the authors of systems such as Shark, `parallel`, *hS*, and PASH are ill-suited for performance characterization.

For a set of benchmarks to support research on the shell and related systems, it needs to meet the following criteria: (1) real-world programs performing real computations on real inputs; (2) diversity in workloads, domains, shell features, and commands used; (3) automated setup, analysis, validation, and reporting; (4) community-wide understanding through extensive analysis and characterization; (5) permanent and scalable availability, allowing anyone to download and use them. KOALA meets all of these criteria.

Using KOALA: The authors of these systems enjoy a variety of options for downloading and setting up KOALA:

```
curl -s up.kben.sh | sh &&
  ./koala/main.sh --min --bare
```

This option sets up platform-specific dependencies, then downloads or generates a minimal set of inputs (§3). It then executes the full suite using its default parameters, such as the default shell interpreter—except for (1) `--min`, which uses minimal inputs (just enough to exercise the entire suite, all output validators, and its reporting infrastructure), and (2) `--bare`, which executes in the current environment instead of a Docker container launched afresh for the execution of each benchmark. KOALA then confirms output correctness, guarding against failures and cross-run interference, and generates a report of the entire execution. On a fresh AWS environment, on a `t3.large` instance, such a minimal bare-metal setup, execution, and reporting completes in about 20 minutes.

Omitting the `--bare` launches KOALA in a Docker container, avoiding cross-run contamination and permanent effects on the host environment beyond result creation (*e.g.*,

dependency installation), and executes KOALA on full-sized inputs, revealing how a system under evaluation is affected by realistic workloads. KOALA aggregates the results over multiple runs (five by default), increasing statistical confidence, and reports the results of the execution. Using the default parameters in the same AWS environment and full inputs bumps execution to about 24 hours.

An example benchmark: To understand how Shark, `parallel`, *hS*, and PASH would benefit from KOALA, consider zooming into a single benchmark. Fig. 1 provides a real-world program (simplified for this discussion) iterating over `start` and `end` years to compute maximum, minimum, and average temperatures from a large dataset (*c.f.*, Tab. 1). The body of the loop consists of one pipeline per metric, each using `cat` to read the input data and `grep` to filter out sentinel values, then applying operation-specific computations. The `parallel` and Shark authors would need to apply manual rewrites for their systems; the rest of the authors could point `KOALA_SHELL` to their system (§4). They would then execute this benchmark on `small` (but, contrary to `min`, *real*) inputs:

```
./main.sh --small weather
```

Each of these systems accelerates **`weather`** differently. Shark eliminates `cat`s at the start of the pipelines by moving inputs to `cut`, and executes the three pipelines in parallel. GNU `parallel` can be applied to both the outer loop and the three pipelines; the user would need to choose which parts of the script to parallelize. *hS* runs commands speculatively, unrolling loop iterations to execute in parallel. And PASH parallelizes each pipeline stage. The four systems exploit different opportunities, optimizing different shell constructs and leaving different parts of each script unchanged.

On commodity infrastructure (§7), speedups average 2.3× for Shark, 2.7× for `parallel`, 1.64× for *hS*, and 1.08× for PASH. Most importantly, in contrast to similar numbers potentially collected over microbenchmarks, the composition and complexity of these benchmarks demonstrate the anticipated benefits—as well as potential limitations—of these systems in real-world settings.

3 KOALA Design Overview

Tab. 1 summarizes KOALA's full set of benchmarks and their characteristics. KOALA offers 126 programs, analogous to but diverse from the earlier **`weather`** example (§2), grouped into sets that share features, sources, or inputs. This section focuses on the first three sets of columns: Identification characteristics (Col. 1) list each benchmark set's name and (a subset of) the programs it contains; Descriptions (Cols. 2–4) summarize application domains ($\mathcal{D}$), the number of programs in the set (#.sh), and the total lines of code (LoC); and Inputs (Col. 5) summarize the size of each input. Later sections discuss other characteristics.

```
#!/bin/bash
d="./data/temperatures";
for y in $(seq $start $end); do
  cat $d/$y | cut -c 89-92 | grep -v 999 |
    sort -rn | head -n1 > max.$y
  cat $d/$y | cut -c 89-92 | grep -v 999 |
    sort -n | head -n1 > min.$y
  cat $d/$y | cut -c 89-92 | grep -v 999 |
    awk "{t += \$1; i++} END {print t/i}" > avg.$y
done
```

Fig. 1: Temperature analytics script. The script calculates temperature `max`, `min`, and `avg` across input files.

Inputs: Before discussing specific programs and inputs, it is worth outlining the general structure of inputs, its goals, and the infrastructure deployed to ensure scalable and permanent storage. These are guided by the experience of several users [9, 29, 72, 85] over multiple years.

KOALA comes with three input sizes for each of its benchmarks. Full inputs (`--full`) are either the original inputs programs were designed to operate on (*e.g.*, **`weather`**, **`covid`**) or, for older programs, realistic large-scale inputs on which these programs would operate today (*e.g.*, **`oneliners`**, **`unixfun`**). Small inputs (`--small`) are subsets of the full inputs useful for smaller-scale characterizations. They range between 0.1–30% of the original input (with some exceptions, noted below) and are carefully truncated to still be meaningful and semantically valid—for example, genomics pipelines still operate on valid genome sequences seen in practice, rather than arbitrary strings terminated at arbitrary points. Minimal inputs (`--min`) are synthetic data created to quickly confirm correct setup and facilitate further automated configuration. These inputs aim at near-immediate results and, depending on the characteristics of the system and environment, are either downloaded or generated. Downloading, detailed below, fetches inputs from cloud servers when high-bandwidth connectivity is available; generation operates repeatedly on benchmark-specific seeds, useful for environments with limited connectivity.

To meet key performance and availability requirements, inputs are hosted on infrastructure that combines two replication tiers—in addition to their source, *e.g.*, NOAA [2] or Wikipedia dumps [87]. The primary tier operates as KOALA's default configuration and stores all inputs on a replicated storage cluster managed by Brown University. The cluster is connected via 1Gb/s switched Ethernet network with access to Internet1 and Internet2 via Brown's fiber-optic backbone, aimed at high (but not permanent) availability—ensuring that inputs are available for concurrent users of the KOALA benchmarks. Additionally, infrastructure managed by Stevens Institute of Technology and UCLA hosts replicas of all inputs to offer additional availability.

The secondary tier ensures permanently available archival storage. Inputs (and the programs using them) are made available on Zenodo servers, split appropriately to comply with

Tab. 1: KOALA benchmark summary. The table summarizes all benchmarks in the KOALA suite. Col. 1: Identification characteristics, listing each benchmark set's name and (a subset of) the programs it contains. Cols. 2–4: Descriptions, summarizing application domains ($\mathcal{D}$), the number of programs in the set (#.sh), and the total lines of code (LoC). Col. 5: Inputs, summarizing the size each benchmark's inputs. Cols. 6–7: Static features, summarizing syntactic characteristics—*i.e.*, the number of shell constructs (#Cons) and the number of distinct commands (#Cmd). Cols. 8–11: Dynamic features, summarizing the execution characteristics—*i.e.*, time spent on shell evaluation (t_S), time spent on commands (t_C), memory consumption (Mem), and total input-output (I/O). Cols. 12–13: System, summarizing the number of system calls (#SC) and open file descriptors (#FD). Col. 14: Source, containing a reference to the source of the benchmark.

Benchmark/Script	Surface			Inputs		Syntax		Dynamic				System		Source

Zenodo's 50GB limit. While it does not offer the same bandwidth as the primary tier, it forms a transition path if input reconstruction becomes necessary—in the unlikely case that all university replicas become permanently unavailable.

Computational domains: KOALA draws from several domains, representing a broad range of computations—including both classic workloads typical of shell programs and modern workloads found pervasively today.

Data analytics programs (DA, 11 programs across three sets) extract, transform, and summarize quantitative datasets such as temperature records, public transit data, and genomic information. System administration programs (SA, seven programs across two sets) include typical system setup and maintenance tasks or system log manipulation. Continuous integration and deployment workflows (CI, 23 programs across two sets) include standalone shell programs or ones that automate software builds, program analysis, and software testing. Machine-learning programs (ML, 27 programs across three sets) include scripts either implementing learning tasks or gluing together third-party components in modeling pipelines. One-off automation scripts (AN, 18 programs across two sets) automate various operations such as file encryption, media conversion and one-off tasks such as spell-checking and content filtering. Other miscellaneous benchmarks (MI, 40 programs across two sets) consist of scripts that do not belong to any particular domain and perform a variety of tasks such as arbitrary text transformations, and web crawling.

Across and orthogonal to these domains, KOALA combines several diverse styles of computations and tasks (after the slash in column $\mathcal{D}$). For example, two data-extraction sets (DE) summarize information from large data sources; four text-processing sets (TP) manipulate text in multi-stage transformation pipelines; and three automation sets (AN) revolve around sequencing and managing task execution.

Benchmark programs: KOALA consists of fourteen sets of programs, presented in alphabetical order.

The **`analytics`** set contains four programs that analyze log files to extract key events [66, 74]. Operations include filtering and summarization. They operate on 78.9GB of line-oriented logs—including TCP traffic, Nginx access logs, and ZMap scan data—all collected from real network traces, as well as logs from a ray-tracing system [23, 26, 70, 82]. The small inputs (1.94GB) include truncated versions of the same log and packet-capture files.

The **`bio`** set consists of four programs for processing genomic and transcriptomic data. One performs population genomics analysis [17, 41], and the other three implement key stages of the TERA-Seq platform [38] for processing and aligning RNA sequences. Inputs include a BAM genome sequencing file [79] and auxiliary data such as gene annotations, totaling 114GB. The scripts exhibit fan-out/fan-in structures, offer opportunities for code de-duplication, implement work-queue-like parallelism, and operate on large files. The small inputs (24.3GB) omit much of the optional auxiliary data.

The **`ci-cd`** set contains 21 build-related programs, including scripts for building eight applications—such as Lua, Memcached, Redis, and SQLite [18]—as well as the `makeself` utility, which creates self-extracting archives [64]. These programs are typically used in continuous integration and deployment pipelines and feature multiple dependencies, but typically have small—if any—data inputs, thus using identical full and small inputs. The `makeself` script executes the program's test suite and requires no inputs.

The **`covid`** set contains five programs that calculate statistics about the public transit activity of a large city during the COVID-19 pandemic [81]. These programs come in two versions, amenable to different optimization strategies: a version that uses typical Unix staples such as `cut`, `sort`, and `unix`; and one written as a monolithic `awk` program. They operate on 5.08GB of CSV data about transit vehicle activity, and the small inputs cover a 3.34GB subset.

The **`file-mod`** set consists of five programs that automate file-level transformations, including compression, encryption, and format conversion. Two of the programs operate on 34.7GB of packet capture files collected from publicly available datasets [58], compressing and encrypting them using `openssl` [71]. The other three perform media format conversions [66, 74], reading from and writing to the filesystem in tight loops that process hundreds of image and audio files (4.4GB). The small version of the benchmark uses a reduced dataset with 4.35GB total of text and media files.

The **`inference`** set contains three programs that perform inference tasks on media files using large foundational models [31, 46, 90]. These include image captioning [43], music playlist generation via embedding interpolation [27], and sequential segmentation and classification of hieroglyphic images using SAM [46] and a custom classifier. These benchmarks process 9.3GB of image and audio data. The deep-learning models use total 2.4GB in size. The benchmarks perform model serving using external run-times [4, 61] interfacing with them via custom wrappers [73]. The small version operates on a subset (3.85GB) of the original images and music using the same back-end models.

The **`ml`** set consist of a typical of machine-learning workload comprising multiple stages written using the Scikit-Learn library [63]. It is a decomposition of a monolithic Python program into a series of scripts operating on 15GB of inputs and performing distinct steps for data ingestion, learning, inference, classification, and evaluation. The small version of this benchmark uses a subset of the same input (4.71GB).

The **`nlp`** set contains 23 scripts implementing natural language processing techniques, drawn from "Unix for Poets" NLP tutorial [45]. Most scripts consist of 1–2 lines, and can be combined in sequential operation. The input dataset contains over 115,000 ASCII books from Project Gutenberg [57], and and 3,000 books (1.42GB) for the small inputs.

The **`oneliners`** set contains 11 shell pipelines drawn from various sources across the academic and popular literature [6, 12, 13, 45, 55, 67, 76]. Some of these programs are classics in the Unix literature [12, 13, 67] and highlight the Unix philosophy, embodied by the shell; others are more recent [6, 55, 76], applying the same principles to mod-

ern workloads. They make extensive and, at times, complex use of streaming constructs, applying maps, filters, reductions, stream duplication, and window operators. Their inputs are shared between script subsets and combine books from Project Gutenberg, commands available in `PATH`, and packages from the `apt` repositories (13.5GB full, 202MB small).

The **`pkg`** set consists of two programs: one automates the installation of packages from the Arch User Repository (AUR) [1], and the other applies a static analysis tool to extract permissions from the node package manager (npm) repository [3, 86]. Its input consists of two lists—195 AUR package names and 1,768 npm package names. The benchmark downloads, builds, and installs the AUR packages in a loop, and analyzes the npm packages to infer their permissions. The small version of this benchmark includes the first 10 and 100 packages from each list.

The **`repl`** set contains two standalone programs. The first performs auditing for security vulnerabilities and misconfigurations. The second replays a development workflow on a large Git repository. Both scripts include non-trivial filesystem access patterns, with the second being metadata heavy. Neither script requires external input at runtime (N/A in Tab. 1).

The **`unixfun`** set contains 36 programs solving the Bell Labs 50-year Unix anniversary challenge [62]. They mimic classic Unix text-processing computations, often short ones that eliminate the vast majority of the input using a `head` or `tail`. They operate on inflated inputs (59.1GB) created by duplicating the original inputs (599MB), while maintaining the expected structure.

The **`weather`** set consists of two program phases calculating statistics on historical temperature data from a Hadoop book [80], with the second one performing some additional analysis and recreating Edward Tuft's famous weather diagram [24]. Some of these phases correspond to MapReduce and Spark computations exemplifying large-scale data processing—not part of KOALA, but useful for comparisons of shell-acceleration systems targeting similar or comparable scalability goals. These phases operate on large inputs (146GB) collected from NOAA [2] spanning multiple years. The small version of these inputs corresponds to a subset of temperatures from the year 2015 (893MB).

The **`web-search`** set contains several programs from a course on distributed systems, implementing web crawl, index, and query. It is implemented as a POSIX-shell streaming program, using complex streaming operators—including duplication, shifting, windows, and dataflow cycles. The input dataset consists of a Wikipedia snapshot (8.61GB), or a subset for the small version (833MB).

Principal component analysis: Before diving into various static and dynamic characteristics of the KOALA suite, it is worth getting a sense of its high-level diversity characteristics.

Fig. 2 shows this diversity using Principal Component Analysis (PCA) [5] on two distinct representations of each benchmark detailed below. PCA maps high-dimensional data to a lower-dimensional space that preserves structural differences for easier comparison and visualization. It computes weights for each of the n original dimensions to create k (where $k < n$) new and uncorrelated composite dimensions that are each linear combinations of the original ones.

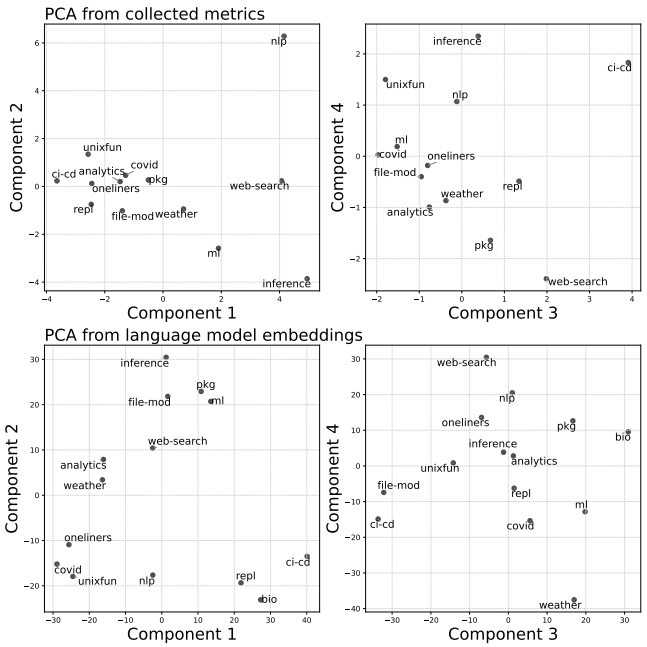

Fig. 2: Principal component analysis results. Top: PCA plot resulting from the static and dynamic analysis of each benchmark. Bottom: PCA plot resulting from embedding calculation of KOALA source code using a pre-trained model [60].

The top row of Fig. 2 visualizes benchmarks projected on this reduced space based on their static and dynamic characteristics (§5–6). The spread of the benchmarks across the principle components suggests that the suite covers a broad and non-overlapping range of syntactic and behavioral profiles. The bottom row of Fig. 2 visualizes each benchmark on the space based on dense vector representations that capture high-level program structure and logic. These embeddings, generated using OpenAI's `text-embedding-3-large` model [60], capture information targeting diversity at the semantic and syntactic level [7, 83]. Well-distributed across the projected space, the results also suggest substantial diversity in both syntax and semantics.

4 Infrastructure and Configuration

Each KOALA benchmark set adheres to a specification that defines installation dependencies, input configuration, benchmark execution, and validation of the final results. This specification, shown in Fig. 3, includes five infrastructure scripts: (1) `install.sh` sets up dependencies required by the benchmark; (2) `fetch.sh` downloads (or generates, §3) and, if nec-

```
sample-benchmark

├── install.sh   # Dependency installation
├── fetch.sh     # Input data download/preparation
├── execute.sh   # Script execution
├── validate.sh  # Hash generation & verification
└── clean.sh     # Input and output file cleanup
```

Fig. 3: Benchmark structure. Each benchmark includes five support scripts (*e.g.*, `install`, `clean`) and a `scripts/` directory containing the source code of each benchmark. A top-level `main` driver executes all support scripts for one or all benchmarks.

essary, pre-processes inputs, accepting an argument that specifies their size; (3) `execute.sh` executes benchmark programs, collecting basic information such as execution time and resources; and (4) `validate.sh` confirms the correctness of the benchmark's output by hashing the output of each script and comparing it to a known-good hash. Finally, (5) `clean.sh` removes inputs, outputs, and temporary files created during the benchmark's execution. These scripts avoid redundant work—*e.g.*, dependency installation or input generation are skipped if possible, except if forced (`-f`).

KOALA also includes a top-level driver (`main.sh`) that executes the five scripts in sequence for any benchmark. The driver checks several configuration parameters, accepted as flags or environment variables, which it then passes to the rest of the scripts. For example, a `KOALA_SHELL` parameter configures the shell interpreter executing the suite—*e.g.*, `bash`, `zsh`, or a path to an executable, and defaulting to `sh`.

KOALA's structure aims to facilitate quick collection of preliminary results, not exhaustive coverage of all possible needs. To accommodate a wide range of systems, it is kept minimal—inviting users to modify it to fit their needs.

Containerization: KOALA provides optional infrastructure for running benchmarks in an isolated environment. It includes a Dockerfile that builds a Debian-based container, installs essential dependencies such as `git` and `sudo`, and fetches the suite. A volume is shared with the host system, simplifying access to inputs and outputs.

It also provides support for dynamically generating container images tailored to each benchmark. These images are self-contained and ephemeral: their Dockerfile contains a `CMD` command executing all infrastructure scripts via `main.sh`.

To avoid problems with permission changes or system-wide modifications, KOALA does not require elevated privileges (except for `fetch.sh` which installs software dependencies) and avoids privileged commands such as `sudo` and `setuid`.

Integration effort: The effort required to add a new benchmark to KOALA depends on its complexity, input size, and correctness constraints. It typically involves five steps: (1) identifying and encoding dependencies in `install.sh`; (2) preparing input datasets in multiple sizes—full, small, and min—via `fetch.sh`; (3) including scripts for automated execution in `execute.sh`; (4) defining output validation logic in `validate.sh`; and (5) specifying cleanup steps in `clean.sh`.

Integrating the current set of benchmarks ranged between 10–80 person-hours per benchmark (Tab. on the right). Small and self-contained benchmarks such as **`oneliners`**, **`unixfun`**, and **`nlp`** each took about 10–12 hours; more complex or data-heavy benchmarks such as **`file-mod`**, **`bio`**, and **`ci-cd`**, and took about 60–80 hours due to their size, dependencies, and nuanced output correctness. Most of our time constructing this release of KOALA was spent in building new logic and adapting datasets, with a significant portion devoted to testing and confirming correctness under various environments and configurations.

Benchmark	$\sim T$(h)
`analytics`	40
`bio`	60
`ci-cd`	75
`covid`	65
`file-mod`	60
`ml`	30

`nlp`	10
`oneliners`	10
`pkg`	30
`repl`	25
`unixfun`	10
`weather`	30
`web-search`	40
Total	520

5 Syntactic Characterization and Analysis

Contrary to single-language environments, the shell often combines components in multiple languages. KOALA thus distinguishes between the characteristics of (and resources spent on, see §6) the shell portion of each benchmark, versus those of components called into by the shell and which often implement the core of a computation (Tab. 1, cols. 6–7).

Methodology: We use `libdash` [53] to parse and analyze both portions using SMOOSH's abstract syntax definition for the POSIX shell [33]: for the shell portion, we count the total occurrences of every AST node; for the command portion, we analyze only AST nodes counting commands, built-ins, and functions—yielding conservative results that exclude dynamic constructs (*e.g.*, `$CMD arg`) but avoid conflating static structure with repeated runtime executions.

Language features: Fig. 4 summarizes the occurrences of each construct across KOALA. Each cell shows the number of times a syntactic construct (vertical axis) occurs in a benchmark (horizontal axis). AST nodes that overlap with more specific nodes or that do not correspond to linguistic features (*e.g.*, escaped characters) are excluded. Overall, KOALA employs all the syntactic constructs of the POSIX shell, in varied combinations that reflect its various styles of computation.

KOALA covers several key shell characteristics worth mentioning. Most sets employ pipelines, shell constructs of the form `a | b` that pass the output of one command (`a`) as input to the next (`b`). Pipelines are an important shell feature, optimized by several data-parallel systems. Two sets use operators `&` and `wait` for explicit parallelism—a feature relevant to performance-oriented shell systems. Two sets use sub-shells, *e.g.*, `(echo hi)`, and several sets use control

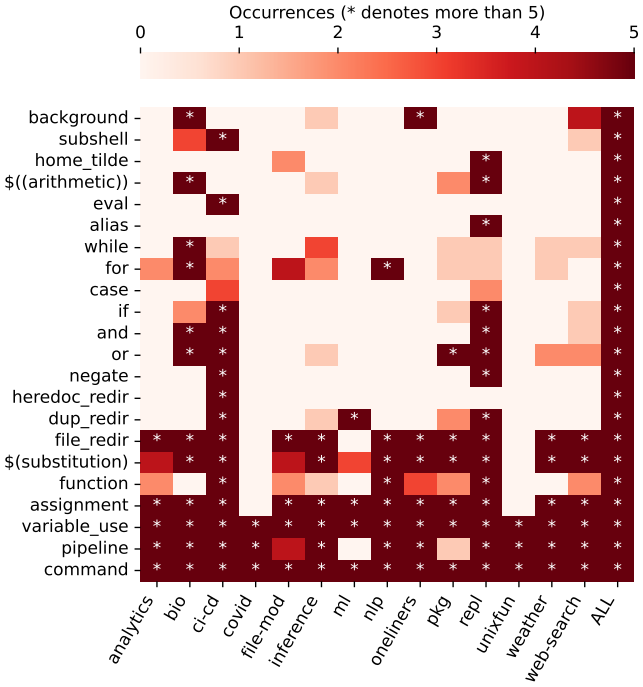

Fig. 4: Syntactic characteristics. Cells show the frequency of the syntactic construct (y-axis) in a benchmark (x-axis), up to five occurrences to maintain clarity of absences (zero counts). Stars denote more than five occurrences.

constructs such as loops and conditionals. Several sets use function definitions, and nearly all use variables, assignments, and stream or file redirections; other kinds of redirections occur less frequently. Many sets use command substitution, *e.g.*, `echo hi $(whoami)`.

Fig. 4 also highlights a key KOALA characteristic: no two benchmarks exhibit the same distribution of syntactic constructs. KOALA represents well the shell's most interesting features—*e.g.*, external command invocations, pipelines, the background operator, subshells, expansion, and redirection. In combination, these features are essential in making the shell the uniquely powerful and complex platform that it is. Different styles of scripts employ these features in different combinations and proportions—and KOALA aims to capture this variation. The proportion of these features align with shell usage studies [22], indicating that the distribution of KOALA's shell features corresponds to current trends and is representative of the programs found in the real world.

Component features: Fig. 5 shows the frequency of all KOALA commands occurring at least 30 times, excluding benchmark-specific functions and binaries. KOALA contains many of the most common commands found in the wild: `echo` tops the list with 441 occurrences; `cat`, `grep`, `sort`, and `tr` count about half of that; other commands exhibit lower frequencies. These results broadly match results from studies of commands in the wild [22], except for path-manipulation commands as most KOALA paths are static.

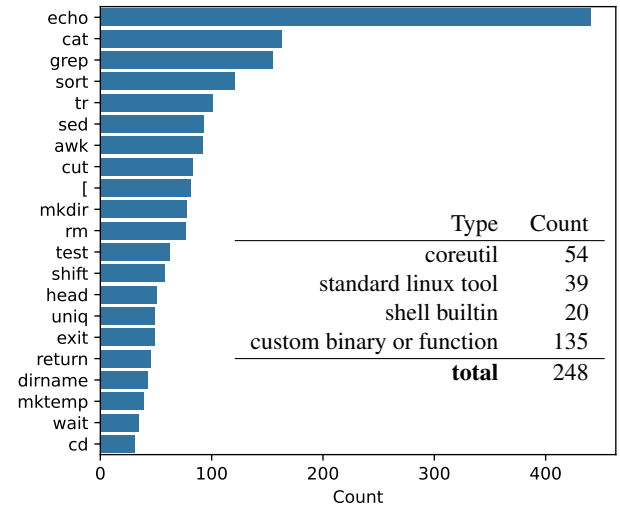

Fig. 5: Command occurrences. The chart shows the frequency of all KOALA commands occurring at least 30 times. The table categorizes the unique commands counted across the entire suite.

The table also groups KOALA's distinct commands into four classes. Most common are GNU Coreutils (*e.g.*, `echo` and `cat`), shell built-ins (*e.g.*, `cd` and `return`), and standard linux tools (*e.g.*, `grep`, `sed`, and `awk`). While the first three classes make up KOALA's vast majority of commands, in terms of frequency, custom binaries and functions account for 134 commands, or 54% of the unique command set.

6 Dynamic Characterization and Analysis

Beyond its syntactic diversity, KOALA also exhibits diverse dynamic characteristics. Exploring this diversity involves executing benchmarks to extract dynamic features such as CPU time, memory consumption, IO characteristics, and interaction with the broader environment (Tab. 1's cols. 8–13).

Methodology: To extract these features, we collect several metrics while executing benchmarks on a machine with 32GB RAM, an 8-core 3.80GHz Ryzen 7 9700X CPU utilizing hyper-threading, and a 1TB NVMe SSD. The shell interpreter is set as `bash --posix`. We measure CPU time and IO by probing `/proc/<pid>/{stat,io}` after the target process exits; and wall-clock time and memory use by calling Python's `time.perf_counter` and `psutil` at 0.01-second intervals. We aggregate results by set by summing timing and IO statistics for each program in that set. We take the maximum high-water-mark memory usage to compute a single set of results per benchmark.

Overview: Fig. 6 presents results both overall and with respect to input sizes. The plots form two coarse groups (x-axis is benchmarks, always): (1) the top two plots (left and right) show total execution time—left is the ratio of CPU time

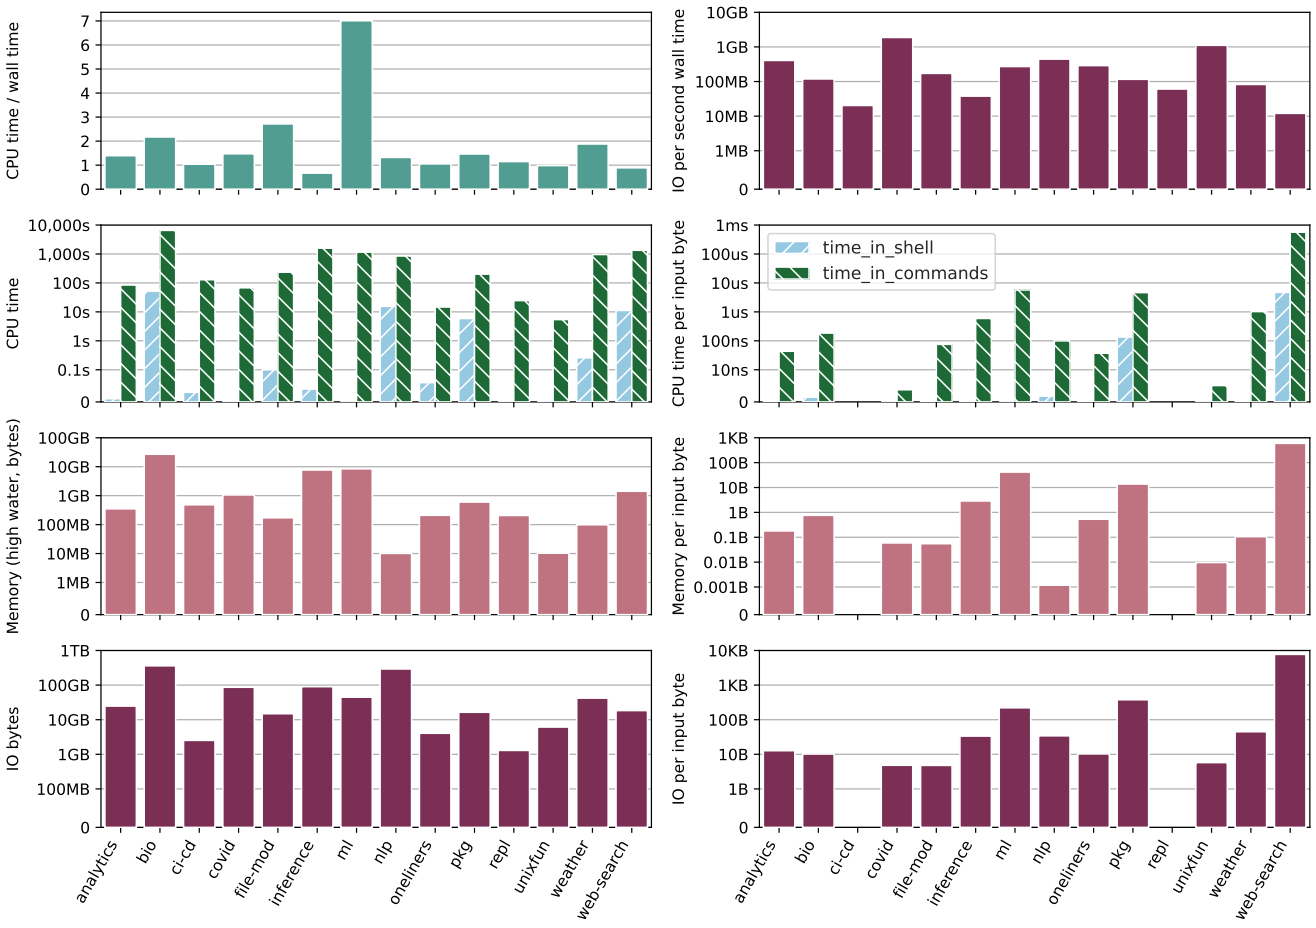

Fig. 6: Dynamic characteristics. The top two plots contextualize the rest: (left) ratio of CPU time to wall-clock time; (right) ratio of IO time to wall-clock time. The bottom three plots (rows 2, 3, 4) show CPU time, Memory, and IO: (left) absolute; (right) normalized over benchmark input. All y-axes except top left are symmetric log scale: values between 0 and the first tick are linearly scaled, and the next are logarithmic.

to wall-clock time, right is the total IO per second of wall-clock; (2) the next six plots (rows 2, 3, 4), show CPU time, high-water-mark memory, and IO—left is absolute, right is per input byte.

Absolute characteristics: As these characteristics vary by orders of magnitude, these plots use a symmetric log scale: values between zero and the first tick are linearly scaled, while the rest are logarithmic. The CPU-time plot (Fig. 6, row 2, left) shows that the benchmark runtime varies from seconds (*e.g.*, **`unixfun`**) to hours (*e.g.*, **`bio`**). CPU time is split between time spent in the shell versus commands: here, too, KOALA demonstrates significant diversity—ranging from a mix of shell execution and commands (*e.g.*, **`nlp`**) to command-dominated workloads (*e.g.*, **`bio`** and **`inference`**).

Similarly, the memory plot (Fig. 6, row 3, left) shows the diversity of memory-intensiveness, varying between 668KB (*e.g.*, **`unixfun`**) and around 10GB (*e.g.*, **`bio`**, **`inference`**, and **`ml`**). Likewise, the IO plot (row 4, left) shows that KOALA exhibits varying degrees of IO-heaviness, ranging from just 75.9MB of IO (*e.g.*, **`ci-cd`**) to 336GB (*e.g.*, **`bio`**).

Tab. 1's last few rows (pg. 4) offer additional context: CPU time, memory consumption, and IO range respectively between 2.1–6544.8s (shown separately for the shell and commands, average: 934.1s), 6.1MB–25.1GB (average: 3.14GB), and 85.7MB–336GB (average: 66.6GB).

Normalized characteristics: Normalized plots (rows 2–4, right) offer a sense of these characteristics normalized by each benchmark's input size, important due to their correlation with input size, which varies widely (0–146GB). This normalization is noticeable with **`bio`** and **`covid`**: these benchmarks have substantial absolute CPU times (on left), but their normalized CPU times (on right) are moderate—reflecting the fact that they are long-running mainly due to the volume of data they process, not the intensity of their computations. On the other hand, **`pkg`** is computationally intense, despite its middling absolute execution time. These characteristics do

not apply to benchmarks with no inputs (*e.g.*, **`ci-cd`** and **`repl`**), which have no bars in the normalized plots.

Overall, across the three dimensions (CPU, row 2; memory, row 3; and IO, row 4), KOALA enjoys significant diversity—multiple metrics vary by several orders of magnitude.

7 Applying KOALA to Optimization Systems

This section summarizes the process and results of applying four optimization systems (§2) on the KOALA benchmarks: Shark [14], GNU `parallel` [59], *hS* [52], and PASH [85] achieve performance gains on different subsets of KOALA.

Hardware & software setup: All experiments in this section were executed on an AWS `c6i.4xlarge` instance with 32GB of RAM and a 16-core 3.5 GHz CPU running Ubuntu 24.04.1 and `bash` v5.2.21 with `-posix` enabled.

Adoption effort: The four systems require different effort to use KOALA (see Appendix II), depending on their needs (*e.g.*, automation, inputs), characteristics, and goals (§2). GNU `parallel` required modifying benchmarks to export parallelizable pipelines and **`for`**-loops as functions passed to `parallel`. Shark required similar transformations guided by its optimizations. PASH and *hS*, both operating as drop-in shell replacements, could simply set `KOALA_SHELL`.

7.1 Shark

To understand whether KOALA aids the characterization of Shark [14], we manually apply its transformations as described in the Shark paper across several KOALA programs.

Methodology: The Shark paper [14] describes several potential syntactic transformations, which we apply manually across all KOALA benchmarks. We then execute the original and optimized versions to characterize the performance of the modified benchmarks.

Results: Shark achieves significant performance gains across KOALA, ranging between 1.01–13.43×, depending on benchmark characteristics. Benchmarks that involve trivially parallelizable loop iterations see major speedups—*e.g.*, Shark improves the **`nlp`** and **`weather`** benchmarks by 6.46× and 13.43×, respectively. Scripts with sequential operations, such as those found in **`ci-cd`**, exhibit less pronounced improvements—at times only marginal gains of 1.16×.

Shark accelerates most benchmarks, though benchmarks with highly interdependent operations that already use pipelines see more limited gains. For example, **`covid`**, **`oneliners`**, **`bio`**, and **`unixfun`** offer less opportunities for Shark-style optimizations, which result in speedups between 1.01–1.06×. The **`web-index`** benchmark sees the least improvement (1.01×) as it already runs the three n-gram calculations in parallel, making Shark obsolete. Shark's optimizations centered around command invocation, do not result in significant performance benefits, speeding up scripts where only such optimization opportunities were present (*e.g.*, web-search) by 1.01× on average. In contrast, optimizations that eliminate temporary files used for intermediate storage can offer more substantial speedups, but they also introduce significant complexity, as pipes require more careful coordination between producers and consumers.

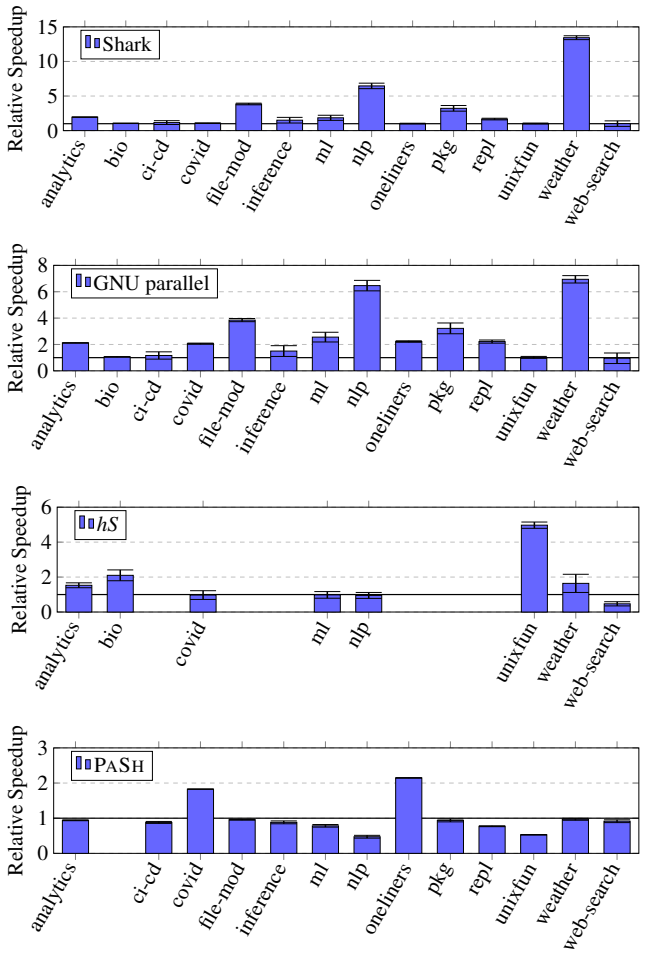

Fig. 7: Shark, GNU `parallel`, *hS*, and PASH speedups. Relative average speedup on the KOALA benchmarks. Baseline is the original runtime in a single-threaded `bash` shell with the `--posix` flag enabled.

Takeaway: KOALA confirms that Shark's optimizations are effective in scripts that involve operations on multiple inputs and independent commands, and less effective for I/O-heavy scripts or scripts that are not easily parallelizable. Its parallelization and pipeline optimizations offer significant speedups, up to 13.43×.

7.2 GNU `parallel`

To understand whether KOALA aids the characterization of GNU `parallel` [59], we apply it on several KOALA programs focusing on natural candidates for such parallel execution.

Methodology: We first identify parallelizable regions within each KOALA program and rewrite them to invoke `parallel`. We aimed for a reasonable use of `parallel`, modifying only parallelizable pipelines that each take under an hour to identify and rewrite—typically ones with (1) independently processed input files, and (2) efficient segment-based processing that requires minimal or no synchronization and aggregation. The latter often takes advantage of GNU `parallel`'s `--pipe` to parallelize input stream processing.

Results: GNU `parallel` achieves substantial speedups in benchmarks that involve I/O-bound operations or are trivially parallelizable. For instance, **`file-mod`** involves converting multiple media files concurrently, resulting in GNU `parallel` speeding it up by 3.84× and fully utilizing all available CPU cores. Similarly, **`nlp`** processes multiple data files independently, resulting in a speedup of 6.46×. GNU `parallel` speedups are less pronounced for scripts that do not have these features, such as those in **`ci-cd`** and **`repl`** that result in 1.16× and 0.95× respectively. These additionally either already use parallelism internally in their command invocations, compiling multiple files or include commands that do not benefit from `parallel`'s parallelization model, such as `git` or `find`.

A few cases do not yield speedup. For example, the **`unixfun`** benchmark involves pipeline stages dependent on the output of previous stages, limiting `parallel`'s approach: the interdependent nature of these stages prevented GNU `parallel` from fully exploiting parallelism, resulting an average speedup of 1.02×.

Takeaway: KOALA confirms that GNU `parallel` can accelerate I/O-bound tasks and loops with no interdependencies—*e.g.*, **`file-mod`**—achieving average speedups of 2.6×. Limited acceleration comes from scripts with sequential operations or ones that require sophisticated splitting and aggregation (*e.g.*, **`unixfun`** and **`web-search`**).

7.3 hS

To assess whether KOALA aids the characterization of *hS* [52], we apply it on KOALA focusing on programs likely to benefit from out-of-order execution.

Methodology: As *hS* is currently under development, we use an early-stage *hS* prototype shared by its authors, configured via the `KOALA_SHELL` variable.

Not all benchmarks are executable by the current version of *hS*. For the following benchmark sets, *hS* succeeded on only a subset of the scripts: **`analytics`**, **`bio`**, **`ml`**, **`nlp`**, **`unixfun`**, **`weather`**, and **`web-search`**. The following benchmark sets as a whole either fail or produce incorrect results with *hS*, and are thus omitted entirely: **`ci-cd`**, **`file-mod`**, **`llm`**, **`nlp`**, **`oneliners`**, **`pkg`**, and **`repl`**. In addition, *hS* was unable to run the `ray-tracing` script in **`analytics`**.

Results: *hS* achieves significant speedups on scripts that include syntactic regions that have no dependencies between them. Speedups range between 1.5–4.97×, with **`analytics`** and **`unixfun`** at the two ends of this range. Other benchmarks resulting in significant speedups include **`weather`** and **`bio`**.

Scripts that involve dependencies between stages do not benefit from *hS*. Such slowdowns range from 0.97× in **`covid`** to 0.47× in **`websearch`**, averaging 0.72× across all benchmarks. They can be attributed to constant costs stemming from *hS*'s speculative execution, related to the environment isolation and tracing, which allows *hS* to roll back effects in cases of misprediction.

Takeaway: KOALA reveals that *hS* can provide benefits that are significant, especially when computations feature independent stages. Typical computations, however, offer a mix of out-of-order optimization opportunities, at times masked by overheads in the *hS* prototype.

7.4 PaSh

We apply PASH on KOALA to understand whether it can characterize PASH's ability to accelerate shell programs.

Methodology: We use the latest version of PASH (commit 0d0a563) and set `KOALA_SHELL` to `./pa.sh --width 4`, *i.e.*, configuring the parallelization degree to 4×. We do not replace script fragments via `alias` and **`function`** constructs that can be annotated with additional parallelizability information; this would allow PASH to extract additional speedup but result in significantly more work. PASH fails when executing the **`bio`** benchmark.

Results: PASH's command-aware parallelization strategy achieves significant speedups in scripts with multi-stage pipelines or **`for`**-loops with no data dependencies across iterations. For example, it achieves speedups of 2.14× and 1.82× on **`oneliners`** and **`covid`** respectively.

Naturally, benchmarks or benchmark fragments for which PASH had no annotations, and thus does not parallelize, see no speedups—*e.g.*, **`pkg`**, **`bio`**, and **`file-mod`**. Additionally, PASH does not speed up scripts that include no syntactic constructs it can parallelize—*e.g.*, **`repl`** and **`ci-cd`** benchmarks, which do not include pipelines or parallelizable **`for`**-loops.

Takeaway: KOALA reveals that PASH can deliver substantial speedups for scripts that fall within its parallelization domain. However, its effectiveness depends on the availability of command annotations and the amenability of programs to the constructs PASH can operate on.

8 Related Work

Benchmark suites: Progress in research depends on apples-to-apples comparisons—and in computer science, that often

means open and reusable benchmark suites. Widely cited benchmark suites in memory-managed environments [15], database transactions [65], parallel processing [19], other areas [20, 36, 42] offer a good examples of their widespread applicability and use. Similar to these suites, KOALA comes with additional support and is expected to release improvements every few years; different from them, it targets performance-oriented systems for the shell—an area that has not yet enjoyed the existence of a systematic benchmark suite.

The DaCapo [15] and Gabriel [28] benchmarks offer particularly good parallels, as they focus on programming environments that did not have a benchmark suite before their release—like these benchmarks, KOALA fills a gap.

Shell studies and datasets: Recent studies collect shell scripts or fragments of scripts—typically in Bash—to analyze their source, understand their properties, and extract key insights. Examples of such studies include the use of Bash in the wild [22], the characteristics of build scripts in Linux distributions [40], and the use of aliases and shell customization in the wild [71], cybersecurity training [84], and interactive coding [89]. These studies do not aim at (creating collections for) evaluating performance optimizations. In contrast, KOALA aims at help characterizing systems and tools that optimize shell programs. KOALA offers curated end-to-end programs with known inputs, dependencies, and behaviors that stress both the shell and the underlying commands.

Shell test and correctness suites: A few test suites focus on evaluating the correctness of shell implementations and their conformance to certain standards. The POSIX test suite [78] is a key resource for validating compliance of a shell implementation with the POSIX standard. The *Smoosh* test suite [33] refines and complements the POSIX test suite. The Modernish shell library/polyfill has a sophisticated diagnostic routine that amounts to shell tests [56]. There are also a variety of testing frameworks designed for automated testing in and of shell scripts [11, 44, 49, 77]. All of these suites focus on testing functionality rather than characterizing performance, and are thus distinct from and complementary to KOALA.

Shell microbenchmarks: Several benchmark suites target the evaluation of specific shell-language constructs via microbenchmarks. `ShellBench` [48] provides a collection of small scripts (ranging from 8–95 lines of code) designed to stress individual shell features—*e.g.*, variable substitution, expansion, and subshell creation. Similarly, `zsh-bench` [68], the Oils benchmarks [8], and UnixBench [47] focus on isolated performance characteristics—*e.g.*, interactive shell behavior or command invocation times. In contrast, KOALA offers larger, more diverse, whole-program benchmarks (95 programs, 17–2428 lines each) that perform end-to-end computations, operate over large datasets, and involve substantial work outside the shell interpreter itself.

Performance properties and characterization: Prior research on benchmark sets often discusses language-specific properties about the programs involved—for example, the impact of garbage collection [15, 28, 51] or the structural features in object-oriented benchmark suites [15, 37, 51]. While important in other domains, these characteristics have no direct equivalent in shell programs; KOALA instead focuses on the shell as glue, carefully distinguishing between the time spent in the shell interpreter and in third-party commands.

Earlier work also studies the behavior of programs in simulation or on hardware [25, 30, 35]. KOALA's characterization focuses on properties that are independent of any particular hardware or operating system implementation. KOALA will make it easy to use shell programs as workloads in the evaluation of general-purpose computational substrates.

Evaluations of shell programs: A variety of systems from several different authors attempt to operate on, optimize, or accelerate shell programs—*e.g.*, achieving elision [14], parallelization [85], fusion [9], synthesis [72], distribution [66], mobile [88], serverless [54], and syscall refinement [29]. These further demonstrate the acute need for a standardized, usable, and replicable benchmark suite for the shell.

9 Discussion and Conclusion

Benchmark programs are crucial for evaluating ideas, comparing and contrasting approaches, and fueling academic and industrial research. They are especially needed in systems research, where many of the key theses revolve around performance-related arguments and their quantitative evaluation. This need is particularly acute in the context of the shell, where no benchmark suite currently exists.

KOALA is a benchmark suite aimed at the characterization of performance-oriented shell research. It combines a systematic collection of diverse shell programs collected from tasks found in the wild, various real inputs to these programs facilitating small and large deployments, extensive analysis and characterization aiding their understanding, and additional infrastructure and tooling aimed at usability and reproducibility in systems research. Static and dynamic characterization confirms that the KOALA programs perform a variety of tasks commonly performed in the shell; combine all major language features of the POSIX shell; use a variety of POSIX, GNU Coreutils, and third-party components; and operate on inputs of varying size and composition.

For the latest source code, software dependencies, and multi-tiered input data for the KOALA benchmark suite, please refer to the project's online repository.

Appendix I Benchmark dependencies

The dependencies of each KOALA benchmark can be found in the project's repository. In general, KOALA benchmarks depend on three elements: (1) the source code of each benchmark; (2) input datasets for each benchmark (e.g., Wikipedia mirror for `web-search`); (3) additional third-party components (e.g., Arch Linux packages for `pkg`). The infrastructure offers highly available replicas of all three elements—including over 600 Debian packages, 50 PyPI packages, 110 AUR packages, 1964 npm packages, and their transitive dependencies totalling more than 400 GB of data—to achieve permanent availability and aid reproducibility. This replication is achieved at two levels, namely (1) across all three universities involved in this research, each featuring additional replication and fault-tolerance support, and (2) scalable cloud storage further backed up by permanently-available archival storage on Zenodo.

Appendix II Adoption effort

Evaluating systems with KOALA requires varying levels of effort depending on their design goals, degree of automation, and artifact maturity. For the Shark and `parallel` systems, this involved manual changes to the benchmark scripts. For Shark, modifications typically included identifying parallelizable regions in loops and applying background execution with `&` and `wait`, along with the removal of unnecessary `cat` commands and the use of tee to preserve I/O semantics (*e.g.*, in **`bio`**, **`analytics`**, and **`file-mod`**). In some benchmarks, such as **`ci-cd`**, **`repl`**, and **`unixfun`**, changes spanned tens

of lines due to multiple independent compilation or execution steps. For `parallel`, adaptations involved wrapping loops or commands using the `parallel` utility. This process required changes in the order of 1-3 LoC in benchmarks with stateless pipelines or simple loops (*e.g.*, **`pkg`** and **`nlp`**), but was more intrusive in cases like **`covid`**, **`analytics`**, and **`repl`**, where it required identifying parallelizable regions, exporting computations as shell functions, and occasionally introducing temporary files to manage intermediate data. These modifications reflect the intended use and capabilities of each system rather than any requirement imposed by KOALA, are documented in the public repositories kbensh/koala-shark and kbensh/koala-parallel. In contrast, both *hS* and PASH were applied without any manual changes to the benchmarks.

Appendix III Artifact

The structure of this section mirrors the artifact evaluation process. All information can be found in the frozen `atc25-ae` branch of KOALA's GitHub repository.

- Artifact available: All links pointing to the benchmark source code and accompanying data hosted on two-tiered storage.
- Artifact functional: Usage documentation for the KOALA harness and how to exercise individual benchmarks.
- Results reproducible: Instructions for reproducing static (§5), dynamic (§6) and diversity (fig. 2) characterization results for all benchmarks.

Scope: The available artifact is a set of benchmark programs, all their inputs, the infrastructure for running them, and tooling for their static and dynamic characterization. Specifically, it includes:

- A diverse collection of real-world shell scripts spanning multiple domains and tasks.
- A scalable and durable infrastructure for managing benchmark inputs at different sizes.
- Reusable infrastructure including automation scripts for dependency setup, execution, validation, and correctness checking.
- A suite of static and dynamic analysis tools to characterize the benchmarks.

This artifact can be used by systems researchers and performance engineers to evaluate prototype systems and conduct reproducible experiments over a common shell benchmark suite.

Contents: The artifact includes:

- **Benchmark programs**: 126 scripts grouped in 14 sets.
- **Input datasets**: Three input sizes (`min`, `small`, and `full`), hosted on both archival and scalable storage.
- **Execution infrastructure**: Scripts to automatically download inputs, set up containers, install dependencies, and run benchmarks.
- **Analysis infrastructure**: Scripts for static/dynamic characterization, correctness validation, and principal-component analysis.
- **Documentation**: A top-level `README` and benchmark-specific subdirectories, describing each benchmark's purpose, usage, and input/output structure.

Hosting: The artifact is hosted at:

- GitHub: kbensh/koala Branch: `main` (latest version), `atc25-ae` (frozen for artifact evaluation)
- Permanent archival storage (Zenodo).
- Scalable, fast-access storage.

See Appendix I in the `README` for the full table of input links, or visit kben.sh/data for an up-to-date index of all inputs and benchmark dependencies across all storage tiers.

Installation: KOALA is available via several means, including:

- Git: `git clone git@github.com:kbensh/koala.git`
- Docker: `docker pull ghcr.io/kbensh/koala`
- Shell: `curl -s up.kben.sh | sh`

Installation instructions can also found at the top-level README.

KVCache Cache in the Wild: Characterizing and Optimizing KVCache Cache at a Large Cloud Provider

Jiahao Wang[†1], Jinbo Han[†1], Xingda Wei[✉1], Sijie Shen[2], Dingyan Zhang[1], Chenguang Fang[2], Rong Chen[1], Wenyuan Yu[2], and Haibo Chen[1]

Abstract

Serving large language models (LLMs) is important for cloud providers, and caching intermediate results (KV$) after processing each request substantially improves serving throughput and latency. However, there is limited understanding of how LLM serving benefits from KV$ caching, where system design decisions like cache eviction policies are highly workload-dependent.

In this paper, we present the first systematic characterization of the KV$ workload patterns from one of the leading LLM service providers. We draw observations that were not covered by previous studies focusing on synthetic workloads, including: KV$ reuses are skewed across requests, where reuses between single-turn requests are equally important as multi-turn requests; the reuse time and probability are diverse considering all requests, but for a specific request category, the pattern tends to be predictable; and the overall cache size required for an ideal cache hit ratio is moderate. Based on the characterization, we further propose a workload-aware cache eviction policy that improves the serving performance under real-world traces, especially with limited cache capacity.

1 Introduction

Large language models (LLMs) have become an important cloud service thanks to their emerging capabilities in various tasks. Both customer-facing services (to-C) like conversation-based chatbots [43] and business services (to-B) through LLM API calls have been widely deployed on the cloud [42, 21, 4]. As online services, serving LLMs with low latency and high throughput is critical, but achieving this in a cost-efficient way is challenging due to the huge computational requirements to serve each LLM request.

Caching intermediate results of served requests (KV$) has become a common methodology to improve serving performance [45, 5]: when two requests share the same input prefix, their KV$ are identical; so if we cache the KV$ of the first (KV$ cache), we don't need to compute the KV$ for the next. Hence, the serving latency is reduced with the throughput improved thanks to the reduced computation under hits.

Like traditional data caching systems [60, 7, 40], the effectiveness of KV$ cache system components like cache eviction policy should be tailored to the KV$ reuse features of workloads. However, LLM serving workloads are complex due to their diverse request types as well as the unique features of each request type. For example, a production LLM service handles both to-C workloads (like chatting) and to-B workloads (like task automation with API calling). These requests can further be processed either as single-turn or multi-turn interactions (§2). Since the KV$ can be reused across different single-turn requests and multi-turn requests, both the single-turn request types and the multi-turn patterns can possibly affect the design choices of KV$ cache.

	Time	Type	UID	Turn	Content
ShareGPT [2]	✗	✗	✗	✓	✓
Mooncake [1]	✓	✗	✗	✗	✓
Traces in this work	✓	✓	✓	✓	✓

Table 1: *A comparison of currently available LLM serving traces. **Time** is the invocation time of each request. **Type** is the request type, e.g., whether it is an API call. **UID** is the user ID that invokes the request. **Turn** is the multi-turn information of the request. **Content** is the (anonymous) input and output tokens of each request.*

There remains a significant gap in the understanding of common LLM serving workloads for KV$ cache due to the lack of in-depth analysis of real-world traces. First, it is unclear whether production workloads have many reuses and which request type contributes most to the reuses. Second, the distributions of the reuse time or reuse probability of KV$ remain unknown, which is critical to cache policy designs. Finally, there is a lack of characterization of the lifespan of KV$, which is essential in helping us estimate the required cache capacity for serving LLMs in the wild.

Characterizing production traces. To bridge this gap, we collected and characterized two representative production serving workloads from one of the world's largest cloud providers (ALIYUN): a to-C workload where users submit requests to the cloud-hosted LLM service via browser-based chatbots or mobile applications, and a to-B workload where developers send OpenAI-compatible requests to the LLM service through API calls in their programs. We collected as much detailed information as possible within the company's strict privacy policy, including request submission times, request types (single-turn, multi-turn, API requests, or others),

[†]The two authors contributed equally to this work.

[✉]Xingda Wei is the corresponding author (wxdwfc@sjtu.edu.cn).

and anonymized content to analyze caching effectiveness. To our knowledge, no other available LLM serving traces match the information depth and scale of our traces (summarized in Table 1). For example, ShareGPT [2] only provides the input and output of each request, not the submission time of each request, which is critical for analyzing the real KV$ hit ratio and usage over time. We believe our collected workloads represent typical LLM serving workloads and can provide a foundation for future KV$ cache system design.

From the perspective of designing an efficient KV$ cache system—both in performance and resource usage, our *key takeaways* are as follows:

1. KV$ reuses are common, but the reuse ratio is smaller than previously reported numbers on synthetic datasets [65, 65]. The reuses follow a skewed distribution: 10 % of KV$ blocks contribute to 77 % of the reuses. The contribution of KV$ reuses also varies across traces: contrary to a straightforward observation that multi-turn requests may dominate most reuses, single-turn requests dominate 97 % KV$ reuses in to-B workloads (§3.2).
2. Key workload features related to KV$ designs, like reuse time and reuse probability distributions—vary across different LLM request types (API vs. chat) and the number of turns in multi-turn requests. Despite this diversity, for each specific request category (type plus turn number), the reuse time is predictable based on the historical information (§3.4). Since the request categories are known by the serving system, we can systematically use the estimated probability for improving cache policies.
3. The lifespan of KV$ is ephemeral: the P99 lifespan of KV$ in to-B workloads is 97 seconds, so a small cache is typically sufficient for the KV$ cache. For example, in the to-B workload, a KV$ with capacity 2 × of the GPU HBM per-GPU is sufficient to approach an ideal hit rate under infinite capacity on common GQA models [3] using standard cache eviction policies like LRU (§3.5).

Our characterizations above reveal several important design decisions that current KV$ cache systems may have overlooked. First, optimizing caching for single-turn requests is equally important as optimizing for multi-turn requests. Second, we could improve cache hits by adopting a workload-aware caching policy instead of only adopting a workload-agnostic policy like LRU. Finally, the ephemeral lifespan of KV$ suggests that a least-frequently-used (LFU) policy is not suitable because a short-lived KV$ may have high frequency in the past. Meanwhile, a small (on-GPU) cache is sufficient for API-dominated to-B workloads, eliminating the cost and complexity of deploying and managing a CPU-RDMA-SSD storage hierarchy for KV$ cache. Besides the main takeaways described above, we also discovered several interesting findings, such as the KV$ hits across users being extremely low (§3.2), despite the possibility of shared prompts via prompt libraries [6].

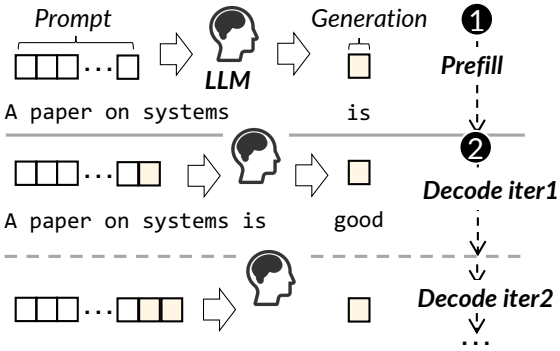

Figure 1: *An illustration showing how an LLM processes requests.*

Improved KV$ cache eviction policy. Based on our findings, we propose a workload-aware KV$ eviction policy (§4.2) that leverages the profiled reuse probability distributions of each workload to enhance cache hit ratios on real-world workloads. Specifically, we leverage the empirically sampled probability distributions of the reuse probability of each workload to decide the priority of each KV$ block, with considerations of both the characterized spatial locality and the lifespan of KV$. To demonstrate the effectiveness of our improved design, we have integrated our policy into vLLM [30]—a popular LLM serving system on the cloud, and our extensive evaluations on production traces show that the improved design can improve 3.9 % cache hits as well as up to 41.4 % mean response time improvements compared to workload-agnostic policies like LRU and LFU.

Discussion. Before moving on, we note two limitations of our work. First, our results are based on one week production traces of large-scale LLM serving workloads. While we believe such workloads (chatbot and API) are representative nowadays, LLM serving workloads are evolving, with new workloads like reasoning [44] emerging. We leave the characterization of these newer workloads to future work. Second, our primary focus is on the KV$ cache policy design, yet we believe the design of other system components for LLM serving like the policy of global scheduling could also benefit from our findings, and we leave other explorations as future work. Nevertheless, we believe our methodology—first characterizing real-world serving features and then optimizing a specific serving component—generalizes to other LLM serving workloads and systems.

A sample of our analyzed trace is available at https://github.com/alibaba-edu/qwen-bailian-usagetraces-anon.

2 Background: LLM serving, KVCache, KV-Cache cache and Multi-turn Serving

LLM serving. Large language models (LLMs) process requests in an auto-regressive way, as shown in Figure 1. Given a request (or a batch of requests), where each request contains multiple tokens (prompt), the model first executes a prefill

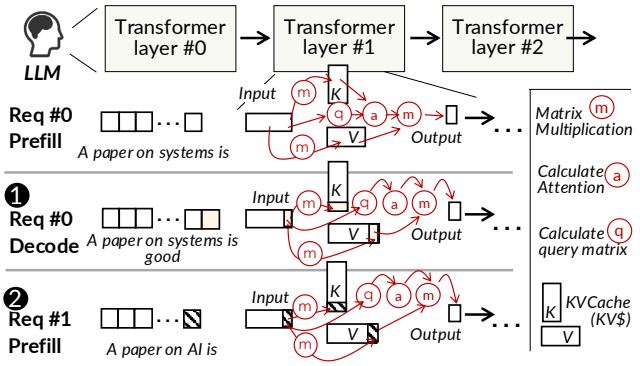

Figure 2: *An illustration of:* ❶ *how* KV$ *from a prefill request (Req#0) can be reused by the decoding of Req#0, and* ❷ *how* KV$ *can be reused for the prefill of a future request (Req#1).*

phase to generate the first token (❶) with a forward pass. The model then enters a decoding phase (❷) that iteratively generating the remaining tokens with multiple forward passes. The iteration ends after the module outputs an end-of-sequence (EOS) token. During each iteration, the input consists of both the original prompt and all previously generated tokens.

KVCache (KV$). LLM performs three steps for a forward pass [55] as shown in Figure 2: (1) calculating the Q, K, and V matrices using matrix multiplication, (2) using Q and K to derive attention scores, and (3) combining the attention scores with the V matrix to produce the attention result. These steps are computation-intensive. Since inputs with the same tokens share the same K and V matrices (see ❶), all LLM serving systems cache the K and V matrices generated during the prefill phase on the GPUs to save computation time. These cached K and V matrices are then reused during the decode phase for the same request to avoid recomputation, so they are termed as KV$.

KV$ cache and KV$ blocks. Besides KV$ reuse across prefill and decode phases when processing a single request, the KV$ can also be reused across different requests if they share the same token prefix. As shown in Figure 2 (❷), the K and V values of "A paper on" are identical for both #Req0 and #Req1. Thus, even when #Req0 finishes decoding, we can still cache its KV$ for #Req1, which dramatically improves the reaction time (also termed time to first token, *TTFT*) of #Req1: it only needs to compute the K and V of "AI is" during the prefill. KV$ caching further increases the serving throughput thanks to the saved computation. Due to the above reasons, existing serving systems all cache the KV$ of completed requests. We term this approach KV$ cache [30, 18, 20, 69, 26, 37, 65], though other names like prefix cache or prompt cache also exist. The KV$ can be cached in GPU memory, on the host memory (or remote machine's memory), or even SSD [30, 18, 65].

Since checking prefix-match may be costly at a per-token level, the cache granularity of existing KV$ system is *block*, where each block contains the KV of a configurable number

Figure 3: *An example of the collected trace record.*

of tokens. For example, vLLM [30] by default groups 16 tokens as a block.

Multi-turn serving. Interacting with LLMs through multi-turn conversations is a common pattern to improve serving quality [58, 56]. Specifically, after receiving the generation from the LLM, the user may issue a next-turn request with a new prompt. Since the LLM needs the previous conversation context for processing, the serving system will concatenate the input and output of requests from the previous turns to the new request's input, and feed the new input to the LLM for serving. To help manage the history of multi-turn requests, requests in a multi-turn conversation are typically grouped in a *session*. A multi-turn request naturally reuses KV$ from previous turns since current LLM systems deliberately append the history of inputs and outputs as a prefix to each new request.

3 Characterize KV$ Workload in the Wild

3.1 Trace data collection

We collected and analyzed two weeks (February 2025 and December 2024) of LLM serving request traces from one of ALIYUN TONGYI's serving clusters. For brevity, we present results from one representative day per trace. The results remain consistent throughout the workdays in each week (see §A.1). *Note that we cannot collect the raw input and output for each request due to* ALIYUN*'s strict privacy policy.* For a specific trace, all its collected requests are served by the same model.

Below, we first describe the detailed anonymized trace record provided by the operational team of the serving cluster, then we move on to highlight the differences between two traces, both representing typical serving workloads nowadays. Figure 3 presents the layout of a collected request:

1. Timestamp: The time when the serving cluster receives the request.

2. Chat ID: The unique ID of the request.

3. Parent Chat ID (under multi-turn serving): For requests in a multi-turn session, the serving system assigns a parent

ID to each request, linking it to the previous request in the session. By traversing the parent IDs, we can identify all requests belonging to the same session. If the parent ID is empty, then the request is the first-turn of a session and we call them *single-turn request*. Otherwise, we call requests with a non-empty parent ID *multi-turn request*.

4. User ID: The unique ID of the user submitting the request. These IDs are mapped to a randomly selected domain for anonymity.

5. Request type: The serving gateway categorizes LLM requests into five types: *Text*: Plain text input via interfaces like ChatBot. *File*: file analysis (e.g., summarizing document content using LLM). *Multimodal*: Image understanding through OCR-enhanced processing. *Search*: Frontend with web-search integrated for knowledge augmentation. *API*: Programmatic access via OpenAI-compatible interfaces [42].

6. Number of Input/Output Tokens: The number of input tokens provided to the LLM and the number of output tokens generated by it.

7. The hashed values of In/Output tokens: Due to the strict privacy policy, the runtime system generate the traces through salted hashing and domain remapping. Specifically, the collector employs SipHash [8] to generate unique hashes for every four consecutive tokens with random salts per trace, then remapping the hash IDs to consecutive natural numbers. This fine-grained hashing enables more fine-grained cache analysis while enhancing privacy protection compared to single-token hashing.

Trace A vs. Trace B. We collected two traces (A and B) representing two representative LLM serving workloads. Trace A represents a common to-C (customer) scenario where users interact with the model through services built by the cloud, i.e., ChatBot (Text) or File/Multimodal/Search services. A key feature of to-C workloads is that they are typically human-in-the-loop. Trace B represents a to-B (business) workload where business users interact with the LLM by calling OpenAI-compatible APIs hosted by the cloud through computer programs [42]. API calling is critical for business users because they can systematically leverage LLM to automate tasks like document translation or user request classification. Trace B has no request type information because, similar to the LLM interface calls currently offered by other vendors [42, 21, 4], this information is concatenated on the client side.

3.2 KV$ reuses analysis in the wild

How many KV$ can be reused? Figure 4 shows the ideal cache hit rates on two traces, i.e., assuming a cache having infinite capacity. We can see that LLM workloads can benefit from caching—it has 62% and 54% hit rates on Trace A and B, respectively. The hit rate is calculated as follows: for a total of N KV$ blocks that needed to be computed by LLM in a trace, if the hit rate is 62%, this implies that 62% of the

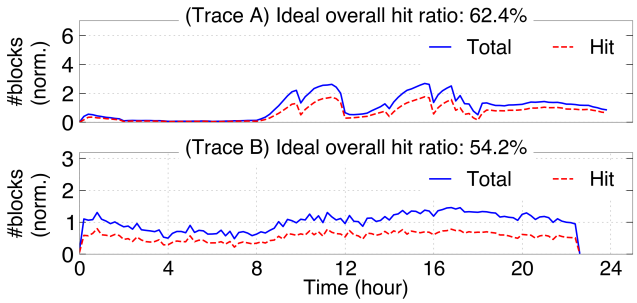

Figure 4: *An analysis of the ideal cache hit ratio of the* KV$ *cache under real-world LLM serving workloads within a day. The reported accessed and hit block numbers are normalized (norm.).*

Types (Trace A)	Workload ratio (%)	Multi-turn Ratio (%)
Text	78	47
File understanding	4	51
Multimodal understanding	3	10
Search	15	49
Types (Trace B)	**Ratio (%)**	**Multi-turn Ratio (%)**
API	100	0.08

Figure 5: *Workload types and multi-turn ratio of requests in our collected traces.*

N blocks can reuse a KV$ computed and cached in a prior request. While the ideal hit ratio is high, it is smaller than the reported hit ratio (e.g., more than 80% [65, 69, 19]) on synthetic workloads.

Single-turn and multi-turn requests are equally important for KV$ reuse. While it is a common belief that multi-turn requests are key contributors to the cache hits [65, 19], this is not the case on the to-B workloads (Trace B). Figure 5 shows the contribution of each request type as well as their multi-turn ratio. For Trace A, it is dominated by the requests sent by the chatbot (78 %), and all request types except for the multimodal have a similar multi-turn ratio (47–51 %). For Trace B, it only has API requests with a negligible multi-turn ratio (less than 0.1 %). Nevertheless, the single-turn requests contribute 97 % of the total cache hits for Trace B.

Single-turn API requests dominate the hits in to-B workloads for two reasons. First, LLM API requests share KV$ through common system prompts. Specifically, each request comprises: (1) a system prompt providing task instructions (e.g., document translation guidelines) and (2) a user prompt containing request-specific data (e.g., target document). When programs make API calls [35], they typically hardcode identical system prompts in the program, thus enabling KV$ sharing across requests, even for single-turn requests. Second, API requests often exhibit rapid submission rates (e.g., > 10 QPS), enabling frequent reuse of the same shared KV$ from system prompts.

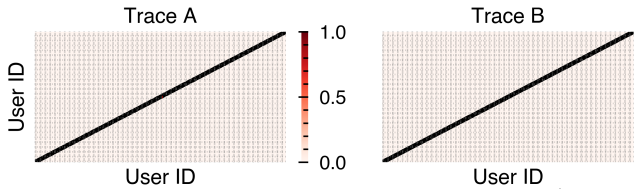

Figure 6: *An analysis of whether a user may hit the* KV$ *cached by another user. The darker the color, the higher the normalized hit count. Note that we have amplified the diagonal line in case it is too thin, since the trace provider serves numerous users.*

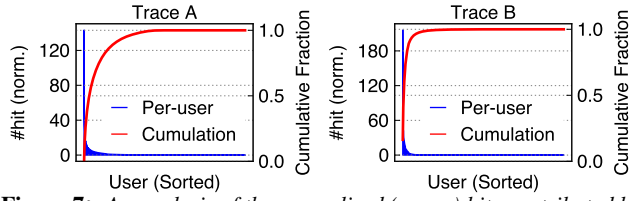

Figure 7: *An analysis of the normalized (norm.) hits contributed by different users in an ideal setup with infinite cache size.*

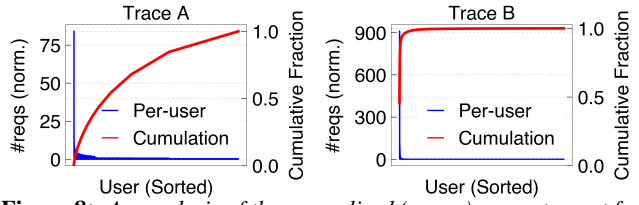

Figure 8: *An analysis of the normalized (norm.) request count for different users.*

Cross-user KV$ hits are rare. Figure 6 shows the heatmap of the cache hits between users, assuming an infinite-size KV$ cache. Darker colors indicate higher normalized hit counts. We can see that for each user, most hits come from requests submitted by themselves (the diagonal line). While users naturally reuse KV$ from their own requests—either via multi-turn conversations or through programs calling API with the same system prompt for the same task, the low inter-user hit rate suggests that users tend to customize their own system prompts rather than using template prompts provided by third-party libraries [6]. As a result, we suggest paying more attention to intra-user KV$ reuses rather than inter-user [20, 69, 26, 37] when designing KV$ systems.

The KV$ reuses are skewed. Figure 7 shows the KV$ cache hits contributed by different users, along with the cumulative hits. The KV$ hit pattern is highly skewed: 19 % of the user requests in trace A and 4 % in trace B account for more than 90 % of the KV$ block hits. This skewness stems from two factors. First, the requests are unevenly distributed across users, especially in Trace B. Figure 8 shows the normalized number of requests sent by different users: 15 % of the users (head users) contribute 90 % of the requests in Trace B. Since KV$ hits primarily occur for requests from the same user (see Figure 6), the skewness in request counts is expected to lead to a similar skewness in KV$ hits. Second, even when requests are sent relatively evenly by different

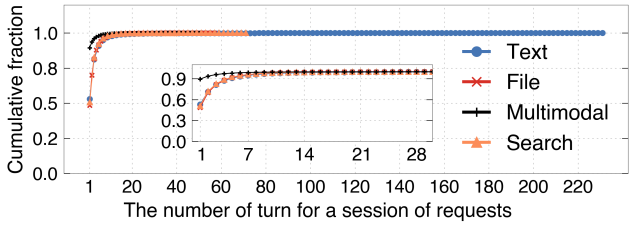

Figure 9: *Distribution of turn number of multi-turn requests on Trace A.*

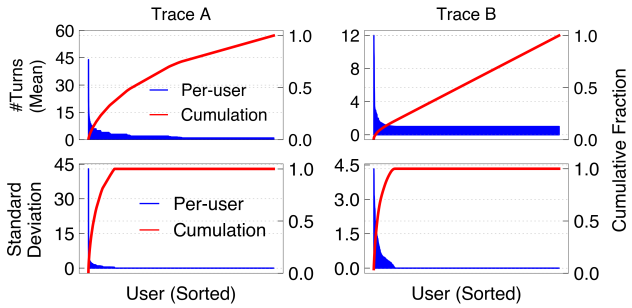

Figure 10: *An analysis of the mean (upper) and standard deviation (lower) of the number of turns of requests sent by each user. The users are sorted across to their mean number of turn (upper) and standard deviation (lower).*

users, individual users vary significantly in their KV$ hits. As also shown in Figure 8, Trace A exhibits a moderately skewed request distribution: 19 % of users generate 50 % of the requests, and 72 % generate 90 % of the requests. Nevertheless, the KV$ hits are still skewed. We suspect that this is due to their tendency to engage in multi-turn requests.

3.3 Analyses of multi-turn requests features

We first examine the features of multi-turn requests, as they still dominate the KV$ reuse in to-C workloads. We omit the results on Trace B because multi-turn requests are rare in it.

Multi-turn requests have high variability. We observed two kinds of variability. First, the number of turns varies significantly across different sessions. Figure 9 shows the distributions of turn numbers on Trace A: 54 % of requests are single-turn requests, while the 50^{th} and 90^{th} percentile turn numbers are 1 and 5, respectively. The distribution has a long tail—the longest session has 232 turns, two orders of magnitude larger than the median (232 ×).

Second, multi-turn request distributions exhibit significant user-level variation. Figure 10 shows that most users have similar mean turn counts, except for a few head users—the top 10% exhibit 8.9 × more turns than the average. Additionally, turn count deviations vary substantially, ranging from 1 to 44. This suggests diverse interaction patterns: some users show high variability, while others remain stable.

The probability of issuing the next turn request is predictable given a workload category and time interval, and the probability differs across request categories. A request

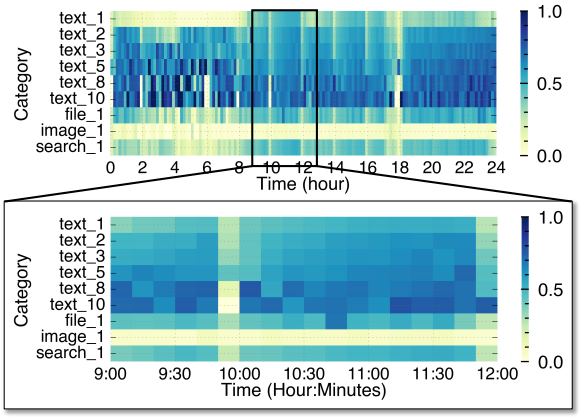

Figure 11: *An illustration of how the frequencies of issuing the next turn request change over time for different request types. The x-axis is the timeline. The workload categories are sorted according to their popularity.*

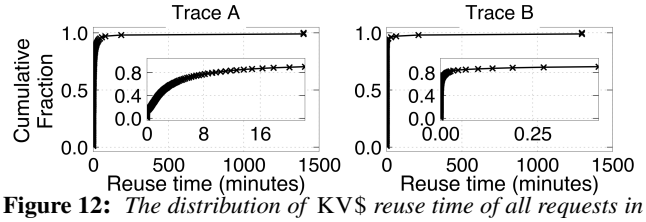

Figure 12: *The distribution of* KV$ *reuse time of all requests in Trace A and B.*

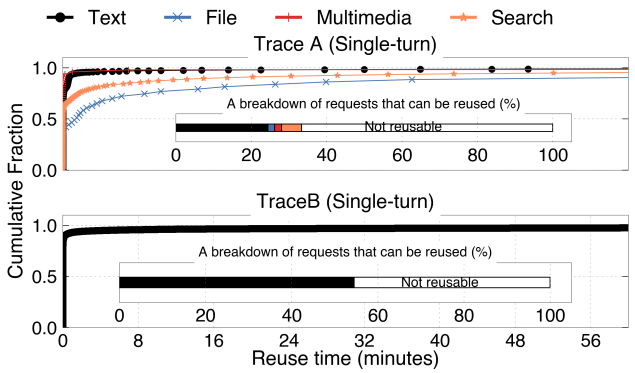

Figure 13: *The distribution of* KV$ *reuse time of single-turn requests in Trace A and B. B has one category of request (API).*

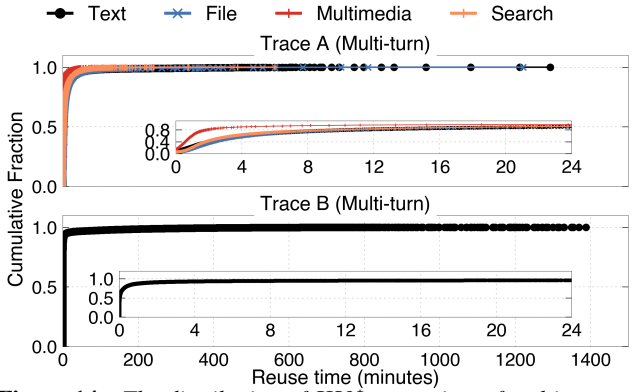

Figure 14: *The distribution of* KV$ *reuse time of multi-turn requests in Trace A and B. B has one category of request (API).*

category includes both the original request type (e.g., Text and Search) as well as the turn number of the request, i.e., a 1-turn text (single-turn text request) is different from the 2-turn text request. Figure 11 shows a heatmap of how the probability of issuing the next-turn request changes over the long time interval (24 hours) as well as a zoomed-in view of a short time interval (3 hours). The intensity of the color indicates the profiled frequencies within a time window (10 minutes). We can see that though different request categories have different frequencies (shown by vertical lines), for a specific category, the frequency of issuing the next-turn request remains consistent over a one-hour time interval (shown by horizontal lines). We attribute this to the fact that the probability distribution of KV$ reuse is quite fixed given a specific time interval and request category. §3.4 further elaborates on that. Interestingly, the frequency of issuing the next-turn request differs across request categories. For example, single-turn requests demonstrate significantly lower rates of issuing next-turn requests (mean=0.5) compared to multi-turn requests (mean=0.8).

3.4 Analyses of temporal and spatial locality

Temporal locality can be characterized by profiling the distribution of reuse time, i.e., the interval between when a KV$ block is reused by another request.

KV$ reuse time is short. Figure 12 shows the distributions of KV$ reuse time on both traces. We can see that the reuse time for both workloads is typically small: In Trace A, 80% of the reuse time falls within less than 10 minutes, while in Trace B it falls within 10 seconds. The differences lie in the human-in-the-loop versus computer-in-the-loop interactions that generated the requests in two traces.

Different workload types have different temporal locality. First, single-turn requests have much lower locality in the to-C workloads, while to-B workloads are the opposite. Figure 13 reports whether a single request can be reused by another single-turn request on both traces in the middle sub-figures. As we can see, less than 30 % of the single-turn requests are reusable in Trace A, but more than 50 % of requests can be reused in Trace B.

Second, different request types show different temporal locality. Figure 14 shows the reuse time distribution of multi-turn requests categorized by their request types. We can see that chat requests (Text) shows longer reuse time than image understanding (Multimodal), but shorter than file understanding (File). This stems from workload characteristics: users typically spend more time processing complex LLM outputs based on file content than casual outputs from conversational chats. Conversely, visual information processing occurs faster than textual processing [48], leading to shorter reuse times for image tasks. Finally, Search workloads exhibit the second-longest reuse time, as users often require substantial time to

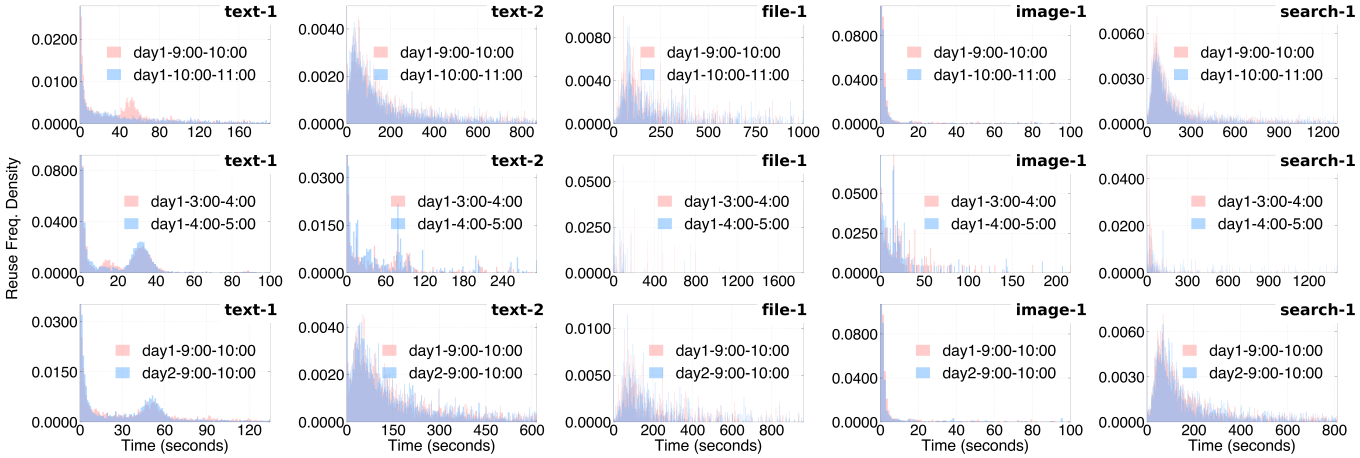

Figure 15: *An empirical analysis of the reuse time probability distribution of* KV$ *blocks. The columns present data from different request categories. The first row: distributions under heavy traffic (daytime). The second row: distributions under low traffic (nighttime). The third row: a comparison of distributions under different days but with similar traffic patterns.*

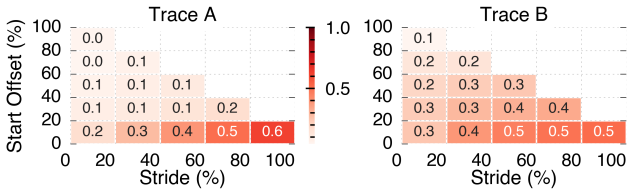

Figure 16: *Overall spatial locality of two traces.*

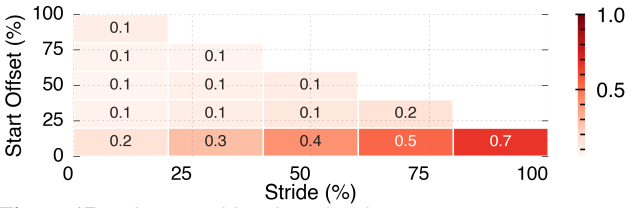

Figure 17: *The spatial locality of multi-turn requests on Trace A.*

analyze the searched results.

Given a time period and request category, the probability distribution of KV$ reuse time follows an exponential distribution. Figure 15 presents the reuse time probability distribution of KV$ blocks across different request categories. For each category, we measure the likelihood of its KV$ reuse at specific time intervals after caching. We plot these distributions by counting reuse event frequencies at each second following request execution.

From the results, we draw three key observations. First, exponential distributions fit well with the reuse probability given a request category. Second, the probability is workload-aware, i.e., the distributions of different request categories, including the same request type but different turns, are different (e.g., text-1 vs. text-2). This implies a workload-aware design that distinguishes different request categories. Finally, the distributions of requests with similar traffic patterns are similar. Take text-1 as an example: as shown in the first row, the distribution drawn from 9:00–10:00 a.m. is similar to that drawn from 10:00–11:00 a.m., but is significantly different from that drawn from the nighttime—3:00–4:00 a.m. (second row). The distributions are also similar across different days (first row vs. third row). The first and third observation in combine imply that we can acquire the distribution of a request category using recent historical data.

Spatial locality. Figure 16 shows the overall spatial locality of KV$ across both traces. We characterize the spatial locality by measuring the ideal cache hit ratio with various cache strides, i.e., the percentage of tokens cached per request, as well as different starting token offsets for caching. This gives a two-dimensional heatmap, for example, offset (10 %, 10 %) means that for each request, we only cache 10 % of the tokens starting from the 10 % token position.

First, KV$ shows better spatial locality when caching from the beginning, which is expected since only requests with identical prefixes can share the KV$ (§2). We emphasize this seemingly trivial point because some KV$ optimizations [27] cache the tail tokens of requests to hide KV$ load time through concurrent computation and loading. However, this approach may reduce spatial locality, as Figure 17 particularly demonstrates that reusing intermediate parts in the cache yields minimal benefits for multi-turn conversations.

Second, the spatial locality, like temporal locality, is also workload-aware. In Figure 18, we observed workloads like text and multimodal exhibit obvious spatial locality, while file and search exhibit almost no spatial locality. Due to the lack of user input content, we suspect the cause as follows: the applications add a fixed system prompt for text and multimodal workloads, whereas the system prompt for file and search is dependent on user inputs.

Finally, we found that increasing the stride size implies a higher cache hit ratio in Trace A (Figure 17), but it is not the case in Trace B (the last column in Figure 18). In Trace A, multi-turn requests contribute to the cache hits, so caching

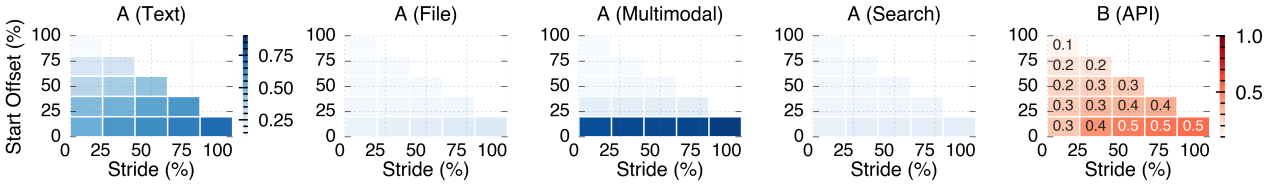

Figure 18: *The spatial locality of single-turn requests.*

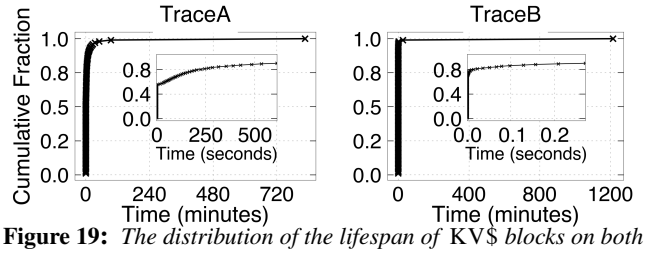

Figure 19: *The distribution of the lifespan of* KV$ *blocks on both traces.*

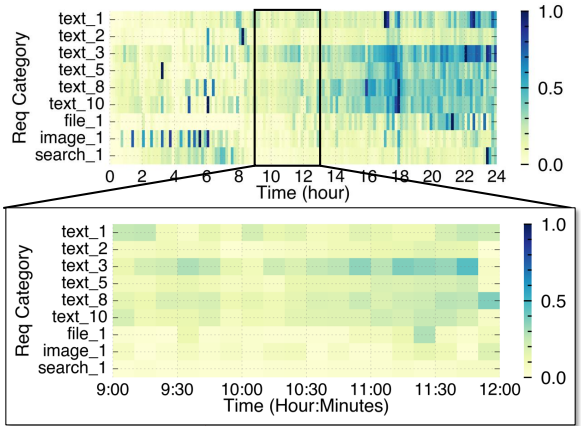

Figure 20: *An illustration of how the mean lifespan of* KV$ *blocks changes over time for different request categories. Note that the x-axis represents the timeline. The request categories are sorted according to their usage.*

more tokens for a request will lead to more cache hits. In Trace B, only the system prompt contributes to the cache hits. Thus, caching a stride of 50 % of the request already achieved a peak hit ratio of 50 %. This implies that most system prompt lengths are below 50% of the total request length in Trace B, though we don't have the detailed request to support this suspicion.

3.5 Analyses of KV$ cache capacity requirement

Determining the right cache capacity is critical for a caching system. Unlike traditional storage systems, the cached KV$ is ephemeral, so identifying the right size requirement can save platform costs. This section analyzes the KV$ capacity using a bottom-up approach: First, we characterize the features of the lifespan of requests' KV$. Then we analyze the storage usage of each request. In combination, this gives us an estimation of the total KV$ capacity required.

KV$ lifespan is ephemeral and predictable. Figure 19 analyzes the lifespan of KV$ blocks. A KV$ block "dies" if it has not been reused anymore. We can see that most KV$ blocks "live" shortly. In Trace A, 90 % of the KV$ blocks are not reused after 612 seconds, and the number for Trace B is 0.3 seconds. This aligns with our analysis in the previous sections, e.g., many multi-turn requests will have a short reuse time (Figure 12), and most requests have a few turns (Figure 9). As a multi-turn request ends, its KV$ will not be reused anymore. Blocks in Trace B have a shorter lifespan despite some outliers. Unlike Trace A, most of its cached KV$ blocks are reused for system prompts, so they can be reused after a long time. For example, in Trace B, the longest lifespan is 1,200 minutes while it is 800 minutes in Trace A.

Figure 20 further shows how the mean lifespan of KV$ blocks changes over time for different request categories. In the graph, the color intensity represents the normalized lifespan, with darker colors indicating longer-lived KV$ blocks. We can see that although the average lifespan at the 24-hour scale is changing over time, when we zoom in to a smaller timescale (9:00 a.m. to 11:00 a.m.), the pattern is quite stable. This implies that we can predict the lifespan of a KV$ block using historical data to reduce the KV$ cache size for saving costs, as storing KV$ at fast storage medium (e.g., CPU's DRAM) is expensive.

Per-request KV$ cache usage is moderate. A key factor when considering caching is the size of KV$ to be cached, which is proportional to the input length of each request and the corresponding model output length. Figure 21 shows the size distribution of requests on different traces. Note that we report the relative size when normalized to the HBM available for serving the request on a serving instance[1]. This is because a relative value gives more intuitive results on the capacity required to cache the KV$ of each request. The available HBM for KV$ is calculated by subtracting the total HBM of the GPU(s) in a serving instance from the model parameter and activation sizes. Since the KV$ size of each request depends on the detailed attention mechanism of the model, we report the results on three representative models with two widely used attention methods: group query attention (GQA [3]) and multi-head attention (MHA [55]). GQA uses less memory for the KV$.

We can see that the overall size of the KV$ is moderate compared to the HBM. Take Trace A as an example. On GQA

[1]A serving instance is the minimal number of GPUs required to serve a model. For example, the serving instance of an 8 B model only needs one GPU, while serving a 72 B model requires 4 in the common case.

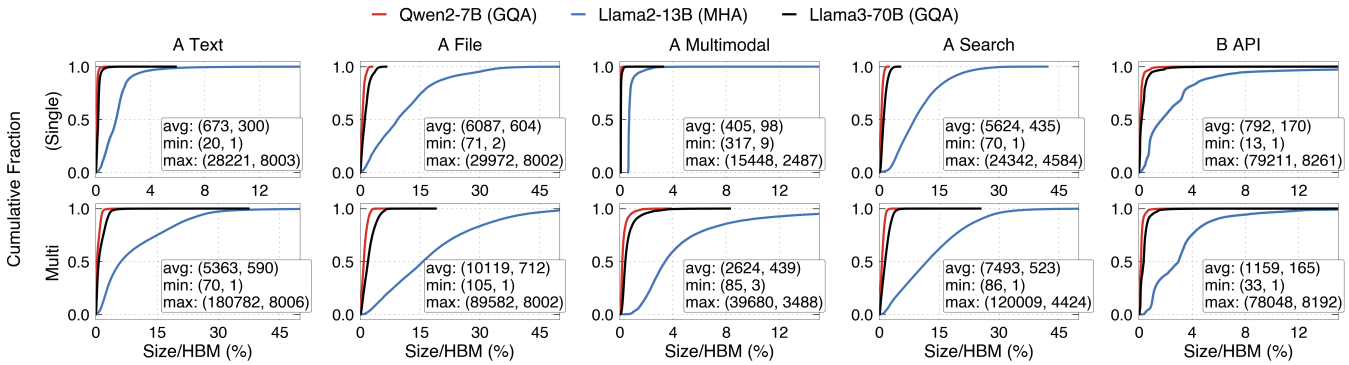

Figure 21: *The distribution of* KV$ *size of requests on different traces for Single and Multi-turn requests. The size is normalized to the GPU memory (HBM) available for serving. The number in the tuple inside each graph represents the length of input and output.*

models like Qwen2-7B, the 50^{th}, 90^{th}, and 99^{th} HBM usage of the request in Text—the dominant request type are 0.09 %, 0.15 %, and 0.37 % and 0.36 %, 1.31 %, and 2.21 % for single-turn and multi-turn requests, respectively. The average usage is 0.09 % and 0.56 % for single- and multi-turn requests, respectively. This small usage is due to the fact that each token consumes few megabytes and requests in production traces tend to be small: in Qwen2-7B, it consumes 0.875 MB KV$ for 16 tokens, while the mean total token lengths (input+output) for single-turn and multi-turn is 973 and 5,953, respectively. For other models, though Llama3-70B also adopts GQA, it has a slightly higher HBM usage due to the reduced number of GPUs per instance: the parameter size increases 10 × while the number of GPUs we measured only increases 4 ×. Finally, MHA models have the highest usage due to the increased KV$ per token. Note that recent open-source models tend to use GQA (or other attention with even fewer KV$ per token like MLA [36]).

Considering that each serving instance typically processes a few requests per second, our characterization implies that an instance can cache a request for a modest time—e.g., for Qwen2-7B, suppose a GPU can process 5 requests per second, it takes at least 1 minute to saturate the HBM assuming an average 0.32 % HBM per request (derived with a 47 % multi-turn ratio of Text request type). This time is within the reuse distance of KV$ in many scenarios (e.g., API). Note that in practical setups, we may not achieve such a long reuse time due to tail requests (e.g., we do observe long context requests with more than 12,000 tokens), and LLM serving systems typically serve requests in large batches to improve computation utilization.

Overall memory required for KV$ cache is moderate. We analyze the KV$ cache capacity required by measuring how large a cache can ensure an ideal cache hit ratio assuming an ideal eviction policy, i.e., never evict a KV$ that will be reused. The measurement is as follows: at a given time, upon processing a request, we update the KV$ size by adding the KV$ of this request if it will be reused, and subtracting the size of all cached KV$ that will never be reused. One tricky

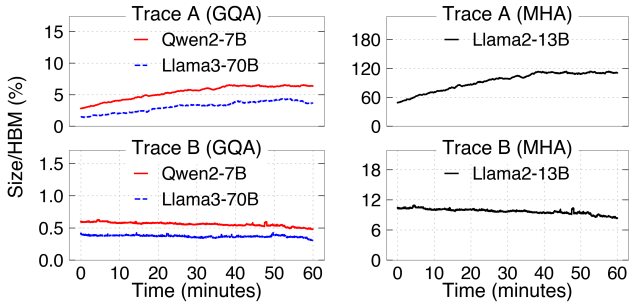

Figure 22: *An analysis of the* KV$ *cache size required to achieve an ideal cache hit ratio on different models and traces. The data is collected from 10:00 a.m. to 11:00 a.m.*

thing is that the size required is dependent on the number of serving instances deployed for a workload: if the instances are over-provisioned, then the estimated requirement would be small. To obtain the maximal requirement, we use a setup that uses the minimal number of serving instances, i.e., each instance serves with the maximum QPS, so there is no over-provisioning.

Figure 22 shows the results normalized to the total HBM of a serving instance. We can see that GQA models require a relatively small cache capacity to reach an ideal cache hit rate: in Trace A, Llama3-70B only needs 4 × of the available HBM for KV$. This is typically achievable in modern serving clusters without the need for more storage hierarchies like remote memory or SSD [19]. For example, in a typical setup featuring 8 A100 GPUs and 1 TB of CPU memory, each GPU has access to an average of 128 GB of CPU memory, which is nearly 4 × the amount of HBM space reserved for storing the KV$. Moreover, for Trace B, the KV$ capacity is even smaller than the reserved HBM, so caching on GPU may be sufficient.

Though GQA needs small cache, we should note that MHA models do require a huge amount of KV$ cache, This is due to their huge per-token KV pairs (see Figure 21). Thus, optimizing cache eviction policies is still important under limited cache capacity.

4 Improved KV$ cache system

4.1 An overview of the design space

Existing KV$ cache systems [19, 30, 69, 65] follow similar caching mechanisms and policies. Below we give a brief overview of their designs before moving on to our improved policy.

Current KV$ cache mechanism and policies. Regarding the mechanism: existing systems cache KV$ primarily on GPU and CPU in a hierarchical manner. The KV$ is managed at block granularity (see §2): when a KV$ block is generated, it is first cached on the GPU HBM. If the GPU is unable to cache newly generated blocks due to out of memory, the caching system adopts an eviction policy (described below) to evict some blocks from the GPU to the CPU. The evicted blocks are asynchronously swapped to CPU in a layer-by-layer manner so the swap cost is negligible. If the CPU is also out of memory, the blocks are removed. Before executing a new request, if the request hits cached blocks, the serving system directly reuses the cached blocks to avoid recomputation. Note that if the hit is on CPU, the block is swapped to the GPU also in a layer-by-layer manner.

Regarding the policies: a KV$ cache system mainly needs two policies: how to determine cache hits and how to evict cached blocks. For the first policy, the design choices differ in their granularity of checking which blocks may contribute to the hits: some systems check for matches across all requests [69, 26] while others only check for matches within requests from individual users [65, 19]. For the second policy, current systems mainly adopt standard eviction policies like LRU or FIFO. Though they adopt some extensions like checking whether the evicted blocks are in the scheduling queue [19], the overall rationale does not change.

The drawback. Existing workload-agnostic policies like LRU may miss the workload features we analyzed in §3, and we argue that they are suboptimal. Take Trace A as an example: given the same amount of time since the last access (e.g., greater than 10 seconds), 10-turn text requests are more likely to have a subsequent turn than 1-turn text requests (see Figure 11). However, if many 1-turn requests are flooding into the system, 10-turn requests can be evicted by LRU because the reuse time is longer.

Our solution: workload-aware reuse-probability-distribution-based KV$ eviction policy. To this end, we propose a workload-aware cache eviction policy that considers the reuse probability distributions of each request category based on the characterizations presented in §3.4. At a high level, at the eviction time, for each block, we calculate a priority—the likelihood of a KV$ being reused in the future based on the profiled reuse probability distribution of its request category (workload). The priority further holistically considers the spatial locality as well as the short lifespan of KV$ blocks. The blocks with the lowest priority are evicted first. Table 2 summarizes our techniques as well as their corresponding observations from §3.

Observations	Techniques
The probability of KV$ reuse follows exponential distributions given a workload (Figure 11 and Figure 15).	① Workload-aware reuse-probability-distribution-based priority estimation.
Spatial locality (Figure 16–18).	② Assign a higher priority to the head KV$ blocks.
Ephemeral KV$ lifespan (Figure 19).	③ Remove frequency when calculating the priority, as well as limiting the time span of probability calculation.

Table 2: *A summary of the main techniques in our workload-aware cache eviction policy based on the findings in §3*

Our caching mechanisms follow existing systems [19, 30, 69, 65]—including asynchronous swapping and pipelined loading, as these techniques have converged to a standard design.

4.2 Workload-aware KV$ cache eviction policy

Existing workload-aware policy. Workload-aware cache eviction policy has been extensively studied in the literature [14, 41, 29, 25, 38, 11, 49]. A representative policy is the Greedy-Dual-Frequency-Size (GDFS) policy [14], which evaluates the priority of each cached object (e.g., KV$) using the following workload-dependent features:

$$\text{Priority} = \text{Clock} + \frac{\text{Frequency} \times \text{Cost}}{\text{Size}} \ (\underline{\text{Existing GDFS}})$$

The `Clock` captures the last access time of an object (similar to LRU), the `Frequency` is the total access count of an object (similar to LFU), the `Size` is the size of the cached object, and `Cost` is the cost to bring the cached content back to the cache. Objects with the lowest priority are evicted first.

While the above GDFS formulation can be retrofitted for calculating the priority of KV$ blocks, we found it does not fully consider the KV$ usage in LLM serving as well as the known probability distributions of requests in different categories. For example, a frequently accessed block may not be reused in the future due to the short lifespan of KV$ blocks, causing a frequently accessed then died block wasting the KV$ space. Besides, a block with higher cost to bring to the cache does not necessarily mean it is more likely to be reused in the future. Instead, we need to bring the more likely to be reused blocks to the cache first. While such workload information is not available in the setup of GDFS, it is readily available in serving LLMs based on our characterization in the previous section.

Our policy. We follow GDFS to calculate the priority of each KV$ block and use the priority to determine the eviction order, but our priority is retrofitted with our characterized

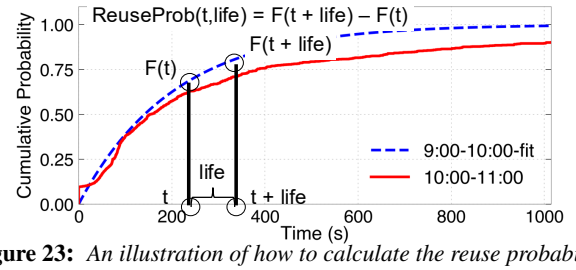

Figure 23: *An illustration of how to calculate the reuse probability of a* KV$ *block given its workload (request category).*

KV$ reuse features:

$$\text{Priority} = (\text{ReuseProb}_w(t, \text{life}), -\text{Offset}) \ (\underline{\text{Workload-aware}})$$

Specifically, the priority is represented with a tuple containing two metrics and we compare the tuple with lexicographical order. The rationale behind the two metrics is:

- **ReuseProb**$_w$ (①) calculates the reuse probability of a KV$ block at a given time t, where t means the time since its last access. For each workload (request category), the reuse probability is calculated using a two-step process. First, we sample a period of the recently accessed data in the background. Second, based on the observations in Figure 15, we fit an exponential distribution to the sampled data, and look up the fitted curve to get the reuse probability. Figure 23 shows an example of how to calculate the reuse probability. We first use the background sampled data from 9:00 a.m. to 10:00 a.m. to fit the cumulative distribution function (CDF) of the reuse probability of a given workload (blue line).

  Note that the fitted curve is close to the real data (red line). Afterward, we can look up the curve to get the reuse probability of a KV$ block in the future. Note that the function further considers the expected lifespan (life) of the block, which is critical considering the short lifespan of KV$ and we describe below.

- **Offset** (②) considers the spatial locality described in §3.4: the priority is reversely proportional to the prefix length of the KV$ block in the entire request.

We don't consider frequency explicitly (③) because we found it can not provide useful information for cache policy due to the short lifespan of KV$ blocks (see Figure 19) even for frequently reused ones. More importantly, we also need to regulate the calculated reuse probability with the lifespan. If not, the fitted reuse probability will return a large probability for a request with long-tailed reuse time distribution for a long time. This contradicts the short KV$ lifespan observation and leads to the inefficient utilization of limited cache space.

The detailed eviction algorithm. Algorithm 24 presents a simplified pseudocode of our workload-aware cache eviction algorithm. Upon eviction, we first iterate through all the cached blocks (line 4–6) and calculate the reuse probability

```
Input:  Bs: cached KV$ blocks;
        Life: expected lifespan of the KV$ blocks;
        H(w): hyper parameters for the workload (w)'s fitted probability.
        distribution that are periodically updated in the background.
Output: B: the evicted KV$ block.
1   CurT = time.time()
2   MinPriority = +∞
3   ChosenBlock = PlaceHolder
4   For b in Bs:
5       Priority = ReuseProb_H(b.w)(CurT - b.cached_t, Life)
6       ▸ Priority is the reuse probability in
          [CurT – b.cached_t, CurT – b.cached_t+ Life)
7       If Priority < MinPriority or (Priority == MinPriority and
                    b.offset > ChosenBlock.offset):
8           MinPriority  = Priority
9           ChosenBlock = b
10  return ChosenBlock
```

Figure 24: *A simplified pseudocode of our workload-aware cache eviction algorithm.*

for each block using the workload ($b.w$). The priority is then compared with the offset of the block to update the block to be evicted (line 7–9).

Performance optimization. One drawback of the above naive algorithm is that it requires computing the reuse probabilities of all KV$ blocks to identify the least reusable candidate. To avoid excessive computation overhead, we observe that all KV$ blocks within each workload are naturally ordered by their last accessed timestamps according to the exponential distribution, so we can avoid computing the reuse probability when comparing blocks within the same workload. Specifically, for each workload, we maintain a priority queue of its KV$ blocks ordered by last accessed time. During eviction, instead of scanning all blocks, we first treat the least-recently-used block of each workload as the candidate for eviction. Afterward, we run the algorithm described in Algorithm 24 to obtain the final evicted block. This reduces the complexity from $O(N)$ to $O(W)$, where W is the number of workloads (typically in the range of tens). As a result, the performance overhead of workload-aware policy is negligible to serving, e.g., we observed a 79 μs policy delay for each eviction, with the aggregated overhead only 1.2 % of the scheduling overhead of a typical serving engine (vLLM [30]).

4.3 Performance evaluation

Testbed. We conducted our evaluations on a server with 8 NVIDIA A800-80GB GPUs. The GPUs are connected via 400 GBps bidirectional NVLink, allowing us to use multiple GPUs (e.g., 4) to serve a single large model with tensor parallelism [39]. The GPUs are connected to the host via PCIe Gen4, offering a bidirectional bandwidth of up to 32 GBps between GPU HBM and the host memory.

Implementations and baselines. Since the state-of-the-art KV$ cache systems that incorporate both CPU and GPU KV$ like CachedAttention [19] and Pensieve [65] are not

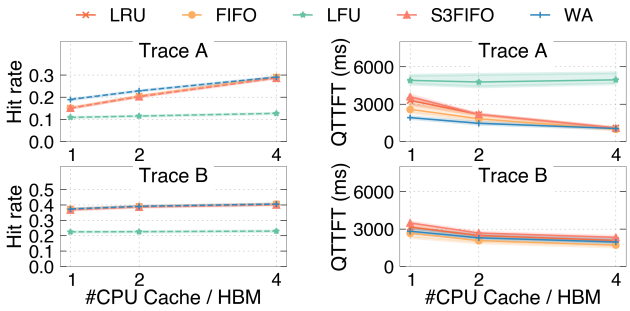

Figure 25: *An analysis of the cache hit ratio and QTTFT with respect to the CPU cache provisioned on Qwen2-7B.*

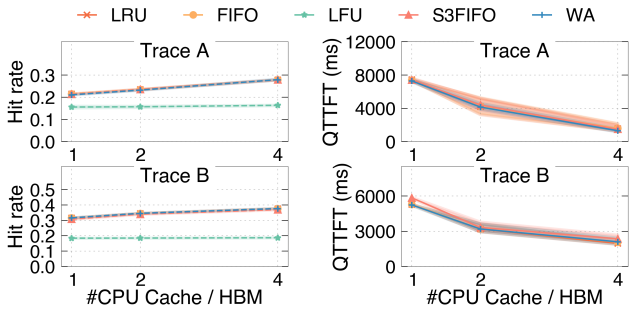

Figure 26: *An analysis of the cache hit ratio and QTTFT with respect to the CPU cache provisioned on Llama2-13B.*

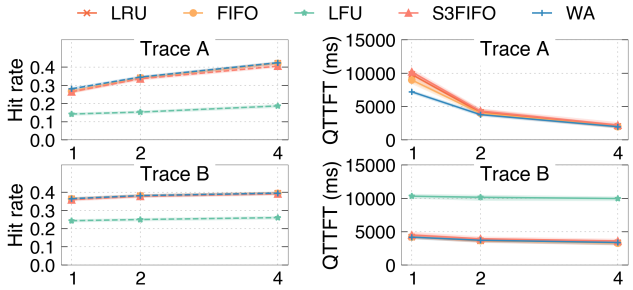

Figure 27: *An analysis of the cache hit ratio and QTTFT with respect to the CPU cache provisioned on Llama3-70B.*

open-sourced, we implement a CPU-GPU KV$ cache on vLLM [30], the state-of-the-art LLM serving system that adopts GPU KV$ cache by default. We have further integrated the policies and mechanisms from state-of-the-art (see §4.1) to it. We have calibrated that our implementation has a similar performance to state-of-the-art like CachedAttention on the same synthetic workload with a similar testbed.

Besides integrating a CPU KV$ cache on vLLM, we have also implemented the KV$-centric global scheduler described in Mooncake [1], because serving LLMs on multiple instances is common. Specifically, the global scheduler will record the global KV$ cache usage and schedule the request to the instance with cached KV$ whenever possible. Note that our workload-aware caching policy only applies to a single serving instance, extending it to a global layer is left as our future work.

Evaluated models and workloads. We use three representative open-source models for the performance evaluations: Qwen2-7B [9], Llama2-13B [54] and Llama3-70B [15]. The rationale for choosing these models and the differences between them have been discussed in the per-request KV$ size analysis in §3.5. For Qwen2-7B and Llama2-13B models, we use one GPU per serving instance. For Llama3-70B, we use 4 GPUs. We use the Trace A and B described in §3.1 as our evaluated workloads. Since we don't have sufficient GPUs to support the real workload, we scale the traces to fit the processing capability of our testbed using the scaling method that preserves the temporal pattern of the trace [51].

Evaluation methodology on anonymous traces. Even though the traces are anonymous, we can evaluate the system serving performance by constructing inputs that accurately reproduce the original trace's cache hit patterns. Specifically, for each anonymous block without assigned tokens, we randomly generate a token list, ensuring each generated list's hash differs from all other token lists. Moreover, to match the original input's iteration count, we constrain the model using the trace's output length. Finally, we replace the model-generated output with the constructed tokens to preserve the cache patterns of multi-turn requests.

Improved cache hit. Figure 25–27 show the cache hit ratio and serving performance for standard cache policies and our workload-aware policy (WA). We compare our policy with the standard policies like least-recently-used (LRU), first-in-first-out (FIFO), least-frequently-used (LFU) and recent optimized FIFO method (S3-FIFO) [61]. We compare with the vanilla GDFS in Figure 28.

Since the performance depends on cache capacity, we report the hit rates (as well as performance) by varying the provisioned KV$ cache capacity. The capacity is normalized to the GPU HBM size for KV$, i.e., the #CPU Cache / HBM in the figures means the CPU memory used to store the KV$ normalized to the GPU HBM. For example, a #CPU Cache / HBM of 1 means the CPU memory used to store the KV$ is equal to the GPU HBM size. We draw three observations from the results.

First, our policy WA achieves 8.1–23.9 % higher hit rate compared to other baselines, and it has a 1.5–3.9 % higher hit rate compared to the best of other baselines. Our policy is more effective thanks to its knowledge of the workload reuse patterns. Second, the effectiveness of WA decreases when the cache capacity increases, this is as expected because a larger cache can tolerate a less effective policy. Finally, WA is more effective on Trace A than Trace B, this is due to two reasons. (1) Trace B has little workload information (> 99 % of its requests are 1-turn requests). Thus, our fitted exponential distribution-based policy essentially falls back to a normal LRU. (2) Trace B requires a relatively small KV$ capacity, so GPU HBM is already close to optimal except for LFU. The poor hit rate of LFU comes from the fact that the most

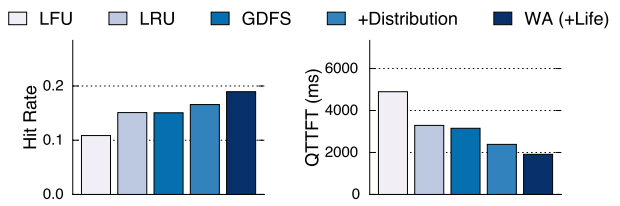

Figure 28: *An ablation study on Qwen2-7B with #CPU Cache / HBM is 1.*

frequently accessed blocks may die early thus polluting the KV$ cache, as we have extensively discussed before.

Improved performance. The improved cache hit ratio leads to a significant performance improvement in the serving performance. Figure 25–27 also reports the queued TTFT (QTTFT) when serving different traces, i.e., the TTFT plus the time when waiting for GPU to process the request. We can see that WA achieves 28.3–41.9% QTTFT reduction thanks to the improved KV$ cache hit rate.

Ablation study. Figure 28 conducts an ablation study on the Qwen2-7B model on Trace A with different policies. Other models share a similar trend. First, we can see that using a distribution-based approach improves the hit rate by 1 % (with technique ① in Table 2). Considering the short lifespan of KV$ with the life regulator further increases the hit rate by 2.4 % (③). Note that we omit describing the locality optimization ② as it is applied to all the policies.

Discussion: fairness issue. Like all existing systems (and their policies), a malicious client can monopolize prefix cache by sending a large volume of requests with long identical prefixes, thus causing fairness issues. Ensuring fairness is an orthogonal topic to cache policy and can be addressed via a co-design of LLM serving strategies like FairRide [47, 52].

5 Related Work

Reuse KV$ across requests via KV$ cache. Reusing KV$ for accelerating LLM serving has been widely studied [30, 63, 19, 20, 69, 62] and used in commercial LLM serving [42, 21, 4, 1]. Currently, production systems only treat cache hits by prefix matches [63, 69, 19, 42, 21, 4, 1], because it preserves the original algorithm of model inference with no accuracy loss. A number of studies [20, 62, 23] have studied methods for non-prefix KV$ cache. We can revisit our characterization once they have matured and been deployed in production.

Other KV$-related optimizations. Emerging works[59, 68, 33, 13] propose runtime KV$ compression and deletion methods to reduce KV$ size. StreamingLLM [59] keeps only a finite attention window for recent tokens combined with a few initial tokens. H2O [68] only involves tokens that contribute most to the attention score for inference. InfiniGen [33] speculatively selects tokens critical for attention scores and drops others. KVQuant [22] enables 3-bit KV cache quantization with minimal perplexity degradation for large language models, achieving fast million-length context inference. These methods require fewer KV$ per-request, albeit with accuracy degradation. Our study is compatible with these works: if an uncompressed/full KV$ is reusable, a compressed or deleted version would also be reusable.

Optimizing caching policies. Optimizing caching has long been studied in the literature, in general-purpose caching policies [41, 29, 28, 53, 32, 25, 38, 71, 10, 24, 16, 11, 49, 67, 14] or specific domains [60, 12, 50, 17]. We continue this line of research, and leverage our characterized KV$ reuse properties for optimizing KV$ cache policies.

Optimizing LLM serving. We continue the line of research in optimizing the performance of LLM serving systems [70, 57, 31, 34, 64, 46, 18, 66], with a particular focus on characterizing serving workloads for KV$ cache. Our work is orthogonal to optimizations other than KV$ cache.

6 Conclusion

We present the first systematic and in-depth characterization of production serving workloads for KV$ cache systems. Our study reveals several important findings that were not captured by synthetic workloads used in previous studies. Based on these findings, we further propose a workload-aware cache eviction policy that improves upon existing workload-agnostic policies like LRU and LFU. We believe our work, as a starting point, can benefit both the research and industry fields in improving current and future LLM serving systems with a workload-driven approach.

Acknowledgment

We would like to thank ATC reviewers and our shepherd Lei Zhang for their insightful feedback. We sincerely thank Guanhu Wang for helping us with the collection of the trace data. We also thank Xiating Xie for proofreading our paper. We thank Xiangfan Wu for helping us correct the presentation about hashing the token IDs. Figure 29: *The evolution of cumulative distribution function of the reuse probability in 5 workdays. The first row: distributions from 9.00 a.m. to 10.00 a.m. The second row: distributions from 10.00 a.m. to 11.00 a.m.*

A Appendix

A.1 Trace results across different days

Figure 29 shows the evolution of cumulative distribution (CDF) function of the reuse probability for each request category in future time window over 5 continuous workdays. We can observe that the reuse probability at 9:00 a.m. to 10:00 a.m. similar between workdays. Therefore, we can analyze the reuse log of last day offline to predict the reuse probability of each category in the next day. However, it is noted that the reuse probability of "image" type is harder to predict than other categories, we infer that this is because image types have coarser reusability granularity compared to text types, and there exists greater variability among different users.

LogCrisp: Fast Aggregated Analysis on Large-scale Compressed Logs by Enabling Two-Phase Pattern Extraction and Vectorized Queries

Junyu Wei[†], Guangyan Zhang[†,*], Junchao Chen[†], Qi Zhou[§]
[†]*Tsinghua University,* [§]*Alibaba Cloud*

Abstract

Cloud providers generate logs at massive scales, often requiring dense compression using log patterns. Meanwhile, aggregated analysis on logs is essential for various applications. However, performing aggregated analysis on highly compressed logs presents two fundamental challenges: 1) it is hard to extract a set of log patterns that have both a global description and high filtering effectiveness; 2) executing full-text queries on numerically encoded data is challenging.

This paper proposes a two-phase pattern extraction paradigm. Such a paradigm decouples messages within patterns into Sketch (global pattern structure) and Specs (local fine-grained pattern specifications). The Sketch is extracted in an offline phase to provide a comprehensive global description, while the Specs are customized in the online phase to enhance pattern filtering effectiveness. Additionally, this paper proposes an efficient prefix/suffix vectorized query algorithm for numerically encoded data, which leverages AVX SIMD instructions to convert full-text queries into high-performance range/point queries.

We implement and integrate all these techniques into a system called LogCrisp, which is evaluated using nearly 7TB of logs from both production environments and public datasets. Experimental results show that LogCrisp achieves an order of magnitude lower analysis latency, 3.8× higher ingestion speed, and an almost identical compression ratio, compared with state-of-the-art works.

1 Introduction

Large cloud providers continuously generate system logs, which can accumulate to the PB scale per day [26, 29, 33, 35]. Cloud logs capture critical system information and user access records. To support error diagnosis, security attack detection, and user behavior profiling [7, 12, 14, 38, 39], it is common to perform aggregated analysis (e.g. counting, summation, getting max/min) on these logs.

*Corresponding author: gyzh@tsinghua.edu.cn

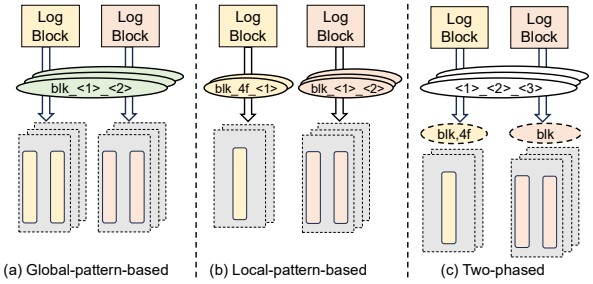

Figure 1: Comparison of different pattern extraction paradigms

In addition, since logs need to be retained for a relatively long time (say 180 days [35]) for audit purposes, existing log storage methods [17, 26, 29, 33–35] propose to compress logs densely using patterns within them. For example, in Hadoop logs, the chunk ID has the pattern of "blk_<hex,3>_<num,2>". During the ingestion process, each variable value (e.g. "blk_4ff_34") will be broken into a group of fragments (e.g. "4ff" and "34") according to the pattern. All fragments occurring at the same place will be encoded as a unit during the compression to achieve a high compression ratio. Patterns can also be used to filter out unrelated units during analysis. For example, when counting logs containing "blk_czf", there is no need to decompress any unit of chunk ID variable, since "czf" is not a three-character hexadecimal value.

However, performing aggregated analysis on highly compressed logs faces two fundamental challenges. The first is the dilemma between global description and filtering effectiveness of log patterns. Pattern-based log compression methods ingest logs as multiple log blocks and compress each block as a compressed file containing a set of units. They thus have a key design choice of extracting patterns. As shown in Figure 1, global-pattern-based methods [29, 35] extract or predefine a set of global patterns shared by all log blocks. On the other hand, local-pattern-based methods [17, 26, 33] extract a set

of patterns for each log block. In order to perform aggregated analysis on multiple log blocks, a global description of each fragment positions is needed. For example, to count how many chunks belong to "4f*" region, we need to perform a prefix query on the *first unit* of chunk ID variables according to the global pattern "blk_<hex,3>_<num,2>". However, global patterns are usually too general to describe the content of each unit precisely, and thus the query process needs to decompress more units because of the limited filtering effectiveness. According to previous work, the analysis latencies of global-pattern-based methods are usually longer than local-pattern-based methods by up to 10× [33].

We thus propose to **extract patterns in two phases** by decoupling messages within patterns clearly. We begin with an *off-line phase* that only extracts the minimum messages necessary to break variables into fragments. We call these messages as *Sketch*. For example, pattern "blk_<hex,3>_<num,2>" has the Sketch "<*>_<*>_<*>". Sketch contains the necessary global description for aggregation and leaves as many messages as possible to be customized for each log block. We then continue with an *on-line phase* when ingesting each log block. This phase extracts other messages of the pattern, such as the constant characters ("blk"), type messages ("hex", "num") and length messages ("3", "2"). We call these messages as *Spec*.

However, to enable two-phase pattern extraction, it is challenging to derive all fragment boundaries before extracting the whole pattern. We thus examine 11,954 fragment boundaries in all 3,259 local patterns extracted by the state-of-the-art method [33] and find over 98% of them are non-alphanumerical (NAU) characters. We thus choose to extract the Sketch according to all NAU characters heuristically. However, the opposite direction does not hold, namely some NAU characters may not be the boundaries and thus variable values originally correspond to the same local pattern may have multiple Sketches. To address this issue, a well-organized Sketch warehouse is maintained for each variable type, enabling efficient selection of the appropriate Sketch during data ingestion.

Besides, we further optimize the on-line ingestion speed by leveraging the total count of units according to the Sketch and generating Spec in a pre-allocated cacheline-aligned manner.

The second fundamental challenge in performing aggregated analysis on compressed logs is the dilemma between numerical encoding format and full-text query semantic. To execute arithmetical aggregation and improve the compression ratio, values in the unit that only contains numerical characters, which takes up 53% of all units, have to be encoded as integers. However, since logs are of text format originally, it is required to support full text queries on real-world logs, i.e. pre/suffix queries on some numerical variables [29, 33]. For example, it is a common practice to count how many chunks has a number starting with "3" (i.e., to query "blk_4FF_3*").

To overcome such a problem, we propose a **vectorized pre/suffix query algorithm** to execute pre/suffix queries directly on integer-encoded units with AVX SIMD instructions. Our key idea is to convert pre/suffix queries into range/point queries which are compatible to numerical encoding format. It is not hard to convert suffix queries since they correspond to querying specific modulo results for all target values. However, converting prefix queries to range queries is more complex, as the resulting range varies with each value. We prove that the corresponding range can be uniquely determined by a squeezing range whose endpoints are both powers of two. Based on this theorem, we: 1) calculate the squeezing range using vectorized shift operations; 2) determine the corresponding range for each value; 3) load each range with an AVX SIMD instruction of conditional blending [10]; 4) perform vectorized range queries accordingly.

Besides, to further reduce analysis latency, we use the AVX SIMD shuffle instruction [10] to construct the indexed bimtap [33], which records intermediate query results for subsequent aggregation and enables efficient merging across different units.

Finally, we implement and integrate all these techniques into a system called LogCrisp. We evaluate LogCrisp on 13 types of logs, nearly 7TB of data in total, including both production logs from our collaborator Alibaba Cloud and public logs used in previous works [18, 29, 33, 35]. We compare LogCrisp with the state-of-the-art works, i.e. CLP [29] and LogGrep [33]. We observe that LogCrisp achieves significantly lower aggregated analysis latency—15.32× and 4.65× faster than CLP and LogGrep, respectively. Additionally, LogCrisp improves ingestion speed by up to 3.8× over LogGrep, while maintaining a compression ratio comparable to CLP (about 1.1×) and LogGrep (about 96%).

The contributions of this paper are threefold:

- We propose a two-phase pattern extraction paradigm that delivers a global description for aggregated analysis while maintaining high filtering effectiveness.
- We propose a prefix/suffix query algorithm that, for the first time, enables vectorized aggregated analysis on highly compressed logs.
- We implement and evaluate LogCrisp, a compressed log storage system that outperforms state-of-the-art methods in analysis latency and ingestion speed.

2 Background and Related Work

Log storage systems target at a high compression ratio, a low analysis latency as well as a high ingestion speed. Table 1 shows four typical log storage systems as well as our work (called LogCrisp) in respect of their compression, ingestion and analysis performance. Besides, not all log storage systems have a global description of each variable, some systems thus can only perform keyword searching on logs.

	ZG [24]	ES [5]	CLP [29]	LG [33]	LC
Compression Ratio	Bad	Bad	Medium	Good	Good
Ingestion Speed	Good	Bad	Good	Medium	Good
Analysis Latency	Bad	Good	Medium	Good	Good
Global Description	No	Yes	Yes	No	Yes

Table 1: Summary of log storage systems. ZG, ES, LG and LC are the abbreviations for Zgrep, Elastic Search, LogGrep and LogCrisp respectively

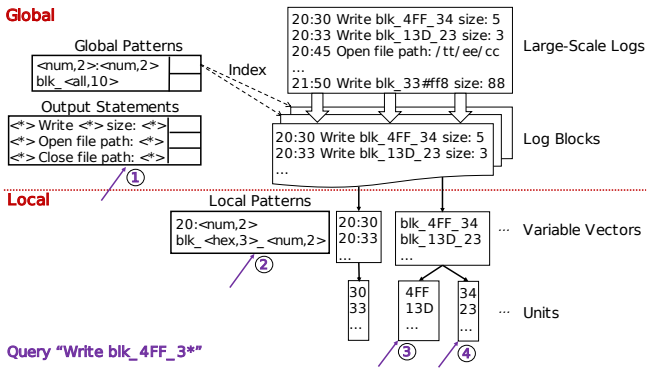

Figure 2: Conceptual diagram of pattern-based log storage

Due to the semi-structured characteristics of logs, pattern-based log storage methods [17, 26, 29, 33–35] are the most common solutions for log storage. Figure 2 shows the conceptual diagram of pattern-based log storage methods, which can be further categorized into global-pattern-based methods and local-pattern-based methods. Both of them need a log parsing process to extract output statements and log variables. In this section, we first introduce the log parsing process and then analyze these two types of pattern-based methods respectively. Finally, we discuss other works related with log storage.

2.1 Log Parsing

Since logs are generated by programs, each log entry can be parsed as an output statement and several variables. This parsing can be done by designating programming standard [6], analysis source code [8, 36] or using a log parser [11, 21]. For example, as shown in Figure 2, output statement *printf("%s Write block: %s with length: %d", time, blk, len)* will print many log entries, each containing three variable values, namely the timestamp, the block number and the write size.

Pattern-based log storage methods are all built based on such output statements and use them to extract log variables as well as locate the to-be-aggregated variables during the analysis. They regard all variable values occurring at the same place of the statement as belonging to the same variable and further extract a *pattern* for each variable to improve the compression ratio and accelerate the analysis.

2.2 Global-pattern-based Methods

Global-pattern-based methods extract or pre-define a global pattern for each variable, which is shared by all log blocks. This pattern is usually very general (e.g. "blk_<all,10>") since it has to describe variable values occurring at all log blocks.

CLP [29] is the state-of-the-art global-pattern-based method. During the ingestion process, CLP extracts variables based on the output statements and breaks them according to the pre-defined global pattern. Such process can be done alongside the ingestion process without any extra data copy. Then CLP reorganizes all fragments of each log entry as an encoded message. Finally, it compresses all encoded messages of the same log block together as a unit and constructs an inverted index to map the global pattern to the unit. During the analysis, it will first query on the output statements to locate to-be-aggregated variables and then query on the corresponding global patterns to decompress part of units based on the inverted index.

CLP achieves a relatively high compression ratio, a high ingestion speed as well as a global description of variables delivered by the global patterns. However, the analysis latency of CLP is sub-optimal in some scenarios [33] due to the limited filtering efficiency of global patterns. Besides, since CLP stores all fragments according to their original order, numerical fragments cannot be processed and aggregated with vectorized instructions.

2.3 Local-pattern-based Methods

Local-pattern-based methods propose to extract a local pattern for each variable within a log block. Compared with global pattern, such pattern will be more concrete and describe the content of each unit precisely (e.g. "blk_<hex,3>_<num,2>") since it only needs to describe variables within this block.

LogGrep [33] is the state-of-the-art local-pattern-based method. During the ingestion process, LogGrep first uses the output statement to extract all variables like CLP and then copies all variables of the same type into a variable vector. Afterward, LogGrep extracts a local pattern for each vector. Then it breaks each variable in the vector into fragments according to the local pattern and stores all fragments occurring at the same position within a unit. Finally, it compresses each unit individually. During the analysis process, LogGrep first locates to-be-aggregated variables like CLP (step ① in Figure 2) and filters units based on the local patterns (step ②). It then only decompresses and searches within a small part of units (step ③ and step ④).

LogGrep can partition log blocks into fine-grained units to achieve a low query latency without compromising the compression ratio. Such a design is also necessary to process numerical units with vectorized instructions together. However, due to the differences of local patterns, LogGrep does not have a global description. It thus can only support key-

word searching like Linux grep. Besides, when processing numerical units with vectorized instructions, full-text queries cannot be supported directly. LogGrep thus compromises to execute ordinary text query on numerical units. Thirdly, LogGrep's lack of prior knowledge about the patterns requires to execute full pattern extraction process for each log block. Consequently, LogGrep's ingestion speed is 2-5× slower than that of CLP.

2.4 Other Related Works

Except for CLP and LogGrep, there are still some related log storage methods. Besides, there are some works that can process directly on column-oriented storage in database or on compressed text data.

Log storage methods. Besides pattern-based methods, some other methods, such as Cowic [25] and LogArchive [16], are designed to compress log. They choose to compress by clustering similar logs together instead of breaking the variables and encoding similar fragments with tailored methods. As a result, their compression ratio is lower than pattern-based methods [35].

A common practice to execute aggregated analysis is using log management tools, such as ElasticSearch [5], Splunk [20], Scalyr [19] and Loki [22]. These tools can manage large-scale logs and are employed in production environments. However, they can not process compressed logs, which hinders them to achieve a low storage cost.

Processing directly on compressed data. Processing directly on compressed data includes two basic types: light-weight encoding methods [3, 15, 27, 28, 30, 31, 40, 41] and partial decompression methods [1, 2, 23, 29, 33] . Light-weight encoding methods do not combine with heavy byte-oriented compression method as its packing method, their compression ratios are lower than partial decompression methods [29, 33] and their supported operations are limited.

Pattern-based log storage methods can be categorized as partial decompression methods but they are different from other methods used in database [1, 2, 23] in respect that they are designed on compressed text logs. They thus need to support full-text queries on the original data.

3 Two-phase Pattern Extraction

A common global description shared by all log blocks can support aggregating fragments within the variable as well as improves the ingestion speed. However, to maintain the filtering effectiveness of patterns, local details for each log block are also needed.

We thus propose to decouple messages within the pattern and extract them in a two-phase manner. The primary challenge of this design is how to minimize the messages extracted globally so as to 1) ensure they are sufficient to describe each fragment's position; 2) maximize locally customized messages to enhance filtering effectiveness.

	Pattern Count	Boundary Count	NAU Boundary Rate
Hadoop	118	570	97.37%
HadoopL	97	358	99.16%
Hive	470	2117	98.87%
OpenStackC	170	850	100.00%
Spark	316	1416	99.44%
Thunderbird	1962	5691	98.84%
Windows	126	952	98.84%

Table 2: Proportion of non-alphanumerical boundaries

In this section, we first discuss the clear decoupling of messages within patterns and then present the two-phase pattern extraction paradigm. Additionally, we explore a cache-line-aware optimization based on this paradigm to further boost ingestion speed.

3.1 Pattern Message Decoupling

To locate and deliver a global description of fragments, we must at least know their boundaries. To investigate fragment boundary characteristics in local patterns, we extract 3,259 local patterns from 7 log types using LogGrep [33]. Among these patterns, which include 11,954 fragment boundaries in total, we find that over 98% of them are non-alphanumerical (NAU) characters, as shown in Table 2. This trend likely arises from two factors: 1) NAU characters often separate semantic components within log variables, making them natural boundaries; 2) State-of-the-art local-pattern extraction methods (e.g., [17, 26, 33, 35]) typically use NAU characters to split variables during pattern extraction.

Based on this observation, we define all NAU characters within a variable value as its Sketch. For example, in Figure 3, the value /pjhe/35/part-0009" has a Sketch /<*>/<*>/<*>-<*>". However, this observation is not bidirectional, namely not all NAU characters function as boundaries. Our method therefore extracts multiple Sketches for each variable type.

To overcome such problem, we organize all Sketches we found for a variable in a Sketch warehouse and represent each Sketch in a compactly: we calculate a 64-bit integer based on all NAU characters shown within the Sketch [32]. Such an integer serves as a fingerprint to merge common Sketches during the extraction as well as to determine the corresponding Sketch of an ingested variable value immediately. To accelerate such process, we build a hashing-based searching index on the Sketch warehouse.

3.2 Two-phase Extraction Paradigm

Pattern message decoupling enables simultaneous global description and local detail maintenance. We therefore propose to locate fragments using pre-extracted Sketches from an off-line phase and extract additional messages, referred to as

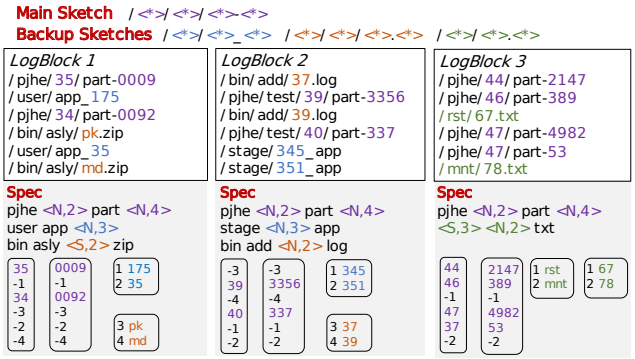

Figure 3: An example of pattern message decoupling

Specs, during ingestion. During analysis, units are filtered by combining both Sketch and Spec information.

Off-line phase. The extraction algorithm's pseudocode is detailed in Algorithm 1. First, we extract the Sketch from each value's NAU characters (line 5). We then merge identical Sketches to build the Sketch warehouse (line 6). The most common Sketch in the warehouse is designated as the main Sketch (line 8), with others classified as backup Sketches.

Algorithm 1 Sketch extraction algorithm

1: Variable value sample set $\mathbb{S}$
2: Main sketch Ψ
3: Sketch warehouse $\mathbb{B} = \emptyset$
4: **for all** s in $\mathbb{S}$ **do**
5: $\quad \mathcal{K} \leftarrow getSketch(s)$
6: $\quad \mathbb{B} \leftarrow \mathbb{B} \cap \mathcal{K}$
7: **end for**
8: Ψ = the most common sketch in $\mathbb{B}$
9: Output Ψ, $\mathbb{B}$

On-line phase. We extract other details, namely Specs, for each Sketch when ingesting logs during the online phase. After parsing variables with output statements, we first calculate the Sketch fingerprint of each incoming variable value based on all NAU characters in that value. We then search for this fingerprint in the corresponding Sketch warehouse. If a Sketch matches, we locate all fragments accordingly. If not, the incoming log entry is stored as an outlier.

We extract Specs in a piggybacked manner alongside ingestion after fragment location. Specifically: 1) (e.g., pjhe" in the Spec of LogBlock1" in Figure 3): We record the latest fragment and compare it with subsequent ingested fragments. If all fragments are constant by the end of ingestion, this value is treated as part of the pattern rather than creating a new unit. 2) for type messages (e.g., N" in <N,2>" in the Spec of LogBlock1" indicates 35" and "34" are numbers): We record type messages using a 6-bit vector [34], updating corresponding bits when new character types occur. 3) for length messages (e.g., 4" in <N,4>" in the Spec of LogBlock1" represents the maximum length of 0009" and "0092" as four): We track the maximum fragment length within a unit, updating it when a longer fragment is ingested.

Since each variable may have multiple Sketches, we store fragments of different Sketches in separate units. The main Sketch's units record the incoming order of variable values that conform to backup Sketches. Each value is assigned a number determined first by the global order of backup Sketches and then by its ingestion sequence. Each fragment unit of the main Sketch stores not only fragment values but also a placeholder. For positions corresponding to backup Sketch values, this placeholder holds the negative of the assigned number.

Used for filtering. During the analysis, if the to-be-aggregated fragment is designated, we directly execute aggregation on the corresponding unit in each log block. If the unit corresponds to constant characters, we return the constant value within the Spec rather than decompress units. If the to-be-aggregated fragment is not designated, we combine Specs in all log blocks with their corresponding Sketches to form patterns and then match the query keyword against these patterns to determine which unit to decompress, as shown in prior work [33]. If a fragment within the backup Sketches is designated or the keyword matches a variable value conforming to backup Sketches, we check one of the main Sketch units to determine its original incoming order based on the assigned number.

A concrete example. We provide an example of pattern decoupling in Figure 3. The variable from "LogBlock 1" includes six variable values, stored in four units: two for fragments in the main Sketch and two for backup Sketches. We also store placeholders for backup Sketch variables in the main Sketch's unit. In this example, the customization feature of Spec is demonstrated by: 1) *Selective Sketch Adoption*: Different log blocks can choose Sketches from the Sketch warehouse. For example, "LogBlock 3" has variable values conforming to the third backup Sketch, while the other two log blocks use values conforming to the first and second backup Sketches. 2) *Spec Variability Across Log Blocks*: Specs for the same Sketch differ in constant, type, and maximum length attributes across log blocks. For example, both "LogBlock 1" and "LogBlock 2" use the first and second backup Sketches, but their Specs are distinct.

3.3 Cache-friendly Ingestion Optimization

Based on two-phase extraction paradigm, pre-extracted Sketches offer position messages for fragments, allowing us to extract Specs in a pre-allocated and cache-friendly manner. We thus introduce two optimizations to further enhance the ingestion speed.

Cache-friendly position batching. During ingestion, pre-extracted Sketches locate fragments, but Specs are determined only at ingestion completion. Specs dictate compres-

sion strategies (e.g., units with constant fragments require no compression). Thus, we need to record fragment positions temporarily.

We represent each fragment position with a (offset, length) pair and batch positions for the same unit. Each batch is sized at 64 bytes (aligned with CPU cache lines), storing up to seven sequential position pairs and a 4-byte pointer to the next batch for the unit. This design enables the compressor to retrieve seven sequential positions for a unit in a single memory access by leveraging CPU cache locality.

Cache-friendly metadata maintaining. Each unit's metadata includes the head/tail of the position batch list, the latest ingested fragment, and type/length attributes for generating Specs. Prior approaches [33–35] use hash tables or tree-based indexes for metadata management, supporting dynamic unit insertion during ingestion.

By contrast, our method pre-allocates and stores metadata for all possible units (based on pre-extracted Sketches) in contiguous memory. This allows seamless, cache-friendly updates to all relevant metadata as each log entry is ingested.

4 Vectorized Query Processing

Pattern-based log storage methods break variables into fragments and group fragments into units. This design choice leads to a significant number of numerical units containing only numerical characters. Based on our statistics on 15,402 units from 7 log types [18], approximately 53% of units are numerical on average, accounting for about 60% of compressed space (exceeding 80% on some logs).

This observation motivates previous works to encode these units as integer vectors, aiming to improve compression ratios and enable efficient arithmetic aggregation. However, since logs are inherently in text format, performing pre/suffix queries on them is common practice—and such queries are naturally incompatible with integer-encoded units. Existing approaches either encode numerical units as plain strings [33] or convert integers back to numerical characters before pre/suffix queries [35].

We propose an efficient method to perform pre/suffix queries on integer-encoded units, fully leveraging the vectorization potential offered by numerical units. As evaluated in Section 6.2, this method is even more efficient than directly executing pre/suffix queries on plain strings. Additionally, we introduce a vectorized generation method for intermediate query results to further accelerate analysis.

4.1 Vectorized Processing of Pre/suffix Queries

Prefix queries. Our key idea is to transform prefix queries into multiple range queries. For example, checking if "502769" has a prefix of "502*" is equivalent to verifying whether it belongs to the range "[502000, 503000)". We term this range as the "*compared range*" of the encoded number. However, the key challenge is how to efficiently determine the correct compared range for each encoded number using vectorized operations.

We propose to calculate a "*squeezing range*" for each encoded number to derive its compared range. Given a parameter b (a power of 2), for any encoded number, there exists a unique integer m such that the range $[b^{m-1}, b^m)$ contains the number. We term this range as the "*squeezing range*" of the encoded number.

It can be proved as follow that when b is a power of two smaller than 10, each squeezing range $[b^{m-1}, b^m)$ contains at most one compared range:

Proof. Consider a positive integer a within a compared range. If its compared range is contained in a squeezing range $[b^{m-1}, b^m)$, then

$$a \in [b^{m-1}, b^m) \tag{1}$$

Multiplying a by 10 yields another compared range. If this new range were also contained in the same squeezing range, we would have.

$$10 * a \in [b^{m-1}, b^m) \tag{2}$$

For $b < 10$, Equations 1 and 2 cannot hold simultaneously. Thus, each squeezing range contains at most one compared range. □

Based on this theorem, we design our vectorized prefix query algorithm. The algorithm first performs SIMD right-shifting operations (*_mm256_srli_epi32*) on all encoded numbers, shifting them by log_2^b bits per step. A number is within the squeezing range $[b^{m-1}, b^m)$ if it becomes zero after m shifts. Using a conditional blending instruction (*_mm256_blendv_epi8*), we load the identified compared range (or [0, 0) if none is found) into corresponding slots of the SIMD register. After loading ranges for all numbers, SIMD comparison instructions check whether each encoded number falls within the queried range, determining if the prefix matches.

In the implementation, to avoid frequent loading of similar compared ranges into the registers, we use the 16 YMM registers [9] to keep all alternative compared ranges stored in the registers. We also maintain a map between squeezing ranges and compared ranges in a table. Additionally, the value of parameter b determines the total execution count of SIMD right-shifting operations. Since a larger b reduces the number of shifts, we choose $b = 8$, the largest power of 2 smaller than 10.

A concrete example is shown in Table 3. Here, we have four encoded numbers. By shifting each number until it becomes zero (after m shifts), we determine its squeezing range. Each squeezing range either contains no compared range (e.g.,"3307") or exactly one compared range. We load the corresponding range as the "*queried range*" and perform vectorized queries within it. Note that the queried range may differ

Encoded Number	Compared Range	Moves to Zero	Squeezing Range	Queried Range	Query Result
502769	[502000, 503000)	7 (>>21)	[262144, 2097152)	[502000, 503000)	Hit
246532	[502000, 503000)	6 (>>18)	[32768, 262144)	[50200, 50300)	Miss
3307	[5020, 5030)	4 (>>12)	[512, 4096)	[0,0)	Miss
45237	[50200, 50300)	6 (>>18)	[32768, 262144)	[50200, 50300)	Miss

Table 3: An example for vectorized prefix queries (query "502*" on integer-encoded units)

from the compared range if the number lacks the queried prefix (e.g., "246532"), but this does not impact the final result.

Suffix queries. Suffix queries are much simpler than prefix queries and only require determining whether the modulo result of an encoded number matches the queried suffix. For example, checking if "6927502" has a suffix of "*502" is equivalent to determining whether "6927502" modulo 1000 equals 502. Since the modulo number (e.g., 1000 in this example) remains constant for all encoded numbers, it is retained as an immediate value to accelerate calculations.

Our algorithm computes modulo results for all encoded numbers and performs vectorized point queries on these results. While the modulo operation itself is not vectorized, the algorithm matches the performance of executing suffix queries directly on plain strings. Vectorized optimization of suffix queries is reserved for future work.

Mask Code	Array Order	Description
00000000	0 1 2 3 4 5 6 7	Original order
00000001	7 0 1 2 3 4 5 6	Move 7 to the head
....	....	
01001101	1 4 5 7 0 2 3 6	Move 1, 4, 5 and 7 to the head in turn
....	....	
11111111	0 1 2 3 4 5 6 7	Original order

Table 4: The shuffle rule to construct index

4.2 Vectorized Construction of Intermediate Results

Since an aggregation can perform queries on multiple variables simultaneously, it needs to store intermediate query results so that subsequent queries can leverage previous results. We adopt the *Indexed Bitmap* proposed in prior work [34] to record intermediate results, consisting of a bitmap and an index array tracking all positions marked "1" in the bitmap. To further accelerate analysis, we propose a vectorized construction strategy for this structure using SIMD shuffle instructions.

A SIMD shuffle instruction takes a "Mask Code" and an original array as inputs; it then reorders elements in the array according to the mapping defined by the Mask Code in a shuffle matrix. In our case, the result bitmap serves as the Mask Code, and the original array contains 32-bit natural number sequences. A customized shuffle matrix is shown in Table 4, designed to move positions corresponding to "1" in the bitmap to the front of the array. For example, if the bitmap (Mask Code) is "01001101", indicating hits at the second, fifth, sixth, and eighth positions, the shuffle instruction moves indices "1", "4", "5", "7" to the front. The array order becomes "1 4 5 7 0 2 3 6", with the first four numbers forming a segment of the index array.

The vectorized construction process involves three steps: 1) Perform vectorized comparison operations on encoded data to generate a bitmap of search results using the scatter instruction (*_mm256_movemask_epi8*). 2) Using the bitmap and shuffle matrix, construct an index array segment via the shuffle instruction (*_mm256_permutevar8x32_epi32*). 3) Gather all segments to build the Indexed Bitmap using the gather instruction (*_mm256_storeu_si256*).

An example of this process is illustrated in Figure 4. The algorithm first performs a vectorized point check "(==2)" on 16-bit encoded data to obtain the corresponding bitmap. It then loads the natural number sequence and bitmap into the register, using the customized shuffle matrix to reorder elements. This process constructs an index fragment for every 8 numbers, with all indices corresponding to "1" in the bitmap gathered at the front. These indices are written back to form the Indexed Bitmap.

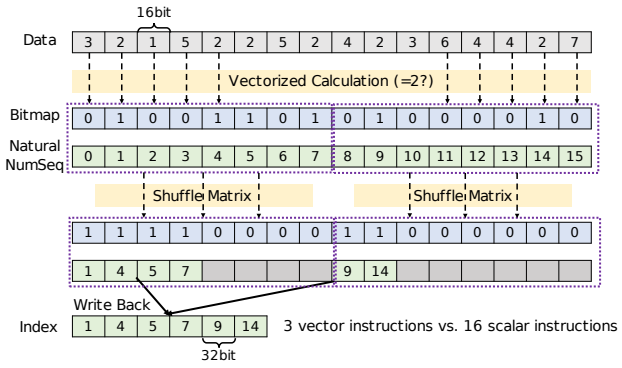

Figure 4: Vectorized construction of Indexed Bitmap

5 Implementation

By integrating all discussed techniques, we implement a log storage system named LogCrisp using approximately 15,000 lines of C++ code. LogCrisp simultaneously achieves high

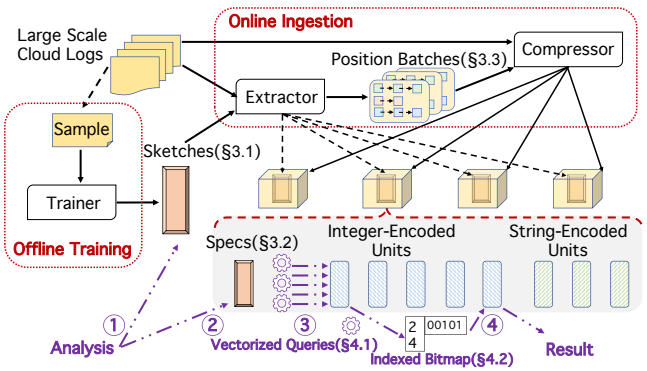

Figure 5: Overview of the LogCrisp system

compression ratios, fast ingestion speeds, and low analysis latency. Figure 5 presents an overview of LogCrisp. The workflow of LogCrisp can be summarized as follows:

Training. LogCrisp employs a *Trainer* to extract global information, including output statements and Sketches, from a log sample. It uses LogGrep's log parser to identify output statements. The specifics of Sketches are discussed in Section 3.1, and the extraction process is detailed in Section 3.2.

Compression. For each log block, LogCrisp uses an *Extractor* to: 1) Parse log variables based on output statements. 2) Locate fragments for encoding using pre-extracted Sketches. 3) Organize fragment positions into batches optimized for CPU cache lines (§3.3). Each compression stream corresponds to a batch group. The Extractor also extracts Specs for each variable type during ingestion (§3.2). A *Packer* then compresses fragments into units using zstd [13]: numerical units are encoded as integer vectors, while others use string vectors. Specs and compressed units are packaged into a zipped file.

Analysis. LogCrisp supports aggregated analysis on designated numerical units using query results from multiple units (e.g., `Count * where IP=xxx" and ERROR"`). Aggregation types include counting, summing, and min/max operations; query types include point, prefix/suffix, and range queries. LogCrisp supports: 1) Grep-like full-text queries, similar to prior works [29, 33, 34]; 2) Queries on specific units. Counting, point, and prefix/suffix queries work in both modes, while other aggregations and range queries require designated units.

The query process involves four steps: (1) Locate Variables: Match output statements to identify queried variables (like prior works [33]). (2) Filter Units (Steps ① and ②): Load zipped files and combine Sketches/Specs to filter relevant units (§3.2). (3) Execute Queries (Step ③): Perform vectorized queries on integer-encoded units and fixed-length queries on string-encoded units (§4.1). Store intermediate results in an Indexed Bitmap (§4.2). (4) Finalize Results(Step ④): Use the Indexed Bitmap to execute subsequent queries and generate final results.

6 Evaluation

We evaluate LogCrisp on a vast volume of logs and compare it with state-of-the-art works. Our evaluation answers the following questions:

- How does LogCrisp 's overall performance compare to state-of-the-art works? (§6.1)
- In LogCrisp, how much benefit does each key technology bring? (§6.2)
- How long is the training time of LogCrisp? How frequently must LogCrisp execute the training process? (§6.3)
- How does LogCrisp perform on different types of query strings? (§6.4)
- What percentage of query latency does each sub-operation in a single query account for? (§6.5)

The logs tested include three parts: 1) The four largest log types from the LogHub Dataset [18]; 2) All log types opened by the authors of CLP [37]; 3) Six types of real-world production logs collected from Alibaba Cloud. The total scale of these logs is nearly 7TB, with their names and sizes listed in Table 5.

We compare LogCrisp with two state-of-the-art methods, LogGrep and CLP:

- CLP [29]: the state-of-the-art global-pattern-based method, CLP is tested by running its open-source code [37] on all open logs. Due to our production environment using a self-developed OS incompatible with CLP, we exclude production log comparisons for CLP. Like LogCrisp, CLP uses zstd for packing.
- LogGrep [33]: the state-of-the-art local-pattern-based method, LogGrep is tested by running its open-source code [4] on both open and production logs. While LogGrep defaults to LZMA for packing, we changed it to zstd for fair comparison.

Since LogGrep does not support designating specific units, we standardize the comparison across all methods by testing counting analysis using grep-like full-text queries. We generated 22 query strings for production logs in collaboration with Alibaba Cloud engineers and 28 query strings for open logs to cover all execution paths of LogCrisp.

Before compression, a training process is required for each log type. For all open logs, sampling 1% of logs suffices to achieve over 99% Sketch matching rate. In practice, engineers can re-run the training when matching rates decline. Log ingestion uses a single thread for all logs except LogF (TB-scale), which employs 8-thread parallel ingestion with results normalized to a single thread.

Testbed. Experiments on open logs were conducted on a server with 2× Intel Xeon Silver 4210R (2.40GHz, 16 cores), 64GB RAM, and Ubuntu 11.3.0 kernel. Experiments on production logs used an Alibaba Cloud server with 2× Intel Xeon CPU E5-2682 v4 (2.50GHz, 32 cores), 188GB RAM, and a self-developed kernel based on Linux 3.10.0.

6.1 Overall Performance

We compare the overall analysis performance, ingestion speed, and compression ratio across all 13 log types. Detailed results are listed in Table 5. LogCrisp consistently optimizes analysis latency, compression ratio, and ingestion speed, outperforming CLP and LogGrep by 15.32× and 4.65× on average in analysis performance. It ingests logs 2.43× faster than LogGrep and achieves 95% of CLP's ingestion speed on average. Regarding compression ratio, LogCrisp matches 1.11× CLP and 96% of LogGrep's ratios on average.

Analysis latency. LogCrisp outperforms other systems in respect of aggregation analysis latency on all tested query strings on all datasets. We list the average analysis latency in the table.

To be concrete, on open datasets, the analysis latency of LogCrisp is 4.03× to 40.11× (average 15.32×) lower than that of CLP. We find LogCrisp outperforms CLP by 40.11× on average on Windows logs. This is because the inverted index on Windows is relatively simple since it does not have many variables. This is good news for compression ratio and ingestion speed but causes a high query latency by almost decompressing all compressed logs without any filtering. Compared with LogGrep, the analysis latency of LogCrisp is 4.30× to 10.90× (average 4.29×) lower. This is mainly because LogCrisp can achieve comparably high efficiency with the help of both Sketches and Specs and it can also achieve efficient vectorized queries on integer-encoded units. For example, LogCrisp can outperform LogGrep on Hadoop by 10.90×, since Hadoop includes many integer-encoded units, these units may cause a reduction on compression ratio, but can accelerate the analysis significantly by fully exploiting the vectorization technique.

As for the production logs, LogCrisp outperforms LogGrep by 2.50× to 7.27× (5.07× on average). Such result confirms the efficiency of LogCrisp to achieve fast aggregation analysis again.

To sum up, we find LogCrisp can outperform other compared systems and achieve significant performance gain in respect of analysis latency on both open and production logs.

Compression ratio. The compression ratio of LogCrisp is 89% and 95% of the highest compression ratio among three systems on average on LogHub dataset and CLP-opened dataset. LogGrep has the best compression ratio on these two datasets by 96% and 97% of the highest compression ratio on average.

We find LogCrisp achieves the highest compression ratio on HadoopL and Hive. Its compression ratio is comparable to LogGrep except Hadoop where LogGrep outperforms LogCrisp by 16%. The compression ratio of LogCrisp is higher than CLP on most logs except OpenStackC and Windows where CLP outperforms LogCrisp by 20% and 33% respectively. Our investigation reveals Hadoop includes many numerical values that are close to each other semantically, as a result, encoding them as strings has a lower storage overhead than encoding them as integers. OpenStackC includes many user-specific formats used by CLP. Windows includes few variables and many entries are in fact totally common, as a result, using global pattern is enough to achieve high compression ratio while more processing may incur extra overhead.

As for the production logs, the compression ratio of LogCrisp is comparable to LogGrep. The compression ratio of LogCrisp and LogGrep are 97% and 99% of the highest compression ratio on average respectively.

To sum up, introducing two-phase pattern extraction and encoding numerical units as integer vectors does not affect the compression ratio on most logs and the compression ratio of LogCrisp is comparable to other compatible systems on the tested logs.

Ingestion speed. The ingestion speed of LogCrisp is 91% and 95% of the highest ingestion speed on average on LogHub dataset and CLP-opened dataset respectively. CLP has the highest ingestion speed on these two datasets.

LogCrisp outperforms LogGrep on all logs significantly by up to 2.38×. LogCrisp outperforms CLP on 2 types of logs (Thunderbird, HadoopL) by up to 1.61×. These two logs has many output statements and variables, which incurs high overhead for CLP to build the inverted index. As for other logs, the ingestion speed of LogCrisp is within 99% of that of CLP on 2 types and lower than CLP on other 3 types by up to 79% (Windows). This is because many log entries in Windows are common, CLP does not need to build complex inverted index.

As for the production logs, the ingestion speed of LogCrisp is significantly higher than that of LogGrep by up to 3.72×.

To sum up, we find the ingestion speed of LogCrisp is comparable to or even outperforms global-pattern-based method, i.e. CLP, on most types of logs.

6.2 Individual Benefits of Proposed Techniques

We evaluate the impact of each proposed technique using all open logs in Table 5. The effectiveness of our vectorized algorithm correlates strongly with query type; we analyze its impact using representative Hadoop log queries: two point queries (Q1: "blk_1075557039_1816215", Q2: "134217728"), one prefix query (Q3: bytes: "1*"), one suffix query (Q4: "*28,"), and one range query (Q5: "bytes > 1342"). Similar trends are observed across other logs and queries.

	Source	Size (GB)	Compression Ratio			Ingestion Speed (MB/s)			Average Analysis Latency (s)		
			CLP	LogGrep	LogCrisp	CLP	LogGrep	LogCrisp	CLP	LogGrep	LogCrisp
Hadoop	LogHub	16.04	27.63	**33.48**	28.85	**97.16**	40.45	96.59	45.09	26.37	**2.42**

Table 5: Overall performance comparison. The best result across the three systems for each log type and metric is highlighted in bold.

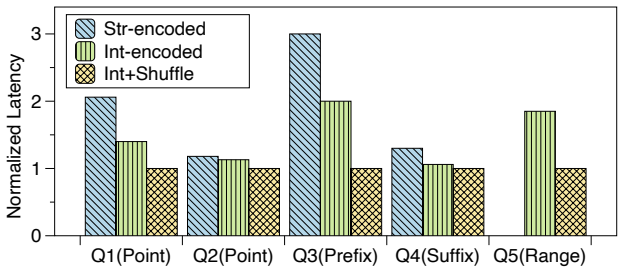

Figure 6: Impact of vectorized per/suffix queries and vectorized construction of indexed bitmap

Two-phase pattern extraction (§3.2). We implement a version called "LC-global" by only extracting a global pattern on our log sample. We use such pattern to ingest logs as well as filter units during the query. We test "LC-global" on all 7 open logs and plot the results of 6 types of logs in Figure 7. We do not put the result on HadoopL here since we do not observe significant impact of such technique, which is mainly because its patterns are relatively static on all log blocks and a single global pattern is enough to filter most units. However, on logs such as OpenStackC and Spark, global pattern will be too general to serve for filtering. After we decouple the Sketches and Specs within the pattern, we can eliminate the average analysis latency by 2.59× on average and up to 5.55× (Spark). Besides, two-phase pattern extraction can maintain or even improve (by up to 7%) the ingestion speed, since it can directly break the variables into fragments during the ingestion without complex pattern matching. It also has less effect on the compression, which only causes the compression ratio to drop by 9% on windows since it has a relatively large Sketch Warehouse. As a result, we need to record multiple assigned numbers for backup Sketches in the units of main Sketch.

Cache-friendly ingestion (§3.3). We implement a version called "LC-w/o-cache" by recording positions in a list and maintain metadata using a tree-based index like LogGrep. According to Figure 7, we find by introducing the cache-friendly design, we can improve the ingestion speed by 6% to 43% (19% on average). Such method will have a more significant improvement when each unit has many fragments such as on Spark and Thunderbird.

Vectorized pre/suffix queries (§4.1). We first encode all NUnits as plain strings and execute queries on them and mark this version as "Str-encoded". Then we change the encoding format of NUnit into integer vector, execute our proposed vectorized queries on them and mark this version as "Int-encoded". According to Figure 6, we find by encoding NUnits as integer vectors and exploiting vectorization on such format, we can reduce the latency of point and pre/suffix queries and support range queries additionally. Specifically, we can eliminate the latency of point queries, prefix queries, and suffix queries by 1.46×, 1.50×, and 1.22× respectively. The results on prefix and suffix queries demonstrate by exploiting vectorization properly, we can overcome the incompatibility between numerical encoding format and full-text queries semantic.

Vectorized construction of indexed bitmap (§4.2). We change the construction process of Indexed Bitmap in "Int-encoded" version to our proposed vectorized manner, and mark such version as "Int+Shuffle". According to Figure 6, we find the vectorized construction process of Indexed Bitmap can eliminate the latency by 1.4× for Q1, 2× for Q3 and 1.85× for Q5. We find these three queries have dense results, as a result, their construction processes of the Indexed Bitmap take up a significant part.

6.3 Analysis of Training Overhead

Since the training process to extract Sketches is crucial for delivering a global description in our design, we measure the training overhead in terms of the training time, miss rate as well as the training frequency.

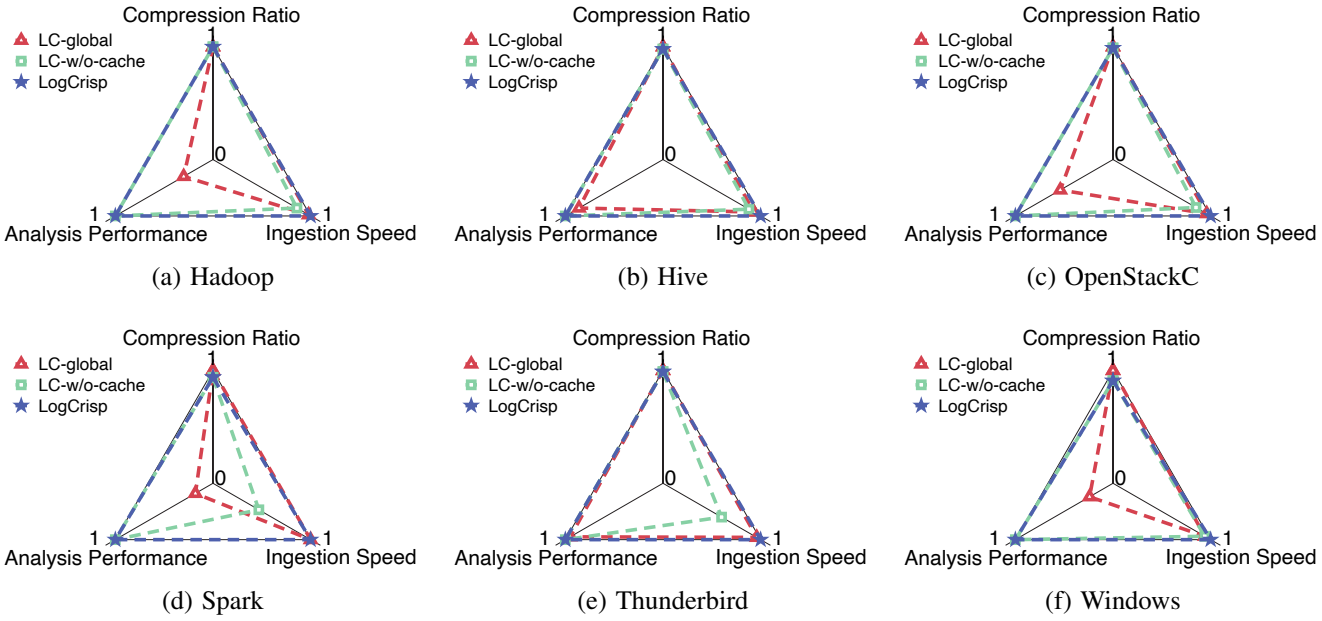

Figure 7: Impact of two-phase pattern extraction and cache-friendly ingestion (normalized to the best result in each dimension)

Training time. We evaluate the training time of different sample rates on an open log (Hadoop) as well as a production log (LogA). The results are shown in Figure 8. We find the training time of production log is relatively larger than that of open log due to the higher number of Sketches in production logs. Generally speaking, in our experiment (sampling 1% log), the relative training overhead, namely the training time divided by the compression time, is 10% (Hadoop) and 5.9% (LogA) respectively. The training overhead is higher on Hadoop since the compression time on Hadoop is shorter than that on LogA.

Miss rate. Miss rates for different sample rates on sampled logs are shown in Figure 8. Open logs exhibited higher sensitivity to sample rate than production logs. Given the sharp increase at 10% sampling, we chose 1% sample rate for experiments to balance training time and miss rate.

Training frequency. To evaluate training frequency, we sorted Hadoop and LogA logs by timestamp and split them into 64MB blocks. We trained on 1% of the first block and applied results to subsequent blocks, triggering retraining (with 1% sampling of all processed blocks) when miss rate exceeded 5%.

Figure 9 shows the miss rate per block and total training counts. For Hadoop (16GB total), we train for 3 times (5.3GB per training on average). For LogA (18GB total), we train for 6 times (3GB per training on average). We find the production logs change more frequently and thus the training process will be executed for more times.

6.4 Performance of Different Query Interfaces

We show the comparison between LogCrisp and other systems across different query interfaces. We evaluate 13 point queries, 7 prefix queries, 5 suffix queries and 3 range queries in total and plot their average analysis speed with maximum and minimum values as error bars in Figure 11.

For CLP, we find it performs better on point queries than prefix and suffix queries, which is due to the complex wildcard processing in CLP's algorithm. LogGrep exhibits nearly identical average performance across query types. As for LogCrisp, it performs better on point and range queries than those on prefix and suffix queries on average, since the integer-encoded units are more compatible with the former two types. But we find LogCrisp still outperforms LogGrep in prefix and suffix queries even though the string-encoded units used by LogGrep are compatible with such queries.

Besides, compared to other systems, LogCrisp exhibits a wider speed range. This is because compared to filtering using only global or local patterns, filtering with decoupled patterns varies more significantly for each queried string. Queried strings containing NAU characters can use the locating messages within Sketches to filter units while other strings can only rely on the Specs.

6.5 Breakdown of Query Latency

We plot a breakdown analysis of query latency for Q1-Q5 in Figure 10. We find for different queries, the Sketch loading and Spec loading latency remain the same. In practice, users

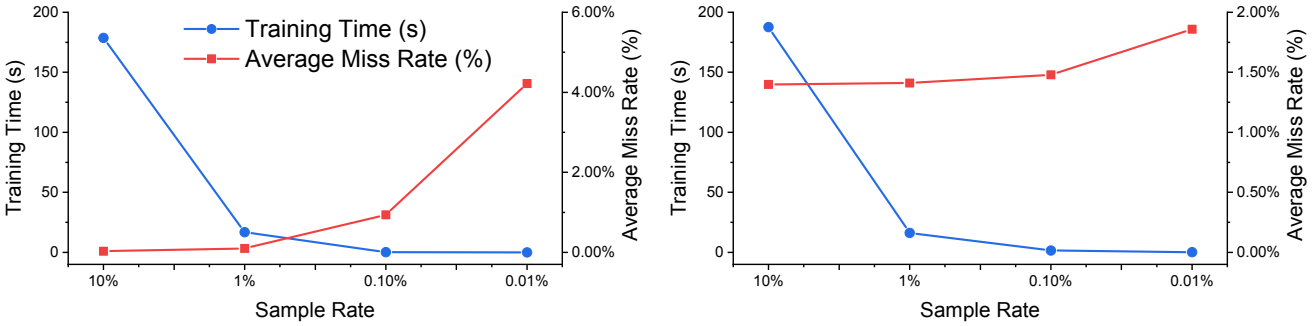

Figure 8: The training time and miss rate for different sample rate

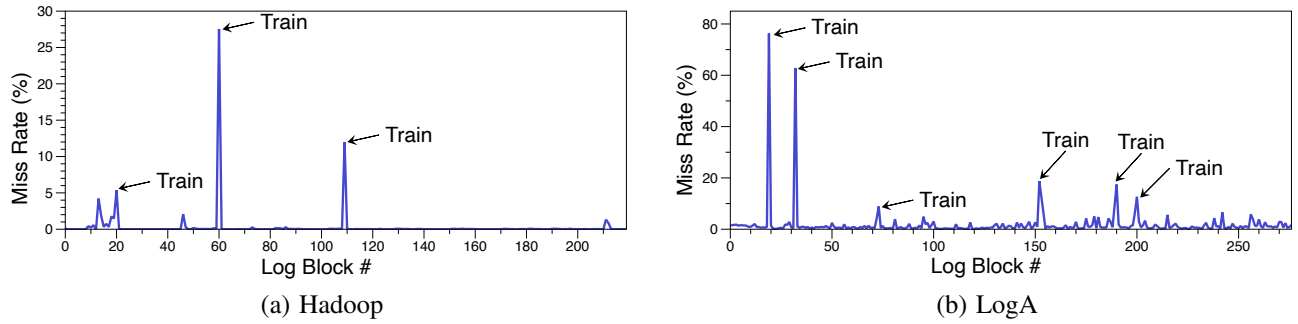

Figure 9: The miss rate on different blocks in the time series (showing the training frequency)

can load them once and execute multiple query strings based on them. We find the point queries and the suffix queries spend much time (0.84 - 1.12 seconds) to match on the patterns, as these queries need to match patterns across multiple log variables. The prefix queries and the range queries can directly find the related log variable based on the output statement and their matching latency is thus as low as only 0.03 seconds. We find the latency of the prefix queries and the range queries is much lower than that of the point queries and the suffix queries. This is because the point queries need to search within more units and the suffix queries need to calculate modulus result for each encoded number.

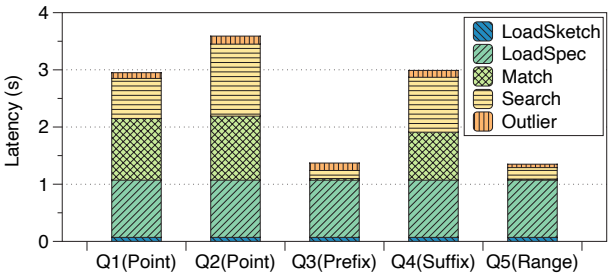

Figure 10: Query latency breakdown

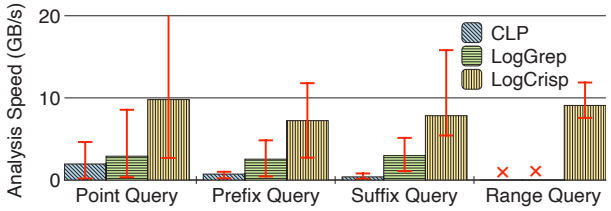

Figure 11: Query performance for different interfaces. CLP and LogGrep cannot support range query.

7 Conclusion

This paper presents LogCrisp, a log storage system designed to enable fast aggregated analysis on large-scale compressed logs. Our evaluation shows that by decoupling messages within log patterns, LogCrisp efficiently generates global descriptions while maintaining filtering effectiveness. The proposed paradigm enhances ingestion speed through hardware-optimized techniques (e.g., cache-line alignment). By leveraging vectorization properly, LogCrisp overcomes the semantic mismatch between numerical encoding and full-text queries, enabling vectorized queries on log data for the first time.

Abstract

Tiered storage architectures are promising to improve cost efficiency by combining small and fast storage with slower but cheaper mediums. However, existing designs of Log-Structured Merge-trees (LSM-trees) on tiered storage cannot simultaneously support efficient read and write accesses. Keeping the upper and lower LSM-tree levels in the fast and slow storage respectively (i.e., tiering) allows efficient writes to the fast disks, but read-hot data may be stuck in the slow disks. Putting all the levels in the slow storage and using the fast disks as a cache (i.e., caching) can handle frequently read data efficiently, but LSM-tree compactions now need to happen in the slow disks.

We present HotRAP, a key-value store based on RocksDB that follows the tiering approach above, but enhances it to timely promote hot records individually from slow to fast storage and keep them in fast storage while they are hot. HotRAP uses an on-disk data structure (a specially-made LSM-tree) to track the hotness of keys in a fine-grained manner, and leverages two pathways to ensure that hot records reach fast storage with short delays. Our experiments show that HotRAP outperforms state-of-the-art LSM-trees on tiered storage by up to 1.6× compared to the second best under read-write-balanced YCSB workloads with common access skew patterns, and up to 1.5× under Twitter production workloads.

1 Introduction

Log-Structured Merge-trees (LSM-trees) [20, 30] are widely adopted to build key-value stores [6, 12, 16, 19, 27, 36] and database storage engines [1, 2, 18, 22, 24] because of their superior write performance on traditional storage mediums. When the underlying storage architecture evolves, the design of LSM-trees also needs to adapt to new hardware characteristics. Specifically, with the recent trend of *tiered storage*, a small fast tier, e.g., local solid-state drives (SSDs), is combined with a slower but cheaper tier, e.g., hard disk drives (HDDs) or cloud storage, to achieve better cost efficiency. Optimizing LSM-trees for tiered storage thus becomes a practical and important topic to explore.

Table 1: Trade-offs on read and write performance among different LSM-tree designs on tiered storage.

	Tiering	Caching	HotRAP
Write-heavy	✓	✘	✓
Read-heavy	✘	✓	✓

Intuitively, there are two basic approaches to porting LSM-trees to tiered storage. Since LSM-trees naturally organize into multiple levels, the *tiering* design[1] locates their upper levels in the fast tier while storing the lower levels with the majority of the records in the slow tier [17, 26, 31, 33, 39, 43]. Alternatively, the *caching* design directly uses the fast tier as a *cache* of the slow tier, with the entire LSM-tree located in the latter [8, 9, 21, 28, 35]. However, neither approach is ideal, as summarized in Table 1. The tiering design is inherently efficient for write operations (i.e., inserts, updates) because the append-only nature of the LSM-tree keeps the most recent writes automatically in the fast tier. However, read-hot records have few ways to be promoted to the upper levels, and are left in the slow tier with high access latency, thus compromising the read performance. The caching design, in contrast, can effectively migrate frequently read records to the fast tier cache. However, compactions in the caching design all happen in the slow tier, which constrains system performance under write-heavy workloads. Moreover, writes to these records would need to be performed twice in both tiers to keep data consistency, leading to extra time and energy overheads.

While slow tier compactions and duplicated writes in the caching design seem fundamental and difficult to avoid, we believe it is possible to introduce additional promotion mechanisms in the tiering design to improve its read performance. Several prior solutions such as LogStore [26] and Mir-

*Corresponding author.

[1] Note that this is different from the tiering compaction policy.

rorKV [33] adjust the placement of blocks/SSTables across storage tiers periodically based on access frequencies. Nevertheless, these approaches still exhibit several key limitations. First, they cannot efficiently utilize the precious fast tier capacity because they move data at a coarse granularity, where many cold records in the identified hot blocks/SSTables are altogether piggybacked to the fast tier (**limitation 1**). Second, even if we directly reduce the granularity to record-level, the huge number of individual records would require excessive metadata information for hotness tracking, easily exceeding the limited memory capacity [40,41] and requiring efficient *in-storage* structures (**limitation 2**). Third, the above solutions can only promote hot data to the fast tier through LSM-tree compactions. To deal with read-heavy workloads where compactions happen infrequently, several systems [26, 31] allow triggering compactions proactively, but they must wait for the hot records to accumulate in the slow tier before promoting them. Such a delay harms read performance because it could overstep the time window when a record is hot (**limitation 3**).

In this paper, we present HotRAP (Hot record Retention And Promotion), an LSM-tree design specifically optimized for tiered storage. HotRAP can accurately identify hot records in the LSM-tree, promote them timely from the slow disk (abbr. as *SD* hereafter) to the fast disk (abbr. as *FD* hereafter) at a fine granularity, and retain them in FD as long as they stay hot. We design HotRAP based on RocksDB [14]. Figure 1 shows its big picture.

HotRAP addresses the aforementioned three limitations in the following ways. First, HotRAP supports hotness tracking and data promotion/retention at the *record level* rather than at the block/SSTable level, thus preventing cold records from being piggybacked to FD (addressing **limitation 1**). It logs each record access in a specifically designed structure, called *RALT* (Recent Access Lookup Table). RALT is essentially a small LSM-tree, located in FD instead of the memory (addressing **limitation 2**). We choose LSM-tree to implement RALT in order to benefit from its low write latency on disks because inserting access records into it is on the critical path. RALT tracks the access history for each logged key and maintains a hotness score for the key. RALT then evicts low-score keys periodically from itself to stay under a size limit that can be automatically tuned according to the workload.

Also, besides waiting for LSM-tree compactions to retain/promote hot records, HotRAP introduces a small in-memory *promotion buffer* to buffer records read from SD and timely promotes the hot ones (via checking RALT) by flushing them to the top of the data LSM-tree (addressing **limitation 3**). More specifically, HotRAP provides the following two pathways for hot records to reside in FD: hotness-aware compaction, and promotion by flush. First, during compactions from FD to SD, HotRAP extracts records within the compaction range from the mutable promotion buffer and adds them to the input of the compaction. Then HotRAP checks the hotness of each record in the compaction output by sequentially scanning the corresponding key range in RALT. Hot records are written to FD instead of down to SD. Consequently, hot records in FD are retained in FD, and hot records in SD are promoted to FD. We call this path *hotness-aware compaction*. Second, when the mutable promotion buffer grows too big due to insufficient compactions, we turn it into an immutable promotion buffer and trigger *promotion by flush* to bulk-insert the hot records in the immutable promotion buffer (also identified via consulting RALT) to L_0 of the LSM-tree. Thus we effectively restrict the size of the promotion buffer. To prevent promotion by flush from overwriting records with a newer version (i.e., promoting a stale record to L_0 that has a higher level than the newly updated version), we perform extra checks and carry out a concurrency control mechanism to guarantee correctness.

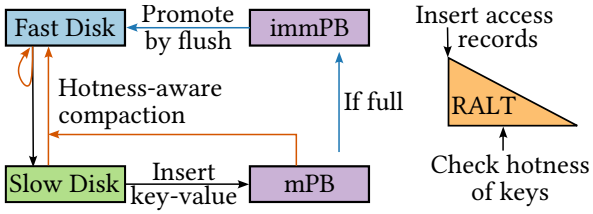

Figure 1: The high-level picture of HotRAP. RALT is a small LSM-tree in FD that tracks the hotness of keys. *mPB* and *immPB* stand for the mutable and immutable promotion buffers. Hot records are retained in FD during compactions. Records accessed in SD are inserted into the promotion buffer and then promoted by compaction or flush if they are hot.

We evaluate HotRAP using YCSB workloads and Twitter production traces [37] on AWS instances with fast local NVMe SSDs and slower cloud storage. We compare against the state-of-the-art LSM-trees on tiered storage, e.g., RocksDB using tiering/caching design, SAS-Cache [9] (caching design, based on RocksDB with secondary block cache [28]), and PrismDB [31] (tiering design, proactively triggering compactions). HotRAP achieves 5.2× speedup over the second best baseline with the tiering design for read-only YCSB workloads, 2.1× speedup with the caching design for write-heavy YCSB workloads, and 1.6× speedup over both designs for read-write-balanced YCSB workloads. HotRAP also achieves 1.5× speedup for Twitter production workloads. These results match the insights in Table 1. Our experiments also show that HotRAP adds $< 4\%$ overhead to the plain RocksDB under uniform workloads and is robust against hotspot shifts, where RALT quickly evicts stale access records and adds keys in the new hotspot into the hot set.

We make three primary contributions in this paper. First, we propose an on-disk data structure (i.e., RALT, a specially-made LSM-tree) for tracking the hotness of key-value records. It operates at the record level so that the system can efficiently utilize the limited space of FD. Second, we design two pathways in a tiered LSM-tree for timely promoting/retaining hot

records to/in FD. Finally, we implement HotRAP, a key-value store based on RocksDB that outperforms state-of-the-art LSM-trees on tiered storage because of its efficient hot record tracking and movement features. The code is available at https://github.com/hotrap/HotRAP.

2 Background & Related Work

2.1 Log-Structured Merge-tree (LSM-tree)

A Log-Structured Merge-tree (LSM-tree) consists of in-memory buffers (i.e., MemTables) and multiple levels $L_0, \ldots, L_n$ on disk. The capacity of level L_i is made T times larger than L_{i-1}, where T is the size ratio of the LSM-tree. Records are first inserted into the mutable MemTable. When it is full, it becomes immutable and then flushed to L_0 as an SSTable (i.e., a file format called Sorted String Table) in the background. When level L_{i-1} reaches its capacity, it will trigger the compaction process to merge its content into the next level L_i. There are typically two kinds of compaction policies: leveling and tiering. The leveling policy only allows one sorted run per level while the tiering policy allows multiple. This paper focuses on the leveling policy because it is RocksDB's default choice [27]. RocksDB also adopts partial compaction: each compaction picks an SSTables from L_{i-1} whose key range overlaps with a minimal number of SSTables in L_i to merge to the next level. Such a compaction strategy leads to a write amplification of $\approx \frac{nT}{2}$ [11].

A lookup first checks the MemTable and then searches the levels from top to bottom until a matching key is found. A block index in memory is used to determine which SSTable data block to search for a particular key in a sorted run. Per-SSTable Bloom filters are used to reduce the number of candidate SSTables to further save I/Os. RocksDB provides snapshot isolation via multi-version concurrency control (MVCC) to prevent compactions from blocking normal read operations. A snapshot in RocksDB, called a superversion, is created after a flush or compaction completes. An old snapshot is garbage collected when no active queries refer to it.

Although many LSM-trees such as RocksDB are initially designed for local SSDs, the multi-level nature of LSM-trees is a good fit for the tiering design. The upper levels contain the recently inserted and updated records and are therefore kept in the fast storage such as local SSDs because they are more likely to be accessed in the near future. To improve the system's cost efficiency, the majority of records in the lower levels are placed in HDDs [13, 14] or low-tier cloud storage based on HDDs [15]. HDDs exhibit higher latency than SSDs, but they are much cheaper. For example, the unit price for a 20TB Seagate Enterprise HDD Exos X20 today is 6.75× cheaper than a 7.68TB SAMSUNG Enterprise SSD PM9A3 [4, 5]. That means a tiered storage with a size ratio of 1:10 based on these hardware can reduce the storage cost by 77% compared to pure SSDs of the same capacity.

2.2 LSM-trees with the tiering design

LogStore [26] maintains histograms in memory to track the hotness of SSTables and retains/promotes hot SSTables in/to the faster storage. However, the granularity of SSTables is too coarse because there can be considerable cold data in the same SSTable that is considered hot.

MirrorKV [33] splits the LSM-tree into the key and value LSM-tree and caches the hottest key SSTables in the faster storage. Additionally, MirrorKV retains the hottest blocks (e.g., 10%) during compactions from L1 to L2. However, the granularity of blocks is still too coarse because small objects are prevalent in large-scale systems [25], and there can be many cold tiny records in a hot data block.

SA-LSM [43] accurately predicts cold data with survival analysis and demotes cold records from the faster storage to the slower storage. However, SA-LSM does not support promoting hot records back to the faster storage, and the training cost of the survival model is heavy.

PrismDB [31] estimates key popularity with the clock algorithm, and the clock bits are indexed with a hash table. Hot records are retained/promoted in/to the fast disk during compactions. However, the hash table can consume considerable memory. Also, the promotion speed of PrismDB is slow because it only promotes during compactions.

Although not an LSM-tree, 2-Tree [44] also uses tiered storage by maintaining two B-trees: one in memory for hot records and one on disk for cold records. However, it does not support tiered disk storage and the in-memory B-tree consumes huge memory.

2.3 LSM-trees with the caching design

Numerous prior studies aim to improve the performance of LSM-trees with in-memory caches [32, 34, 38, 42, 45]. However, the size of hot records can be far larger than the memory capacity. RocksDB, therefore, introduces the secondary cache on fast SSDs for data blocks not hot enough for the in-memory block cache [28]. SAS-Cache [9] further proposes several optimizations on the block cache, such as actively removing the cached blocks invalidated by compactions. However, the granularity of blocks is too coarse.

It is also a common practice to employ a separate key-value cache such as CacheLib [8] on top of the LSM-tree. However, the cache incurs extra disk I/O when updating, because it needs to update the key in both the cache and the LSM-tree. It is also challenging to ensure consistency between the cache and the LSM-tree. As a common problem of the caching design, write performance suffers because all compactions happen in the slow storage.

2.4 Memory footprint of hotness tracking

As discussed above, the granularity of SSTable/block is too coarse for retention and promotion. However, tracking the

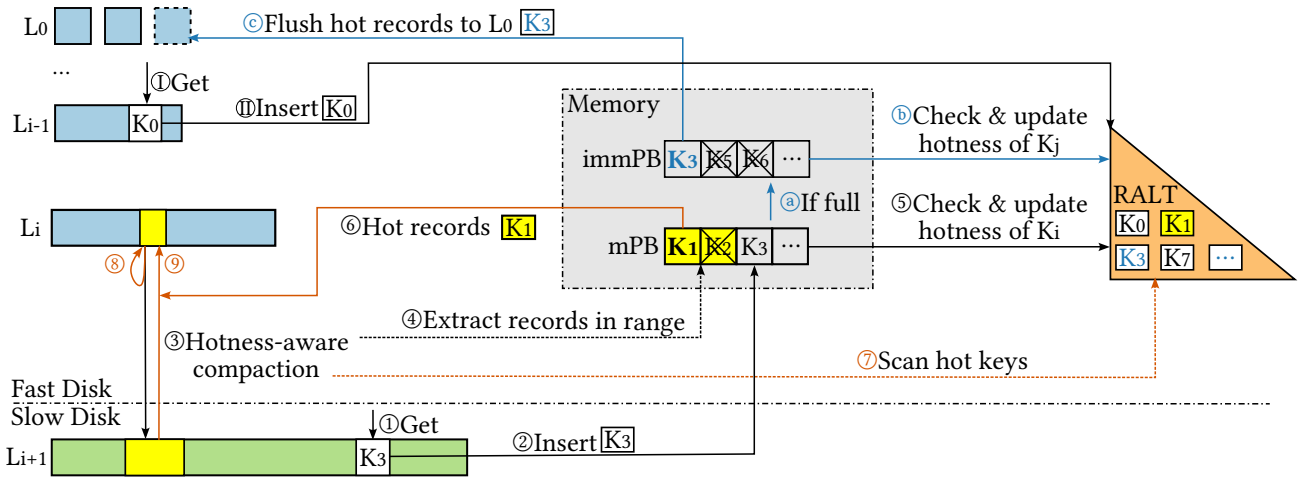

Figure 2: Overview of HotRAP. *mPB* and *immPB* stand for the mutable and immutable promotion buffers. Solid arrows are data flow. Dashed arrows are control flow. The accessed keys in SD are firstly inserted into the mutable promotion buffer (① to ②). A compaction can piggyback hot records in its range to FD (③ to ⑥). Hot records are retained in FD during compactions (⑦ to ⑧). If the mutable promotion buffer becomes full, hot records in it will be flushed to Level 0 (ⓐ to ⓒ).

access history of (potentially) hot records in memory can incur a large footprint. According to the Twitter trace [37], for example, 50% of the workloads have a value size smaller than 5× the key size. We take the AWS EC2 i4i.2xlarge instance for example, which is equipped with 64GB memory and an 1875GB local AWS Nitro SSD [3]. The configuration reflects the typical memory-disk ratio in the industry. If 1TB of its local SSD is used to store hot records, we need at least $1\text{TB}/(1+5) = 166.7\text{GB}$ memory to track those hot keys, which exceeds the physical memory of the instance.

3 Design & Implementation

3.1 Overview

The overview of HotRAP is shown in Figure 2. There are two components to facilitate retention and promotion: Recent Access Lookup Table (*RALT*) and the promotion buffer. RALT is responsible for tracking the hotness of records. It maintains a set of hot keys (without values) worth promoting and retaining. The promotion buffer consists of a mutable promotion buffer and a list of immutable promotion buffers. Records read from SD are inserted into the mutable promotion buffer. The mutable promotion buffer is turned into immutable when full. Immutable promotion buffers are flushed to disk in the background. The promotion buffers reside between the last level of FD and the first level of SD. To read a key, HotRAP first searches in MemTables and levels in FD, then in the mutable promotion buffer, and finally in levels in SD.

When a record in FD is accessed (①), its key will be inserted into RALT to record the access (Ⅱ). When a record in SD is accessed (①), HotRAP first inserts the key into the mutable promotion buffer (②), and the key's hotness information in RALT is updated later.

Hotness-aware compaction. During compactions from FD to SD (③), HotRAP extracts records within the compaction range from the mutable promotion buffer (④). For the example in Figure 2, K_1 and K_2 are extracted. HotRAP consults RALT about whether each key is hot, and updates the hotness score in RALT accordingly (⑤). Hot records (K_1) are added to the input of the compaction (⑥). Cold records (K_2) are dropped and future lookups to them would go to SD. Then HotRAP checks the hotness of each record in the compaction output, and writes hot ones to FD. It does so by constructing a RALT iterator in the compaction range. This iterator produces the hot records identified by RALT in the order of keys. Therefore, we can advance the compaction iterator and the RALT iterator in a sort-merge manner (⑦), to decide the records to be written into new SSTables in FD instead of SD. Consequently, hot records in FD are retained in FD (⑧), and hot records in SD are promoted to FD (⑨). The I/O incurred by the RALT iterator is small because RALT does not store values of HotRAP records. Compactions within SD are also hotness-aware: hot records are retained/promoted in/to the higher level in SD. Unlike the compactions from FD to SD, no records are extracted from the mutable promotion buffer.

Promotion by flush. For read-heavy workloads, there may not be enough compactions, and hotness-aware compaction alone may not effectively limit the size of the mutable promotion buffer. Therefore, when the size of the mutable promotion buffer grows to the target size of SSTables (64MiB by default), HotRAP converts it to an immutable promotion buffer, and a new mutable promotion buffer will be created (ⓐ). For the example in Figure 2, K_1 and K_2 have been handled by hotness-aware compaction. Therefore, only $K_3, K_5, \ldots$ are packed into an immutable promotion buffer. The immutable promotion

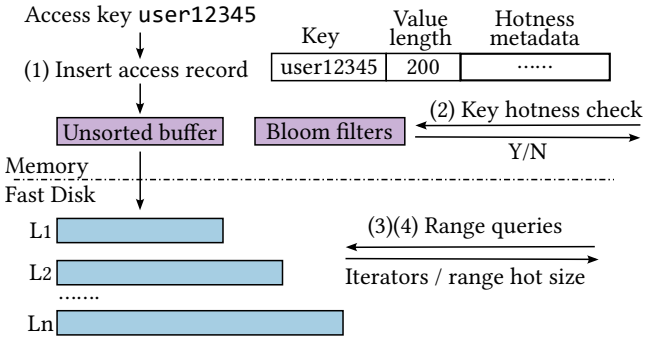

Figure 3: RALT structure. Suppose key `user12345`, whose value length is 200B, is accessed in HotRAP and an access record is inserted to RALT. The figure shows the RALT access record format, as well as the four supported operations (1) to (4). The HotRAP size is len(`user12345`) + 200 = 209 bytes. The physical size is $(9+4)+4+8=25$ bytes, where we use 4 bytes each for the length of the key and value, and 8 bytes for the hotness metadata used by our eviction policy.

buffer consults RALT whether the records are hot (ⓑ). Hot records (K_3) will be flushed to L_0 in FD (ⓒ), while cold records (K_5, K_6) are dropped. To avoid creating tiny SSTables in L_0 which will trigger compactions from L_0 to L_1 prematurely, if the total size of hot records is less than half of the target SSTable size, we insert them back into the mutable promotion buffer instead of flushing to L_0. The original records promoted by flush will remain in SD. Hotness-aware compaction can promote these duplicates to FD and merge them with previously promoted records, thus reducing disk usage.

This section is organized as follows. We first introduce RALT (§3.2, §3.3) and analyze its cost (§3.4). Then we detail the implementation of promotion by flush and its correctness (§3.5, §3.6). Next, we examine the influence of hotness-aware compaction on the benefit-cost scores (§3.7) and write amplification (§3.8). Finally, we analyze the relationship between the promotion buffer and the block cache (§3.9).

3.2 Recent Access Lookup Table (RALT)

RALT is a lightweight LSM-tree on FD, logging the accesses to records in HotRAP. Its structure is shown in Figure 3. Each access record in RALT consists of the key, the length of the value (instead of the value itself), and the scoring metadata tick and score. Keys are considered hot if their scores are greater than a threshold. We distinguish the size of the original key-value record in HotRAP (called the *HotRAP size*) and the size of the RALT access record itself (called the *physical size*). The total HotRAP size of hot records is called the *hot set size*. RALT has two parameters: the *hot set size limit* and the *physical size limit*, which constrain the total size of hot records and the disk usage of RALT itself, respectively. We set their values based on workload characteristics in §3.3.

RALT supports four operations, as shown in Figure 3:

(1) Inserting access records. When HotRAP inserts an access record into RALT, it first goes into an in-memory unsorted buffer. We use an unsorted buffer to improve performance because a sorted memory table does not benefit much: if a key is accessed again while its last access record is still in the buffer, it should be super hot and promoted very fast. When the unsorted buffer becomes full, it is sorted and flushed to FD. There are several levels on FD, following the leveling compaction policy. To avoid blocking reads, RALT maintains multiple versions of the LSM-tree structure.

(2) Checking the hotness of a key. Reading keys from SSTables is expensive. So for each SSTable, RALT stores bloom filters in memory that contain hot keys (keys with scores higher than the threshold). When checking whether a key is hot, RALT checks the bloom filters at each level and returns true if any bloom filter gives a positive result. We use 14-bit bloom filters to achieve a low overall false positive rate ($\ll 1\%$). The small number of false positives does not affect performance. Thus we do not perform a second verification.

(3) Scanning hot keys in a range. During hotness-aware compactions, HotRAP scans hot keys within the compaction range. To achieve this, RALT builds iterators for each level, similar to other LSM-trees. These iterators, which produce hot keys for their respective levels, are then merged into a single iterator that is returned to HotRAP.

(4) Calculating the hot set size in a range. RALT needs to calculate the hot set size in a given range, for HotRAP to select which SSTable to compact (details in §3.7). Similar to a normal LSM-tree, we have data blocks and index blocks for SSTables. For each data block, its first key and the sum of the HotRAP size of hot keys in all previous data blocks are added to the index block. For a range query, at each level, we read the two edge index blocks and calculate the difference of their stored sums, to obtain the total HotRAP size of hot keys in the range. The results of all levels are summed up and returned, as an estimation of the hot set size in the range.

The above result is slightly overestimated because of two error sources. First, the total HotRAP size of hot keys in the one or two edge data blocks is small, so we choose to tolerate the error and not read them. Second, there may be duplicate keys in different levels. If the number of levels is small and the size ratio between levels is large, we can expect the overestimation rate to be small. For example, if the size ratio is 10, the result in the second largest level may be about $1/10$ of the result in the largest level on average. So the overestimation is only about 10%. §3.7 discusses how we handle such overestimation in HotRAP.

3.3 Auto-tuning RALT size limits

In §3.2, RALT takes two parameters: the hot set size limit and the physical size limit, to constrain the total size of hot records and the space of RALT itself, respectively. However,

Algorithm 1 Algorithm for auto-tuning size limits

```
1:  Let the set of tracked keys T ← ∅
2:  for each access k_i do
3:      c_{k_i} ← c_max
4:      if k_i ∉ T then
5:          T ← T ∪ {k_i}
6:          t_{k_i} ← 0
7:      else
8:          t_{k_i} ← 1
9:      end if
10:     if accessed data amount reaches R then
11:         forall k_i ∈ T do c_{k_i} ← max(c_{k_i} − 1, 0)
12:     end if
13:     if hot set size limit or physical size limit is exceeded then
14:         Evict unstable keys with low scores
15:         If not enough, evict stable keys with low scores
16:         % Update size limits.
17:         t ← HotRAP size of stable records
18:         p ← Physical size of stable records
19:         r ← Average ratio between physical and HotRAP size
20:         Hot set size limit ← min(t + D_hs, R_hs)
21:         Physical size limit ← p + rD_hs
22:     end if
23: end for
```

the hot set size is determined by the distribution of the workload, which is usually unknown to the user and may further dynamically vary over time. Therefore, an automatic tuning approach for these size limits is necessary.

We define a key as hot if the expected amount of data accessed (in terms of HotRAP size) between two accesses to the key is below a threshold R. We aim to automatically adjust the hot set size limit and the physical size limit so that hot keys are identified as hot with a high probability. Our algorithm is outlined in Algorithm 1.

We maintain a counter c and a tag t in each RALT access record. Records are deemed *stable* if $c > 0$ and $t = 1$, and *unstable* otherwise. Accessing a key sets $c = c_{\max}$ (Line 3). The first access sets $t = 0$ (Line 5 to 6). A hit on an existing key sets $t = 1$, making the key stable (Line 8). We lazily update counters and tags during compactions. Every time the amount of data accessed (in terms of HotRAP size) reaches R, we decrease all counters by 1, eventually making cold records no longer stable (Line 11). The maximum counter value $c_{\max}$ ensures that keys not reaccessed can be evicted after accessing at most $c_{\max} \cdot R$ data.

When the hot set size or physical size exceeds the limit, RALT evicts 10% of access records, and all access records are merged into a single sorted run. 10% is a good trade-off between the I/O cost and the stability of HotRAP's hit rate. We maintain a score for each access record with exponential smoothing [23]. During evictions, we first evict unstable records with low scores (Line 14). If the size is still too large, stable records with low scores will also be evicted (Line 15).

After each eviction, we update the two limits (Lines 17 to 21). R_{hs} is the upper bound of the hot set size to cap the write amplification of retention. We set $R_{hs} = 0.85 \times$ last level size in FD, allowing a maximum additional SD write amplification of about 3.3 as analyzed in §3.8. D_{hs} is the maximum HotRAP size of unstable records. Essentially, we set the new size limit (HotRAP size at Line 20, or physical size at Line 21) to be the size of stable records plus the maximum size of unstable records, subject to constraints of R_{hs}.

Analysis. Our algorithm ensures that if we set D_{hs} and c_{max} properly and accesses are identically distributed and independent, then almost all hot keys will become stable, while the size of stable cold keys is bounded. We have formally proved these properties, but we omit the proof due to the space limit. Intuitively, because of the tag t, we need to access an originally untracked key at least two times with less than D_{hs} other data accessed in between, to make it stable. Suppose each key k has an access probability of p_k. While the difference between $\sum_{k \text{ is hot}} p_k$ and $\sum_{k \text{ is cold}} p_k$ may not be large enough due to the very large number of cold keys, the difference between $\sum_{k \text{ is hot}} p_k^2$ and $\sum_{k \text{ is cold}} p_k^2$ is typically large enough to separate them apart.

We set $R =$ FD size, $D_{hs} = 0.05 \times R$, $c_{max} = 5$. With these parameters, the probability that keys with access probability $> \frac{1}{0.5 \times \text{FD size}}$ become stable is $\approx 99.8\%$. The HotRAP size of cold keys with access probability $< \frac{1}{6 \times \text{FD size}}$ is smaller than $0.1 \times$ FD size. Therefore, these parameters should work well under most workloads. The experiments are shown in §4.6.

3.4 Cost analysis of RALT

Disk and memory usage. Suppose the HotRAP record size is 200B, and the key length is 24B with 5% hot keys. The disk usage of RALT is about $5\% \times (24+16)/200 = 1\%$ of the data size. Bloom filters and index blocks are cached in memory so that checking key hotness and calculating range hot size do not incur random disk I/O. The memory usage of the bloom filters in RALT is $5\% \times 14/8/200 = 0.0438\%$ of the data size. An index block record is less than 40B, and a data block in RALT is 16KiB. Therefore, the memory usage of the index blocks is $5\% \times 40/16/1024 = 0.0122\%$ of the data size. In total, the memory usage is only 0.056% of the data size. By storing RALT on disk instead of in memory, we can save $1 - 0.056\%/1\% \approx 95\%$ of memory.

I/O cost. Suppose RALT has N_L levels, and the size ratio is T. Since we evict 10% of data each time, the total write amplification is $\frac{T}{2}N_L + \frac{1}{10\%}$. The total read amplification is $\frac{T}{2}N_L + \frac{2}{10\%}$ because we need two full scans to calculate the score threshold. In our experiments in §4.4, $T = 10, N_L \approx 2$, the read amplification is about 30 and the write amplification is about 20. The experiment results show that RALT only accounts for 5.2%–9.7% of the total I/O, because a RALT record does not contain the value in a HotRAP record, therefore the total I/O of RALT is small compared to HotRAP.

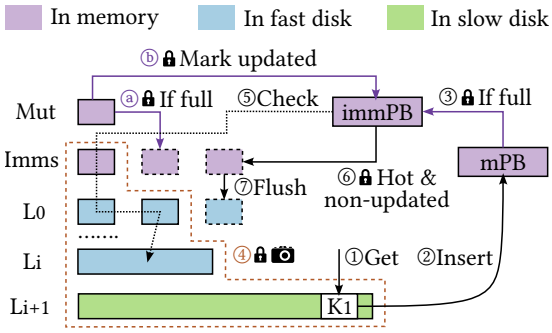

Figure 4: Concurrency control of promotion by flush. Processes with lock icons are protected by the DB mutex lock. ⑤ ensures that no newer versions exist in the snapshot of the LSM-tree. ⓐ and ⓑ mark all updated keys in immutable promotion buffers. Records with updated keys are excluded in ⑥. The snapshot is taken (④) after the creation of the immutable promotion buffer (③), therefore, a key updated before ⑥ is either found out by ⑤ or by ⓐ and ⓑ.

3.5 Checks before promotion buffer insertion

The promotion buffer resides between FD and SD. Therefore, before promoting a record into the promotion buffer, it is crucial to verify the absence of a newer version of this record in SD, which would otherwise be shielded by the inserted older record in the promotion buffer. For a point read that wants to insert the latest version just retrieved from SD into the promotion buffer, it is known that no newer version exists in the same superversion (i.e., the LSM-tree's snapshot). However, it is still possible that a newer version of the record is compacted into SD before the previous record has finished being inserted into the promotion buffer.

To address this issue, HotRAP marks SSTables as being or having been compacted when setting up compaction jobs. When searching for the value of a key in SD levels, SD SSTables whose range contains the key are recorded. Before inserting the key-value pair into the promotion buffer, HotRAP checks if any of the recorded SSTables is being or has been compacted. If there is, HotRAP aborts the insertion. The abort rate is low because of the small number of compaction jobs. Our experiments show that this check only aborts less than 1% of insertions into the promotion buffer.

3.6 Concurrency control of promotion by flush

Now we discuss the details of promotion by flush in Figure 4. As mentioned before, a read to SD record (①) inserts it to the mutable promotion buffer (②), which may be later made immutable when full (③). At this point, a snapshot is taken by incrementing the reference count of the caller's superversion (④). We pass the immutable promotion buffer's reference and the superversion's reference to a background thread called *Checker*, which handles the rest part. This minimizes the impact on foreground reads. *Checker* then picks out hot records in the immutable promotion buffer by consulting RALT. These hot records are candidates to be flushed to L_0.

Proper concurrency control is needed to avoid the issue that flushing a hot record to L_0 may shield a newer version of this key in the FD levels. *Checker* looks for newer versions of the hot records in the snapshot's immutable MemTables and the levels in FD (⑤). *Checker* only checks bloom filters for levels in FD for speed. The key is marked updated[2] if any filter returns a positive result. Hot records without possible newer versions are packed into a new immutable MemTable (⑥)[3]. Those records will eventually be flushed into L_0 (⑦).

However, there is still a corner case: newer versions can be flushed into L_0 in the normal access path when HotRAP is looking for newer versions during step ⑤. To address this issue, when a mutable MemTable becomes immutable during normal accesses (ⓐ), for every record in it, HotRAP checks whether the same key exists in immutable promotion buffers. If so, HotRAP marks the key as updated[2] (ⓑ), and the record will not be packed into the immutable MemTable at step ⑥.

We create immutable promotion buffers with the DB mutex (the only major lock in RocksDB) held at step ③. Since flushes are protected by the DB mutex, there are only two possible cases and both are correct: (1) An immutable MemTable is created before an immutable promotion buffer is created. The newer versions of records in the immutable MemTable will be detected by the check of ⑤. (2) An immutable promotion buffer is created before an immutable MemTable is created. The newer versions of records in the immutable MemTable will be marked updated by ⓐ and ⓑ.

3.7 Cost-benefit analysis of compaction

RocksDB calculates a score for each SSTable and picks the one with the highest score to compact into the next level. By default, the score is defined as $FileSize/OverlappingBytes$, where *OverlappingBytes* represents the total size of the target level's SSTables whose key ranges overlap with the picked SSTable. This is essentially a cost-benefit trade-off score: *FileSize* is the benefit, and $(FileSize + OverlappingBytes)$ is the cost, in which *FileSize* is optimized out.

However, the cost-benefit score needs some adjustment to better support HotRAP. During a cross-tier compaction from FD to SD in HotRAP, hot records in the chosen SSTable will be retained in the source level. Therefore, the benefit becomes (*FileSize* - *HotSize*), and the cost is still (*FileSize* + *OverlappingBytes*). Their ratio is the new cost-benefit score.

HotRAP estimates the HotSize of an SSTable by querying RALT about the hot set size in the corresponding range (§3.2). Recall that the obtained HotSize is an overestimation.

[2] By inserting the key into the *updated* field attached to the immutable promotion buffer.

[3] Or inserted back into the mutable promotion buffer if there are too few of them.

Therefore, it is possible, although very unlikely, that all benefit values are zero. In such cases, HotRAP falls back to choosing the oldest SSTable for compaction.

3.8 Write amplification of retention

Suppose the fraction of cold data in the last level of FD is p. Since each compaction from FD to SD only compacts p of the selected data to SD and writes the remaining $(1-p)$ of data back to FD, $\frac{1}{p}\times$ more compactions are needed to compact the same amount of data. Therefore, suppose the size ratio of the LSM-tree is T, FD and SD respectively have n_{FD} and n_{SD} levels, the write amplification in FD is $\frac{T}{2}n_{FD}+\frac{1-p}{p}$ and the write amplification in SD is $\frac{T}{2p}+\frac{T}{2}(n_{SD}-1)$, which are $\frac{1-p}{p}$ and $\frac{T}{2p}-\frac{T}{2}$ larger than a normal LSM-tree, respectively.

Write amplification can be lowered by tuning the level size ratios. Specifically, we can shrink the first level of SD to make the size ratio between the last level of FD and the first level of SD be pT. To keep the size of the LSM-tree in SD unchanged, we can add an extra level after the last level with a size ratio of $\frac{1}{p}$. The size ratio between other levels in SD remains T. In this way, the write amplification in SD is $\frac{T}{2}n_{SD}+\frac{1}{2p}$, which is only $\frac{1}{2p}$ larger than a normal LSM-tree.

3.9 The promotion buffer and block cache

The promotion buffer and the block cache complement each other. When a record is in the promotion buffer, its readers are served by the promotion buffer. After being flushed into FD, its readers are served by the block cache. Therefore, the promotion buffer serves reads to SD, while the block cache mainly serves reads to FD. Our design is orthogonal to Leaper [38] and Range Cache [32], i.e., their optimization techniques can also be applied to HotRAP, and by promoting hot records to FD with our techniques, records evicted from their cache will be read from FD instead of SD.

The main function of the promotion buffer is to batch records from SD before flushing them to L0, to avoid many tiny SSTables in L0. Serving readers is only the secondary function of the promotion buffer to avoid accessing SD when the record is already in the promotion buffer but must wait for more records to be batch-flushed into FD. Therefore, we fix its size to the target size of SSTables (64MiB by default). As a result, the promotion buffer contributes less to the hit rate when the hotspot is larger. However, we do not need to increase the promotion buffer size for a larger hotspot (either due to higher hotspot percentage or larger dataset), because the record's readers will be served by the larger block cache after it is flushed to FD.

Table 2: Disk performance on our EC2 instances.

	Fast Disk	Slow Disk
Type	AWS Nitro SSD	gp3
16 threads rand 16K read IOPS	≈83000	10000 [4]
Sequential read bandwidth	≈1.4GiB/s	300MiB/s[4]
Sequential write bandwidth	≈1.1GiB/s	300MiB/s[4]

Table 3: Read-write ratios of YCSB workloads in our tests.

Notation	Meaning	Read-write ratio
RO	read-only	100% read
RW	read-write	75% read, 25% insert
WH	write-heavy	50% read, 50% insert
UH	update-heavy	50% read, 50% update

4 Evaluation

4.1 Experimental setup

Testbed. We evaluate HotRAP on AWS EC2 i4i.2xlarge instances running Debian 12. Each instance has 8 vCPU cores, 64GiB memory, and a 1875GB local AWS Nitro SSD. We use local SSDs as FD and gp3 as SD. Their performance characteristics are shown in Table 2.

Sizes of tiers. We set the space ratio between tiers to 10: the initial expected used size of SD and FD is set to 100GB and 10GB respectively, and the memory budget is 1GB. HotRAP is also evaluated with a larger dataset in §4.7.

Compared systems. We compare HotRAP with PrismDB [31], SAS-Cache [9], and the following three variants of RocksDB: RocksDB-FD, RocksDB-tiering, and RocksDB-CL. RocksDB-FD stores all data in FD, which is used to indicate the upper-bound performance that HotRAP can achieve. RocksDB-tiering tunes its size ratios between levels so that the total size of FD levels becomes 10GB, which is the same as HotRAP. PrismDB is also tuned to use about 10GB of FD expectedly. RocksDB-CL caches records on FD using CacheLiB [8], while SAS-Cache caches blocks on FD. Among the baseline systems, RocksDB-tiering and PrismDB use the tiering design like HotRAP, while RocksDB-CL and SAS-Cache use the caching design.

Configurations. All experiments run with 16 threads. To minimize the impact of the file system cache, direct I/O is used in all systems. We set the initial hot set size limit and RALT physical size limit to 50% and 15% of the FD size respectively. HotRAP is configured with a 256MiB block cache, while other systems are configured with 64MiB more block cache to compensate for the memory usage of RALT. The 256+64=320MiB block cache uses about 1/3 of our 1GB memory budget, which is recommended by the RocksDB tuning guide [29]. Other configurations are set following the RocksDB tuning guide [29], e.g., 16KiB block size, 10-bit bloom filters, and 6 maximum number of background jobs.

[4] The maximum sustainable IOPS and throughput of gp3.

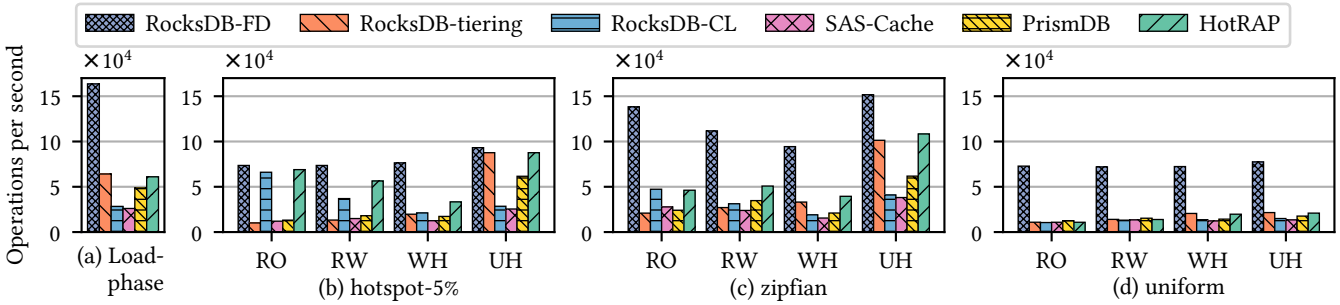

Figure 5: Throughput comparison with 1KiB record size.

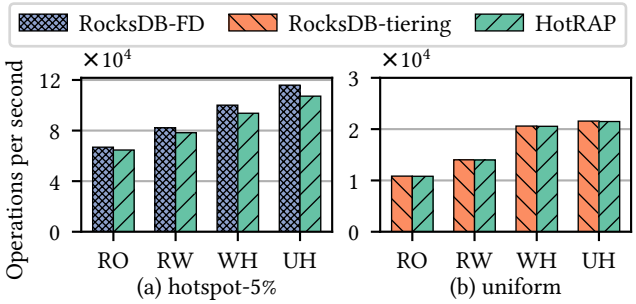

Figure 6: Throughput comparison with 200B record size.

4.2 Performance on YCSB workloads

To assess the performance of HotRAP under various key distributions and read-write ratios, we evaluate HotRAP with the YCSB workloads [10] shown in Table 3. *RO* (read-only) tests the effectiveness of promotion by flush. *RW* (read-write) and *WH* (write-heavy) test the effectiveness of hot-awareness compaction. *UH* (update-heavy) is the worst case for HotRAP. With UH, the key distributions of reads and updates are the same. Therefore, newer versions of read-intensive records are frequently inserted into the database and flushed into FD, making the proactive promotion of HotRAP barely needed.

We test three skewness types: hotspot-5%, Zipfian, and uniform. In the hotspot-5% distribution, 5% of records are accessed by 95% operations uniformly. The other 5% operations uniformly access the other 95% of records. In the Zipfian distribution, the access probability of the k-th hottest record is proportional to $1/k^s$ [7]. In our experiments, $s = 0.99$. In the uniform distribution, the access probability of all records is the same. We evaluate two record sizes, 1KiB (≈24B key and 1000B value) and 200B (≈24B key and 176B value).

All workloads have a load phase and a run phase. The load phase loads 110GB of records into the LSM-tree. The run phase executes read/write operations. For workloads with 1KiB records, the run phase executes 2.2×10^8 operations. For 200B records, the run phase executes 1.1×10^9 operations.

Figures 5 and 6 compare the average throughput (over the final 10% for the run phase) of evaluated systems under different read-write ratios and skewness types, with 1KiB and 200B records, respectively. Since the trends are similar, we only show a representative subset in Figure 6 to save space: hotspot-5% to show near-optimal efficiency compared to RocksDB-FD, uniform to show low overhead compared to RocksDB-tiering.

During the load phase, HotRAP's behavior is the same as RocksDB-tiering; thus, their performance is the same. We next focus on the run phase. The performance of HotRAP when running non-write-heavy hotspot-5% workloads is close to that of the ideal RocksDB-FD, because HotRAP promotes almost all hot data into FD and achieves about 95% hit rate. Compared to other systems, HotRAP achieves 5.2× speedup over the second best baseline with the tiering design under read-only (RO) workloads, 2.1× speedup over the caching design under write-heavy (WH) workloads, and 1.6× speedup over both designs for read-write-balanced (RW) workloads. Additionally, HotRAP matches the performance of RocksDB-CL for read-only (RO) workloads, and RocksDB-tiering for update-heavy (UH) workloads. On the other hand, HotRAP is only 4.0% slower than RocksDB-tiering under uniform workloads, showing the overhead of HotRAP is low when promotion has no benefits. For the Zipfian distribution, there is a noticeable gap in Figure 5 between HotRAP and the upper-bound RocksDB-FD, because the hit rate is lower (79%) compared to hotspot-5%. There is also a gap between HotRAP and RocksDB-FD under write-heavy (WH) workloads, because compactions saturate SD[5]. But HotRAP still outperforms other designs in these scenarios.

For the baseline designs, SAS-Cache shows negligible improvements over RocksDB-tiering, as its block-level caching is too coarse. PrismDB also only has small improvements over RocksDB-tiering due to its inefficient promotion mechanism. While RocksDB-CL performs comparably to HotRAP under read-only (RO) workloads, its performance degrades under other workloads (RW, WH, UH) due to SD being overwhelmed by compactions.

Among different read-write ratios, we notice that systems using the tiering design exhibit significantly higher throughput

[5]As hot records progressively migrate to FD, read latency reductions create proportional write throughput gains due to the workload's fixed 1:1 read-write ratio. This synchronized acceleration ultimately triggers excessive compactions that saturate SD's throughput ceiling at 300 MiB/s.

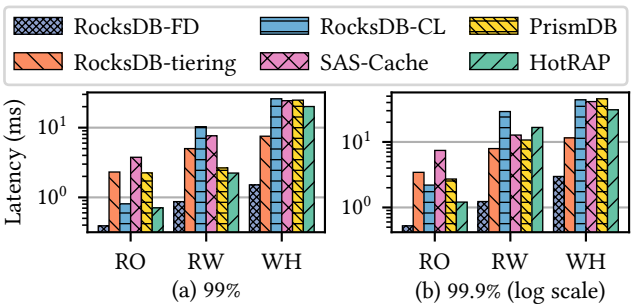

Figure 7: *Get* tail latency comparison under hotspot-5% workloads with 1KiB record size.

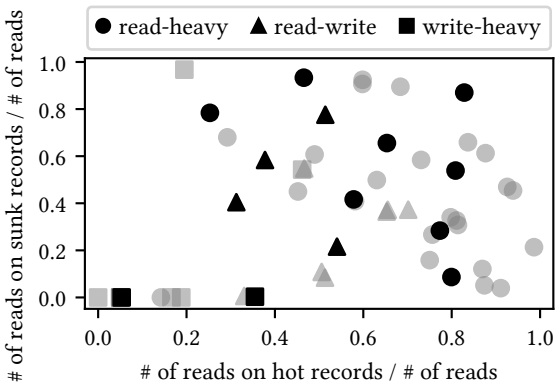

Figure 8: Characteristics of Twitter production traces. Each point stands for a cluster's trace. Dark black points are our selected traces for evaluation in Figure 9.

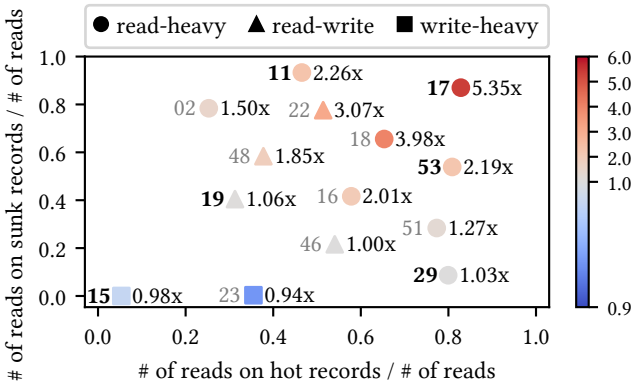

Figure 9: Speedup of HotRAP over RocksDB-tiering on Twitter production traces. Numbers on the two sides of a point are the cluster ID and the speedup. Traces with bold cluster IDs are selected for further analysis in Figure 10.

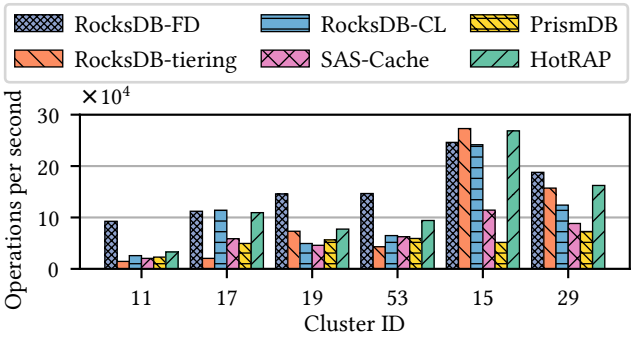

Figure 10: Throughput comparison under several Twitter production traces.

under update-heavy (UH) workloads. This is because the updated data have a skewed distribution, and thus update operations can be considered as promotions to FD. However, PrismDB performs relatively poorly in this case, because it suffers from lock contention and inefficient random writes to FD. RocksDB-CL and SAS-Cache barely benefit from the update-heavy workloads because they use the caching design and all levels are stored in SD.

Figure 7 shows the tail latencies (again over the final 10% of the run phase) under hotspot-5% workloads with 1KiB record size. For read-only (RO) workloads, HotRAP achieves lower tail latency than other systems except RocksDB-FD. It is because HotRAP has a higher FD hit rate and thus reduces accesses to SD, so there are proportionally fewer long-latency accesses affected by the SD tail latency among all FD and SD accesses. In contrast, under write-heavy workloads (WH), HotRAP has a higher tail latency than RocksDB-tiering. We believe this is because the throughput of HotRAP is higher than RocksDB-tiering, therefore compactions in HotRAP are more frequent, which deteriorates the tail latency.

4.3 Performance on real-world Twitter traces

To show the performance of HotRAP under real-world workloads, we evaluate HotRAP with the Twitter production traces [37]. We pre-process every trace into two phases: the load phase and the run phase. In the load phase, we ignore reads and keep inserting about 110GB of data. In the run phase, we execute 5×10^8 operations. We augment small traces by repeating operations until reaching 110GB of data. For example, if a trace has 40GB of data, we repeat each operation 3 times, e.g., an operation "`INSERT user1`" becomes "`INSERT 0user1, INSERT 1user1, INSERT 2user1`".

Traces are categorized based on their read proportions: read-heavy has >75% reads; read-write has >50% and ≤75% reads; write-heavy has ≤50% reads. In some traces, it is common for a frequently read key to be also frequently updated. Proactively promoting this key has little benefit because its newer version will be automatically inserted into FD. We define that a read is performed on a *sunk* record if the data amount written since the last update of its key exceeds 5% of the DB size, so that the latest version is now likely sunk to SD when being read. For example, suppose we first update keys A, C, D, B, then we read key A. If the total size of records C, D, B surpasses 5% of the DB size, then we say A is sunk when being read. Similarly, we define that a read is performed on a *hot* record if the data amount read since the last read of

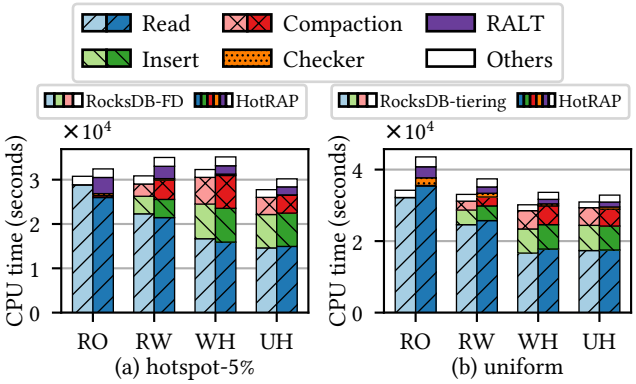

Figure 11: CPU time breakdown with 200B record size.

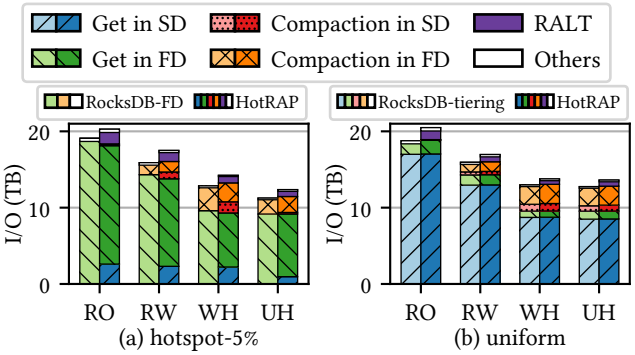

Figure 12: I/O breakdown with 200B record size.

this record is less than 5% of the DB size, so that the record is likely to be identified as hot. If there are many reads on such sunk and hot records, then promoting them to FD is necessary.

Figure 8 shows the categories and proportion of reads on sunk/hot records in the Twitter traces. We select some representative traces to evaluate the speedup of HotRAP over RocksDB-tiering in Figure 9. HotRAP performs better when the proportions of reads on sunk and hot records are higher, e.g., achieving up to 5.35× speedup under the trace of cluster 17. On the other hand, HotRAP is not significantly slower than RocksDB-tiering under traces with low proportions of reads on sunk and hot records, showing its low overhead.

We further analyze several traces with high (11, 17), medium (19, 53), and low (15, 29) proportions of sunk record reads, and present their throughput in Figure 10. HotRAP is almost always the best among compared systems, achieving up to 1.5× speedup over the second best. As the proportion of sunk record reads decreases, almost all systems perform better, but HotRAP's relative speedup diminishes. At medium and high sunk record read proportions, if we increase the amount of hot record reads, HotRAP throughput would significantly increase, while PrismDB and SAS-Cache perform moderately better, and RocksDB-tiering does not benefit from it at all. Although RocksDB-CL performs well under workloads with few writes like cluster 17, it underperforms under other workloads.

4.4 Cost breakdown

Figures 11 and 12 show CPU time and I/O breakdowns for the run phase of YCSB workloads with 200B record size. The size of RALT here exceeds our 1GB memory budget, and thus needs to be stored in FD instead of memory. The results show that RALT accounts for only 3.7%–11.2% of total CPU time and 5.2%–9.7% of total I/O. The I/O cost of RALT[6] is background FD I/O. Since the throughput of FD is abundant, the I/O cost of RALT barely affects the overall system performance.

[6]Measured by maintaining the number of bytes read/written in the file system interface wrapper.

Table 4: Costs with/without hotness-aware compaction under the RW hotspot-5% workload with 1KiB record size.

Version	Promoted	Compaction	Hit rate	Disk usage
HotRAP	5.5GB	2092.5GB	94.8%	170.0GB
no-hot-aware	35.8GB	2841.8GB	72.0%	178.6GB

In hotspot-5% workloads, HotRAP incurs more CPU time and I/O on compactions than RocksDB-FD, because retention increases write amplification. Interestingly, HotRAP uses less CPU time and I/O on reads than RocksDB-FD. We believe it is because hot records are promoted to higher levels, so there are fewer levels to probe to read those records. In uniform workloads, HotRAP consumes more CPU time than RocksDB-tiering because most accesses are in SD and thus the records are inserted into the promotion buffer. However, few records are promoted into FD due to the hotness checking (⑤ & ⓑ in Figure 2), therefore they have similar compaction I/O.

4.5 Effectiveness of individual techniques

Hotness-aware compaction. We disable the hotness-aware compaction mechanism in HotRAP and call the design *no-hot-aware*. Table 4 shows that *no-hot-aware* incurs higher promotion costs and achieves a lower final hit rate compared to HotRAP. The reason is that although *no-hot-aware* still promotes records into FD by flush, the promoted records are compacted into SD again during subsequent compactions. Consequently, hot records have to be promoted repeatedly, with much more promotion traffic. Additionally, HotRAP incurs less disk usage than *no-hot-aware*. It is because hotness-aware compaction gradually promotes duplicate data (left in SD by promotion by flush) into FD and merges them with previously promoted records.

Promotion by flush. We disable the promotion by flush mechanism and call the design *no-flush*. Figure 13 shows that the hit rate increases very slowly without promotion by flush, especially for read-heavy workloads. In contrast, the hit rate of

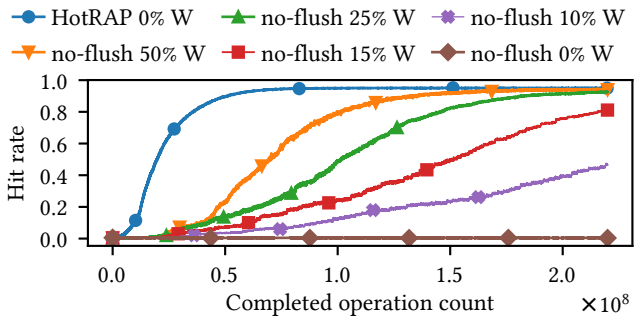

Figure 13: Effectiveness of promotion by flush. $x\%$ W means $x\%$ of operations are writes and $(1-x)\%$ are reads.

Table 5: Promotion costs with/without hotness checking under the RO uniform workload with 1KiB record size.

Version	Promoted	Retained	Compaction
HotRAP	1.0GB	15.7MB	34.8GB
no-hotness-check	200.6GB	4.3GB	5870.3GB

HotRAP increases rapidly even under the read-only workload.

Hotness checking before promotion. HotRAP promotes only hot records to reduce the overhead introduced by promotion. To show its effectiveness, we remove the hotness checking and promote all accessed records, and call the design *no-hotness-check*. Table 5 shows that under uniform workloads, *no-hotness-check* promotes 204.1× more records and thus incurs 167.7× more compaction I/O than HotRAP.

4.6 Performance on dynamic workload

To show that HotRAP can adapt to changes in the access pattern, we evaluate it under a dynamic workload. The details of the dynamic workload and the results are shown in Figure 14.

The first stage has a uniform distribution, so there are few stable records, and the hot set size stays low. At the second stage, the key distribution becomes hotspot-2%. With the auto-tuning method, HotRAP gradually increases the hot set size limit until all hotspot keys are added to the hot set. Eventually, the hot set size stabilizes around the hotspot size. After the hotspot expands from 2% to 4% and from 4% to 6%, the FD hit rate temporarily drops because new hot keys are not yet promoted. Then HotRAP gradually increases the hot set size limit until all new hot keys are added to the hot set, thus recovering the hit rate. After the hotspot expands from 6% to 8%, the hotspot size exceeds the max hot set size (≈ 7GB). Therefore, the performance of HotRAP is relatively low. When the hotspot shifts, HotRAP reacts adaptively by evicting old hot keys after they become unstable, and gradually adding new hot keys to the hot set. Both the throughput and the hit rate recover eventually. After the hotspot shrinks from 5% to 3% and from 3% to 1%, the throughput and the hit rate do not drop because new hot keys are already considered hot

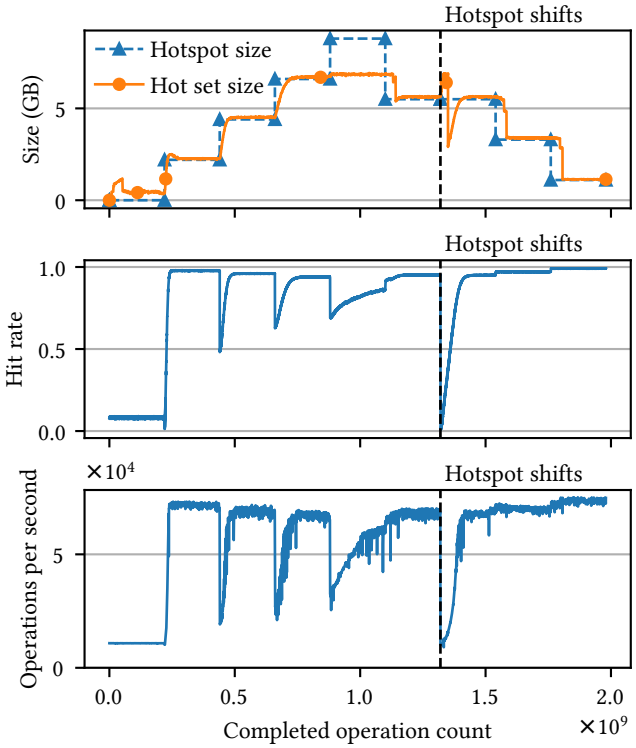

Figure 14: HotRAP under dynamic workload. The run phase consists of nine stages, whose data distributions are first uniform, then hotspot-2% → 4% → 6% → 8% → 5% → 5% → 3% → 1%. Each stage executes 2.2×10^8 read operations. The two 5% hotspots in the 6th and 7th stages are non-overlapping. When the hotspots increase from 2% to 8%, the new hotspot completely contains the old hotspot. When they decrease, the new one is completely contained by the old one.

and have already been promoted. Nevertheless, HotRAP in this case could decrease the hot set size limit after old access records become unstable.

In summary, the results show that the auto-tuning mechanism enables HotRAP to find the most suitable hot set size limit under a dynamic workload with hotspot expanding, shrinking, and shifting.

4.7 Large dataset

Figure 15 compares the average throughput (over the final 10% of the run phase) of RocksDB-FD, RocksDB-tiering, and HotRAP under different read-write ratios and skewness types, with 1.1TB datasets and 1KiB record size. HotRAP is configured with a 2GiB block cache while other systems are configured with 1GiB more block cache to compensate for the memory usage of RALT. The run phase of HotRAP executes 2.2×10^9 operations. The run phase of RocksDB-FD and RocksDB-tiering executes 1.1×10^9 operations to save test time since their performance barely changes during the run phase. The results are similar to Figure 5, showing the

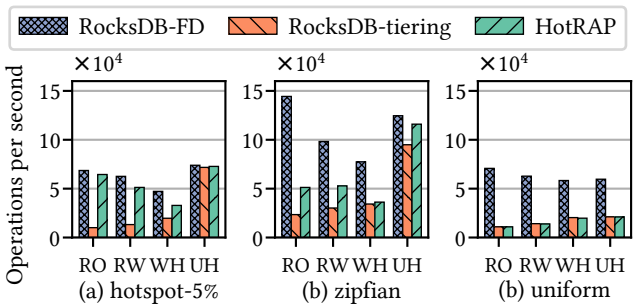

Figure 15: Throughput comparison with 1KiB record size and 1.1TB datasets (1TB in SD and 100GB in FD).

Table 6: Comparison with Range Cache under the read-only Zipfian YCSB workload with 1KiB record size. *OPS* means *Operations Per Second*.

System	OPS	FD IOPS	SD IOPS
RocksDB-tiered	20927	1311	9998
Range Cache	29217	1019	9995
HotRAP	46156	14632	9998
HotRAP + Range Cache	46180	8443	9986

scalability of HotRAP.

4.8 Comparison with Range Cache

Range Cache [32] addresses the block-cache invalidation problem by introducing a separate in-memory key-value cache on top of the LSM-tree. Since Range Cache is not open-source and this paper focuses on point query performance, we simulate Range Cache by enabling the row cache in RocksDB. Table 6 shows the experimental results collected during the final 10% of the run phase. Range Cache improves throughput compared to RocksDB-tiered by finer-grained caching. However, the in-memory cache is insufficient to hold all hot records due to the limited memory capacity; therefore, many accesses to SD still occur. HotRAP outperforms Range Cache by promoting all hot records to FD, which is possible due to the large capacity of FD. Combining Range Cache with HotRAP further alleviates the load of FD by caching some hot records in memory. The throughput is not improved because the performance remains bottlenecked by SD.

5 Discussion

Scan workloads. HotRAP behaves the same as RocksDB-tiering under scan workloads: scanned records are not inserted into RALT or the promotion buffer, and there is no metadata lookup for RALT during scans. It is our future work to speed up range scans by maintaining the set of promoted ranges so that a range scan does not need to read SD if it is in a promoted range. Details will be revealed in our future paper.

Limitation of the auto-tuning algorithm. The algorithm keeps unstable records of HotRAP size D_{hs} to detect hot records. It assumes that hot records are accessed randomly, so every hot record has a probability > 0 of being detected. However, if a hot record is accessed only once every $> D_{hs}$ accesses, it will not be captured. In extreme cases such as "sequential flooding", the algorithm cannot work unless D_{hs} is increased. But this is uncommon in real-world datasets (e.g., the Twitter traces in §4.3).

Portability. The key HotRAP techniques (RALT and promotion by flush) can be easily applied to other modern LSM-tree implementations. (1) RALT is implemented as a standalone library with a minimum interface (insert, key hotness check, iterate, and range hot size) to ensure cross-system portability. (2) Promotion by flush leverages the multi-version concurrency control (MVCC) of the LSM-tree structure to minimize the impact on foreground tasks. The MVCC capability should be available in modern LSM-tree implementations.

6 Conclusion

We introduced HotRAP, an LSM-tree-based key-value store on tiered storage. Unlike previous solutions, HotRAP adopts an efficient on-disk hotness tracker, along with a fine-grained record-level retention and promotion mechanism that offers two pathways for hot records to be stored in the fast tier. These techniques allow HotRAP to efficiently manage data across tiers to fully utilize the fast tier under various workloads.

Mitigating Resource Usage Dependency in Sorting-based KV Stores on Hybrid Storage Devices via Operation Decoupling

Abstract

LSM-tree-based key-value (KV) stores mainly employ sorting-based operations (e.g., flush and compaction) to manage the KV pairs on disk. Through analysis and experiments with RocksDB, we identify that the sorting operations cause critical issues of operation coupling, including intertwined resource consumption within an operation, interdependencies and contention among operations. These coupling problems lead to dependency in resource usage and are particularly exacerbated on hybrid storage devices, causing significant resource fragmentation and increased write stalls. Existing approaches to mitigating write stalls rely on either fixed differentiated data management or superficial scheduling of data sorting operations, but they fail to fundamentally address the resource usage dependency caused by operation coupling.

In this paper, we propose DecouKV, designed to alleviate resource usage dependency and enhance resource utilization on hybrid storage devices through operation decoupling. Specifically, DecouKV decouples data sorting operations into CPU-intensive index merge tasks and I/O-intensive data append and data flush tasks by separating indexes from data files, managing indexes with a mergeable skip list-based structure and managing data with append-only files. Furthermore, we propose an elastic scheme for tuning level capacity and introduce a parameterized queue-based task scheduling strategy to maximize resource utilization. We implement DecouKV and conduct experimental evaluations. Compared to RocksDB, as well as state-of-the-art systems such as MatrixKV, PrismDB, SplitDB and ADOC, DecouKV improves CPU utilization by 25.4%–32.3%, increases throughput by 2.3–4.9×, and reduces tail latency by 74.3%–91.4% under write-intensive workloads. DecouKV also achieves a modest throughput improvement of 1.2–2.3× under read-intensive workloads.

1 Introduction

Key-value (KV) stores manage data in the form of KV pairs, enabling fast lookup, insertion, and deletion operations. As a result, KV stores are widely used in distributed systems [1,23], graph storage systems [5,18,31,51], and OLTP/OLAP databases [3, 7, 9, 15, 19, 24, 26, 36, 40, 52]. Modern KV stores typically employ the Log-Structured Merge-tree (LSM-tree) [38], a sorting-based data structure, as their core storage mechanism (e.g., LevelDB [22], RocksDB [20], Cassandra [3], X-Engine [25]). KV pairs are first cached in memory, and then persistently stored on disk through sorting-based flush and compaction operations. By converting random writes into sequential writes, LSM-tree-based KV stores are able to provide efficient write operations and good scalability.

With the continuous advancement of hardware performance, LSM-tree-based KV stores are increasingly deployed on fast devices, such as NVMe SSDs [10, 32, 45] and Persistent Memory (PM) [17, 29, 30, 47], also known as Non-Volatile Memory (NVM). However, these high-performance devices are often expensive [45], leading to the growing popularity of hybrid storage systems that combine fast devices with slower but inexpensive devices such as SATA SSDs and HDDs (e.g., [10, 29, 42, 47]). In such solutions, the common strategy is to store hot data on fast devices while storing large volumes of cold data on slower devices (e.g., [10, 29, 47]). This approach delivers high performance with minimal use of expensive fast devices, ensuring cost efficiency.

LSM-tree and its derivative optimizations [12, 17, 29, 33, 35, 47, 49] primarily adopt a sorting-based multi-level tree structure. These designs rely on heavyweight and unavoidable data sorting operations, such as flush and compaction, to manage KV pairs. However, sorting-based KV stores suffer from significant *operation coupling issues*, which manifest in three main aspects: (i) both flush and compaction operations consume a certain amount of CPU and I/O resources, leading to intertwined resource consumption; (ii) a sorting operation at a certain level can cause the size of the next level to exceed its threshold and trigger a subsequent sorting operation, resulting in interdependencies among operations; (iii) concurrent two sorting operations compete for system resources, leading to resource contention between these operations. Operation coupling issues lead to severe resource usage dependency, making it difficult to isolate CPU and I/O resources and schedule them effectively. These issues are exacerbated on hybrid storage devices due to the performance disparity between fast and slow devices, which causes fluctuating resource consumption. This results in alternating performance bottlenecks over time and increased write stalls.

Recent related works propose two main strategies for miti-

*Yongkun Li is the corresponding author.

gating write stalls. The first strategy leverages the high bandwidth of fast devices to perform differentiated data management across fast and slow devices (e.g., [29, 47]). However, data management is predefined and fixed, which remains misaligned with the fluctuating resource consumption on hybrid storage devices, leading to resource underutilization. The second strategy focuses on superficial scheduling of data sorting operations (e.g., [4, 48]), attempting to reduce latency fluctuations by adjusting the frequency, timing, and placement of sorting operations. Nevertheless, intertwined resource consumption still persists. Superficial scheduling fails to identify the resource-bound nature of sorting operations, and scheduling sorting operations of the same resource-intensive can even exacerbate resource bottlenecks.

To address these issues, we propose DecouKV, which mitigates resource usage dependency in sorting-based KV stores on hybrid storage devices via *operation decoupling*. DecouKV first decouples the indexes of KV pairs from data files, as in data sorting operations, CPU resource consumption primarily originates from index sorting, while I/O resource consumption is primarily associated with data reading and writing. This decoupling transforms data sorting operations into CPU-intensive index merge tasks and I/O-intensive data append and flush tasks by managing data with append-only files (AOFs) and indexes using a mergeable skip list-based structure called IndexTable, thereby reducing intertwined resource consumption. Additionally, DecouKV introduces two queues, the Index Merge Queue and the Data Flush Queue, to manage IndexTables. By auto-tuning queue parameters, DecouKV proactively schedules decoupled tasks. Specifically, DecouKV minimizes competition between resource-intensive tasks and optimizes resource utilization by coordinating tasks with different resource demands. Finally, DecouKV relaxes level amplification factor limit and uses elastic capacity to reduce interdependencies among data sorting operations.

We implement DecouKV and compare its performance against RocksDB, one of the most widely adopted systems in the industry, as well as two state-of-the-art systems representing the two categories of optimization strategies mentioned before: MatrixKV and ADOC. Experimental results show that under write-intensive workloads, DecouKV improves CPU utilization by 25.4%–32.3%, increases throughput by 2.3–4.9×, and reduces tail latency by 74.3%–91.4%. DecouKV also achieves a modest throughput improvement of 1.2–2.3×, under read-intensive workloads. In summary, our main contributions are summarized as follows.

- We analyze the data sorting operations of sorting-based KV stores and identify operation coupling as the root cause of resource usage dependency and resource fragmentation on hybrid storage devices.
- Based on the analysis above, we propose a decoupling solution, decoupling data sorting operations into CPU-intensive tasks and I/O-intensive tasks to reduce intertwined resource consumption within an operation.

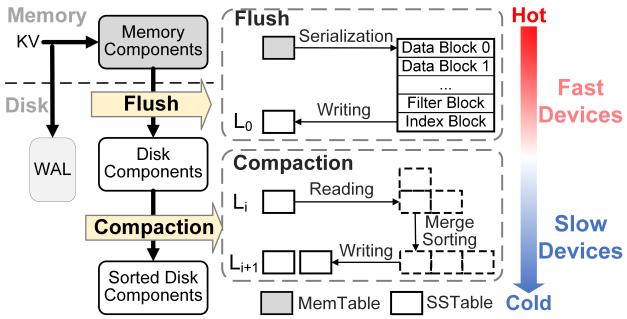

Figure 1: Architecture of LSM-tree.

- We design an elastic strategy for tuning the level capacity of LSM-trees, relaxing the level amplification factor to reduce interdependencies among data sorting operations.
- We develop an efficient task scheduling strategy to minimize competition between resource-intensive tasks and optimize resource utilization by coordinating tasks with different resource demands.

The source code of DecouKV is available online [50].

2 Background and Motivation

2.1 KV Stores on Hybrid Storage Devices

Architecture of LSM-tree-based KV stores. As shown in Figure 1, an LSM-tree consists of memory components (MemTables) and disk components organized into Sorted String Tables (SSTables) across multiple levels. Each level has a fixed storage capacity, and the amplification factor between levels is typically set to 10. The system uses background flush and compaction operations, defined here as data sorting operations, to manage data movement between components. These operations are triggered when the component capacity exceeds predefined thresholds. When the MemTable reaches its capacity limit, a flush operation serializes the data (generating metadata like Bloom filters and index blocks) and persists it to disk as SSTables at level 0. When a specific level reaches its capacity limit, the system performs compaction operations, which involve data reading, merge sorting, and data writing. These operations consume significant CPU and I/O resources, leading to resource competition and system performance degradation.

Deployment of LSM-trees on hybrid storage devices. Recently, LSM-tree-based KV stores have been extended to cost-effective hybrid storage devices, which consist of fast and slow devices. Fast devices, such as NVMe SSDs and Persistent Memory (PM), typically provide high bandwidth and low latency. Although Intel Optane DCPMM [2] has been discontinued, the trend in hardware development continues to prioritize performance improvements (like CXL SSDs [27]). However, their high cost remains a significant barrier—for example, the price of Intel Optane DCPMM per terabyte is more than 10 times higher than that of SATA SSDs [45]. Meanwhile, slower devices such as traditional SSDs and HDDs

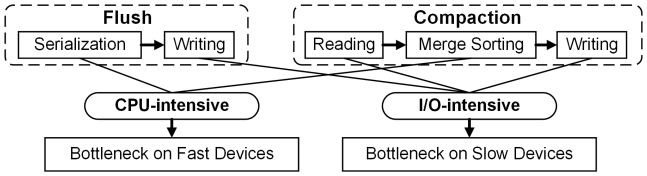

Figure 2: Intertwined resource consumption within an operation.

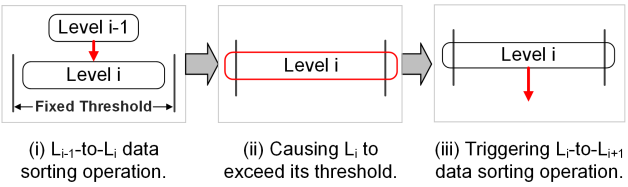

Figure 3: Interdependencies among operations.

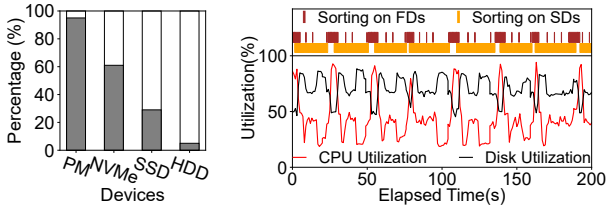


(a) CPU Percentage. (b) Resource fluctuations.

Figure 4: Resource utilization of RocksDB on hybrid devices.

remain indispensable due to their large capacity and lower cost. Thus, hybrid storage devices become a popular solution offering a balance between performance and cost.

In hybrid devices scenarios, a common approach is to store hot data (e.g., MemTable and lower levels of the LSM-tree) on fast devices (FDs) and cold data (e.g., higher levels) on slow devices (SDs). For example, NoveLSM [29] uses PM as an extension of DRAM and deploys the MemTable on PM. MatrixKV [47] places the level 0 of the LSM-tree on PM through a matrix management approach. SpanDB [10] treats NVMe SSD as a performance device, deploying the low levels of the LSM-tree on it. PrismDB [42] identifies hot and cold data, storing hot data on PM and cold data on slow devices. Overall, by strategically balancing the use of fast and slow devices, these systems achieve high throughput while reducing storage costs.

2.2 Problems of Operation Coupling

Typically, both RocksDB and its derivative optimizations adopt a multi-level, sorting-based design. As mentioned earlier, these designs rely on heavyweight and unavoidable data sorting operations, such as flush and compaction, to manage KV pairs. Below, we first analyze three categories of operation coupling issues. Then, we discuss how these issues exacerbate the underutilization of CPU and I/O resources in sorting-based KV stores deployed on hybrid storage devices, which ultimately results in resource fragmentation and increased write stalls.

2.2.1 Operation Coupling Issues

Specifically, the operation coupling issues in LSM-tree manifest in three key aspects:

Intertwined resource consumption within an operation. Data sorting operations require substantial CPU cycles and I/O bandwidth simultaneously. As shown in Figure 2, the serialization (generating metadata like Bloom filters and index blocks) in the flush operation consumes substantial CPU cycles, categorizing it as a CPU-intensive task, whereas data writing primarily consumes I/O bandwidth, classifying it as an I/O-intensive task. Similarly, in the compaction operation, merge sorting is CPU-intensive, while data reading and writing are I/O-intensive. Within a single data sorting operation, the intertwined nature of CPU-intensive and I/O-intensive tasks leads to intertwined resource consumption.

Interdependencies among operations. In sorting-based KV stores, data sorting operations are strictly triggered by fixed thresholds, creating dependencies between adjacent levels. As shown in Figure 3, an L_{i-1}-to-L_i data sorting operation may increase L_i's size, causing it to exceed its threshold and trigger an L_i-to-L_{i+1} data sorting operation. Such interdependencies mean that operations are passively triggered, leaving the system unable to choose the level and timing of data sorting based on resource availability. This results in resource conflicts and waste.

Resource contention between operations. Under high write loads, data sorting operations often occur simultaneously across multiple components of the sorting-based KV stores, leading to competition for system resources. In resource-constrained systems, resource contention reduces the efficiency of sorting operations, causing severe write stalls.

2.2.2 Exacerbation on Hybrid Storage Devices

Furthermore, the coupling problem becomes further exacerbated on hybrid storage devices. Due to the performance disparity between fast and slow devices, their capabilities for handling I/O requests differ significantly, leading to varying performance bottlenecks for data sorting operations on different devices. We validate the analysis through experiments with RocksDB deployed on hybrid storage devices.

Varying bottlenecks on different devices. First, we measure the percentage of CPU time consumed by data sorting operations on different devices (refer to Section 4 for detailed configurations). Figure 4(a) shows that on fast devices (PM, NVMe SSD), CPU time accounts for over 60% of compaction time, making that the CPU becomes the performance bottleneck for these devices. On slow devices (SATA SSD, HDD), the CPU accounts for less than 30% of the compaction time, with a large proportion of time spent on I/O wait. As a result, I/O bandwidth remains the performance bottleneck for slow devices.

Alternating bottlenecks on hybrid storage devices. Next, we test RocksDB's performance on hybrid storage devices, following the common approach introduced in Section 2.1, where levels 0 and 1 are stored on fast devices (PM) and other levels on slow devices (SATA SSD). We import 100M update requests into a 100GB database, and record sorting times on fast and slow devices, as well as CPU and disk utilization over time. We present a representative 200-second subset, with similar patterns observed throughout the experiment. Figure 4(b) shows that under write-intensive workloads, resource utilization fluctuates significantly, with low averages and severe resource fragmentation. Disk and CPU utilization exhibit opposing patterns: during sorting on fast devices, CPU utilization is high (94%) but disk utilization is low (48%), indicating a CPU bottleneck; during sorting on slow devices, disk utilization is high (88%) while CPU utilization is low (21%), indicating an I/O bottleneck. These bottlenecks alternate between data sorting operations on two devices, hindering the full utilization of CPU and I/O resources and ultimately increasing write stalls.

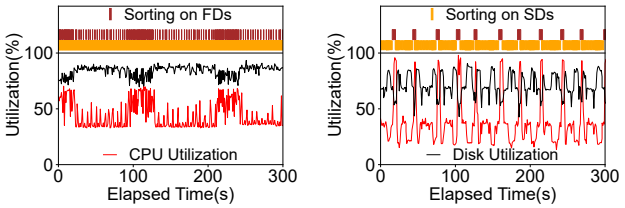
Overall, data sorting operations consume intertwined CPU and I/O resources, and the disparity I/O bandwidth between devices leads to different resource bottlenecks on different devices. Additionally, the fluctuating resource consumption is misaligned with the fixed hardware capabilities. Due to interdependencies among operations, the system cannot proactively trigger operations to utilize resource fragments efficiently (e.g., triggering sorting on fast devices when the CPU is idle).

2.3 Limitations of Existing Solutions

There are two main strategies from recent related works for mitigating write stalls: (i) fixed differentiated data management and (ii) superficial scheduling of data sorting operations.

Fixed differentiated data management. This category of work [10, 29, 42, 47] argues that the performance disparity between fast and slow devices necessitates differentiated management strategies, rather than applying the same approach to both. These works typically modify data sorting operations on specific devices, mitigating intertwined resource consumption to some extent. However, severe interdependencies still exist among the data sorting operations. Data management is predefined and fixed, which remains misaligned with the fluctuating resource consumption on hybrid storage devices, leading to resource underutilization.

Taking MatrixKV [47] as an example, which places L_0 of the LSM-tree on persistent memory and employs a matrix container for differentiated management. As shown in Figure 5(a), the amplitude of resource utilization fluctuation is reduced compared to RocksDB (though still exceeding 50%). The result indicates that fine-grained compaction reduces the CPU and I/O resources consumed in each operation, mitigating intertwined resource consumption to some extent. However, the issue of interdependencies among operations



(a) Differentiated data management. (b) Superficial operations scheduling.

Figure 5: Resource utilization fluctuations of existing solutions.

persists. Frequent sorting on fast devices keeps CPU utilization at a high level (100–120s in Figure 5(a)). When the data on fast devices exceeds the threshold, a large number of threads shift to sorting on slow devices, causing CPU utilization to drop significantly due to I/O bottlenecks. As a result, the fluctuating resource consumption on hybrid storage causes the average resource utilization to remain low.

Superficial scheduling of data sorting operations. Some works [4, 13, 48] aim to improve performance by superficial scheduling data sorting operations. After detecting the system state, they superficially adjust the frequency, timing, and location of these operations to reduce latency fluctuations, alleviating interdependencies among operations to some extent. However, intertwined resource consumption within operation still persists. These works fails to identify the resource-bound nature of sorting operations, as well as the varying performance bottlenecks on hybrid storage devices. Moreover, scheduling sorting operations of the same resource-intensive can even exacerbate resource bottlenecks.

Taking ADOC [48] as an example, which adjusts parameters to control the components and rates at which data sorting operations occur to reduce data blockage. The experiment on hybrid storage devices (Figure 5(b)) shows more pronounced fluctuations in its resource utilization. Compared to RocksDB in Figure 4(b), sorting on fast devices causes a significantly higher CPU utilization, approaching 100%. At the same time, disk utilization decreases significantly, indicating a more severe CPU bottleneck. This occurs because, when data blockage occurs on components in the fast devices, ADOC schedules more sorting threads for sorting on fast devices. Meanwhile, sorting threads on slow devices are reduced. Resource contention between these operations leads to a more severe CPU bottleneck, while the bandwidth of slow devices is underutilized. Conversely, when data blockage occurs on slow devices, ADOC achieves higher disk utilization but lower CPU utilization, indicating a more severe I/O bottleneck. As a result, the bottlenecks significantly alternate due to the intertwined resource consumption within operation.

Although these efforts have made progress in alleviating the write stall issue in LSM-trees, they cannot fundamentally solve the problem of resource fragmentation and underutilization on hybrid storage devices caused by operation coupling. To address this issue comprehensively, decoupling the operations within the sorting-based KV stores is necessary.

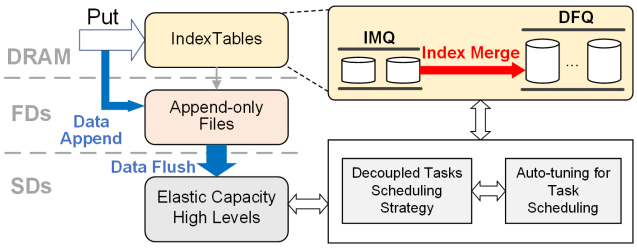


Figure 6: DecouKV overview.

3 DecouKV Design

3.1 Design Goals and Challenges

DecouKV focuses on decoupling data sorting operations into resource-independent CPU-intensive tasks and I/O-intensive tasks, enabling the system to flexibly schedule tasks based on current resource utilization. The design goals and challenges of DecouKV are as follows:

Decoupling operations. DecouKV needs to decouple operations to achieve relative isolation while maintaining correctness and consistency, thereby facilitating subsequent task scheduling and resource utilization. Specifically, DecouKV needs to address the three operation coupling issues discussed in Section 2.2.1.

Managing decoupled components. Decoupled operations need to achieve the original objectives of coupled operations. Coupled sorting operations improve data orderliness, addressing two key issues: unordered indexes degrade query performance, and unordered data on disk leads to random access patterns. Decoupled operations must similarly resolve these two issues.

Efficient scheduling of decoupled tasks. DecouKV needs to efficiently schedule decoupled tasks to maximize CPU and I/O resource utilization. This requires accurately assessing resource states and making appropriate scheduling decisions to improve resource efficiency.

3.2 System Overview

This section introduces DecouKV, designed to mitigate resource usage dependency in sorting-based KV stores deployed on hybrid devices via operation decoupling. Now, we begin by outlining the architecture of DecouKV.

In sorting-based KV stores, data sorting operations involve CPU-intensive sorting tasks mainly for indexes and I/O-intensive read/write tasks mainly for data. Therefore, to isolate these tasks, DecouKV first decouples indexes from data files. Next, suitable structures are required to manage the separated indexes and data while maintaining their isolation. The structure managing indexes must satisfy the following requirements: (i) fast insertion and query speeds, as these are fundamental for indexes, and (ii) support for independent sorting tasks without impacting access during merging. The structure managing data must meet these criteria: (i) fast insertion speed, and (ii) an unordered design to avoid excessive CPU consumption for data sorting. As shown in Figure 6, DecouKV manages data on fast devices using append-only files (AOFs) and manages their indexes in DRAM using IndexTables, a mergeable structure based on skip list.

In this way, DecouKV decouples data sorting operations into three types of tasks: CPU-intensive *index merge* tasks and I/O-intensive *data append* and *data flush* tasks, reducing intertwined resource consumption. Specifically, index merge tasks focus solely on sorting indexes in DRAM without involving data read/write operations, making them CPU-intensive. Data append and flush tasks primarily consume disk I/O without sorting, making them I/O-intensive.

Additionally, DecouKV employs two DRAM-based queues—Index Merge Queue (IMQ) and Data Flush Queue (DFQ)—to manage IndexTables. By autotuning queue parameters, DecouKV actively schedules the decoupled tasks. Specifically, DecouKV minimizes competition among the same resource-intensive tasks and optimizes resource usage by coordinating tasks with different resource demands. Finally, DecouKV introduces elastic capacity design for high levels (HLs) of the LSM-tree on slow devices, relaxing the strict level amplification factor to reduce interdependencies among operations. The subsequent sections detail the design of these decoupling mechanisms.

3.3 Decoupled Components

DecouKV manages indexes with DRAM-based IndexTables and data with AOFs. Below, we describe their structures.

IndexTable. DecouKV employs IndexTables, a mergeable skip list-based structure, to store indexes in DRAM (Figure 6). Each IndexTable uses a skip list to manage indexes, enabling efficient lookups and subsequent index merge tasks. DecouKV leverages the index to precisely locate data in fast devices, with each index entry containing a key and the corresponding data address in fast devices (comprising an 8-byte file number and an 8-byte offset). Unlike RocksDB's MemTable, IndexTables avoid storing values, supporting more entries within the same memory footprint. To ensure efficient index insertion and memory utilization, the initial capacity of the IndexTable, denoted as *max_index_size*, is set to a relatively small value (8 MB). Note that to minimize the impact of I/O operations on the indexes after decoupling, DecouKV employs asynchronous insertion. By recording the data address, DecouKV allows insertion to proceed without waiting for the data append to fast devices to complete. Once the IndexTable reaches *max_index_size*, it becomes non-insertable, and a new IndexTable is created. Queries traverse IndexTables sequentially, from newest to oldest, until the required key is located. When the number of IndexTables exceeds a threshold, DecouKV triggers an index merge operation, which will be discussed in the next subsection.

Append-only file (AOF). DecouKV stores KV pairs as AOFs on fast devices, with the corresponding indexes in DRAM-based IndexTables. Although AOFs are unordered files prone

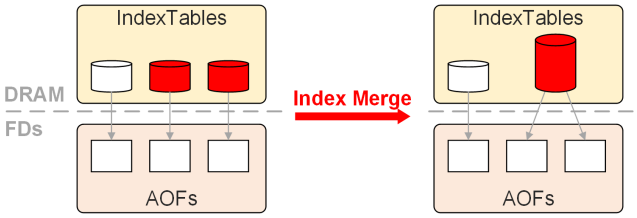

Figure 7: Index merge. The red cylinders represent the IndexTables before and after merging, and the arrows indicate the correspondence between the IndexTables and AOFs.

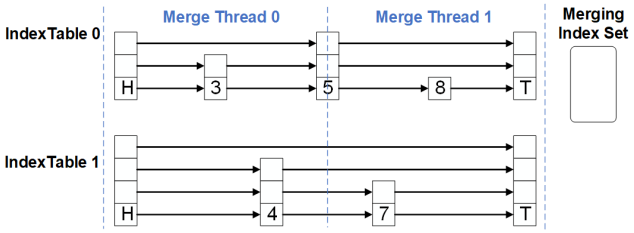
to random access, DecouKV leverages the high bandwidth and concurrency of fast devices to achieve random access performance comparable to sequential access. Consequently, AOFs maintain unordered data without compromising performance. Furthermore, the original Write-Ahead Logs (WALs) of the LSM-tree are eliminated as DecouKV can recover data with AOFs during system failures. Additionally, AOFs also eliminate the extra CPU overhead associated with generating Bloom filters for the data on fast devices, and reduce the memory overhead required for caching these Bloom filters during query processing. Because of the excellent random access performance of fast storage devices, the impact on read performance caused by removing the Bloom Filter in AOF is effectively mitigated.

3.4 Decoupled Tasks

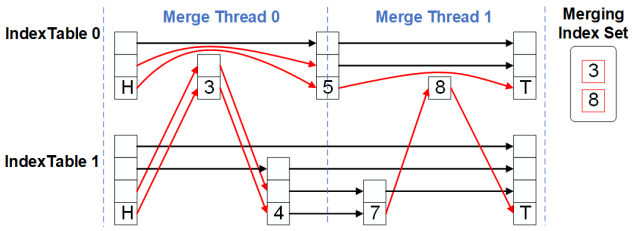
Based on IndexTables and AOFs, DecouKV decouples data sorting operations into CPU-intensive index merge tasks and I/O-intensive data append and data flush tasks. In the following, we explain how to handle these decoupled tasks to achieve the objectives of the original coupled tasks outlined in Section 3.1.

Index merge. Obviously, the number of IndexTables directly impacts query performance. To address the first issue mentioned in Section 3.1—unordered indexes degrade query performance—index merge tasks reduce the number of unordered IndexTables. As illustrated in Figure 7, DecouKV employs index merge tasks to consolidate two red IndexTables into a larger one. Note that index merge tasks occur entirely in DRAM without affecting the data in AOFs. Therefore, index merge is a CPU-intensive task. Initially, each IndexTable corresponds to one AOF; after merging, one IndexTable may correspond to multiple AOFs.

Index merge effectively merges two skip lists. Recent studies have introduced many optimizations for merging skip list structures [17,30]. Specifically, by altering the pointers within skip lists, the two skip lists can be merged efficiently without blocking query requests. DecouKV further implements multithreaded parallelism based on these optimizations, making full use of CPU resources. As shown in Figure 8, DecouKV uses multiple threads to perform parallel index merge. In Figure 8(b), the red arrows are pointers that are currently being modified. Meanwhile, DecouKV maintains a Merging Index



(a) Initial state.



(b) Multithreaded parallel merging.

Figure 8: Illustration of multithreaded parallel index merge. The figure shows two threads performing parallel merging. The arrows represent skip list pointers.

Set (a lock-free set implemented using CAS) to store atomic pointers to the index nodes being merged (3 and 8 in the figure). In this way, after accessing IndexTable 0, the query operation will first check the Merging Index Set and then access IndexTable 1 to ensure the correctness of the query. Once the node insertion is complete, the thread removes the corresponding pointer from the Merging Index Set.

Data append and data flush. DecouKV employs the data append task, an I/O-intensive operation, to write KV pairs into the AOFs on fast devices. Additionally, DecouKV performs the data flush task to flush KV pairs into slow devices. Notably, to avoid the performance gap between random and sequential access on slow devices, DecouKV organizes KV pairs in an ordered data structure (SSTables) on slow devices. When the size of a merged IndexTable reaches the threshold *data_flush_trigger_size*, DecouKV triggers a data flush operation to consolidate the IndexTable and its corresponding AOFs into the slow devices. Specifically, the data flush task sequentially scans all indexes in the IndexTable, retrieves the data from the AOFs and writes them into the SSTables on slow devices. Finally, the system deletes the outdated IndexTable and its corresponding AOFs. Note that while the data flush task inevitably introduces some CPU overhead, I/O remains the primary performance bottleneck on slow devices. Furthermore, since the indexes in the IndexTable are already organized as sorted skip lists, the data flush task is still predominantly classified as an I/O-intensive operation.

3.5 Scheduling Strategy of Decoupled Tasks

In this section, we discuss the scheduling of decoupled CPU-intensive and I/O-intensive tasks to maximize system resource utilization. DecouKV employs two distinct queues to evaluate

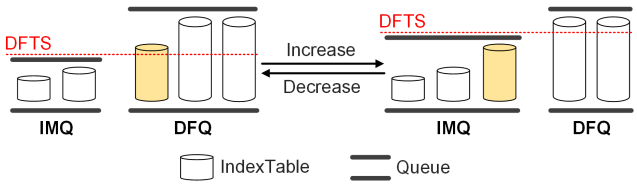


Figure 9: Auto-tuning DFTS. The height of the cylinder represents the size of the IndexTable. The yellow cylinder is the IndexTable that has been moved during auto-tuning DFTS.

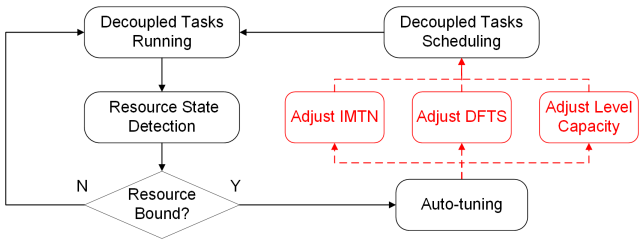

Figure 10: Control flow of task scheduling.

system resource status and uses corresponding parameters to manage task scheduling effectively.

Index Merge Queue (IMQ). DecouKV enqueues small non-insertable IndexTables into the IMQ, awaiting index merge. Since index merge is a CPU-intensive task, the length of the IMQ (L_{IMQ}) reflects the availability of CPU resources. When CPU resources become bottlenecked, the number of IndexTables waiting for merge increases, causing the IMQ to grow. The threshold for triggering an index merge task is referred to as *index_merge_trigger_num* (IMTN). We define $Score_{IM} = \frac{L_{IMQ}}{IMTN}$ to represent CPU resource pressure. When $Score_{IM}$ exceeds a certain value (1.5 is optimal in our experiments), DecouKV identifies the system as CPU-bound.

DecouKV can adjust CPU resource demand by modifying the IMTN parameter. By increasing IMTN, the IMQ can accommodate more IndexTables, thereby reducing the frequency of index merge triggers and alleviating the pressure on CPU resources. Conversely, decreasing IMTN increases the demand for CPU resources.

Data Flush Queue (DFQ). For IndexTables that reach the threshold size of *data_flush_trigger_size* (DFTS), DecouKV places them into the DFQ awaiting data flush. Similarly, the length of the DFQ (L_{DFQ}) reflects the pressure of I/O resources. Since data flush is an I/O-intensive task, when I/O resources become bottlenecked, the DFQ length increases. We define $Score_{DF} = L_{DFQ}$ to represent I/O resource pressure. When $Score_{DF}$ exceeds a certain value (3 is optimal in our experiments), DecouKV identifies the system as I/O-bound.

DecouKV adjusts the DFTS to schedule different resource-intensive tasks. As shown in Figure 9, increasing the DFTS causes some IndexTables to move from the DFQ back to the IMQ, thereby increasing CPU demand and alleviating I/O pressure. Conversely, decreasing the DFTS alleviates CPU pressure and increases I/O demand.

3.6 Elastic Capacity High Levels

For the high levels (HLs) stored on slow devices, DecouKV still uses leveled compaction. Due to memory limitations and the random access performance of slow devices, we cannot leverage the same decoupling design as lower levels. Therefore, we chose to use elastic capacity to mitigate the coupling issue at high levels by relaxing the strict amplification ratio between levels. In Section 2.2, we mentioned three key aspects of the operation coupling issue, with the second point discussing how interdependencies among operations stem from fixed thresholds. Elastic capacity is mainly optimized to address this problem. For example, a large number of HL_0 compactions may lead to an IO-bound situation, which also causes HL_1 to exceed its threshold and trigger further compaction, leading to an even worse IO-bound situation. In this case, DecouKV relaxes the capacity threshold for HL_1, postpones the sorting for that part, and schedules CPU-intensive index merges to improve CPU utilization.

However, relaxing the amplification ratio between levels in other KV stores may temporarily lead to increased size in certain levels, potentially introducing some challenges. (i) Increased write amplification: When the size of L_i increases while the size of L_{i-1} remains relatively smaller, the compaction between L_{i-1} and L_i will involve more data from L_i, causing additional write amplification. (ii) Higher read overhead: With the larger size of L_i, the cost of read operations accessing L_i will increase.

Fortunately, the decoupling design in DecouKV, as described in Section 3.3, successfully addresses both challenges. For the first one, the DFTS parameter (which directly influences the file size written to HL_0) is adjustable. This allows DecouKV to control the size of files written to HL_0. By adjusting the capacity of the high levels according to DFTS, DecouKV ensures that the size ratio between adjacent levels does not become excessively large, thereby controlling write amplification. Additionally, the use of the index merge operation reduces some of the write amplification caused by duplicate keys. For the second one, DecouKV stores hotter data in fast devices, while cold data in the high levels is accessed less frequently. Moreover, data written to higher levels is pre-sorted, resulting in larger sizes for high levels but fewer overall levels. Subsequent experiments demonstrate that even under read-intensive workloads, DecouKV achieves a slight improvement in throughput.

3.7 Auto-tuning for Task Scheduling

As shown in Figure 10, first, DecouKV monitors the IMQ and DFQ to assess the system resource state. It then determines whether the system is in a resource-constrained state based on the scores defined in Section 3.5. Following this, DecouKV performs auto-tuning according to the actual system state. By adjusting IMTN, DFTS, and the level capacity, DecouKV schedules resource-intensive tasks accordingly. This ensures

efficient utilization of system resources and reduces fragmentation. Detailed parameter settings and tuning methods are presented below.

The parameter setting in DecouKV is based on the default values of similar parameters in RocksDB. As a widely adopted industrial storage engine, the parameters in RocksDB are fine-tuned through numerous experimental optimizations. We also validate the efficiency of the selected values via experiments. Specifically, the default value of IMTN in our evaluation is 2. Since IMTN directly impacts read performance, we set it according to the default number of MemTables, which similarly affects read performance. The default value of DFTS is 32MB (4 * 8MB), which is approximately the size of 4 merged IndexTables according to the number of files in L_0 (default 4). When the system is CPU-bound, DecouKV increases the IMTN to reduce CPU resource demand. Simultaneously, DecouKV decreases the DFTS to minimize the triggering of CPU-intensive index merge operations while scheduling more I/O-intensive data flush tasks. Conversely, when the system is I/O-bound, DecouKV reduces the IMTN and increases the DFTS to lower I/O resource demand, thereby scheduling more CPU-intensive tasks. Additionally, proportionally adjusting the capacity of the high levels based on DFTS further regulates I/O resource pressure on slow devices. Note that DecouKV adjusts IMTN by increasing 2 (or decreasing 2) and adjust DFTS by multiplying (or dividing) by 2 according to the state, since the number of IndexTables typically increases incrementally, while the data size often increases exponentially (e.g., two IndexTables of 16MB each are merged into a 32MB IndexTable).

Naturally, these parameters are capped and cannot grow indefinitely. If both CPU and I/O are bound (indicated by congestion in both IMQ and DFQ), DecouKV recognizes that the incoming data writes exceeds the system's processing capacity and slows down data write through write stalls. Finally, when neither queue experiences congestion over a certain period (set to 60 seconds in our implementation), DecouKV identifies that system resources are idle. In this case, it reduces the IMTN, DFTS, and the capacity of the high levels simultaneously to schedule both CPU- and I/O-intensive tasks effectively. In this way, DecouKV improves data orderliness to enhance read performance.

4 Evaluation

In this section, we evaluate and compare DecouKV with RocksDB v9.3.0 and the two categories of solutions mentioned in 2.3 using hybrid storage devices. Among the works following the fixed differentiated management approach, MatrixKV stands out as a typical representative. In the superficial scheduling direction, ADOC represents the state-of-the-art. Therefore, we select RocksDB, MatrixKV and ADOC as the basic benchmarks for comparison. Besides, some state-of-the-art works on hybrid storage, such as PrismDB [42] and SplitDB [6], mainly focus on different scenarios like workload skewness or read-intensive workloads. To ensure a comprehensive evaluation, we also include them in our comparative analysis under YCSB workloads. The test data are obtained from three experimental runs, with minimal variation in the results. The average values are presented.

Hardware environment. The experiments are conducted on a server equipped with two 20-core Intel Xeon Gold 5218R processors and 128 GB of DRAM. The server runs Ubuntu 20.04.6 LTS with the Linux kernel 5.15. For storage devices, we use 128 GB Intel Optane DCPMM and INTEL SSDPE2KE032T8 NVMe SSDs for fast devices, and 960 GB Intel S4520 SSDs with SATA 3.0 interfaces for slow devices.

Configuration of key-value stores. For all KV stores, we use the recommended configuration [21], setting the Memtable size and SSTable size to 64MB, configuring Bloom filters to 10 bits per key, and allocating a block cache size of 1GB. By default, four CPU cores are assigned, with four background compaction threads, following the optimization tuning guide. We also use direct I/O to avoid the impact of the operating system's page cache. For fairness, we limit the amount of fast devices allocated to each KV store to 10% of the dataset size (e.g., 10 GB for a 100 GB dataset). Specifically, for DecouKV, we use the configuration described in Sec 3, deploying AOFs on fast devices while controlling space usage. The initial size of the IndexTable is set to 16MB. For RocksDB and ADOC, we place L_0, L_1, and the WAL on fast devices, slightly increasing the sizes of L_0 and L_1 to ensure an equal allocation of fast devices. For MatrixKV, PrismDB and SplitDB, we follow the configuration from their paper, placing their differentiated data structures on fast devices and allocating an equivalent amount of space.

First, we evaluate the resource utilization, throughput, average latency, and tail latency of various fundamental KV operations using the following workloads: (i) inserting 100 GB KV pairs, (ii) updating 100 GB KV pairs, (iii) reading 100 GB KV pairs, and (iv) scanning 10 GB KV pairs with a maximum scan length of 100. Prior to each experiment, we clear the entire database to avoid interference. By default, we perform the microbenchmark evaluations using a uniform workload with a KV size of 1KB (24B for the key and 1000B for the value). We also conduct the same operations under a zipfian distribution and observe similar results, so we omit the results in the interest of space.

4.1 Microbenchmark

Resource utilization. We evaluate the variation in CPU and disk utilization using psutil [44] during insert and update operations over a 1500-second period. We calculate the average CPU utilization and fluctuation range during this time, as shown in Figure 11. For the insert operation, compared to RocksDB, MatrixKV, and ADOC, DecouKV achieves a 32.3%, 25.4%, and 27.3% increase in average CPU utilization, respectively, while significantly reducing the fluctuation range. This improvement is a key factor contributing to the

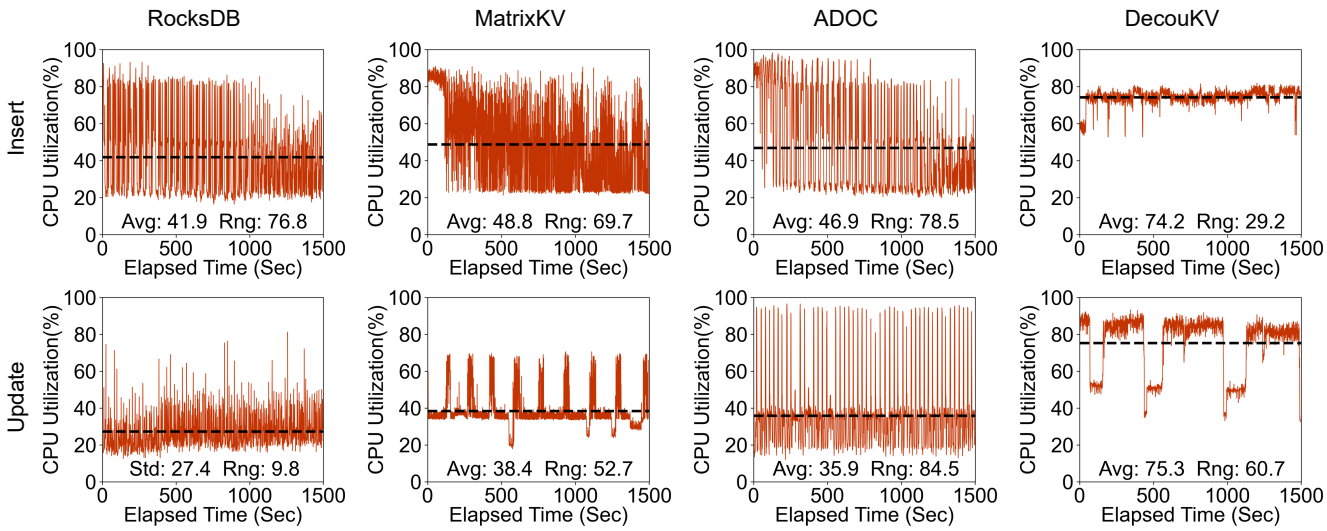

Figure 11: The red solid line represents the real-time CPU utilization over a 1500-second period, measured at a granularity of one second. The black dashed line indicates the average CPU utilization over this period. In the figure, "Avg" denotes the average value, and "Rng" represents the range, reflecting the extent of fluctuation in utilization.

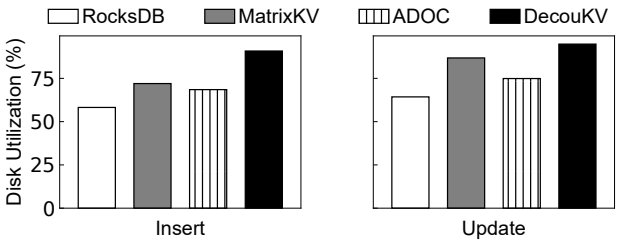

Figure 12: Disk utilization.

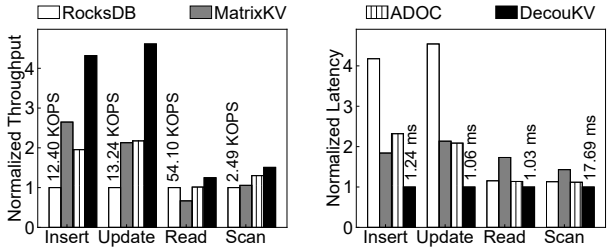


(a) Throughput. (b) Average latency.

Figure 13: Performance under different operations.

significant write performance gains achieved by DecouKV. For the update operation, compared to RocksDB, MatrixKV, and ADOC, DecouKV improves average CPU utilization by 47.9%, 36.9%, and 39.4%, respectively. Due to the capacity limitations of fast devices, DecouKV experiences resource fluctuations. However, upon examining the fluctuation intervals, we observe that DecouKV maintains relatively stable resource utilization over extended periods. Figure 12 presents the average disk utilization over the same period. Compared to RocksDB, MatrixKV, and ADOC, DecouKV achieves a 17.6%–31.6% increase in disk utilization for the insert operation and an 8.0%–19.9% increase in disk utilization for the update operation. Additionally, we observe that MatrixKV exhibits high disk utilization, indicating that fine-grained compaction can mitigate intertwined resource consumption and improve disk utilization. However, due to interdependencies among operations, it still suffers from significant resource fluctuations. ADOC reduces blocking by scheduling data sorting operations, improving average resource utilization compared to RocksDB. Nonetheless, on hybrid storage devices, it experiences even more severe resource fluctuations due to intertwined resource consumption. In summary, DecouKV improves average resource utilization and reduces fragmentation by mitigating resource usage dependency.

Throughput. Figure 13(a) presents the throughput results for various operations. To facilitate comparison, we normalize the experimental results using the throughput of RocksDB as the reference and annotate the absolute values in the figure. Compared to RocksDB, DecouKV achieves 4.3× the throughput for inserts and 4.6× the throughput for updates. Additionally, DecouKV achieves 1.2× the throughput for reads and 1.5× the throughput for scans. Under read-intensive workloads, the background threads remain idle and DecouKV is adapted to allow a very limited number of overlapping IndexTables and files, resulting in a higher degree of data order and fewer levels in the LSM-tree (e.g., HL_0 is empty in most cases). Meanwhile, benefiting from the excellent random access performance of fast storage devices, the impact of removing the Bloom Filter in AOF is effectively mitigated. As a result, DecouKV's read performance is not significantly affected and even shows a slight improvement.

Compared to MatrixKV and ADOC, DecouKV also demonstrates a significant advantage under write-intensive workloads. Specifically, DecouKV achieves 1.6× and 2.2× the

Latency (ms)	Insert		Update	
	90%	99%	90%	99%
RocksDB	9.454	37.557	11.619	16.132
MatrixKV	5.571	12.532	10.010	22.219
ADOC	6.995	17.881	7.545	21.075
DecouKV	**1.579**	**3.227**	**2.275**	**14.480**

Table 1: Tail Latency.

Workload	Characteristics
A (Update Heavy)	50%updates, 50%reads
B (Read Mostly)	5%updates, 95%reads
C (Read Only)	100%reads
D (Read Latest)	5%inserts, 95%reads
E (Scan Mostly)	5%inserts, 95%scans
F (Read-Modify-Write)	50%read-modify-write, 50%reads

Table 2: YCSB core workloads.

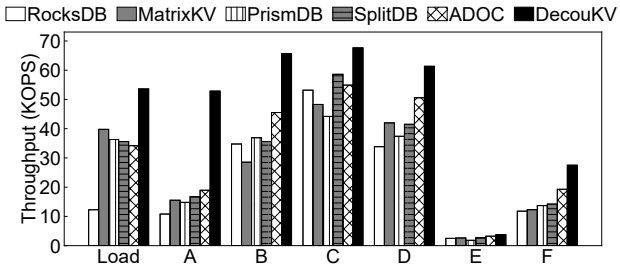
throughput of MatrixKV and ADOC, respectively, for insert operations, and 2.2× and 2.1× the throughput for update operations. Additionally, DecouKV shows good performance in both read and scan operations.

Average latency. Figure 13(b) presents the experimental results normalized to DecouKV's average latency, with DecouKV's latency values annotated in the figure. Compared to RocksDB, DecouKV reduces the average latencies for inserts and updates by 76.0% and 77.9%, respectively. In comparison to MatrixKV and ADOC, DecouKV achieves a reduction in average latencies for inserts and updates ranging from 38.7%–56.9%. Additionally, DecouKV achieves average latencies for reads and scans comparable to those of other KV stores.

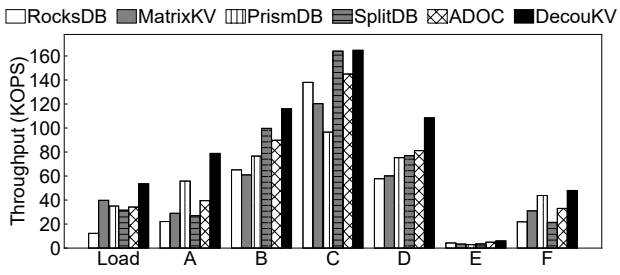
Tail latency. Table 1 presents the P90 and P99 tail latency results for insert and update operations. We observe that compared to RocksDB, MatrixKV, and ADOC, DecouKV reduces the P90 tail latency of the insert operation by 71.6%–83.3% and the P99 tail latency by 74.3%–91.4%. For the update operation, DecouKV reduces the P90 tail latency by 69.8%–80.4%. These improvements are attributed to the stable resource utilization and the reduction in resource bottlenecks in DecouKV. However, DecouKV does not show a significant advantage in P99 tail latency, which corroborates the fluctuations in resource utilization shown in Figure 11.

4.2 YCSB Benchmark

In this section, we evaluate DecouKV using the YCSB-C [39, 43], a C++ version of YCSB [11] benchmark. YCSB (Yahoo! Cloud Serving Benchmark) is a widely used testing tool that generates workloads based on real-world data characteristics. We conduct our evaluation using the six workload configurations shown in Table 2. Each workload runs 100 million operations on a randomly loaded 100GB database, with a KV size of 1KB (24B for the key and 1000B for the value). All other settings remain consistent with those used in



(a) Uniform workloads.



(b) Zipfian workloads.

Figure 14: Throughput under YCSB workloads.

previous experiments. Figure 14(b) and Figure 14(a) present the throughput of RocksDB, MatrixKV, PrismDB, SplitDB, ADOC, and DecouKV under the YCSB uniform and zipfian workloads.

Write-intensive workloads (load, YCSB-A, and -F). For write-intensive workloads, DecouKV demonstrates significant throughput improvement. Compared to RocksDB, DecouKV achieves a 2.3–4.9× improvement. In comparison to MatrixKV and ADOC, DecouKV shows a smaller improvement under the load workload, with a 1.4× and 1.6× increase, respectively. This indicates that MatrixKV and ADOC, as optimized solutions for addressing write stall issues, effectively reduce the occurrence of write stalls under pure write workloads, leading to superior performance. However, for read-write mixed write-intensive workloads like YCSB-A and YCSB-F, the resource bottlenecks caused by frequent writes also impact read performance. DecouKV successfully mitigates resource fragmentation, reducing its impact on both read and write performance, thus providing an advantage with a 1.5–3.4× improvement. Compared to PrismDB and SplitDB, DecouKV demonstrates significant advantages under uniform workloads, achieving improvements of 1.5–3.6×. Under heavily skewed Zipfian workloads, PrismDB performs particularly well in write-intensive cases (YCSB-A, YCSB-F). This is because PrismDB employs a slab-based structure and in-place update strategy on the fast devices. When the workload is highly skewed, a large portion of write requests are handled on the fast devices and are not pushed to the slow device, thus achieving high throughput. However, DecouKV still achieves strong performance overall.

Additionally, according to our previous analysis, the sys-

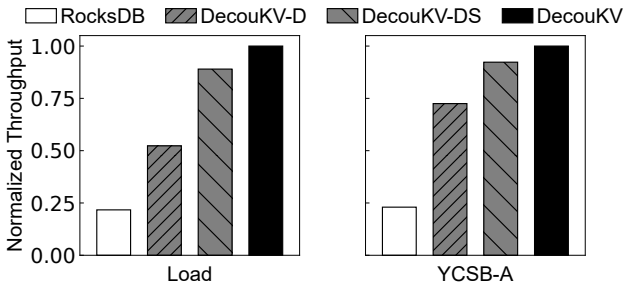


Figure 15: Normalized throughput of different DecouKV versions.

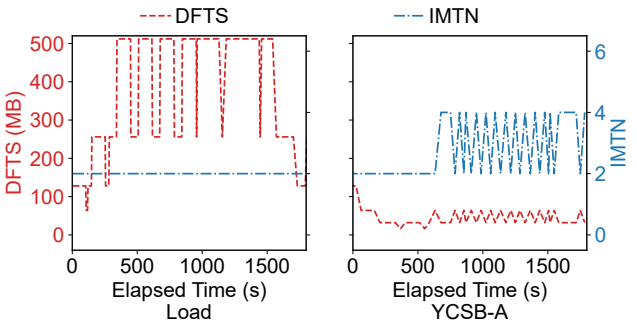

Figure 16: Tuning actions for load and YCSB-A workloads.

tem often enters a resource-constrained state under write-intensive workloads. In such cases, DecouKV relaxes certain parameters, resulting in the creation of multiple overlapping files (e.g., IndexTables or SSTables in HL_0), which could impact read performance. However, in our experiments, we observe that DecouKV's read performance is not significantly affected. This is because, under write-intensive workloads, with the scheduling of decoupled tasks in DecouKV, the burst in CPU usage is short-lived, thereby preventing excessive IndexTables (in the evaluation, the number of IndexTables never exceeds 6, which is even lower than the number of files in L_0 in RocksDB, even during write stalls). As shown in Figure 16, the maximum value of IMTN is only 4, further validating this result. Regarding overlapping SSTables in HL_0, we set the number of files to one in order to trigger the compaction of data from HL_0 to HL_1, giving HL_0 compaction a higher priority. In the evaluation, even under write-intensive workloads, the number of files in HL_0 does not exceed two. Under read-intensive workloads, HL_0 is empty in most cases.

Read-intensive and scan-intensive workloads (YCSB-B, -C -D, and -E). For read-intensive and scan-intensive workloads, DecouKV also demonstrates modest improvements. Compared to RocksDB, MatrixKV, and ADOC, DecouKV achieves a 1.2–1.9× improvement under the zipfian workload and a 1.2–2.3× improvement under the uniform workload. These gains primarily stem from more efficient resource utilization and a reduction in the number of high levels on slow devices. Compared to PrismDB and SplitDB, DecouKV also exhibits slight advantages under uniform workloads, achieving a 1.1–1.8× improvement. For highly skewed zipfian workloads, DecouKV shows no advantage, whereas SplitDB performs remarkably well. SplitDB employs a cascading skiplist index–which constructs fast paths between adjacent LSM-tree levels to reduce lookup latency–and a data promotion and demotion mechanism that migrates hot data from slower SSDs to faster NVM and cold data to SSDs, thereby optimizing read performance under skewed workloads.

4.3 Performance Breakdown

In our design, we consider three primary techniques to optimize system performance: decoupling, scheduling strategies, and elastic capacity for high levels. In this section, we evaluate the performance contribution of each technique to DecouKV. However, task scheduling relies on decoupling, while elastic capacity high levels depends on scheduling strategies. Consequently, we evaluate three versions of DecouKV against RocksDB: DecouKV-D (decoupling only, with the queue parameters set to the average of the auto-tuning results from the experiment), DecouKV-DS (decoupling + scheduling strategies), and DecouKV (decoupling + scheduling strategies + elastic capacity high levels, i.e., the complete version of DecouKV). Figure 15 shows the throughput of different DecouKV versions during insert and update operations, normalized to DecouKV as the baseline. In the following, we will explain the contribution of each component.

Decoupling technique. By comparing the performance of DecouKV-D with RocksDB, we can roughly estimate the contribution of the decoupling technique. The decoupling technique contributes significantly to both the load and YCSB-A workload, with a greater contribution observed under the YCSB-A workload. This is because DecouKV's decoupling technique primarily targets data on fast devices, and a substantial portion of the updates in the YCSB-A workload can be completed solely on fast devices.

Scheduling strategies. Similarly, by examining the differences between DecouKV-DS and DecouKV-D, we can roughly assess that the scheduling queue technique has a greater contribution to the load workload. To further understand this, we record the variations in the parameters DFTS and IMTN during load and YCSB-A workload in the 2000s, as shown in Figure 16. After decoupling, during the load workload, DFTS is significantly increased, indicating a clear performance bottleneck in I/O. DecouKV mitigates this bottleneck by increasing DFTS to schedule more CPU-intensive operations, thus reducing the demand for I/O resources. In contrast, during the YCSB-A workload, DFTS and IMTN are not significantly adjusted, suggesting that the CPU and I/O resources are well balanced after decoupling, and no excessive scheduling is required. Therefore, the scheduling queue technique contributes more to load workload.

Elastic capacity high levels. The performance difference between DecouKV and DecouKV-DS demonstrates that the elastic capacity for high levels technique provides greater ben-

(a) Throughput on NVMe SSDs. (b) Memory budget comparison.

Figure 19: Comparison of throughput after replacing fast devices with NVMe SSDs and memory budget.

efits for load workload compared to YCSB-A workload. This is primarily because the load workload has a more significant impact on the high levels than the YCSB-A workload. Moreover, the elastic capacity high levels technique further mitigates the interdependencies among operations, minimizing the impact of excessive data sorting tasks on other operations during the write-intensive load phase.

4.4 Performance under Other Workloads

YCSB workloads with a huge size dataset. We conduct performance evaluations on a larger YCSB uniform workload, which includes a 500GB dataset (i.e., 500 million key-value pairs), as shown in Figure 17(a). Compared to RocksDB, DecouKV demonstrates performance improvements of 5.2×, 2.8×, and 2.4× under write-intensive load, YCSB-A, and YCSB-F workloads, respectively, consistent with the results obtained with the 100GB dataset. In comparison to MatrixKV and ADOC, DecouKV achieves performance improvements of 1.6–2.4× under the same workloads, even slightly outperforming the results from the 100GB dataset. This is attributed to the slight performance degradation observed in MatrixKV and ADOC with larger datasets, whereas DecouKV maintains its performance advantage due to more efficient utilization of system resources.

Nutanix production workloads. We also evaluate the throughput performance of various KV systems using a real-world workload from Nutanix, which closely resembles a write-intensive workload with 57% updates, 41% reads, and 2% scans. The results, shown in Figure 17(b), demonstrate that DecouKV outperforms other systems, achieving a throughput improvement of 1.3–2.0×.

4.5 Understanding DecouKV Performance

Impact of KV size. We evaluate the variation in throughput performance of the load under different value sizes. As shown in Figure 18(a), DecouKV demonstrates the most significant advantage when the value size is 1KB and 4KB. It is known that as the value size increases, the demand for I/O bandwidth also increases. Conversely, when the value size decreases, the load's demand for CPU resources becomes more significant. When the value size is too large (16KB) or too small (256B), severe imbalances in the demands for CPU and I/O resources results in performance degradation, leading to resource shortages of a single type. Consequently, the benefits of decoupling decrease, and ADOC, which smooths the data flow through scheduling, still performs well.

Impact of core number. We evaluate the impact of the number of CPU cores on load performance. As shown in Figure 18(b), when the number of CPU cores is low (e.g., 2 cores), the performance improvement of DecouKV is modest due to limited CPU resources. As the number of cores increases, DecouKV 's performance advantage becomes more pronounced, indicating that DecouKV can better leverage the additional CPU resources. However, when CPU resources become excessive (e.g., 16 cores), the performance of DecouKV no longer increases, as it becomes constrained by disk I/O.

Performance on different devices. We evaluate the throughput performance of DecouKV on different fast devices. Specifically, we use the INTEL SSDPE2KE032T8 NVMe SSD as the fast device and leverage io-uring to fully exploit the asynchronous I/O capabilities of the NVMe SSD. As shown in Figure 19(a), DecouKV demonstrates a throughput improvement of 1.4–2.4× over RocksDB, MatrixKV, and ADOC when deployed on hybrid storage devices consisting of an NVMe SSD and a SATA SSD.

Memory budget. We record the maximum memory usage during the experiments, with YCSB-A requiring the highest memory. As shown in Figure 19(b), about 23% (0.7GB) of memory is used for the IndexTable–more than RocksDB's MemTable (0.3GB). Approximately 45% (1.4GB) is used

for DecouKV's Tablecache, less than RocksDB's (1.56GB), because there's no need to cache the AOF's Filter Block and Index Block. The memory usage of DecouKV is comparable to that of MatrixKV and ADOC, with only a slight increase over RocksDB, while achieving higher performance.

Recovery time. We also test the recovery capability of DecouKV in the event of system crashes. Specifically, we verify that data persisted in the AOFs on fast devices before a crash can be used to rebuild the index upon reboot. The results show that DecouKV successfully recovers after multiple crash tests. In terms of performance, the recovery speed of DecouKV and RocksDB is nearly identical, with recovery times of 8.76s and 8.12s, respectively, for a 10GB database. This is because the high sequential read bandwidth provided by the fast devices enables rapid index rebuilding.

5 Related Work

Performance optimization of LSM-tree-based KV stores. A lot of research focus on optimizing the performance of LSM-tree-based KV stores. One line of investigation addresses the issue of write stalls. SILK [4] aims to mitigate the tail latencies caused by write stalls by adjusting the priority of background threads and rate-limiting their operations. ADOC identifies data overflow in various components of LSM trees as the direct cause of write stalls and fine-tunes parameters such as the number of threads and batch size to schedule flush and compaction operations more effectively. Another line of research focuses on reducing write amplification through KV separation. WiscKey [35] is the first to propose storing values in a separate append-only log, while Bourbon [12] extends WiscKey by indexing values through a learned approach. HashKV [8] and BadgerDB [16] have optimized the additional overhead introduced by garbage collection in the context of KV separation. Other studies focus on optimizing read and scan performance, including systems such as LSM-trie [46], UniKV [49], ElasticBF [34], and DiffKV [33].

Deploying LSM-tree-based KV stores on new devices. Recent studies also focus on new types of storage media, with some research targeting hybrid storage solutions, similar to the scenario discussed in this paper. NoveLSM extends memory components to PM and employs in-place updates to reduce compaction overhead. SLM-DB [28] improves upon this by constructing a global B+-tree index on PM and using optional compaction to minimize write amplification. MatrixKV identifies L_0-L_1 compaction as the root cause of PM device write stalls and addresses this issue by using matrix containers for differentiated management of L_0 on PM. Fine-grained matrix compression is employed to reduce write stalls.

Besides, some works [6, 42, 45] mainly focus on different scenarios like workload skewness or read-intensive workloads. PrismDB modifies the hierarchical structure to reduce compaction overhead and uses a cold-hot awareness approach to improve read performance. SplitDB employs a cascading skip list index and a data promotion and demotion mechanism that migrates hot data from slower SSDs to faster NVM and cold data back to SSDs, thereby optimizing read performance under skewed workloads. PRISM [45] analyzes the advantages of each storage device and adopts hybrid management for heterogeneous storage. However, abandoning the tree structure leads to some loss in scan performance and complicates garbage collection management. Other studies focus on scenarios where cost is not a primary concern, and fast devices nearly replace slow ones. KVell [32] relaxes data ordering and employs a share-nothing design to fully utilize the bandwidth of fast devices. ListDB [30] deploys the entire LSM-tree on a system with only DRAM and PM and replaces SSTables with a NUMA-aware skip list. MioDB [17] leverages the byte-addressable feature of PM, managing data on PM using skip lists and performing zero-copy compaction for merging between skip lists.

Tuning and scheduling of LSM-tree-based KV stores. Many studies observe that configuration settings significantly impact the performance of LSM-trees. Monkey [13] proposed a configuration tuning framework that optimizes memory allocation strategies and read/write performance under worst-case scenarios. Dostoevsky [14] employs a hybrid strategy to determine the levels at which compaction occurs. Rafiki [37] and TiKV [41] utilize offline training methods to compute optimal configuration settings. These works achieve substantial performance improvements in their respective scenarios; however, their tuning and scheduling approaches are often highly dependent on workload characteristics.

6 Conclusion

In this work, we analyze the data sorting operations of sorting-based KV stores and identify operation coupling as the root cause of resource usage dependency and fragmentation on hybrid storage devices. While two existing approaches—fixed differentiated data management and superficial scheduling of data sorting operations—fail to fundamentally address the problem of inefficient resource utilization.

We propose DecouKV to mitigate resource usage dependency in sorting-based KV stores on hybrid storage devices via operation decoupling. Experimental results demonstrate that, compared to RocksDB and the aforementioned solutions, DecouKV improves CPU utilization by 25.4%–32.3% and increases throughput by 2.3–4.9× under write-intensive workloads, while reducing tail latency by 74.3%–91.4%. Furthermore, under read-intensive workloads, DecouKV also achieves a modest throughput improvement of 1.2-2.3×.

A Artifact Appendix

Abstract

Our artifact includes the prototype implementation of DecouKV and three other state-of-the-art comparison systems, along with the YCSB benchmark evaluated in the Evaluation section. Additionally, we provide the experimental scripts necessary to reproduce our results on hybrid devices. Please note that running the full evaluation requires several tens of hours to complete.

Scope

This artifact allows reviewers to reproduce the main experimental results of the paper, including:

- *DecouKV improves CPU utilization compared to other systems and reduces utilization fluctuations under write-intensive workloads (Load, YCSB-A).*
- *DecouKV achieves higher throughput than other systems under write-intensive workloads (Load, YCSB-A, -F); it also provides moderate improvements under read- or scan-intensive workloads (YCSB-B, -C, -D, -E).*
- *DecouKV reduces average latency compared to other systems under write-intensive workloads; it also brings slight improvements under read- or scan-intensive workloads.*

Contents

The artifact is hosted in a git repository. This repository includes DecouKV's source code as well as documentation and experimental scripts. It is structured as follows:

db_impl/: *This folder contains the source code implementation of DecouKV, as well as three other comparison systems (RocksDB, MatrixKV and ADOC). Users can switch between the test systems by modifying the value of 'systems' in the script. The source code is structured as follows:*

- ***adoc/****: This folder contains the source code implementation of ADOC.*
- ***decoukv/****: This folder contains the source code implementation of DecouKV.*
- ***matrixkv/****: This folder contains the source code implementation of MatrixKV.*
- ***rocksdb/****: This folder contains the source code implementation of RocksDB.*

test_results/: *This folder is automatically created after running the test script, and the test results will be saved here. The* ***ycsb_latency.csv*** *file stores the latency results after running the test, while the* ***ycsb_throughput.csv*** *file stores the throughput results.*

workloads/: *This folder contains the main parameters for the YCSB workload. Each YCSB workload file can be modified to change parameters such as database size (recordcount), number of operations (operationcount), read/write ratio, and key distribution (Uniform or Zipfian).*

db_config.yaml: *This file includes some system-level configurations that can be customized, including SSTable size, MemTable size, and other internal parameters.*

test.sh:*This file is the unified test script. It will compile all four systems, run Load, YCSB-A to F workloads, and output the CPU utilization fluctuation plot into* ***./test_results/****. This step may take over 50 hours to complete, and you can monitor the script's progress in the* ***test.log*** *file. Reducing the data volume (default: 100GB) can shorten the runtime, but it may affect the final results.*

Hosting

The artifact is hosted on GitHub at: `https://github.com/QingyangZ/DecouKV.git`*. Please refer to the* `main` *branch and the latest commit version for the exact code used in this paper.*

Requirements

The artifacts have been developed and tested on Ubuntu 20.04.6 LTS with Linux kernel 5.15. The hardware includes 128 GB Intel Optane DCPMM for fast devices and 960 GB Intel S4520 SSDs with SATA 3.0 interfaces for slow devices. Approximate resource requirements are a dedicated server with at least 10 CPU cores, one SSD with over 200GB of free space, and one PMEM device with over 50GB of free space.

A.1 Installation

1. *First, to clone the repository, run the following commands:* `git clone https://github.com/QingyangZ/DecouKV.git`*.*
2. *Then, to initialize and update the submodules, run:*

```
git submodule init
git submodule update
```

3. *Next, to install the required packages, use:*

```
sudo apt install libsnappy-dev
libgflags-dev zlib1g-dev libbz2-dev
liblz4-dev libzstd-dev
libpthread-stubs0-dev libnuma-dev
libstdc++-dev libpmem-dev liburing-dev
```

A.2 Experiment workflow

To run the full experiment, execute the `test.sh` *script in the background. This script compiles all four systems, runs* ***Load*** *and* ***YCSB-A to F*** *workloads, and outputs the CPU utilization fluctuation plot into the* `test_results/` *directory. After the test completes, generate throughput and latency figures by running* `draw_throughput.sh` *and* `draw_latency.sh`*.*

Abstract

Mobile cloud backup applications are widely used to safeguard user data. This paper found that current cloud backup is inefficient on resource-limited mobile devices because it consumes excessive CPU resources for delta synchronization that requires intensive hash computation to identify the modified ranges of file data. To address this issue, this paper presents SolFS, an operation log versioning file system to optimize mobile cloud backup efficiency. The core idea is that if the cloud backup application knows the modified offset and length of each write since the last backup, it will be able to identify the new modified data and upload them only, avoiding data hashing throughout the entire file. SolFS proposes a series of designs to achieve this design goal. First, SolFS introduces per-file mergeable operation logging that allows each file to manage its write operation logs (i.e., offset and length) in an extent tree and merge operation logs with contiguous or overlapping modified ranges of file data. Then, SolFS proposes the operation log persistence and versioning mechanism that allows different cloud backup applications to manage their own file versions without interfering with each other. In addition, SolFS incorporates techniques such as compact log and dynamic granularity, to optimize the memory and storage overhead to the system. Finally, SolFS achieves hash-free file difference identification with minimum additional overhead and extends the ability of cloud backup applications. The experimental results show that SolFS can significantly reduce the computational overhead of both APP-side or server-side by over 90% on average and the total cloud synchronization time by over 88.8% when files are updated.

1 Introduction

Mobile devices have become an essential part of our daily lives, with around 1.34 billion smartphones sold in 2023 [32]. These devices are now an important venue for personal data storage, making data loss a serious concern. To mitigate this risk, mobile cloud backup applications (APPs) are widely adopted to protect user data, such as Dropbox, OneDrive, and smartphone vendors' built-in cloud backup APPs. These mobile APPs usually choose to upload the entire file data, but this approach could result in high network traffic and low backup efficiency, especially when uploading files with minor data changes. Therefore, some APPs adopt delta synchronization to speed up the cloud synchronization time by leveraging hashing to identify and upload modified file data only [3,9,10,23,34]. However, the intensive hash computation caused by delta synchronization increases CPU utilization, resulting in excessive power consumption. In addition, it also leads to conflicting demands of limited mobile CPU resources between cloud backup APPs and other user applications. On the resource-limited mobile devices, the high cost could directly affect the user experience in daily usage, such as shortening the mobile device's battery life [9, 16]. Hence, these cloud backup APPs face a dilemma between cloud backup efficiency and user experience. This paper aims to improve cloud backup efficiency on mobile devices, with a particular focus on overcoming the dilemma between high network traffic and intensive CPU resource consumption.

There are many previous works to improve the efficiency of delta synchronization [5, 6, 10, 11, 24, 34, 36, 38]. A typical design is to divide a file into multiple chunks and then calculate their checksum (i.e., strong hash algorithms like MD5 and SHA256). By comparing the local file's checksum list with that from the cloud server, this approach can identify the modified chunks and upload them only to the cloud server to reduce network traffic, but the minimum network traffic transmitted is limited by the chunk size. The *rsync* [34] algorithm further improves this issue, which employs rolling checksum to identify byte-level modified data before performing chunk-level hashing. One issue of rsync is the high cost at the client side, because rolling checksum requires byte-by-byte comparison. *WebR2sync+* [38] optimizes the client-side overhead of rsync by moving the heavy byte-by-byte comparison to the server side and then the client only needs to perform chunk-level weak hashing and strong hashing. *QuickSync* [9] adopts

*Corresponding author: Yu Liang: yulianglenny@gmail.com.

the Content-defined Chunking (CDC) to detect redundant bytes and *NetSync* [36] reduces the computation cost of the chunk matching process with a fast CDC-based weak hashing. In addition, some researchers introduce lightweight hash algorithms to improve their computational cost [22, 37, 44]. However, on resource-limited mobile devices, these works still impose a high computational cost on identifying old and new modified data.

To address this issue in delta synchronization, we present SolFS, a lightweight operation log versioning file system built with existing mobile file systems. The key idea behind SolFS is to identify old data and new modified data through write operation logs (i.e., each write's offset and length) rather than hashing, thus significantly mitigating the computational cost. However, incorporating this idea into the file system introduces many challenges, including extra access overhead, more resource usage, and file version management across different cloud synchronization and cloud backup applications. SolFS presents a series of designs to overcome these challenges.

First, to reduce the memory and storage usage for operation logs, SolFS proposes per-file mergeable operation logging (or MLogging). MLogging allows each file to manage its own write operation logs in an extent tree that merges operation logs with contiguous or overlapping modification ranges. In addition, MLogging introduces the mlog cache design to improve the logging cost in sequential write operations and the on-demand loading design to minimize the memory usage. SolFS needs to persist operation logs to the disk after file data writebacks for subsequent modification range tracking. To minimize the storage cost, SolFS further introduces dynamic log granularity and compact operation logs. Unlike traditional versioning techniques, SolFS performs versioning for operation logs rather than file data, thus avoiding the issues of file fragmentation and double storage usage. A file's different versions of operation logs are stored and managed in a versioned inode chain, which enables cloud backup APPs to accurately track their individual cumulative modifications based on version number without interfering with each other. Therefore, cloud backup APPs are able to identify old data and new modified data without hashing the entire file to improve the efficiency of delta synchronization.

We evaluate SolFS's performance on a commercial smartphone and compare it with existing delta synchronization solutions. The experimental results show that SolFS can significantly reduce the computational overhead of both APP-side or server-side by over 90% on average and the total cloud synchronization time by over 88% when files are updated.

2 Background and Motivation

2.1 Cloud Backup on Mobile Devices

Mobile cloud backup APPs are commonly utilized to ensure user data security and save storage space by backing up various types of files, such as executable files, database files, and text documents. These APPs can be divided into third-party APPs and built-in APPs. Third-party APPs, such as Dropbox, aim to back up users' personal files and allow users to access their files elsewhere. Built-in APPs are provided by smartphone vendors and can further back up applications' internal files. This enables users to restore their mobile devices to a specific state if their devices are reset or lost.

Cloud backup APPs typically follow a design [11] with two major steps: reading file data and uploading file data to the cloud. For the second step, some APPs adopt delta synchronization to save the network bandwidth and to speed up the upload process [3, 9, 10, 23, 34], while other APPs choose to upload entire file data to avoid intensive hash computation and excessive power consumption caused by delta synchronization. We present and categorize common cloud backup APPs in Table 1 based on our observations.

Table 1: Delta synchronization support in seven common cloud backup APPs.

Mobile APP	Type	Delta Synchronization
Dropbox	Third-party	Not support
OneDrive	Third-party	Not Support
GoogleDrive	Third-party	Not Support
Seafile	Third-party	Supported
Huawei	Built-in	Supported
Samsung	Built-in	Supported
Oppo	Built-in	Supported

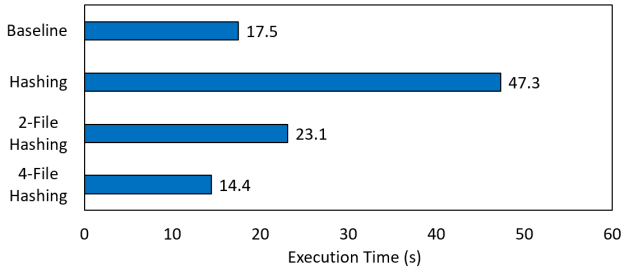
Importance of Frequent Cloud Backup. A fast, timely, and low-overhead file data cloud synchronization scheme has significant practical importance. Delta synchronization is very useful to reduce network traffic and improve upload efficiency in unstable mobile networks [36]. However, it relies on computationally intensive hash calculations and comparisons to identify file differences [3, 9, 10, 23, 34]. Such a high cost drives smartphone vendors and users to restrict their cloud backup frequency (e.g., once a week) to minimize the impact on user experience. However, the most recent user data, such as newly edited documents, is typically more valuable and should be backed up instantly, as cloud backup applications (e.g., Dropbox) do on desktops/servers [9, 24]. APP-specific data in health-care-related or business-related applications, could be important for users to have up-to-date backups because of important body status data and high-value business documents. In addition, as the volume of user data continues to grow, the limited storage space on a single device could become insufficient to store all user data, further making cloud data synchronization an increasingly frequent operation. These scenarios suggest that there is a dire need for mobile users to frequently conduct mobile cloud backups. Mobile users need a low-computation-cost cloud backup mechanism that allows them to avoid compromising between performance and data security.

2.2 Expensive File Hashing

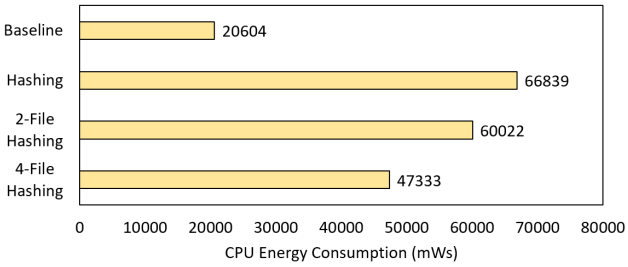
The current delta synchronization efficiency is not satisfactory on mobile devices, as it needs to perform hashing throughout the entire file to locate the modified ranges of data. Specifically, a typical design of delta synchronization involves: 1) the server divides a file into multiple chunks and computes each chunk's checksum based on hashing (e.g., SHA256 and MD5); 2) the file's checksum list is sent to the APP and the APP also performs chunking and hashing for the file to identify and upload the chunks with different checksum [3]. Despite how much file data is modified, this approach requires the hash calculation and comparison processing of all file data to identify data differences, leading to a long identification time and high CPU usage [31, 38]. It is expensive for resource-limited mobile devices because the excessive use of CPU resources not only degrades the user experience (competing with other applications for CPU resources), but also shortens the battery life of the mobile device in daily usage [9, 16]. To quantitatively evaluate this impact on a recent mobile device (Google Pixel 8), we develop an APP following this typical delta synchronization design.

This APP backs up 15GB of data in total[1] and the backup procedure includes reading the files, dividing them into chunks, and leveraging the built-in SHA256 algorithm for hashing, similar to the content hash used by the desktop version of Dropbox [12]. As depicted in Figure 1, *Hashing* introduces an additional 170% execution latency and 224% CPU energy consumption on average due to the intensive computation, compared to reading files only (*Baseline*). In addition, we also notice that the read operation contributes around 30.8% of total cost during hashing. To achieve better performance, the APP can perform parallel hashing for multiple files rather than single-threaded hashing, such as *2-File Hashing* and *4-File Hashing*. The parallel hashing could achieve a lower execution time compared with the single-threaded reading (4-File Hashing v.s. Baseline), but consumes more CPU resources at the same time, increasing the competition of CPU resources with other applications. Furthermore, its energy consumption with four threads (i.e., 47333 mWs) is still more than twice that of the baseline (i.e., 20604 mWs).

There are previous works available on the desktop/server platform to improve the upload efficiency of delta synchronization. Rsync [34] is proposed to employ a weak hash algorithm called rolling checksum, which uses a sliding window and performs byte-by-byte comparison to obtain byte-level file differences instead of that of chunk-level. This algorithm is easily prone to hash collisions and thus rsync has to use strong hashing for all unmodified data chunks to ensure that these data chunks are truly not modified. Hence, rsync still consumes many CPU resources on the APP side. WebR2sync+ [38] improves this issue by moving the heavy byte-by-byte comparison to the cloud server side, but the weak and strong hashing are still required on the APP side. *QuickSync* [9] adopts the Content-defined Chunking (CDC) to detect redundant bytes during network transmission and *NetSync* [36] employs the CDC technique to further avoid the computation cost of overlapping chunks. These previous efforts have focused on reducing the computation cost during delta synchronization; however, all these approaches still require hashing the entire file data to identify data differences, making intensive computation unavoidable, increasing CPU loads and energy consumption on mobile devices.



(a)



(b)

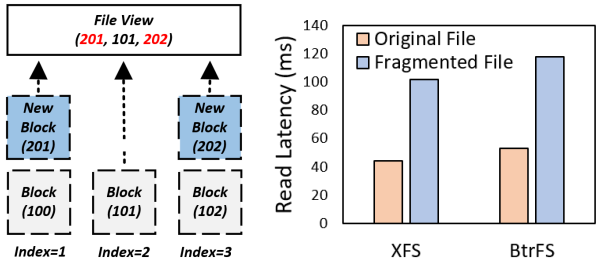
Figure 1: (a) execution time in seconds; (b) CPU energy consumption (mWs). The energy data is collected by the On Device Power Rails Monitor [2]. For reference, the device energy consumption from top to bottom is 37520, 120136, 86911, 65222 mWs, respectively.

Reducing computation is challenging. We rethink the nature of delta synchronization—uploading only modified file data. In other words, reading and hashing entire file data may be unnecessary if we have a proper system mechanism to identify the range of file changes. Then, we could either directly upload the modified range of data, or perform hashing on this selected range to further reduce network traffic, because sometimes the data after modification is the same as before modification. As small writes dominate [8, 19] on mobile devices, it is expected that this hash-free identification approach could reduce the computation cost on mobile devices by avoiding hashing the entire file data. Therefore, file system is a very suitable scenario to implement this idea, because it can instantly record file changes without incurring a high overhead. For example, the file snapshotting and versioning techniques in file system design [20, 28–30], such as the reflink feature of XFS and BtrFS, have the potential ability to achieve this goal. The copy-on-write (CoW) approach

[1] As a reference, we collected used storage space from 35 real users' mobile devices and found that each device stored 118GB of data on average.

adopted in these works allows cloud backup APPs to identify old data and new modified file data without hashing.

As shown in Figure 2(a), the CoW approach always allocates new blocks for new modified data (e.g., PBA 201 and 202), while old blocks (PBA 100-102) serve as old data, allowing the file system to classify them. However, this design will introduce file fragmentation issues after multiple file updates [15, 18, 39]. For example, the file view in Figure 2(a) includes PBA 201, 101, 202, becoming non-consecutive after updating data in a CoW manner. Figure 2(b) presents the impact of file fragmentation that could remarkably degrade the sequential read performance. BetrFS [42] tries to mitigate this drawback based on a copy-on-abundant-write design and WaybackFS [7] avoids file fragmentation by replacing old data with an undo log. However, supporting these features on F2FS [21], the most widely used file system on mobile devices, is complex and often requires changes to the disk layout [43]. In addition, all these solutions, whether based on CoW or undo logs, have to continuously allocate additional memory and storage space to manage multiple versions of file data, which is still expensive for resource-limited mobile devices.



(a) (b)

Figure 2: (a) CoW-based hash-free solution, where the number in each block presents a physical block address (PBA); (b) sequential read latency in a 10MB file. The fragmented file is created based on the reflink feature and we randomly update 1MB data on it.

3 SolFS Design

In this section, we introduce *SolFS* to cope with the mentioned challenges. SolFS[2] is a lightweight *operation log versioning file system* to mitigate hash computation during delta synchronization while overcoming the limitations of snapshotting and versioning file systems. The main design goals of SolFS involve:

- **Hash-free Identification**: SolFS is designed to identify modified ranges of file data without hashing by the collaboration with file system.
- **Overhead Minimization**: SolFS minimizes the I/O, memory and storage overhead discussed in Section 2.2.
- **Generality**: SolFS supports multiple backup APPs (e.g., built-in and third-party) on the same device to manage their respective file differences without interfering with each other.
- **Backward Compatibility**: There are over 6.5 billion of mobile devices in the world [13] and we expect that all existing mobile devices could benefit from SolFS.

[2]The source code of SolFS is available at https://github.com/MIoTLab/SolFS.

3.1 Architecture Overview

To achieve these design goals, SolFS introduces several effective designs to existing mobile file systems, as shown in Figure 3. Our designs are based on the observation that if the cloud backup APP knows the modified offset and length of each write since the last backup, it can accurately identify newly modified data. This allows cloud backup APPs to selectively upload the modified data directly, or apply hashing (e.g., chunk-level hashing and rolling hashing) to only the modified data range and then upload it without requiring hashing throughout the entire file.

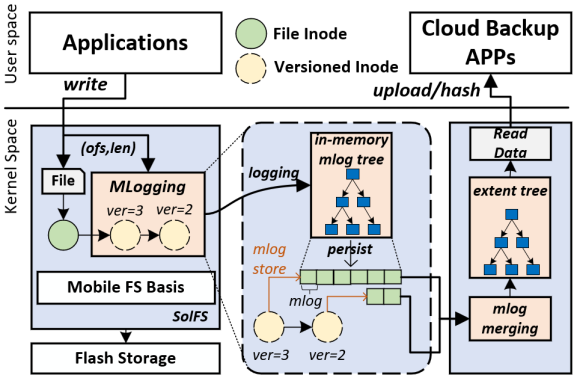


Figure 3: SolFS architecture (shown in blue).

Therefore, SolFS first introduces per-file mergeable operation logging (or *MLogging*, see Section 3.2), which keeps track of each write's offset and length by recording them as operation logs in a new auxiliary inode. This design avoids the file fragmentation issue when the file is continuously updated and minimizes the storage cost of operation logs by not storing actual file data. Specifically, MLogging enables mergeable operation logs (*mlogs* for short) by managing operation logs in an in-memory mlog tree, which is based on a modified extent tree design. The mlog tree will merge contiguous or overlapping operation logs if possible and minimize its additional overhead on write operations. To control uploaded data in different cloud backups, SolFS proposes the mlog versioning mechanism to manage different versions of mlogs. This technique leverages extended file attributes [26] to integrate the inode versioning functionality for mlogs while ensuring backward compatibility. Additionally, SolFS persists different versions of mlogs to different versioned inodes, supporting

multiple cloud backup APPs to accurately manage their own mlogs for unuploaded file data. During delta synchronization, a cloud backup APP can traverse the file's versioned inodes to merge mlogs into an extent tree that indicates the modified data ranges (see Section 3.3). Based on these ranges, the APP can either directly upload the modified data or apply hashing (e.g., rolling checksum) to further reduce network traffic.

3.2 Per-file Mergeable Operation Logging

MLogging identifies old and new modified file data by logging each write's offset and length (i.e, *mlog*). The different write's mlogs can be merged and the offset and length of each mlog can be aligned to two different granularities: byte-aligned and page-aligned. This design enables SolFS to balance memory/storage costs with the identification granularity of modified data. In addition, because MLogging writes new data to the original file inode and stores mlogs in additional inodes, no file fragmentation is introduced, ensuring good sequential read performance.

3.2.1 Mergeable Operation Log Tree.

To prevent the rapid growth in memory and storage usage for mlogs, MLogging introduces an in-memory mlog tree to manage mlogs of the head versioned inode (see Section 3.2.2). Based on the the extent tree design, the mlog tree can merge mlogs with contiguous or overlapping modification ranges. Specifically, a new mlog is inserted into the tree using its offset as the key. During insertion of a new mlog, MLogging traverses the mlog tree to identify the contiguous or overlapping mlogs. If found, they are merged, and memory/storage space is released; otherwise, the new mlog is inserted into the tree.

Figure 4 demonstrates this mechanism. For example, request 3 `(25,10)` overlaps with an existing mlog `(20,7)` so that MLogging only updates the existing mlog to `(20,15)`. In this way, MLogging reduces the high storage overhead of storing new operation logs. For sequential writes or appends, they only update the last-accessed mlog so that the direct mlog tree insertion is not optimal (i.e., $O(logN)$ operations). Therefore, SolFS introduces an mlog pointer cache at the root of the mlog tree, which records the last-accessed mlog. This design reduces mlog updates for sequential writes and appends to $O(1)$ operations, further improving additional cost on write operations. For instance, in Figure 4, request 1 and 2 are two subsequent write requests. Request 1 does not hit the mlog cache, requiring a traversal of the mlog tree, while request 2 hits the cache, allowing direct updates to the target mlog.

Persistence with Compact Mlogs. In the MLogging design, an in-memory mlog tree is allocated to track file differences when a file is opened and is persisted to the disk when the modified file data is written back. As shown in Figure 4, the on-disk layout of the mlog tree is an array of mlogs, where

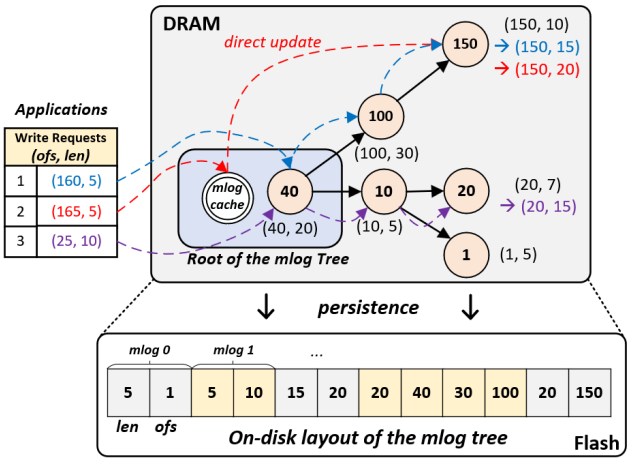

Figure 4: MLogging mechanism.

each mlog entry stores two integers—offset and length—both are aligned to a specific granularity (e.g., byte-level). Given the prevalence of small files and small writes (e.g., < 1MB) on mobile devices [8, 17, 19], the offset and length integers are designed to take 4 bytes each. In order to minimize the storage cost, MLogging persists the length first, followed by the offset, leveraging the highest bit of the length to support compact mlog design. As illustrated in Figure 5, a compact mlog is a compact form of an mlog entry, which embeds the offset into the unused bits of the length (i.e., storing both offset and length in four bytes). Specifically, the 0~15 bits are used to store the inline offset and the 16~30 bits are used to store the length. The highest bit of the length serves as an indicator of compact mlogs, because it is not used in the normal form of mlog entry (the maximum write buffer length is 2GB, requiring only 19 bits [27]). SolFS will reconstruct the mlog tree by scanning the on-disk mlog array, where the scanning process will dynamically skip to the next mlog based on the compact mlog indicator.

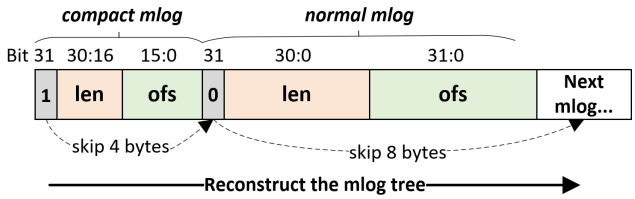

Figure 5: On-disk structure of normal and compact mlog.

Minimizing Memory Usage. A file may accumulate numerous mlogs after continuous random updates, and loading all of them into the in-memory mlog tree can significantly increase memory usage. To mitigate this issue, SolFS employs an on-demand loading design. During the open process, SolFS allocates an empty mlog tree rather than loading all mlogs from disk. All new mlogs generated during file updates are inserted into this tree. When persisting the mlog tree, SolFS

reads the existing mlogs from disk, merges them with the new mlogs in the in-memory mlog tree, and persists the updated mlog tree to disk. To minimize the additional cost on the I/O critical path of applications, SolFS uses a dedicated worker thread to handle this process asynchronously. When the file data is written back, the inode with a dirty mlog tree is sent to the worker thread, ensuring minimal impact on application performance.

Dynamic Granularity Alignment. SolFS allows the offset and length stored in mlogs to be dynamically aligned to different granularities. The main purpose of this design is to reduce the total number of mlogs by increasing the granularity from the byte-level to page-level, thereby lowering the memory and storage usage. In addition, this design helps SolFS avoid the integer overflow issue of the offset when updating very large files. Specifically, SolFS limits the number of in-memory mlogs per file (i.e., 5000 in SolFS). When more than this threshold, SolFS increases the granularity of the mlog tree. A new mlog tree is created and set to a higher granularity. Then, SolFS traverses mlogs in the low-granularity mlog tree, converts their offsets and lengths to the larger granularity and finally inserts them into the new mlog tree. While a larger granularity reduces memory and storage usage, it also decreases the resolution of file changes and increases network traffic during delta synchronization.

3.2.2 Mlog Versioning

Cloud backup APPs will continuously upload files to protect user data and thus a file may be uploaded multiple times. This necessitates SolFS to manage and classify file differences between any two cloud backups, and to support multiple cloud backup APPs on the same device. Inspired by classic versioning techniques, SolFS proposes the mlog versioning design to achieve this goal.

Versioned Inodes for Mlogs: Similar to prior works [7, 28, 29], this design introduces additional versioned inodes to the original file inode. However, unlike previous approaches, the versioned inodes store mlogs instead of file data, and the inode version is driven by each backup rather than write operations. Each versioned inode maintains its own set of mlogs, enabling SolFS to identify file modifications between any two versions by merging mlogs across different versioned inodes. The versioned inode includes four additional attributes: *ino_ver*, *ver_link*, *ino_flag* and *next_ino*. The *ino_ver* attribute represents the backup-driven inode version, while the *ver_link* attribute indicates the number of cloud backup APPs referencing this inode version. The *ino_flag* attribute tracks the state of this versioned inode, including its dirty state and the granularity of its persisted mlogs. The *next_ino* attribute is utilized to establish a connection between two inodes of consecutive versions, forming a chain of versioned inodes. To reach the design goal of backward compatibility, these four additional attributes are stored in the extended file attributes [26] of the inode, which ensures compatibility with the on-disk structures of the existing mobile file system. The versioned inodes shown in Figure 3 present the relationship between the original file inode and versioned inodes. The file inode and two versioned inodes (ver=3 and ver=2) are connected and indexed based on each inode's *next_ino*.

Backup-driven Versioning: Since a mobile device may install multiple cloud backup APPs (e.g., built-in and third-party), each with its individual backup times and progress, SolFS introduces backup-driven versioning to manage file versions across different backups and across different APPs. Specifically, when an APP backs up the latest data of a file, a new versioned inode (with a higher version number) is inserted at the head of the file's versioned inode chain by updating *next_ino*. A new mlog tree is also created to accommodate incoming mlogs since this backup, as shown in Figure 6. During the insertion of new versioned inode, the old mlog tree is persisted to the old head versioned inode and then releases its memory. In cases where the head versioned inode does not contain any mlogs, such as no modifications since the last backup, SolFS avoids inserting a new versioned inode to maintain a compact and concise versioned inode chain to reduce storage usage, such as the second backup in Figure 6. With backup-driven versioning, all file modified locations are recorded in a versioned inode chain. Given a start version and a target version, SolFS can traverse the corresponding versioned inodes in the chain to retrieve mlogs, which are used to calculate the final modified range of that file since the start version. In this way, SolFS ensures that each cloud backup APP can track its own file differences between any two backups without interference from other apps.

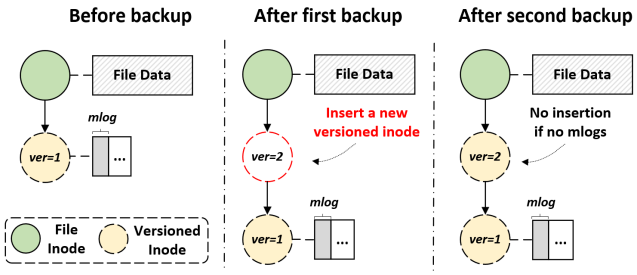

Figure 6: Backup-driven versioning.

3.3 Hash-free Delta Synchronization

In this section, we will introduce how SolFS achieves delta synchronization by enabling hash-free file difference identification through the collaborative version management and the extent tree that stores cumulative file modifications, as shown in Figure 7.

Collaborative Version Management: As discussed in Section 3.2.2, each backup is assigned a specific version number, which allows the cloud backup APP to manage file versions between the local and the cloud server. For example, after

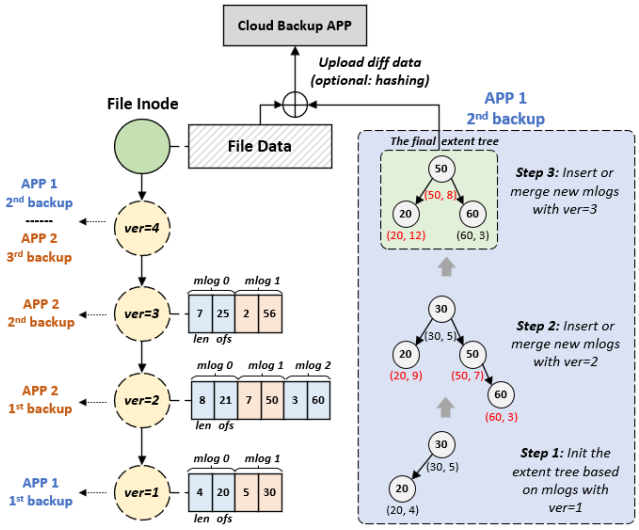

Figure 7: Delta Synchronization with Hash-free File Difference Identification.

backing up a file, the APP will obtain a version number from SolFS and synchronize this version number to the cloud server. The cloud server will maintain this version number for each file, and the version number is also stored in the extended file attributes. For the next backup, the APP receives the version number from the cloud server and tracks new file modifications from this version to the latest version. Cloud backup APPs can start their backup in any version of a file, but in the first backup, they will upload the entire file data.

We illustrate this collaborative version management in Figure 7. There are two APPs (APP 1 and APP 2) backing up the same file. Before any backups, the version of the original file data is zero (ver=0). After APP 1 performs the first backup, the first versioned inode (ver=1) is inserted and APP 1 obtains this inode's version number, indicating that the next backup of APP 1 starts from ver=1. Following this, APP 2 performs three consecutive backups, each with new modified data, thus increasing the inode version from ver=1 to ver=4. Note that the first backup of APP 2 will upload the entire file data as APP 2 does not maintain the version of this file before. Then, APP 1 performs its second backup based on its own version (ver=1), in which it traverses mlogs stored in the versioned inodes from ver=1 to ver=4 to identify cumulative file modifications to facilitate delta synchronization. Finally, both APP 1 and APP 2 will reach the versioned inode with ver=4, as the latest versioned inode (ver=4) does not contain mlogs. This collaborative version management also reduces the hash computation overhead on the cloud server, as it eliminates the need to generate and send a checksum list to APPs for hash comparison. By exchanging version information instead of checksum lists, network traffic is further minimized, particularly for large files where checksum lists can be substantial.

Upload with the Extent Tree: Given an original version,

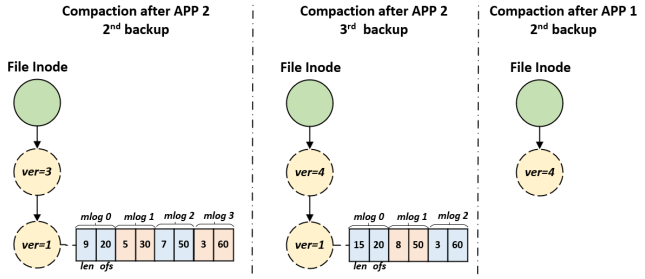

Figure 8: Versioned Inode Compaction.

SolFS enables the APP to track mlogs from that version to the latest version. SolFS employs an extent tree to merge mlogs stored across different versioned inodes to calculate the cumulative file modified range of the data. Based on this range, the APP can directly upload the corresponding file data to achieve hash-free delta synchronization. Optionally, the APP could choose to perform hashing on the specified data range to mitigate hash overhead of identifying file differences and further reduce network traffic. Note that this approach also avoids the overhead of reading the entire file data.

We demonstrate this design in the second backup of APP 1 in Figure 7. SolFS first initializes the extent tree based on mlogs from the version held by APP1 (ver=1). It then scans the versioned inode chain from ver=1 to ver=4, merging their mlogs to produce a final extent tree representing the cumulative modified range. If the mlog granularity is byte-level/page-level, the modified range includes bytes/pages 20–31, 50–57, and 60–62. APP 1 could use this location information to upload the corresponding file data to the cloud. The mlogs stored in different versioned inodes may have varying granularities, but during merging, all mlogs are converted into byte-level granularity for consistency.

Versioned Inode Compaction: Multiple backups can lead to redundant versioned inodes in the chain, as they may no longer be indexed or used by cloud backup apps, wasting storage space. To address this issue, SolFS employs a reference counter (i.e., *ver_link*) for each versioned inode to track the number of cloud backup APPs referencing it. Based on the example shown in Figure 7, after APP 2 performs three backups and before the second backup of APP 1, the reference counts for the four versioned inodes are one (ver=1), zero (ver=2), zero (ver=3) and one (ver=4). The versioned inodes with ver=2 and ver=3 are redundant as no APPs use them, allowing SolFS to compact them to save storage space. Specifically, SolFS compacts redundant versioned inodes by merging their mlogs into the adjacent versioned inode with a lower version number and positive reference counter, and then deletes redundant versioned inodes. After the second backup of APP 1, the reference count of versioned inode with ver=4 increases to two since both APP 1 and APP 2 point to it. At this moment, SolFS cannot find an adjacent versioned inode for compaction as the reference count of ver=1 inode becomes zero, which indicates versioned inodes lower than

the latest version are useless for subsequent backups.

We illustrate the proposed compaction process in Figure 8. After the second backup of APP 2, all mlogs stored in ver=2 inode are merged with mlogs stored the ver=1 inode, because the ver=2 inode is no longer used. After the second backup of APP 1, versioned inodes except for the head versioned inode are useless so that SolFS removes them to release resources. Finally, when all APPs reach the latest version, all versioned inodes with zero link are deleted. SolFS collects the reference count of each versioned inode during the delta synchronization process and compacts them by an asynchronous worker thread mentioned in *Minimizing Memory Usage* in Section 3.2.1.

4 Implementation Discussion

In this section, we will introduce the implementation details of the SolFS prototype on F2FS [21], which is the most popular file system on mobile devices. In addition, how to ensure version consistency and how to create an optimized cloud backup APP based on SolFS are also discussed in the following subsections.

4.1 File System Implementation

When opening a file in SolFS, an empty in-memory mlog tree is created using *kmem_cache_alloc* to reduce allocation cost and it is stored in the F2FS's inode info. During page writebacks, the inode with a dirty mlog tree is passed to a worker thread for asynchronous persistence via a shared list. As a result, SolFS only introduces minimal overhead to file opening and closing. SolFS does not change the original read and write processes of the existing mobile file system, but instead intercepts file operations that modify file data, such as write operations. Additionally, SolFS also supports *fallocate*, *truncate* and *mmap* with PROT_WRITE by inserting a new mlog for the data range specified by these functions' parameters. For *rename*, SolFS marks the newly renamed file as entirely changed. The asynchronous worker thread is primarily responsible for persisting mlog trees. Specifically, it wakes up periodically to process dirty mlog trees from inodes. The dirty mlog tree is converted into an mlog array as discussed in Section 3.2.1. SolFS then copies this mlog array to the pages of the corresponding head versioned inode, and marks all pages as dirty for asynchronous writebacks to complete the persistence process.

4.2 Version Consistency

When the system crash occurs, the consistency of file data is protected by the existing mobile file system. However, SolFS has to ensure version consistency in case of identifying inconsistent modified data during delta synchronization. This is critical because the persistence of newly modified file data and its corresponding mlogs is not atomic. An unexpected crash could disrupt their consistency, resulting in mismatches between local and cloud file data. To address this issue, SolFS introduces an *all-or-nothing* mechanism that leverages F2FS's write-ordering guarantees to maintain version consistency between the version number (i.e., *ino_ver*) and file data. For inode chain operations, the F2FS checkpointing is employed to ensure data consistency.

All or Nothing. Since system crashes are rare events and abandoning previous version controls does not affect the consistency of the file data itself, SolFS introduces an *all-or-nothing* mechanism to ensure version consistency, as shown in Figure 9. Specifically, SolFS employs a special dirty flag (i.e., *ino_flag*) in the file inode to indicate whether the mlog tree has been modified. When dirty data pages of the file inode are written back to the disk, SolFS marks the *ino_flag* as dirty (=1) and sends the corresponding inode to the worker thread. This flag is clear after successfully persisting the mlog tree. The write order of F2FS ensures that data writebacks occur before metadata (e.g., inode) writebacks and the *ino_flag* is written back to the disk along with the inode. If data pages are written back successfully but the system crashes before the file inode is persisted, the written blocks are released, and the inode reverts to its pre-write state. If the crash occurs after metadata writeback but before mlog writeback, the *ino_flag* remains dirty, allowing SolFS to detect inconsistencies between file data and mlogs. In this scenario, SolFS removes the versioned inode chain and reinitializes the file version starting from the version higher than the one at the time of the crashing. If the APP provides a stale version of the old versioned inode chain, SolFS cannot locate this version in the new versioned inode chain, as it is lower than the new version. Consequently, the APP is required to upload the entire file data and maintain a new version.

Checkpointing Inode Chain Operations. SolFS leverages F2FS's checkpointing mechanism to ensure the consistency of inode chain operations. Specifically, SolFS temporarily disables checkpointing while updating *next_ino* during inode chain operations and re-enables it once the operations are complete. This prevents inconsistent inode connections in the event of a system crash. If a crash occurs, SolFS relies on F2FS's roll-back/roll-forward recovery process to restore the file system to the last checkpointed state.

4.3 Cloud Backup APP Optimization

SolFS introduces three new ioctl interfaces for cloud backup APPs: *delta_open*, *delta_close* and *delta_getdiff*. Given a file to be backed up, the cloud backup APP first opens the file to obtain its file descriptor (FD), and retrieves the file's version number from the cloud server. With this FD, the APP can invoke *delta_open* to find the corresponding file inode and register a context to get the file difference. This function is also used to block write operations and flush all dirty

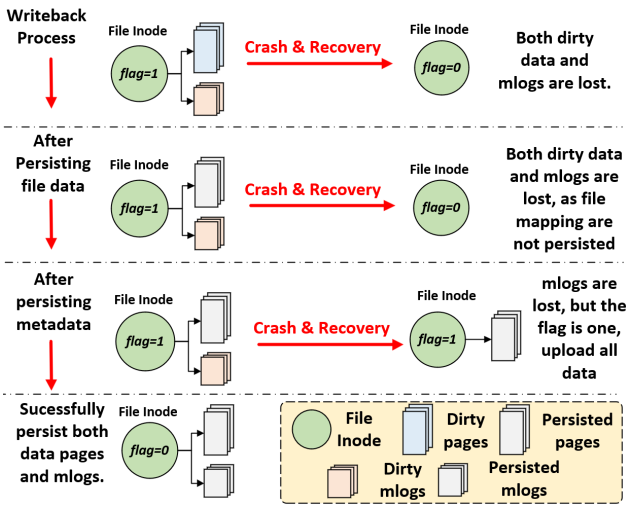

Figure 9: Version Consistency.

pages and mlogs of the file. Then, the APP leverages the file descriptor and the version number as input for *delta_getdiff*. As the number of returned modified ranges (mlog) is not certain, the APP can call *delta_getdiff* multiple times to recursively obtain all mlogs. To support recursive access, the context created by *delta_open* will record the progress of getting the file difference. This interface returns the cumulative file modified range and the latest version number, while also inserting a new versioned inode into the chain. The APP uses the cumulative modified range to access the corresponding file data. After identifying all modified ranges, the APP can invoke *delta_close* to release the resources of the context and unblock write operations.

To further reduce network traffic, we experimentally introduce a simple selective hashing approach for the modified range of data. Specifically, the cloud backup APP prioritizes the computational cost on mobile devices so that it chooses to directly upload modified file data, except for mlogs encompassing the entire file data. For this type of mlog, the entire file data is conducted with a rolling checksum, similar to WebR2sync+. In the scenario where the version inputted by the APP does not match any version of versioned inodes (i.e., version inconsistency), *delta_getdiff* will return a special modified range that covers the entire file data. SolFS is similar to existing file systems and does not include optimizations for file metadata backup. The backup APP can use the common fstat()/getxattr() interfaces to retrieve available metadata information and synchronize it to the cloud server.

5 Evaluation

In this section, we present a comprehensive evaluation of the proposed SolFS in comparison to the state-of-the-art delta synchronization designs, including *HashSync*, *Rsync* and *WebR2sync+*. *HashSync* refers to the typical design of delta synchronization [11] that separates a file into multiple chunks and uses MD5 as the hashing algorithm to identify modified data chunks. Rsync and WebR2sync+ employ rolling checksum in the APP side and server side, respectively, allowing them to detect byte-level data differences. We do not compare with *NetSync* because it is not open-sourced. The existing solutions do not support the Android system and thus we implement and cross-compile them to the mobile platform based on C++ and NDK [14]. The server side is implemented based on cpp-httplib [41] which receives requests from APPs and supports different cloud synchronization based on the parameters of HTTP POST requests.

Our evaluations are conducted on a Pixel 8 device based on Android 14 with Linux kernel version 5.15, and the cloud server is running on an Ubuntu 20.04 platform with a 24-core Intel i9 14900k and 32GB of memory. We assume that users upload files using only one cloud backup APP, as this is the most widely used scenario. In the following subsections, we will first introduce some micro-benchmarks to illustrate how SolFS achieves better performance. Then, the performance and overhead of SolFS on real applications will be discussed. Lastly, we also conduct some experiments to discuss the overhead of inode chain operations.

5.1 Cloud Synchronization Efficiency

In this section, we quantitatively measure the cloud synchronization efficiency of SolFS with a series of micro-benchmarks, including cloud sync time, network traffic and latency breakdown. The network bandwidth is set to ~100 Mbps, the chunk size is set to 2048 bytes and the granularity of mlog is byte-level. We use 10MB files and up to 1KB I/O size, considering small files and I/Os on mobile devices. For these experiments, we first create a 10MB file and upload it to the server. Then, we modify this file in different ways: random update, sequential update and insertion, where insertion means moving back all the file data behind the insertion location by re-writing the whole file. In our experiments, we insert data into the position of 5MB of the file. In addition, we further evaluate the effect of modification sizes. The modification size indicates the total modified bytes to that file and when the update/insertion size is larger than 1KB, this modification will be separated into multiple sub-modifications (each with 1KB). Finally, this file is uploaded again to the server and we record the relevant experimental results.

5.1.1 Cloud Sync Time and Network Traffic

We present the total sync time and network traffic of SolFS and existing solutions in Figure 10 and Figure 11. SolFS significantly outperforms hash-based solutions in both random and sequential updates. Specifically, SolFS reduces the sync time by 88.8% on average in random updates, since it identifies modified data based on offsets and lengths, mitigating the

overhead of hash computation and data reading. In addition, SolFS generates significantly less network traffic, averaging only 12.3% of the traffic when updating 1MB of data.

This efficiency stems from two key factors. First, the three hash-based approaches require transmitting a checksum list, whose size grows with the file size (e.g., 120KB for a 10MB file). Second, since random updates are not aligned with the chunk size, these updates often affect neighboring chunks, resulting in more modified data (e.g., over 2MB of data is modified when randomly updating 1MB of data). SolFS avoids these issues by precisely uploading only the modified data at the byte level. The performance of a sequential update also has the similar observation to that of random updates due to the same benefits of SolFS. For data insertion, both Rsync and WebR2sync+ support rolling checksum, enabling them to upload only the inserted data (around 1MB when inserting 1MB data). HashSync cannot identify the inserted data and has to upload all data following the insertion point, resulting in approximately 5x more network traffic (i.e., 5MB) and longer sync times compared to the other three approaches. As discussed in Section 4.3, SolFS can collaborate with the rolling checksum approach, achieving performance comparable to WebR2sync+.

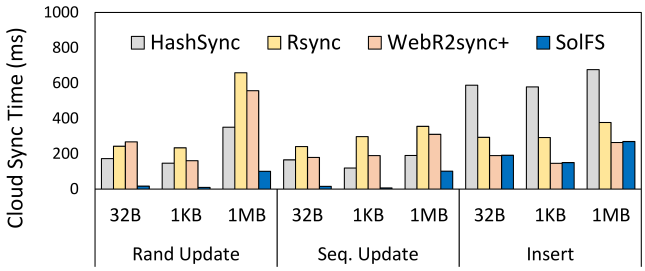

Figure 10: Cloud sync time on different types of file modifications.

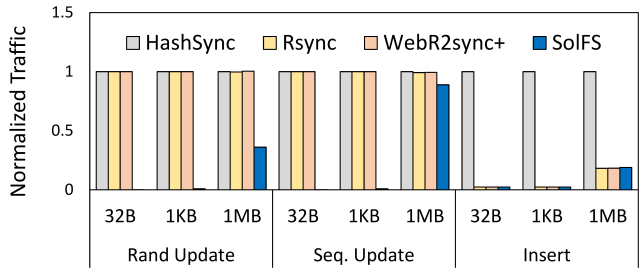

Figure 11: Normalized network traffic on different types of file modifications. HashSync serves as the baseline.

5.1.2 Sync Time Breakdown

To analyze the contribution of each part to sync time, we illustrate the sync time breakdown for a 1MB random update in Figure 12. SolFS outperforms other approaches by significantly reducing hash computation overhead on both the client and server sides (92% on average). For instance, Rsync exhibits lower server-side latency, while WebR2sync+ achieves lower client-side latency due to their differing design goals. SolFS, however, achieves lower latencies on both sides. Due to its low software overhead, network bandwidth becomes the primary factor limiting SolFS's performance. On a 50Mbps network, the client and server sides contribute approximately 21.8% (HashSync), 49.3% (Rsync), 42.2% (WebR2sync+), and 10.8% (SolFS) of the total sync time. On a 200Mbps network, these contributions increase to 52.7% (HashSync), 79.5% (Rsync), 74.5% (WebR2sync+), and 32.7% (SolFS). As network bandwidth grows, computation on both the client and server sides leads to significant software overhead. SolFS mitigates this issue by minimizing hash computation.

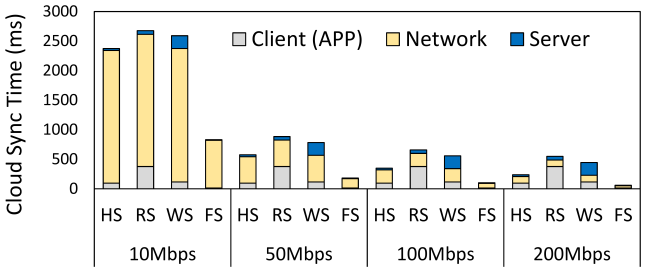

Figure 12: The sync time breakdown over different network bandwidths. HS, RS, WS, FS indicate HashSync, Rsync, WebR2sync+, SolFS, respectively.

5.2 Real Mobile Application Workloads.

5.2.1 Cloud Backup Performance on Real Workloads.

To evaluate the overall cloud backup performance, we dump file data from four popular applications, including Facebook with 220MB data, Twitter with 112MB data, Capcut with 220MB data and Dropbox with 843MB data. After a period of time (i.e., 20 minutes), we dump their file data again and store them in the server side. In this period, we play each application for 5 minutes: for Facebook and Twitter, we browse and pull new content; for Capcut we edit existing videos by adding effects, filters and text; for Dropbox, we edit a Word documents by adding new text, a PPT slide by adding a new page with image and text, and write several numbers to an Excel file. During playing applications, we collect file update traces from these four applications, including file names, file sizes, file update offsets and lengths. Then, we can compare SolFS with existing solutions based on the consistent file data and trace. We perform file synchronization using SolFS and other solutions and record their sync time.

The experimental results are shown in Figure 13. SolFS significantly outperforms existing solutions on mobile application workloads, by improving 71% of sync time on average. For example, SolFS reduces the HashSync's average sync time over these four APPs from 89s to 29s. The main reason

is that random writes dominate the mobile platform, such as many SQLite database updates on Facebook and Twitter. We observe that data insertions are rare on mobile workloads and applications usually operate on binary data so that the performance of HashSync is better than Rsync and WebR2sync+ on mobile workloads. By avoiding hashing, SolFS has a greater performance than HashSync. In addition, the SolFS design helps reduces by around 70% of CPU usage on average of the four APPs during delta synchronization.

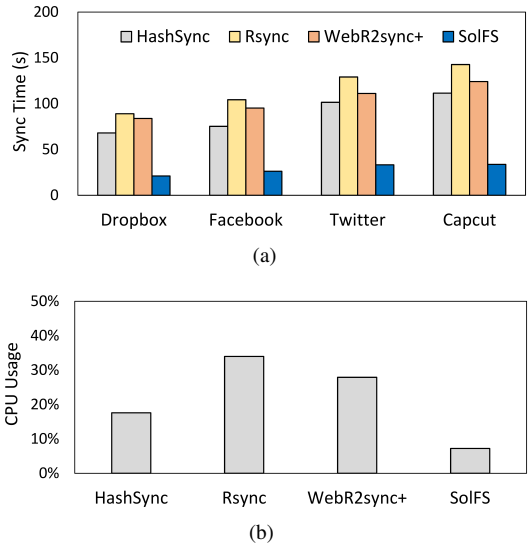

Figure 13: (a) cloud sync time over different applications; (b) CPU usage on average of the four commonly-used APPs.

5.2.2 Overhead Analysis on Real Workloads

In this section, we focus on the potential overhead of SolFS, including the I/O performance, and additional memory and storage usage compared with the original mobile file system (i.e., F2FS). To comprehensively evaluate the performance of SolFS on different file operations, we choose to replay long-duration file operations traces collected in real mobile devices. Hence, nine open sourced file operation traces [25] are used in our evaluation, where each trace represents a specific application running for two hours. The traces include nine applications, including Candycrush (CC), Chrome (CH), Earth (EA), Facebook (FB), Map (MA), TikTok (TT), Twitter (TW), Youtube (YT) and Zombie (ZB).

Read and Write Overhead. We evaluate the read and write performance based on the trace replay time. Before running each trace, we clear the page and inode caches, and record the running time of each trace. As shown in Figure 14(a), SolFS shows a comparable I/O performance (difference < 1.5%) with the original F2FS. On average, the I/O performance of SolFS is around 99.2%. During trace replay, the average CPU usage of F2FS and SolFS is 8.3% and 8.5%, respectively, representing the overhead when MLogging is disabled or enabled during normal operations. The slight increase in SolFS's CPU usage occurs because SolFS inserts a small mlog entry (4 or 8 bytes) into the mlog tree during write operations. For write operations that hit the mlog cache (e.g., sequential writes and appends), SolFS uses a fast path to update the mlog at $O(1)$ cost; for cache misses, SolFS needs to traverse the in-memory mlog tree. As SolFS does not load mlogs from the existing versioned inode to the mlog tree , the number of a file's mlogs is relatively small, which reduces the searching cost. SolFS does not change the read process of the F2FS so that the read performance is the same. The additional overhead of file open is also low, because the on-demand mlog loading design avoids reading mlogs from disk synchronously in the open operation.

Memory and Storage Overhead. SolFS consumes additional memory and storage space to maintain the mlog tree and mlogs while a file is open. First, we measure the additional memory usage by running traces from different APPs. To evaluate the worst-case scenario, we use a byte-level mlog tree and retain mlogs even after the file is closed. As shown in Figure 14(b), the additional memory usage after running nine traces (simulating 18 hours of app runtime) is 470KB. This is because many operations, such as sequential writes, appends, or updates to the same location, only require fewer mlogs. Additionally, the on-demand loading design reduces memory usage, as SolFS does not load all mlogs from disk into memory and only maintains an in-memory mlog tree for new mlogs. For storage overhead, SolFS further reduces memory usage through its compact mlog design. Given the prevalence of small writes on mobile devices, mlogs are frequently compacted, reducing storage space by 33% compared to memory usage. Note that increasing the granularity of mlogs can further decrease memory usage. Memory allocated for the mlog tree and mlogs are released once the file is closed, further minimizing SolFS's memory footprint. In summary, the memory and storage overhead of SolFS are acceptable for mobile devices.

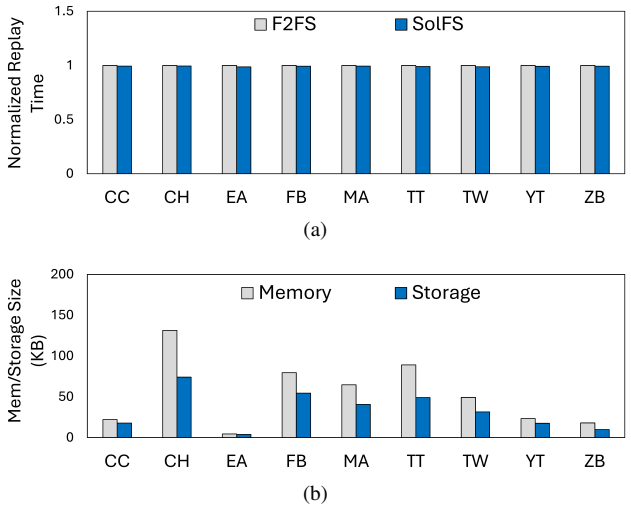

Figure 14: (a) normalized I/O performance; (b) additional memory and storage overhead.

5.3 Discussion about Inode Chain Operations

Depth of Version Inode Chain. As SolFS supports multiple cloud backup APPs based on a versioned inode chain, the running time of searching file differences could be affected by the depth of the versioned inode chain. To evaluate the effect of the depth, we create a 10MB file and randomly update total 2MB of data. Given a depth of X, each level of versioned inode will be updated by 2MB/X of data. After clearing page cache and inode cache, we use the *delta_getdiff* interface to search for file differences and record the searching time. As presented in Figure 15(a), with the growth of the versioned inode chain, the search time increases from 1.67ms to 7.6ms due to the additional I/O overhead. Even with the depth = 10, this cost is still significantly lower than hashing. In addition, users generally do not use many cloud backup APPs at the same time, and thus the depth of the versioned inode chain can be kept small.

Impact of Mlog Quantity. In SolFS, the number of mlogs in an mlog tree primarily affects the overhead of two operations: 1) converting the mlog tree from small granularity (byte-level) to large granularity (page-level), and 2) merging the in-memory mlog tree with the on-disk mlog tree. First, for mlog tree conversion, Figure 15(b) shows that the conversion time increases with the number of mlogs, ranging from 0.95ms for 1K mlogs to 10ms for 10K mlogs. Second, when persisting an in-memory mlog tree, SolFS loads and merges on-disk mlogs into the in-memory mlog tree before writing it back. This overhead also scales with the number of mlogs. In our evaluation, loading and merging a large mlog tree (10K mlogs) introduces around 30ms of latency, including read I/O and in-memory merging time. Since scenarios with intensive random updates to the same file are relatively rare, the number of mlogs typically remains small (e.g., < 100). Therefore, both mlog tree conversion and merging operations introduce minimal overhead on applications.

Granularity and Memory Overhead. To evaluate the impact of different mlog granularities, we conduct sequential and random write experiments by writing 2MB of data to a 10MB file using a 1KB buffer size. Initially, with byte-level granularity, SolFS consumes 0.133KB and 102.6KB of additional memory for sequential and random writes, respectively. When increasing the granularity to page-level, memory usage for random writes decreases by approximately 80%, to 20.35KB. The larger granularity enhances opportunities for mlog merging, but as expense of more network traffic during delta synchronization.

Inode Chain Compaction Overhead. The overhead of inode chain compaction includes two parts: mlog merging and inode re-connection. The first part depends on the number of mlogs, which is discussed in *Granularity Conversion*. Inserting 1K mlogs takes around 0.95ms, which is relatively low-cost. For the second part, the inode re-connection is similar to the rename operation, i.e., updating two inodes' metadata, which consumes around 2 ms. Inode chain compaction as a periodic asynchronous task, its overhead is acceptable for mobile devices.

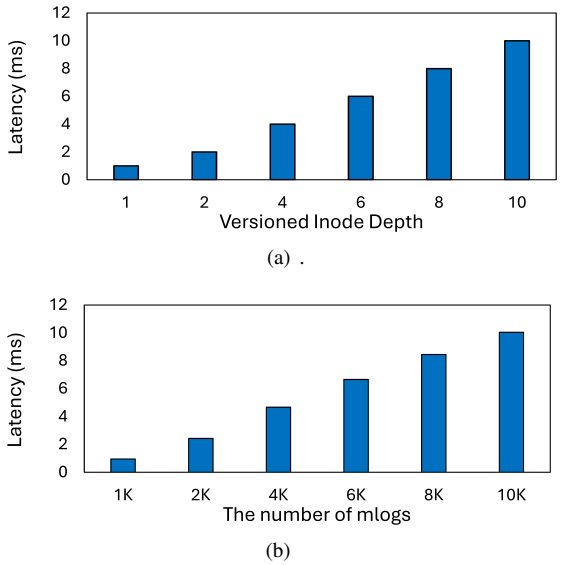

Figure 15: (a) searching time over versioned inode depths and (b) conversion time over the different numbers of mlogs.

6 Related Works

Delta Synchronization in Cloud Backup. Many previous works discuss how to use delta synchronization to improve the cloud backup efficiency [5, 6, 10, 11, 24, 34, 36, 38]. Drago [10, 11] introduced five critical capabilities of cloud backup: chunking, bundling, deduplication, delta-encoding, and compression. Tridgell [34] introduces rsync algorithm that uses rolling checksum to identify modified data. Cui [9] considered the backup efficiency of mobile cloud backup applications and proposed QuickSync to reduce unnecessary sync traffic. Xiao [38] moves the heavy hash computation and comparison from the client side to the server side. Xia [36] introduces content-defined chunking to improve the hash comparison during delta synchronization. Wu [35] designs a faster delta synchronization mechanism in encrypted cloud storage. In addition to the protocol improvement of delta synchronization, some researchers propose lightweight algorithms to improve their computational efficiency [22, 37, 44] However, these efforts still require intensive computation on hash calculation and comparison, significantly increasing the CPU usage and power consumption on resource-limited mobile devices. SolFS mitigates hash computation in delta synchronization based on the collaborative design between cloud backup APPs and file system.

File Snapshotting and Versioning. Many file systems implement file snapshotting or versioning mechanisms. Most of file systems support snapshotting or versioning based on a copy-on-write manner [1, 4, 28–30, 33], in which newly modi-

fied data is written to a new block while the old data is kept accessible to the snapshot file. file fragmentation because file data is scattered in multiple inodes, which reduces the sequential read performance. BetrFS [42] mitigates the fragmentation issue in snapshot file systems by caching random writes. In addition to copy-on-write, data logging is another common approach for snapshotting or versioning mechanisms. NOVA-Fortis [40] implements snapshotting by inserting private data logs into each inode. WaybackFS [7] implements versioning by storing old modified data as undo logs in an auxiliary inode. However, these efforts require additional storage space to store modified data because they need to keep track of the file data for a specific snapshot/version of the file. Therefore, SolFS does not adopt these designs to identify old and new modified data. It stores operation logs only rather than file data, and thus significantly reduces the storage usage.

7 Conclusions

Cloud backup is high-cost on mobile devices. SolFS aims to improve its computation overhead of delta synchronization on mobile devices. It introduces MLogging, which allows each file to manage its write operation logs (i.e., offset and length) in an extent tree, and the operation log persistence and versioning mechanism. Combining these techniques together, SolFS achieves hash-free difference identification while minimizing the additional cost to the original system. We evaluated SolFS on commercial smartphones and the results show that it can significantly reduce the computational overhead of both APP-side or server-side by over 90% on average and the total cloud synchronization time by over 88% when files are updated.

Abstract

This paper presents a novel zoned namespace (ZNS) tailored log-structured file system (LFS) called `Z-LFS` for commodity small-zone ZNS SSDs. Specifically, `Z-LFS` first enables append-only updates on metadata while leveraging the unique metadata characteristic of LFS on ZNS SSDs. Second, `Z-LFS` devises speculative log stream management according to the workload temperature to maximize active zone utilization. Finally, `Z-LFS` adopts conflict-aware zone allocation to minimize resource contention within ZNS SSDs while considering LFS features. We implement `Z-LFS` based on F2FS in the Linux kernel and evaluate it with commodity ZNS SSD. Our evaluations show that `Z-LFS` achieves higher performance by up to 33.44× and 3.5× compared with F2FS and a state-of-the-art interface for commodity ZNS SSDs, respectively.

1 Introduction

The zoned namespace (ZNS) SSD is a new storage device and has received significant attention from researchers and enterprise storage vendors [7, 19, 42, 52]. In contrast to legacy SSDs (i.e., conventional namespace (CNS) SSD), the ZNS SSD divides the physical address space into fixed-size zones. Each zone must be written sequentially (i.e., append-only update) and reset explicitly for reuse while shifting the responsibility of data management to the host (e.g., garbage collection) [8, 44, 55]. This minimizes the DRAM usage and over-provisioning space inside SSDs [9, 45, 53, 57], resolves the log-on-log issue [17, 56], and mitigates I/O interference [10, 18, 33, 51].

Unfortunately, adapting an existing mature file system on the ZNS SSD is not trivial due to the ZNS constraints. For example, in-place updating file systems (e.g., EXT4 [40] and XFS [54]) cannot be utilized on ZNS SSD. Meanwhile, out-of-place updating file systems including log-structured file systems (LFSs), such as SpriteLFS [49], F2FS [29], and NILFS2 [27], can naturally be utilized on ZNS SSD by performing out-of-place updates. Specifically, F2FS [29] is a representative LFS supporting the utilization of ZNS SSD. Accordingly, F2FS has been widely adopted to utilize ZNS SSD in previous studies [1, 17, 30, 50]. Nevertheless, current Linux LFSs with multiple log streams (e.g., F2FS) may meet two issues due to their CNS-based designs on ZNS SSD. Specifically, 1) LFS has a potential inability to use ZNS SSD as a standalone SSD [1] resulting from CNS-based metadata design and its in-place updates and 2) there can be a performance issue due to CNS-based data placement and I/O operations.

CNS-based metadata design and update: The existing LFSs manage metadata in block-level granularity and perform in-place updates for the metadata in a fixed location to handle well-known LFS issues such as update propagation (i.e., wandering tree problem [13,23,25,29,41,49,59,60]). For example, F2FS performs in-place updates for its metadata stored at a block-aligned and fixed location to solve the wandering tree problem [29]. Accordingly, when utilizing a commodity ZNS SSD, the LFSs require an additional CNS SSD to support the in-place updates. However, this leads to an increase in the cost of a storage system.

CNS-based data placement and I/O operations: The existing LFSs place data on sequential logical block addresses (LBAs) to fully utilize the high sequential write performance of CNS SSD while minimizing GC overhead [16, 34]. Meanwhile, the LFSs may encounter potential under-utilization issues in ZNS SSDs, especially small-zone ZNS SSDs. Specifically, small-zone ZNS SSDs have two main features [15,21,42]: 1) fine-grained mappings between zones and internal resources [43, 46] such as channels and dies and 2) a large number of zones that support parallel write operations (i.e., active zones [44]) at the cost of reduced internal parallelism within a zone (i.e., intra-zone parallelism). Accordingly, to maximize the ZNS SSD performance, the LFSs with multiple log streams should efficiently utilize active zones based on their log streams and consider the mappings to avoid the conflicts among zones that share identical SSD internal

*Corresponding Author: Yongseok Son (`sysganda@cau.ac.kr`).

resources (e.g., dies and channels).

Previous studies have introduced different techniques to efficiently utilize ZNS SSDs on various layers [9, 17, 42, 43]. ZenFS [9] is a storage backend for running RocksDB on ZNS SSDs. ZNS+ [17] introduces a new customized ZNS SSD design and interface which enables offloading data copy operations to the SSD. eZNS [42, 43] is an elastic ZNS interface that allocates active zones based on the application workloads and enhances performance isolation through an I/O scheduler. Our study is inspired by these studies and in line with them in terms of efficiently exploiting ZNS SSDs or maximizing the utilization of active zones for ZNS SSDs. In contrast, our study focuses on designing ZNS-tailored metadata and logging strategies of LFS on a standalone commodity ZNS SSD.

Our goal in this study is to design a ZNS-tailored LFS to maximize 1) the cost-efficiency of the storage system and 2) the resource utilization of small-zone ZNS SSDs. To this end, we propose a novel ZNS-tailored log-structured file system for small-zone ZNS SSDs called `Z-LFS`. Our key idea of `Z-LFS` is to enable 1) ZNS-tailored metadata management to enable standalone usage of ZNS SSD and 2) ZNS resource control by leveraging log stream utilization and addressing resource conflicts.

Specifically, `Z-LFS` first enables append-only updates on metadata to efficiently store metadata on ZNS SSDs without relying on CNS SSD. To do this, `Z-LFS` leverages the unique metadata characteristics of LFS on ZNS SSDs, which differ from those on CNS SSDs due to ZNS constraints. In our observation, LFS metadata on ZNS SSD can be classified into two categories based on their life cycle: immutable and mutable metadata. Immutable metadata is not updated after being written, and its life cycle is identical to that of the associated LFS segments. Meanwhile, mutable metadata is updated frequently and has a distinct life cycle from the segments. With these characteristics, `Z-LFS` appends immutable metadata to its corresponding segment and stores mutable metadata separately using a delta logging approach.

Second, `Z-LFS` devises speculative log stream management that dynamically coordinates active zones to maximize their utilization. We observe that allocating zones without considering the write intensity of log streams can limit the effective use of zone-level parallelism. To address this, `Z-LFS` speculatively determines the active zone quota for each log stream based on its write intensity, which varies according to workloads. Finally, `Z-LFS` adopts conflict-aware zone allocation designed to minimize contention among zones that share SSD internal resources including dies and channels. In our analysis, when a host uses zones mapped to the same die or channel, zone-level parallelism is reduced due to the die or channel-level conflicts. Based on this analysis, `Z-LFS` allocates zones and distributes data across zones mapped to distinct internal resources, thereby reducing the resource conflicts.

Note that our approach is a fully software-based and targets commodity devices to ensure broader applicability and compatibility without requiring modification to ZNS SSDs. By doing so, our file system can be easily deployed on mature storage systems with commodity ZNS SSDs.

We implement `Z-LFS` with the three techniques based on F2FS in Linux kernel 5.17.4. We evaluate `Z-LFS` with various micro/macro benchmarks and RocksDB in a single-tenant environment. The result shows that `Z-LFS` improves the performance by up to 33.4× and 3.5× compared with F2FS and a state-of-the-art interface for commodity ZNS SSD (eZNS [42]) with F2FS, respectively. Finally, we open the source code of `Z-LFS` at `https://github.com/Z-LFS/Z-LFS` to aid future studies in file systems and storage stacks for ZNS SSDs.

2 Background and Motivation

2.1 Small-zone and Large-zone ZNS SSDs

ZNS SSD has two main constraints [32, 35, 44]. Specifically, 1) data must be written sequentially within a single zone, and once data is written, it cannot be overwritten until the zone is reset. In addition, 2) ZNS SSD also restricts the maximum number of active zones where write operations can be performed in parallel [42]. A zone has one of six states (i.e., *opened, closed, full, empty, read-only, and offline*), which can be changed according to operations such as write requests or zone management commands [44]. Within the states, *opened* and *closed* states represent active zones. The active zone shifts to the *full* state when it is filled or through a FINISH zone command, and shifts to the *empty* state through a RESET zone command, allowing the active zone to be reclaimed.

A zone in the ZNS SSD is allocated across channels, and the zone size is determined by the manufacturer [6, 7, 39]. Thus, the degree of internal parallelism can vary depending on the zone size [11, 12, 20, 21]. In a ZNS SSD with a large-zone (large-zone ZNS SSD), each zone spans more dies across channels [42], supporting higher intra-zone parallelism. Meanwhile, since it provides only a few active zones (e.g., up to 14 zones [8, 9]), the large-zone ZNS SSD can limit flexibility and show low performance isolation [15, 42, 46]. On the other hand, a small-zone ZNS SSD exposes finer-grained physical zones; each zone is contained within a die [15, 46]. Thus, the small-zone ZNS SSD can support more active zones (e.g., up to 384 zones), providing higher flexibility and performance isolation. Meanwhile, the small-zone ZNS SSD can show lower parallelism when only a small number of active zones is utilized. To exploit the internal parallelism of the small-zone ZNS SSD (zone-level parallelism), hosts should aim to process I/O requests across a large number of active zones.

2.2 Challenges of LFS on ZNS SSDs

Considering ZNS SSD, the design of LFS based on CNS SSD faces challenges, particularly in addressing three main issues

as follows. We will explain the details of the LFS challenges using F2FS as an example since it supports the ZNS SSD and is one of the representative and widely used LFSs.

Enabling append-only update metadata on ZNS SSD: F2FS places its metadata in a block-aligned and fixed location and updates them in place on CNS SSD. On the other hand, in the case of a ZNS SSD, since it disallows random writes and in-place updates within a zone, the metadata management scheme in F2FS requires an additional CNS SSD, increasing the overall cost of a storage system. To utilize the ZNS SSD as a standalone SSD, we can adapt the existing CNS-based metadata approach (i.e., F2FS) with minor modifications to fit within the ZNS constraints. In this approach, each metadata type has a pair of zones, and the metadata is written alternatively to one of the pair with zone granularity. However, due to the ZNS constraint, when the metadata is randomly updated, this approach may need to read the metadata from one zone in one of the pair, modify the metadata, and write the modified metadata to the other zone. This approach can significantly decrease the performance (up to 9.32×) and increase the amount of write (up to 7.8×) in our preliminary evaluation. Therefore, it is a challenge to efficiently design the metadata under the ZNS constraints and perform append-only updates.

Maximizing utilization of active zone under ZNS constraints: In the case of node/data in the main area of F2FS [29], the multi-head logging design separates the node and data into six types based on their hotness (i.e., hot/warm/cold). F2FS allocates a zone for a log stream and writes corresponding data or nodes sequentially in the zone. When the zone becomes full, F2FS allocates a new zone. Consequently, F2FS uses only six *active* zones at most, limiting zone-level parallelism and under-utilizing the device bandwidth, especially for small-zone ZNS SSDs. To make the best use of the available active zones at maximum, there can be a static and straightforward approach. For example, we can statically map six log streams to available active zones as much as possible. However, the number of available active zones is limited, and the I/O traffic on each log stream varies according to the workloads. Specifically, when the I/O traffic becomes skewed toward a particular log stream, the log streams with low I/O traffic can waste active zones while the log streams with high I/O traffic cannot harness the resources. Thus, this approach may still have the issue of under-utilization of active zones. Consequently, it is a challenge to optimally scale the active zones in an opportunistic manner to maximize the parallelism under the active zone constraints.

Mitigating SSD internal resource conflict among zones: Small-zone ZNS SSD uses fine-grained mapping between host-exposed zone and SSD internal resources such as channel and die. For example, the ZNS SSD used in our evaluation maps each zone to a single die and a single channel, rather than spanning a zone across multiple dies or channels. Accordingly, although an LFS may use multiple active zones to improve zone-level parallelism, if these zones are mapped to the same channels or dies, the LFS may fail to achieve optimal performance due to limited parallelism. Therefore, an LFS should consider and manage the mapping between zones and the internal resources to avoid the resource conflicts.

3 Analysis of ZNS SSD performance

3.1 Basic performance of ZNS SSD

To demonstrate the impact of zone-level parallelism on read and write performance with varying number of zones to issue I/O, we evaluate the base read and write performance of small-zone ZNS SSDs on the testbed described in §6.1. We use FIO [22] to perform direct I/O operations on the raw device, bypassing the page cache, with 16 threads and a queue depth of 32. The number of zones issuing I/O (i.e., active zones for writes) and the request sizes are varied during the evaluation.

As shown in Figure 1, write performance improves as the number of active zones increases across all request sizes. However, the degree of performance improvement and the maximum throughput are significantly influenced by the request size. Specifically, for 128KB requests, write performance saturates at 128/256 active zones, reaching approximately 2.4 GB/s. In contrast, small (e.g., 4KB) and large (e.g., 2MB) request sizes lead to performance degradation. For example, with 128 active zones, the write performance for 4KB and 2MB requests is only 20% and 47%, respectively, of the peak performance achieved. For small requests, the performance degradation is primarily due to the excessive number of I/O operations. For large requests, the I/O processing time within a zone increases, delaying subsequent write requests on other zones, thereby reducing zone-level parallelism and overall performance. Similarly, read performance also increases as the number of active zones increases but saturates with fewer zones (i.e., 32) than write operations. Unlike write operations, read performance is not sensitive to request size. These results highlight the importance of leveraging zone-level parallelism for both read and write operations, particularly given the limited intra-zone parallelism of small-zone ZNS SSDs, as discussed in §2.1.

3.2 Interference among internal resources

To evaluate the impact of interference among internal resources and understand the internal structure of the ZNS SSD, we measure the read performance using two threads to read from two different zones. In this evaluation, one thread reads data sequentially from zone ID 0, while the other reads data sequentially from a different zone, varying from zone ID 1 to 256. Figure 2 illustrates the read throughput of the two threads as the second thread's zone ID changes.

As shown in the figure, we observe two conflict points (i.e., channel-level and die-level) that degrade the performance compared with no conflict points as described in previous studies [43]. The performance degradation occurs when the

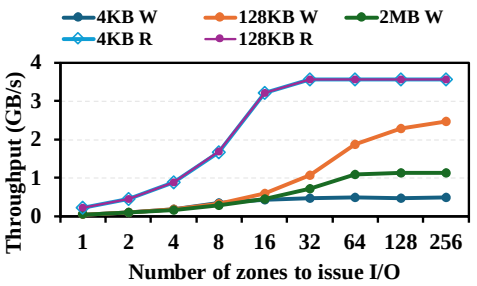

Figure 1: Raw write (W) and read (R) performance of a small-zone ZNS SSD.

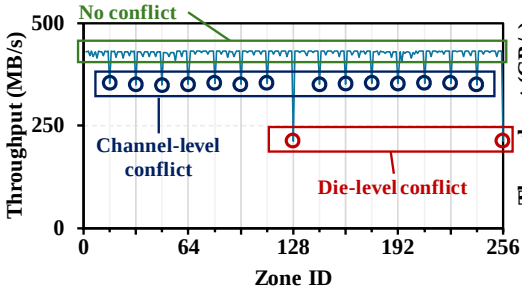

Figure 2: Performance of scenarios with/without resource conflict.

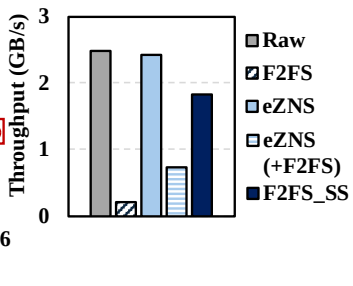

Figure 3: Write performance of various techniques.

zone ID is a multiple of 16, where throughput drops by 19% compared with the no conflict scenario. This degradation results from channel-level conflicts, where I/O requests from both threads contend for access to the same channel in the ZNS SSD even if two different zones are utilized. Second, the performance drops significantly when the zone ID is a multiple of 128. At these points, die-level conflicts arise, reducing performance by more than 50% compared with the no-conflict scenario.

These results indicate that an LFS should allocate zones while minimizing conflicts with the internal resources of the ZNS SSD to achieve optimal performance. Based on these observation, we infer that the ZNS SSD used in the evaluation consists of 16 channels and 128 dies, with zones statically mapped to internal resources in a round-robin manner. Leveraging this model, we design a conflict-aware zone allocation technique described in §4.6.

3.3 File system performance on ZNS SSD

We evaluate the write performance of F2FS, eZNS with F2FS (eZNS (+F2FS)), and F2FS with static stripping (F2FS_SS) as shown in Figure 3. eZNS [42, 43] is a state-of-the-art technique to exploit zone-level parallelism by distributing the write operations to the active zones via logical zones (i.e., v-zone [42, 43]). F2FS_SS represents an extension of F2FS with a static striping approach that evenly distributes active zones across log streams (e.g., 64 active zones per log stream) to further utilize zone-level parallelism in F2FS. For the evaluation, we use FIO with 16 threads performing sequential writes. These threads issue direct I/Os for the raw device and eZNS, while buffered I/Os are used for F2FS, eZNS with F2FS, and F2FS_SS.

F2FS exhibits significantly lower performance compared with the potential performance of the raw device, as described in §2.2 due to a lack of awareness of limited intra-zone parallelism. Specifically, F2FS allocates a single zone for each log stream, utilizing a total of six zones. eZNS delivers full performance in scenarios without F2FS, as FIO threads write uniformly to v-zones, ensuring balanced utilization. However, when combined with F2FS, eZNS experiences write performance degradation due to two main reasons from lack of cross-layer awareness as follows. (1) Similar to standalone F2FS, F2FS even with eZNS recognize v-zones as normal zones. Therefore, F2FS allocates a single v-zone for each log stream and cannot utilize more v-zones [43]. (2) eZNS adjusts the number of active zones mapped to v-zones based on whether write operations occurs in a v-zone, rather than intensity of those operations in the v-zone. As a result, even when a v-zone is heavily utilized, eZNS allocates the same number of active zones to all v-zones regardless of the utilization of each v-zone. Consequently, while eZNS with F2FS improves active zone utilization compared with standalone F2FS, it delivers sub-optimal performance when I/O traffic is skewed toward a specific log stream.

The lack of cross-layer awareness may be addressed through coordination between F2FS and eZNS layers. However, such cross-layer coordination necessitates additional interaction mechanisms and tight coupling between the layers. Specifically, this requires communication burden between F2FS and eZNS whenever the write intensity of log streams changes. For example, when the write intensity of a log stream changes, F2FS transfers the intensity information to eZNS. Using the information, eZNS can increase or decrease the number of active zones mapped with the v-zone associated with the log stream. Therefore, this cross-layer coordination approach can increase system complexity and maintenance overhead.

F2FS_SS demonstrates better performance than F2FS and eZNS with F2FS. However, static striping exhibits sub-optimal performance. It is because, similar to eZNS with F2FS, static striping allocates the same number of active zones to all log streams, regardless of their write intensity, thereby limiting the utilization of zone-level parallelism. The performance gap between eZNS with static stripping primarily arises from differences in request size. eZNS issues small requests (e.g., 4KB) for each v-zone to minimize latency while static stripping issues larger requests (e.g., 2MB).

These results demonstrate that evenly distributing active zones across log streams can waste active zones and limit the zone-level parallelism of write-intensive log streams. To maximize zone-level parallelism across log streams, LFS should dynamically allocate active zones based on the write intensity of each log stream.

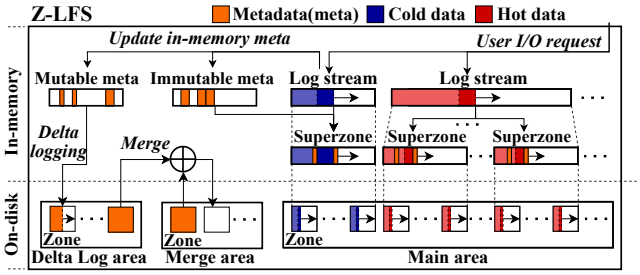

Figure 4: Overall architecture and procedure of Z-LFS.

4 Design and Implementation

4.1 Design Goals of Z-LFS

We design Z-LFS to meet the following three design goals:

- **ZNS-tailored metadata management:** To maximize the cost-efficiency, Z-LFS should update metadata in an efficient append-only manner while considering unique characteristics and constraints of LFS on ZNS SSD.
- **Speculative log stream management:** To maximize active zone utilization, Z-LFS should identify write intensity of each log stream and optimally scale active zones for that stream.
- **Conflict-aware zone allocation:** To avoid conflicts among zones mapped to overlapping internal resources (dies or channels), Z-LFS should track the mapping between them and allocate conflict-free zones as much as possible.

4.2 Strategies of Z-LFS

We present the three key strategies and explain how they meet the design goals of Z-LFS.

Strategy #1: *To enable efficient append-only metadata update while considering LFS features on ZNS SSD, Z-LFS classifies metadata into immutable and mutable types based on their alignment with segment life cycles. Z-LFS manages the two types of metadata separately: it appends immutable metadata to the corresponding segments and adopts delta logging mutable metadata in a dedicated area.*

Strategy #2: *To maximize zone-level parallelism while considering workloads, Z-LFS speculates on and determines the active zone quota for each log stream and dynamically scales active zones to log streams as workload changes.*

Strategy #3: *To avoid channel-level conflict, Z-LFS organizes consecutive zones without channel overlap into a superzone. To prevent die-level conflict, Z-LFS groups superzones mapped to the identical dies as a interference group and selectively allocates superzones from different groups to a log stream.*

4.3 Overall Architecture of Z-LFS

Figure 4 shows the overall architecture of Z-LFS.

Architecture: Z-LFS manages six log streams categorized by their types and temperature similar to F2FS. There are two primary types of log streams: data and node. Data log streams stores user data, while node log streams stores inode or index information for data blocks. Each type is further divided into hot, warm, and cold streams based on hotness. For LFS metadata management, Z-LFS classifies metadata into immutable and mutable metadata based on their life cycle. Immutable metadata shares the same life cycles as their corresponding segments, while mutable metadata has distinct life cycle independent of segments.

In Figure 4, the on-disk layout of Z-LFS is organized into three areas: the delta log area, the merge area, and the main area. Delta log area is dedicated to logging mutable metadata, while merge area stores tables of mutable metadata that is arranged and consolidated from the delta log area. Main area stores data and node log streams, along with their associated immutable metadata. In the main area, considering resource conflicts, Z-LFS organizes consecutive zones into a superzone, which is further divided into multiple fixed-sized segments.

Procedure: As illustrated on the right side of Figure 4, when handling user I/O requests, Z-LFS writes blocks to the appropriate data or node log streams. During this process, it speculates on the write intensity of each log stream as workloads change and dynamically allocates superzones. Specifically, Z-LFS allocates the number of superzones to each log stream in proportion to the ratio of its write requests to the total write requests within a given time window (**Strategy #2**). This ensures that log streams with higher write intensity can utilize more zone-level parallelism. To avoid resource contention, Z-LFS also considers channel-level and die-level conflicts when organizing and allocating superzones (**Strategy #3**). Z-LFS then selects a segment from allocated superzones to a log stream in a round-robin manner and writes blocks sequentially to the chosen segments.

As data and node blocks are written, Z-LFS updates their associated metadata as illustrated on the left side of Figure 4. For immutable metadata, which shares the same life cycle as its corresponding segment, Z-LFS appends the metadata to the end of the segment within the same superzone (**Strategy #1**). This ensures that immutable metadata is naturally cleaned alongside its segment during GC, eliminating the need for additional metadata operations such as metadata GC.

On the other hand, mutable metadata is managed via a different mechanism from immutable metadata. As mutable metadata entries are small (typically tens of bytes) and frequently updated, Z-LFS buffers the changes (deltas) and logs them to a dedicated delta log area. The delta log area operates as a circular log and is cleaned when half of the area is filled. For cleaning, Z-LFS performs a merge operation which consolidate logged deltas from the delta log area into a table and then writes them to the merge area. To reduce the impact on user I/O performance, this merge operation is performed asynchronously.

4.4 Append-only metadata management

4.4.1 Life cycle based metadata management

In LFSs on CNS SSD, life cycles of metadata is distinct from those of segments since segments can be updated after being written. For example, slack space recycling [29, 47], used in LFSs to reduce GC costs, enables writing new data into invalidated space within already written segments. This necessitates frequent updates to metadata associated with the segment, resulting in metadata life cycles that diverge from those of the segments.

LFSs on ZNS SSDs, unlike those on CNS SSDs, have metadata that share the same life cycle as a segment due to the sequential write constraints of ZNS SSDs. Specifically, in LFSs on ZNS SSDs, once a segment is written, its blocks cannot be updated until GC. Instead, the blocks can only be invalidated, and the segment must be erased before reuse. Accordingly, the life cycle of certain metadata is identical to that of its associated segment. For example, a metadata (e.g., segment summary (SS) in F2FS) stores reverse mapping information of blocks within a segment, including 1) the IDs of all nodes pointing to the blocks and 2) their offsets within the nodes. This information is never modified once written, as the blocks within the segment cannot be updated. Such metadata is utilized during GC, and its life cycle ends when the corresponding segment is cleaned by GC. After GC, the metadata is always newly written. We classify such write-once and never-updated metadata as immutable metadata. In contrast, metadata like bitmaps indicating valid blocks in a segment (e.g., segment information table (SIT) in F2FS) and block addresses of nodes (e.g., node address table (NAT) in F2FS) are frequently updated, which we categorize as mutable metadata.

Leveraging the observation that the life cycle of immutable metadata aligns with its corresponding segment, `Z-LFS` appends immutable metadata to the end of the segment and stores them together in the same zone. this approach ensures that the immutable metadata remains valid as long as the segment lives and is naturally cleaned together during GC. As a result, `Z-LFS` eliminates the need for additional operations such as metadata GC and over-provisioned area to perform them for the immutable metadata. In addition, since the location of the immutable metadata is fixed to the end of the segment, `Z-LFS` avoids tracking metadata locations, typically required when metadata is stored in an append-only manner.

4.4.2 Metadata delta logging

`Z-LFS` manages mutable metadata using an append-only approach with delta logging. Specifically, mutable metadata is typically small, with most entries consisting of only a few dozen bytes. In addition, since each entry holds independent information, only some entries may be updated while others remain unchanged. Thus, a block which contains mutable metadata can be partially updated. To efficiently handle the partial metadata updates, `Z-LFS` collects only the modified entries (i.e., deltas), aggregates them into a new metadata log block, and logs the block in delta log area. We demonstrate that the write amplification of `Z-LFS` is comparable to that of F2FS on CNS SSD, even under metadata-intensive workloads with frequent fsync operations (see Figure 11).

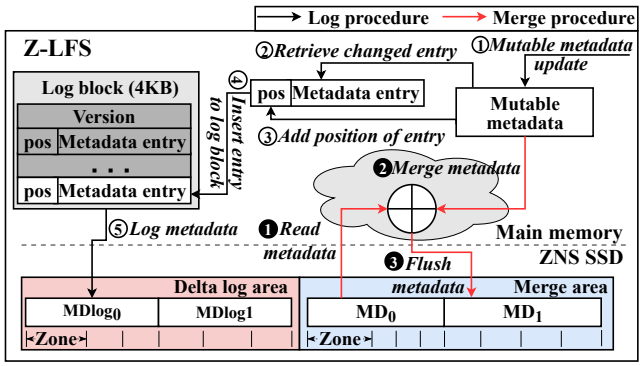

Figure 5: Architecture and procedure of delta logging (MD_x: one side of metadata table pair, $MDlog_x$: one side of metadata log pair, pos: position of the metadata entry).

Meanwhile, a pure log-structured approach that logs metadata blocks with a GC procedure could be a candidate for managing mutable metadata. However, with this approach, updating the metadata changes its location, causing the metadata to be dispersed across the ZNS SSD. As a result, the file system should track and persist the location of each metadata block. This can lead to the need for metadata of metadata and add an additional complexity to metadata management. In contrast, `Z-LFS` consolidates metadata locations to eliminate the need to track the locations of individual metadata blocks.

Architecture: Figure 5 depicts the architecture and overall procedure of delta logging in `Z-LFS`. For metadata delta logging, a pair of logs consisting of zones (e.g., $MDlog_0$, $MDlog_1$) is maintained in the delta log area. The metadata deltas are written to the pair in a circular manner. To keep the consistency of mutable metadata, `Z-LFS` maintains a pair of metadata tables (MD_0, MD_1) in the merge area. `Z-LFS` alternatively updates one side of the metadata table pair, ensuring that one side always contains valid metadata while the other may contain outdated metadata. By combining circular logging deltas in the delta log area with alternative metadata updates in the merge area, `Z-LFS` prevents partial metadata updates and ensures crash consistency, as described in §4.7.

Delta logging procedure: During user I/O requests processing, mutable metadata are updated in memory (①). Only when `Z-LFS` needs to perform a checkpoint[1], the delta logging is triggered. For delta logging, `Z-LFS` retrieves changed entries (①) and appends their positions (`pos`) to each entry (②). `pos` indicates the location of the metadata entry in the metadata table, stored in the merge area, ensuring it can be identified after system recovery. Then, `Z-LFS` inserts the en-

[1]The trigger condition of the checkpoint is the same as that in F2FS.

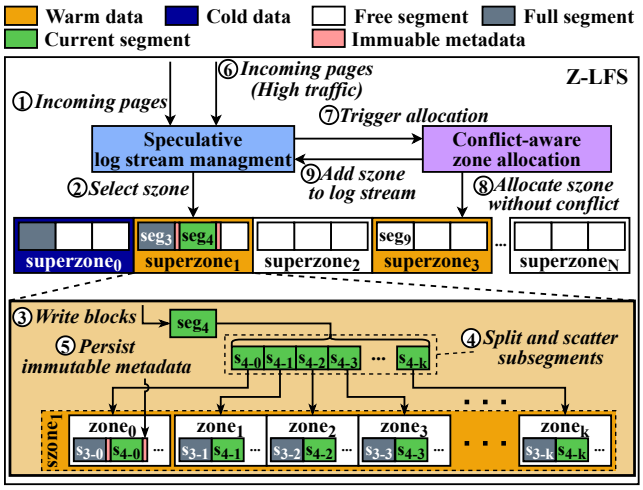

Figure 6: Architecture and procedure to process user data in Z-LFS (szone: superzone, seg_n: n^{th} segment, $s_{n\text{-}k}$: k^{th} subsegment of n^{th} segment).

tries in a 4KB log block (④). When the log block becomes full, it is written to the delta log area ($MDlog_0$) (⑤). This procedure of ①-⑤ is repeated until Z-LFS logs all of changed entries in the delta log area. If the current delta log areas ($MDlog_0$) overflows during logging, the remaining entries are written to the next delta log area ($MDlog_1$). During delta logging, Z-LFS records a log version number in log blocks. The log version increments whenever delta logging is invoked and is used during system recovery to determine which log block should be recovered, as described in §4.7.

Asynchronous merge procedure: When a delta log area (e.g., $MDlog_0$) becomes full during a log operation, Z-LFS triggers an asynchronous merge operation to clean the area and reclaim space for future logs. In this process, Z-LFS first reads the valid side of the metadata table pair (MD_0) into memory (❶). It then merges this metadata with the entries logged in the delta log area (❷). To reduce overhead, Z-LFS buffers the entries in memory when they are logged in the delta log area. This allows Z-LFS to avoid scanning the delta log area on the ZNS SSD when retrieving logged metadata entries, at the cost of additional memory consumption (§6.3). However, the total size of memory buffer is limited by the total size of the delta log area. After merging, Z-LFS flushes the updated metadata table to the storage device (❸). Once the flush operation completes, Z-LFS safely resets the delta log area ($MDlog_0$) applied to the merge area (MD_1), reclaiming the space for future use.

4.5 Speculative log stream management

Figure 6 shows the architecture and overall procedure to process user I/O requests.

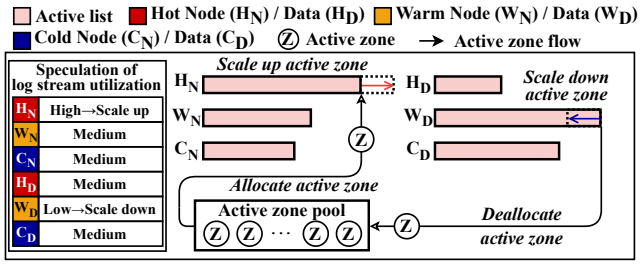
Architecture: Z-LFS organizes all zones in the main area into superzones. Superzones are logically divided into segments for finer space management, and the segments contain subsegments. The subsegments in a segment are logically continuous but physically mapped to non-contiguous blocks (e.g., a distinct 128KB). The organization of superzones, segments, and subsegments is determined during file system initialization. Z-LFS has six log streams (e.g., hot/warm/cold data and node) and tracks the current segment, which indicates the last written position for each log stream. For crash consistency, the information of the current segments persists in checkpoint blocks and can be recovered as in F2FS.

Procedure: In Figure 6, when Z-LFS flushes data and node, it identifies the type of log stream (i.e., warm data) associated with incoming pages (①). Then, to store the pages, Z-LFS selects a superzone of the identified log stream ($superzone_1$). Subsequently, to initiate the I/O operation, it selects the first free segment (seg_4) within the superzone and then allocates blocks from the segment (②). For a segment, Z-LFS splits the segment (seg_4) into smaller subsegments ($s_{4\text{-}0}$-$s_{4\text{-}k}$) and scatters each subsegments across the zones ($zone_0$-$zone_k$) in the superzone (③,④). Z-LFS keeps the order of segments (seg_3, seg_4, ...) within each superzone as the order of subsegments ($s_{3\text{-}0}$, $s_{4\text{-}0}$, ...) within each zone. By doing so, it can keep the sequential write constraint within each zone and easily recover the mapping of subsegment and LBA. When a segment becomes full, its corresponding immutable metadata is appended to the end of the segment (⑤).

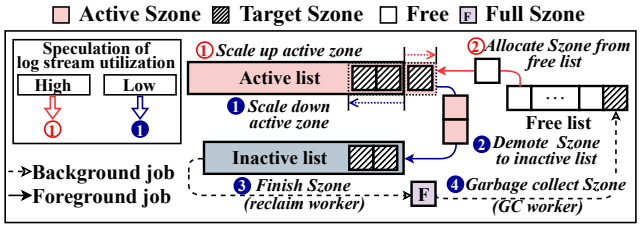
When the warm data log stream is speculated to be high-traffic (⑥), Z-LFS scales up the active zones for the log stream. Then, to allocate an additional free superzone to increase active zones, Z-LFS triggers conflict-aware zone allocation (⑦). Z-LFS allocates superzone without conflict with previously allocated superzones (⑧) and adds the superzone to the log stream (⑨). With the superzones (i.e., $Superzone_1$ and $Superzone_3$) allocated for the log stream, Z-LFS selects a superzone in a round-robin manner (e.g., $superzone_3 \rightarrow superzone_1 \rightarrow superzone_3$) and selects the first free segment (e.g., seg_9) within the selected superzone ($superzone_3$) to provide higher zone-level parallelism.

Speculation of I/O utilization of log streams: To determine the optimal number of active zones for each log stream, Z-LFS employs a speculative, quota-based approach for managing active zones. This approach speculates on write intensity and allocates an appropriate quota of active zones to each log stream. Additionally, Z-LFS performs the speculation separately for data and node log streams. This separation is based on our observation, as described in §4.6, that data and node log streams are typically not used concurrently.

To do this, we define the total available active zones for data or node log streams (A). A is determined as the smaller of the following values: (1) the number of active zones required to achieve peak throughput (A_{peak}) and (2) half of the maximum number of active zones available after reserving zones for file system metadata management (A_{avail}). Z-LFS uses the smaller value to keep the maximum number of active zone constraint of ZNS SSD. Thus, A is defined as $A = min(A_{peak}, \frac{A_{avail}}{2})$.



(a) Overview of scaling active zones of multiple log streams



(b) Procedure of scaling active zones within a log stream.

Figure 7: Dynamic scaling of active zones of log streams.

The number of active zones allocated to a specific log stream i (A_i) is determined proportionally to its write request volume (W_i) relative to the total request volume among log streams of the same type ($W_T = \sum_{i \in T} W_i$, where T represent either data or node) within a time window. This is expressed as: ($A_i = A \times \frac{W_i}{W_T}$). After each time window elapses, Z-LFS tracks the write traffic for each log stream and adjusts the allocation of active zones accordingly.

Scaling active zones of log streams: Figure 7a depicts an overview of scaling active zones across log streams. Z-LFS maintains a global active zone pool to keep the active zone constraint of ZNS SSD while scaling active zones of log streams based on the speculation. For each log stream, Z-LFS compares the allocated number of active zones by the speculation with the current number of active zones utilized by the log stream. If the allocated number is greater than the current utilization, Z-LFS determines that the log stream's traffic to be low. Conversely, if the allocated number is smaller, the traffic of the log stream is considered high. As shown in the figure, for a log stream speculated as high I/O traffic (e.g., hot node log stream: H_N), Z-LFS scales up active zones by allocating them from the active zone pool to the log stream. Meanwhile, when a log stream exhibits low utilization (e.g., warm data log stream: W_D), Z-LFS scales down and deallocates the active zones occupied by the log stream.

Scaling up active zone: Figure 7b shows an example of a procedure for scaling active zones within a log stream. As shown in the figure, Z-LFS manages active, inactive, and free lists of superzones for efficient active zone scaling. The active list contains superzones where write requests are actively performed. Z-LFS selects a superzone in the active list in a round-robin manner and allocates a segment in the superzone. In this example, as utilization of the log stream increases,

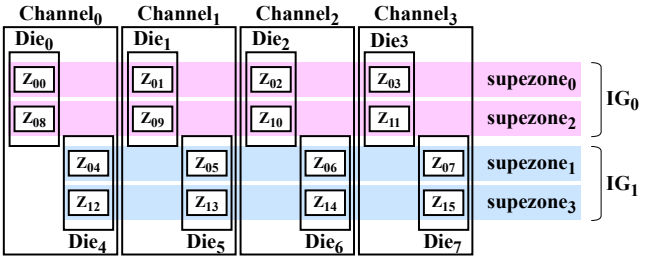


Figure 8: Superzone and IG organization for conflict-aware zone allocation. (Z_n: n^{th} zone, IG_n: interference group n)

Z-LFS tries to scale up the active zones allocated to the log stream (①). To do this, it allocates a free superzone from the free list and inserts the superzone into the active list (②). Then, the allocated superzone is utilized by Z-LFS in a round-robin manner, naturally increasing zone-level parallelism.

Scaling down active zone: As shown in Figure 7b, when the utilization of the log stream decreases due to workload change, Z-LFS scales down active zones (❶). To do this, Z-LFS demotes two superzones in the active list to the inactive list (❷) and reclaims the active zones of the superzones in the inactive list by issuing FINISH zone commands in a background manner (❸). Finally, after a GC worker frees the superzones according to the GC policy, the superzones are shifted from the full state to the free state and are inserted into the free list (❹). Note that the reclaim and GC processes are decoupled from the normal I/O path by the background workers to minimize the overhead caused by the FINISH zone commands and GC, respectively.

4.6 Conflict-aware zone allocation

Superzone and IG organization: Figure 8 illustrates the organization of superzones and interference groups (IGs) based on the modeling of ZNS SSD internal resources, as described in §3.2. Since zones are mapped to dies and channels in a round-robin manner, allocating consecutive zones can help avoid resource conflict. For example, in a ZNS SSD with 8 dies and 4 channels as shown in the figure, Z_{00} ($zone_{00}$), Z_{01}, Z_{02}, and Z_{03} are mapped to different channels, while Z_{00} and Z_{04} are mapped to the same channel. Similarly, Z_{00}-Z_{07} are mapped to different dies, while Z_{00} and Z_{08} are mapped to the same die.

Based on this model, to avoid conflict while reducing the complexity of zone management, Z-LFS organizes consecutive zones (Z_{00}-Z_{03}) into a superzone ($superzone_0$) to avoid the channel-level conflict. As a result, each superzone consists of zones equal to the number of channels. Furthermore, Z-LFS groups superzones mapped to the same die ($superzone_0$ and $superzone_2$) into an interference group (IG_0). This static organization, in which the number of interference groups corresponds to the number of dies divided by the number of channels, is determined by the zone IDs as well as the number of channels and dies. Based on the analysis in §3.2, Z-LFS organizes a superzone with 16 zones and groups superzones

into 8 IGs for our testbed ZNS SSD.

Superzone allocation for log streams: To minimize the die conflicts, Z-LFS allocates active zones in units of superzones to the log streams and prioritizes the allocation of superzones from non-overlapping IGs, avoiding overlap with superzones from the previous IG. Furthermore, we observe that data and node log streams are typically not used and written concurrently. Specifically, node log streams are primarily written during checkpointing, while data log streams are blocked during this process. Thus, enforcing non-overlapping IG allocations without differentiating between data and node log streams may unnecessarily limit active zone utilization. For example, if there are two IGs and a superzone is allocated from one IG to a node log stream, data log streams can only use a superzone from the other IG. This limits the number of superzones that can be utilized even if no die conflicts occur. As a result, this observation is incorporated into the allocation strategy to further exploit active zone utilization.

To do this, Z-LFS maintains separate IG allocations for data and node log streams by maintaining distinct IG lists. When a superzone is allocated to a data or node log stream, Z-LFS marks its corresponding IG in the respective allocation list to prevent other concurrent log streams from being assigned superzones within the same IG. By doing so, since blocks of the same log stream are written to zones that do not overlap at the die level, this approach avoids conflicts during write operations. Similarly, it ensures conflict-free sequential reads, since blocks were already written to non-overlapping zones. We note that if all superzones within an IG become completely exhausted, Z-LFS can allocate superzones from overlapping IGs as a fallback. To minimize such cases, Z-LFS prioritizes selecting a superzone from the IG with the fewest remaining free superzones as a victim during a GC procedure.

4.7 Crash Consistency

Z-LFS recovers the file system state against a system crash with roll-back and roll-forward recovery mechanisms, similar to F2FS. Roll-back restores the state to that after the last committed checkpoint (CP), meanwhile, roll-forward restores the state to that after the last `fsync()` call from the last committed CP. We focus on explaining the roll-back recovery of metadata since other recovery procedures are performed in the same way as F2FS.

Immutable metadata is appended directly to the end of its corresponding segment. However, if a segment is partially written, its corresponding immutable metadata is written to the checkpoint block during checkpointing. As a result, Z-LFS ensures the consistency between segment and its metadata through the checkpoint process as F2FS does.

To recover mutable metadata, Z-LFS scans deltas in all the log blocks in the delta log area and merges the deltas with the valid metadata tables to the outdated merge area. Specifically, Z-LFS first references checkpoint blocks. In Z-LFS, these blocks store information about which of the mutable metadata tables in pairs in the merge area is valid. This allows Z-LFS to read the valid sides of metadata table pairs and identify the valid mutable metadata table. During the recovery procedure, Z-LFS scans log blocks in the delta log area and retrieve valid log blocks. Specifically, the checkpoint blocks in Z-LFS store the latest log version when the checkpoint is performed. Thus, Z-LFS can compare the versions in log blocks (i.e., log version) with the version in the last committed checkpoint (i.e., checkpoint version). If the log version is equal to or less than the checkpoint version, Z-LFS considers it valid. Otherwise, Z-LFS ignores the log block since the corresponding checkpoint for the log block is not committed. Then, Z-LFS identifies the position (pos) of each metadata entry (delta) from the valid log blocks. Using these positions, Z-LFS merges the deltas with the valid metadata table. Finally, Z-LFS flushes the merged metadata table to the outdated merge area and proceeds to other recovery procedures, including roll-forward.

After Z-LFS recovers from the system crash with roll-back and roll-forward, Z-LFS does not recover the active zone pool. Instead, it initializes the active zone pool while reclaiming the active zones within ZNS SSD, starting with a clean and consistent active zone state. To reclaim the active zones, Z-LFS changes the zones from the *closed* state[2] to the *full* state. Specifically, Z-LFS scans the states of zones in the ZNS SSD via a REPORT zone command and finishes the zones in the *closed* state via a FINISH zone command. We note that this recovery does not affect the consistency of Z-LFS since FINISH zone commands do not change the contents of blocks. Similarly, IG allocation lists are initialized since allocated superzones for log streams are reclaimed.

4.8 Implementation

We implement Z-LFS based on F2FS and categorize metadata in F2FS into immutable and mutable metadata. For example, Z-LFS classifies segment summary (SS) as immutable metadata, and segment information table (SIT) and node address table (NAT) as mutable metadata. Since SS, which stores reverse mapping information, is write-once and never-updated metadata, Z-LFS considers SS as immutable metadata. On the other hand, SIT includes bitmaps indicating valid blocks in a segment and NAT includes the logical address of node blocks, which are frequently updated regardless of segment life cycles. Z-LFS manages these metadata as mutable metadata through delta logging and merge.

Since SIT and NAT may have different lifetimes, managing them together can lead to unnecessary merge overhead. For instance, if SIT is updated more frequently than NAT, NAT may experience unnecessary merges as SIT exhausts the delta log area. To avoid this, Z-LFS allocates separate delta log areas, merge areas, and memory buffers for SIT and NAT, and

[2] After a system crash, the ZNS SSD changes zones from the *opened* state to the *closed* state. However, the zones with *closed* state still occupy active zones [30, 44].

performs delta logging and merging independently for each. This approach allows Z-LFS to efficiently handle metadata updates according to each metadata type, minimizing write amplification and performance degradation.

5 Discussion and limitation

Large-zone ZNS SSDs: Z-LFS can be adopted for large-zone ZNS SSDs. Since append-only metadata management of Z-LFS requires a small amount of active zones, it can be adopted on a large-zone ZNS SSD even if it has a more strict constraint on active zones than a small-zone ZNS SSD. Furthermore, Z-LFS can use the small random writable area in the large-zone ZNS SSD [9] by placing mutable metadata and updating it in-place. On the other hand, speculative log stream management and conflict-aware zone allocation may not be beneficial for the large-zone ZNS SSD even if adopted, because the large-zone ZNS SSD we used already leverages zone parallelism at the device level. However, if a large-zone ZNS SSD has sufficient active zones for higher flexibility at the cost of intra-zone parallelism, Z-LFS can leverage the active zones, increasing zone-level parallelism.

Single-stream LFS: All Z-LFS techniques are effective in an LFS with multiple log streams. However, in an LFS with a single log stream, speculative log stream management may not yield meaningful performance improvements since it scales active zones across multiple log streams. Meanwhile, the other techniques of Z-LFS, such as append-only metadata management and conflict-aware zone allocation, still are effective, since issues caused by CNS-based metadata design and SSD resource conflict persist even in the single-stream LFS.

Multi-tenant environments: While Z-LFS is designed and evaluated in a single-tenant environment, it can also be deployed in a multi-tenant environment. However, Z-LFS can be further optimized to better support multi-tenancy. For instance, we can incorporate I/O scheduling and rate-limiting mechanisms in Z-LFS as in prior studies [38, 42]. This can improve performance and fairness, especially under bursty write workloads. We leave such optimization and evaluation as future work.

Space overhead of Z-LFS: Z-LFS can reduce the storage system cost by append-only metadata management. However, Z-LFS introduces additional space overhead to manage LFS metadata on a standalone ZNS SSD due to the ZNS constraints. In the delta log area, Z-LFS requires at least two zones to circularly log mutable metadata. In the merge area, similar to an existing LFS (e.g., F2FS), Z-LFS maintains a pair of metadata table. However, since the pair should be managed by a zone granularity, the space overhead increases. By appending immutable metadata to the end of its associated segment, Z-LFS reduces the space overhead by 10.7× compared to performing delta logging for both immutable and mutable metadata. The total space overhead of Z-LFS, including both delta log and merge areas, accounts for approximately 0.02% of the total ZNS SSD capacity. This result demonstrates that the space overhead of Z-LFS is negligible.

6 Evaluation

6.1 Experimental setup

Testbed: We use a machine equipped with i7-13700K 3.4GHz CPU (16 physical cores) and 32GB main memory. We use a commodity ZNS SSD [5] and its equivalent CNS SSD [3]. The ZNS SSD consists of 40,704 zones, each with a size of 96MB, providing a total space of 3.92TB. The maximum number of active zones is 384. We use Linux kernel 5.17.4 and f2fs-tool 1.15.0 for the mkfs tool.

Comparison: We compare Z-LFS with F2FS [29], F2FS with static striping (F2FS_SS) as described in §3.3, ZenFS [9], eZNS [42, 43] which is the state-of-the-art ZNS interface for commodity ZNS SSDs, and eZNS with F2FS. F2FS and F2FS_SS are mounted on ZNS SSD with CNS SSD, denoting F2FS (+CNS SSD) and F2FS_SS (+CNS SSD), respectively. To evaluate eZNS without any file system (i.e., raw device), we denote it as eZNS. To evaluate the performance of eZNS with a file system, we mount F2FS on ZNS SSD with eZNS and denote it as eZNS with F2FS (+CNS SSD), since it also requires an additional CNS SSD. We configure a namespace in eZNS to allow all threads in the namespace to utilize all available active zones (384) regardless of the namespace.

6.2 Workloads

Micro-benchmark: We employ FIO [22] to evaluate Z-LFS using the sequential and random read/write workloads with 16 threads. With file systems (e.g., F2FS, F2FS_SS, eZNS with F2FS (+CNS SSD), and Z-LFS), each thread performs 10GB I/O to its dedicated file with a 4KB request size[3]. For comparisons without any file system (e.g., Raw, eZNS), each thread issues 10GB I/O with a 128KB request size. In this case, we use the 128KB request size to demonstrate ideal performance on a raw device and use it for comparison. Unless otherwise stated, we use this configuration in all the FIO evaluations. We also evaluate file system-level garbage collection (GC) to show the effectiveness of Z-LFS even in GC. In this experiment of GC, to reduce the aging time, we create a 150GB partition of a ZNS SSD, pre-fill 128GB in the partition, and then perform random writes for 10 minutes to trigger file system-level GC. Furthermore, we use MDtest [36] to evaluate Z-LFS, under the metadata-intensive workloads. For the evaluation, we create 1 million files with various file sizes of 4/32/128KB and fsync after each file creation.

Macro-benchmark: We use Filebench [2] with four workloads including fileserver, varmail, webserver, and videoserver. We use 16 threads, 16MB file size in fileserver, 1MB in varmail and webserver, and 1GB in videoserver.

[3]We mostly use 4KB as a request size since it is the default size and usually used in most OS and applications [24, 31, 48].

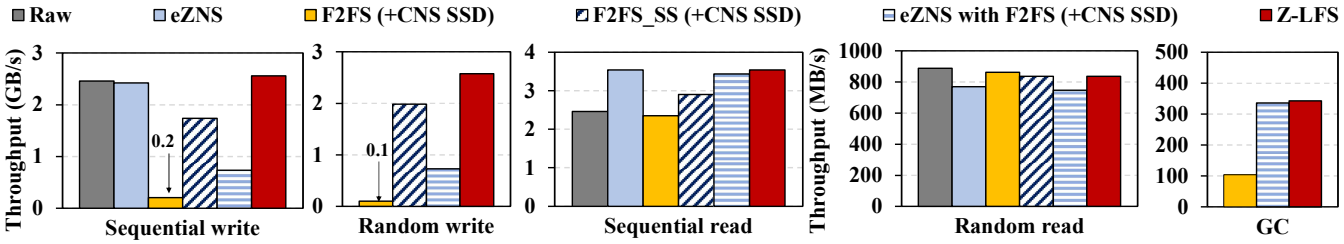

Figure 9: Throughput of sequential/random write/read and garbage collection (GC).

File system	F2FS (+CNS SSD)	F2FS_SS (+CNS SSD)	eZNS with F2FS (+CNS SSD)	Z-LFS
Average latency	626 us	31.9 us	89.4 us	**24.5 us**
Tail latency	47 ms	103.9 us	39 ms	**45.3 us**

Table 1: Write average and tail latency (99.9%)

RocksDB: To evaluate Z-LFS with the real-world application, we use RocksDB [14] and its benchmark tool, db_bench with fillseq, fillrandom, readrandom, and overwrite workloads as in Figure 14. We use 16 threads, 50 million operations, and 1KB value size.

6.3 Micro-benchmark

Write throughput: In Figure 9, Z-LFS achieves higher performance by up to 12.4×/25.2× and 47%/30% compared with F2FS and F2FS_SS in the case of sequential/random writes, respectively. The performance gap between F2FS and Z-LFS results from the better exploitation of zone-level parallelism by utilizing multiple active zones per log stream. Z-LFS further improves utilization of zone-level parallelism and performance over F2FS_SS by speculative log stream management technique. Specifically, Z-LFS utilize up to 128 active zones for the most intensive log stream (i.e., warm data log stream) while the static striping in F2FS_SS limits the maximum utilization as 64 zones.

Z-LFS improves performance by up to 3.5× on both sequential and random write workload compared with eZNS with F2FS. As described in §3.3, due the lack of cross-layer awareness of F2FS, eZNS achieve sub-optimal utilization of active zone, leading to performance degradation. On the other hand, since Z-LFS is the file system itself, it can measure the current utilization for each log stream at the file system level, identify the intensively utilized log streams, and allocate more active zones to them than less utilized log streams.

Read throughput: In Figure 9, interestingly, Z-LFS improves the sequential read performance by 50% compared with F2FS. It is because Z-LFS scatters data across multiple zones while leveraging internal parallelism, even in the read operation. Similarly, F2FS_SS and eZNS with F2FS also achieve higher performance compared with F2FS. Furthermore, Z-LFS improves performance by 22% over F2FS_SS, resulting from the conflict-aware zone allocation of Z-LFS as described in §4.6. The random read performance of the file systems is overall low due to low locality, and Z-LFS exhibits similar random read performance to F2FS without additional overhead.

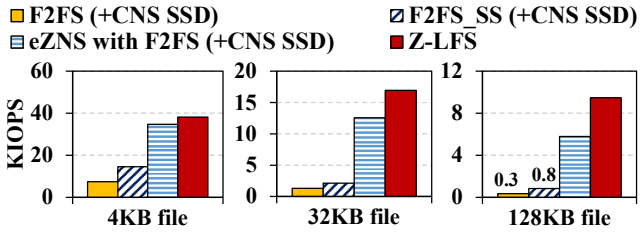

Figure 10: Throughput of metadata-intensive workloads

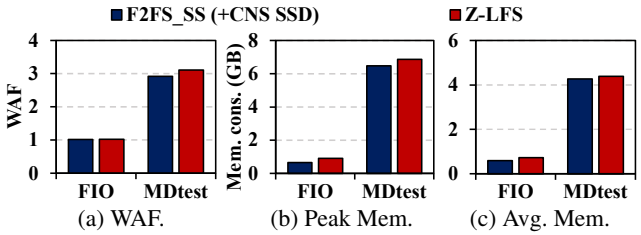
Write latency: Table 1 presents the average and 99.9th percentile tail latency in the random write workload. As shown in the table, Z-LFS reduces the average latency by up to 96.1%, 23.23%, and 72.63% and tail latency by up to 99.90%, 56.4%, and 99.88% of F2FS, F2FS_SS, and eZNS with F2FS, respectively. This result demonstrates that Z-LFS successfully improves the write latency as well as throughput. This is because Z-LFS can quickly flush the page cache by exploiting zone-level parallelism. Thus, upcoming application write requests can be cached in the page cache with reduced delay.

GC-intensive workload: In Figure 9, Z-LFS exhibits up to 3.3× higher throughput compared with F2FS on ZNS SSD under file system GC operations, while showing similar performance to eZNS with F2FS. The performance improvement over F2FS is attributed to speculative log stream management of Z-LFS, which distributes GC operations of log streams across multiple active zones similar to the normal write operations. Meanwhile, the overhead from the file system GC operations limits the GC performance of Z-LFS. These results indicate that Z-LFS can leverage zone-level parallelism even in the scenario involving frequent file system GC operations.

Metadata-intensive workload: Interestingly, a metadata-intensive workload (e.g., file creation) in F2FS frequently writes the metadata (i.e., inode or dentry blocks) in ZNS SSD instead of CNS SSD. Thus, even in metadata intensive workloads, the efficient utilization of active zones can considerably impact performance. Accordingly, as shown in Figure 10, Z-LFS achieves a significant improvement of up to 27.7× and 11.4× compared with F2FS and F2FS_SS in the file creation workload in MDtest, respectively. Compared with eZNS with F2FS, Z-LFS achieves up to 1.6× higher performance since it can scale up the node log stream via speculative log stream management. This highlights the importance of managing active zones for LFS log streams more flexibly. These results



(a) WAF. (b) Peak Mem. (c) Avg. Mem.

Figure 11: Write amplification factor and memory consumption.

(a) Fileserver (b) Varmail (c) Webserver (d) Videoserver

Figure 13: Throughput of various filebench workloads.

demonstrate that Z-LFS can improve the performance even in the metadata-intensive workloads.

Write amplification: To evaluate write amplification factor (WAF) impact of Z-LFS in both data and metadata-intensive workloads, we measure WAF using random write of FIO and MDtest with a 4KB file size. Figure 11a represents that the WAF of Z-LFS is similar to that of F2FS_SS on both workloads. This result demonstrates that the append-only metadata management of Z-LFS minimizes the metadata WAF.

Memory consumption: We measure the average and peak memory consumption of Z-LFS. In Figure 11b, the peak memory consumption of Z-LFS is higher by up to 38% and 3% compared with F2FS in FIO and MDtest, respectively. Figure 11c shows that the average memory consumption of Z-LFS is higher by up to 22% and 6% compared with F2FS in FIO and MDtest, respectively. Although this result shows Z-LFS has a higher memory consumption than that of F2FS due to the memory consumption from memory buffers used in delta logging, the absolute amount of consumed memory is relatively low. Specifically, Z-LFS consumes an extra 250MB and 380MB memory compared with F2FS in FIO and MDtest, respectively. Furthermore, the amount of memory required in Z-LFS does not grow indefinitely since the maximum memory consumption of all the memory buffer is bounded by the size of all the delta log areas. Consequently, this result demonstrates that Z-LFS achieves append-only metadata management at the cost of memory consumption but the additional absolute amount of memory is relatively small and limited.

Effectiveness of active zone scaling: We evaluate the effectiveness of scaling active zones of log streams compared with the four static allocation schemes (static) in Z-LFS as in Figure 12. For static (even), we use F2FS_SS which allocates even number of active zones for all log streams. For each static (hot/warm/cold) scenario, we allocate 128 active zones for each hot/warm/cold data log stream and 32 active zones for the others, respectively. We use an FIO random write workload to configure three phases (hot, warm, cold) and generate data for each phase by varying file extensions. During each phase, each data is written to its corresponding data log stream. Each phase is executed for 100 seconds, resulting in a total of 300 seconds. Z-LFS with active zone scaling achieves comparable performance compared with each optimal static scheme for each phase. Consequently, the results indicate that Z-LFS optimally scales active zones in response to varying workloads at runtime.

6.4 Macro-benchmark

Fileserver: Figure 13a shows Z-LFS improves the performance by up to 7.21×, 1.6×, and 2.47× compared with F2FS, F2FS_SS, and eZNS with F2FS, respectively, in the fileserver workload. The result shows Z-LFS yields a significant improvement even in a realistic data-intensive workload.

Varmail: Figure 13b shows that Z-LFS achieves improvements of up to 33.44×, 6.30×, and 2.04× compared with F2FS, F2FS_SS, and eZNS with F2FS, respectively. Since varmail generates and flushes nodes frequently, Z-LFS can accelerate the flushing of the nodes to the main area, similar to the MDtest result.

Webserver: In Figure 13c, Z-LFS outperforms F2FS and F2FS_SS by up to 2.09× and 1.62×, respectively, even if webserver is a read-intensive workload. It is because the read operations can benefit from the high utilization of multiple zones, similar to the read cases depicted in Figure 9. Furthermore, Z-LFS improves performance over F2FS_SS, resulting from the conflict-aware zone allocation similar to the result of read throughput in §6.3. eZNS with F2FS also shows high read performance since it can leverage the internal parallelism from multiple zones where data is scattered.

Videoserver: In Figure 13d, Z-LFS improves the performance by up to 13.7×, 1.62×, and 3.33× compared with F2FS, F2FS_SS, and eZNS with F2FS, respectively, in the videoserver workload. Since videoserver includes more data-intensive operations compared with fileserver, Z-LFS can achieve higher performance.

6.5 Real-world Application

In this evaluation, we compare Z-LFS with a recent RocksDB optimized file system, ZenFS [9], F2FS, F2FS_SS, and eZNS with F2FS. We note that we use a CNS SSD for ZenFS to support the in-place updates for RocksDB's log/lock files

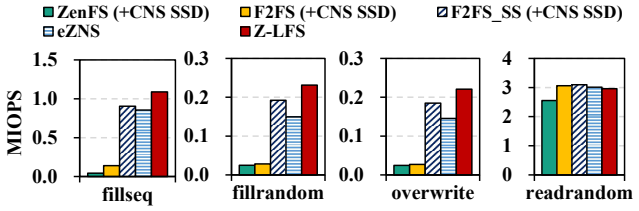

Figure 14: RocksDB performance under various workloads.

using F2FS. Figure 14 shows that Z-LFS improves the performance by up to 25.0×, 7.83×, 1.20×, and 1.27× in fillseq; 9.28×, 7.83×, 1.20×, and 1.55× in fillrandom; and 9.01×, 8.12×, 1.19×, and 1.52× in overwrite compared with ZenFS, F2FS, F2FS_SS, and eZNS with F2FS, respectively. As expected, in readrandom, Z-LFS achieves similar performance compared with F2FS, F2FS_SS and eZNS with F2FS. These results demonstrate that three techniques in Z-LFS can also be effective even in real-world applications.

7 Related Work

Interfaces on ZNS SSDs: eZNS [42] proposes an elastic ZNS interface which allocates active zones based on the application workload profile and enhances performance isolation with an I/O scheduler. CSAL [61] is a storage acceleration layer to take advantage of high-density QLC SSD by adopting ZNS interface on the QLC SSD in a cloud environment. ZMS [20] is a zone interface on mobile flash storage to address the lack of on-device memory and the frequent fsync. Our study is in line with these studies [20, 42, 61] in terms of improving ZNS-based storage systems while we focus on devising a ZNS-tailored file system instead of an interface.

Storage backend of RocksDB for ZNS SSDs: Bjørling et al. [9] claim advantages of ZNS SSDs and propose ZenFS for RocksDB [14] on ZNS SSDs. Im et al. [21] and ZenFS+ [46] are enhanced versions of ZenFS as backend IO engines to maximize the parallelism of ZNS SSDs. WALTZ [32] is also an enhanced version of ZenFS to provide tight tail latency by leveraging ZONE APPEND commands. WA-Zone [37] suggests wear-aware zone management to balance inter-zone and intra-zone wear considering the access pattern of LSM-tree. These studies [9, 21, 32, 37, 46] are in line with our study in terms of improving the performance on ZNS SSD. Meanwhile, Z-LFS is a general and ZNS-tailored log-structured file system to run any application instead of specific applications.

Linux kernel subsystems on ZNS SSDs: ZNSwap [8] is a swap subsystem optimized for ZNS SSDs. It introduces a host-side GC mechanism which is co-designed with the swap logic to reduce GC overheads and improve the performance. RAIZN [26] is a logical volume manager which exposes a ZNS SSD array as a single ZNS interface to applications. BIZA [58] is also an interface for ZNS arrays to further improve endurance and performance by exploiting the zone random write area and internal parallelisms within ZNS SSDs. Our study is in line with them [8, 26, 58] in terms of investigating a Linux kernel component while we target designing a suitable file system for ZNS SSDs.

File systems for ZNS SSDs: ZoneFS [4, 28] is a simple file system exposing each zone of a ZNS SSD as a file. OPRW [30] leverages the write pointer of ZNS SSDs to accelerate the `fsync()` performance. Our work is in line with these works [4, 28, 30] in terms of supporting or optimizing file systems for ZNS SSDs. On the other hand, we redesign the metadata of LFS to enhance its compatibility with ZNS SSDs by considering LFS features on ZNS SSD. Furthermore, we efficiently scale the active zones of log streams to maximize the internal parallelism of ZNS SSD.

8 Conclusion

This paper presents a ZNS-tailored log-structured file system called Z-LFS for commodity ZNS SSDs. Z-LFS enables standalone usage of ZNS SSDs by an append-only metadata approach, leveraging the unique characteristics of LFS metadata to minimize write amplification. Z-LFS efficiently utilizes active zones for log streams via speculative log stream management. Z-LFS resolves conflicts between zones sharing internal resources within ZNS SSD via conflict-aware zone allocation. In our evaluations, Z-LFS achieves higher performance by up to 33.44× and 3.5× compared with F2FS and a state-of-the-art interface for commodity ZNS SSDs, respectively.

CLONE: Customizing LLMs for Efficient Latency-Aware Inference at the Edge

Chunlin Tian, Xinpeng Qin, Kahou Tam, Li Li†, Zijian Wang, Yuanzhe Zhao, Minglei Zhang, and Chengzhong Xu

University of Macau

Abstract

Deploying large language models (LLMs) on edge devices is crucial for delivering fast responses and ensuring data privacy. However, the limited storage, weight, and power of edge devices make it difficult to deploy LLM-powered applications. These devices must balance latency requirements with energy consumption and model accuracy. In this paper, we first quantify the challenges of deploying LLMs on off-the-shelf edge devices and then we present CLONE, an in-depth algorithm-hardware co-design at both the model- and system-level that intelligently integrates real-time, energy optimization while maintaining robust generality. In order to maximize the synergistic benefits of these algorithms in always-on and intermediate edge computing settings, we specialize in a 28nm scalable hardware accelerator system. We implement and extensively evaluate CLONE on two off-the-shelf edge platforms. Experiments show that CLONE effectively accelerates the inference process up to 11.92×, and saves energy up to 7.36×, while maintaining high-generation.

1 Introduction

Large language models (LLMs) [19, 80, 96, 109, 132] are reshaping artificial intelligence for their remarkable performance to comprehend human language and handle language-related tasks [120, 129, 136]. Though born from the cloud, deploying LLMs on edge devices such as personal PC, smartphones, robots, and even IoT devices is becoming an important trend [81, 119]. First, on-device LLM can be widely used to support different kinds of applications, including chatbots [6, 114], robotics [61, 162], and autonomous vehicles [144]. Moreover, directly accessing the LLM on the edge not only preserves data privacy but also can provide instant service without relying on a stable internet connection. Despite the potential benefits, deploying LLMs on commercial-off-the-shelf (COTS) edge devices faces stringent space, weight, and power (SWaP) constraints [10, 138] due to the billion-parameter size coupled with intensive computing costs. For instance, the widely used Llama-7B model [132] requires approximately 14GB of memory for inference, even when utilizing 16-bit precision (FP16) format. However, the available RAM on typical edge devices only ranges from 4GB to 12GB [125]. Furthermore, inferring a single token with Llama-7B requires approximately 14 TFLOPs for an 11-token prompt [25], which is roughly 360× the 39 GFLOPs needed by VGG-19 to process a single image with an input resolution of 224 × 224 [36]. Moreover, LLMs' inference process demands substantial energy consumption. For instance, GPT-3 [31] consumes 300 J/response [20] on an NVIDIA A100 GPU, which is 400× the 0.75 J/response required by ResNet-50 [72]. Thus, intensive memory footprint, high computational demands, and significant energy costs pose severe bottlenecks to deploying LLMs at the edge.

Limitation of Prior Arts. To break the SwaP constraints, several optimization techniques have been proposed. Techniques such as model architecture search [54, 60, 88], quantization [26, 55, 57, 91, 143], and pruning [27, 30, 32, 84] help to reduce the size of models while preserving their performance. However, these methods typically focus on optimizing the model itself and may not fully address the system-level trade-offs related to storage and weight. Additionally, recent improvements in LLM compilers and software stacks [56, 99, 113, 128] have facilitated the adoption of co-processors to sustain high performance by leveraging co-processors or near-sensor processing alongside GPUs [4, 44, 57, 74, 74, 86, 107, 111, 118, 122, 148, 159]. However, they incur additional computational/communication overhead that significantly reduces the edge device lifecycle and interferes with the smooth execution of other applications. To address power constraints, Dynamic Voltage and Frequency Scaling (DVFS) [10, 47, 48, 65, 112] has been widely adopted to adjust the power usage of processors by dynamically changing their voltage and frequency. However, most existing approaches are designed for discriminative CNN or RNN and treat the entire network as a black box during tuning. Generative LLMs have not undergone the necessary scrutiny due to the auto-regressive inference schemes and the heterogeneity

of stochastic requests and generated outputs. *Thus, an edge-tailored LLM system that intelligently coordinates model- and system-level optimizations, balancing energy efficiency, latency, and model performance is urgently required.*

Challenge. Designing such a customization system is not straightforward and faces the following critical challenges. First, the "billion-parameter" poses a significant barrier to deployment on resource-constrained edge devices due to the high memory footprint and computation cost. How to customize the LLM according to the hardware profile of a specific edge device to effectively meet the memory constraint and reduce the computing latency while ensuring the generating capability is the first critical challenge. In addition, when deploying customized LLMs on edge devices, LLM-powered applications feature stochastic and dynamic I/O, unlike traditional models with stable inputs. Moreover, tailored layers introduce unique approximation characteristics, while interference from co-running applications during mobile execution can cause runtime variance. Therefore, designing an efficient system-level controller to meet latency targets while optimizing energy consumption is another challenge. Furthermore, model-level (accuracy/latency) and system-level (energy/latency) optimizations in isolation can be naive, often resulting in unnecessary energy consumption or reduced accuracy. Effectively coordinating these optimizations to balance accuracy, latency, and energy efficiency is the third challenge.

In this work, we present CLONE, a comprehensive system that intelligently customizes LLM for efficient latency-aware inference on commercial-off-the-shelf edge devices. It adopts a hierarchical structure to jointly handle model- and system-level optimization in a unified manner to consider real-timeliness, model accuracy, and energy efficiency jointly. Specifically, CLONE consists of two main phases: offline device-specific model tailoring and online latency-aware system optimization. Within the offline tailoring process, for a specific device, CLONE reformulates the tailoring of target LLMs for a specific device as a generative task within a continuous representation space. Using an encoder-evaluator-decoder architecture, it generates optimal pruning configurations through gradient-based optimization, effectively bridging the gap between resource constraints and model performance. To support diverse edge applications [6, 138, 146], CLONE performs parameter-efficient fine-tuning on the customized LLM using multiple plug-and-play Low-Rank Approximation (LoRA) [52] adapters, ensuring adaptability and optimized performance. Once the customized model is ported to edge devices, during online inference, CLONE employs a Mixture-of-Experts (MoE) [59, 131] router to dynamically integrate optimal LoRA adapters, enabling more precise responses to stochastic, complex, or mixed-task end-user requests. At the system level, CLONE applies Dynamic Voltage and Frequency Scaling (DVFS) to the per-token, autoregressive inference process of LLMs, optimizing the supply voltage (V_{DD}) and operating frequency (F_{req}) to minimize energy consumption while meeting real-time constraints. Recognizing the LLM layer characteristics, especially post-pruned uneven parameter, CLONE enhances the granularity of DVFS adjustments at layer boundaries. This provides greater flexibility and adaptability for power-sensitive systems compared to traditional workload-level (whole model) black-box optimizations. While existing vanilla DVFS on edge devices are typically discrete, CLONE introduces a learning-based DVFS approach to reduce budget gaps that maximize system efficiency and model performance. To fully harness the benefits of these technologies, we have developed a specialized 28nm scalable hardware accelerator system. It contains a LoRA Processing Unit (LPU) for hot-swapping adapters, enabling dynamic model performance adjustments through dedicated data paths, and a Special Function Unit (SFU) designed for fine-grained and continuous DVFS adjustments equipped with a fast-switching low-dropout (LDO) voltage regulator and an all-digital phase-locked loop (ADPLL). The LPU supports the runtime MoE router algorithm to handle stochastic requests, eliminating bottlenecks of general-purpose processors and boosting computational efficiency. The SFU implements the learning-based DVFS algorithm to effectively manage runtime variance and swiftly achieve the desired V_{DD} and F_{req}. Specifically, we make the following key contributions:

- We propose CLONE, an efficient software-hardware co-design system for customized LLM inference on resource-constrained edge devices, where the model- and system-level coordinators cooperate to intelligently balance the inference speed and energy efficiency while maintaining robust generative performance.
- We design hierarchical offline/online optimization phases that effectively coordinate customization by addressing static model weights, hardware characteristics, stochastic I/O patterns, and runtime variance. Additionally, a 28nm accelerator with specialized datapaths supports these algorithms for optimized performance.
- To evaluate the effectiveness of CLONE, we conduct extensive experiments based on commercial-off-the-shelf edge devices, representative LLMs and benchmarks.

2 Background and Related Work

2.1 Large Language Models

LLM Architecture. In contrast to traditional deep neural networks (DNNs) and convolutional neural networks (CNNs) [38, 76], which integrate diverse types of layers (e.g., convolutional (CONV), fully connected (FC), recurrent (RC), pooling, etc.) designed for specific tasks, large language models (LLMs) predominantly consist of a uniform stack of transformer decoder layers. For instance, Llama-7B [132] adopts

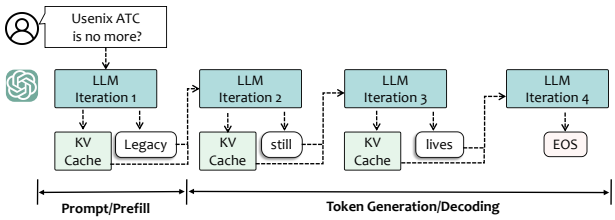

Figure 1: Overview of LLMs autoregressive inference.

a homogeneous architecture composed of 32 identical LlamaDecoderLayers. Each decoder layer encompasses two core components: LlamaAttention and LlamaMLP. Despite the structural uniformity across decoder layers, their contributions to model efficiency and effectiveness vary significantly [26, 137]. Consequently, optimizing the inference execution of LLMs necessitates a detailed analysis of the individual impact of each layer (§3.1).

LLMs Inference. LLMs process a structured sequence involving multiple forward passes through the model to sequentially generate each output token. Figure 1 shows the inference process with a simple example. Typically, this process mainly contains two stages [3, 75, 118]. **1) Pre-fill** takes a prompt sequence and generates the key-value (KV) cache for each Transformer layer of LLM. Upon receiving the prompt *"Usenix ATC is no more?"*, the tokenizer embeds input as tokens, denoted as $X_{in} \in \mathbb{R}^{n \times d}$, where d is the hidden size and n is the length of input token. Then, the LLM handles all input tokens in parallel during a single forward iteration to generate a KV cache. The output of attention is sent to MLP to generate the first output token *"Legacy"*. Large-scale matrix multiplications are required to generate the KV cache, which makes the pre-fill computing intensive. **2) Decoding** utilizes and updates the KV cache to generate tokens step-by-step. Following the generation of the first token, the LLM leverages the KV caches prepared earlier and adds new information to them. The creation of each new token is influenced by the tokens generated before it. During each token generation, for the input $X_{dec} \in \mathbb{R}^{1 \times d}$, attention layers load the previously stored KV cache, and new KV pairs are computed and concatenated to the existing cache. The output of the last decoder layer is sent to the final prediction layer to predict the next token sequentially. It executes iteratively until an End of Sequence (EOS) token is encountered or a predefined termination criterion is met. Unlike traditional models with fixed input formats and structured workflows [38, 76], LLM inputs and outputs are highly non-deterministic. This stems from the diverse, open-ended nature of user prompts, which vary widely in structure, intent, and context [15, 87, 89]. Additionally, autoregressive token generation is inherently probabilistic, driven by sampling methods [50, 111, 115, 132] and variability in training datasets [11, 13, 134], making outputs context-sensitive.

2.2 Bottlenecks of Deploying Edge LLMs

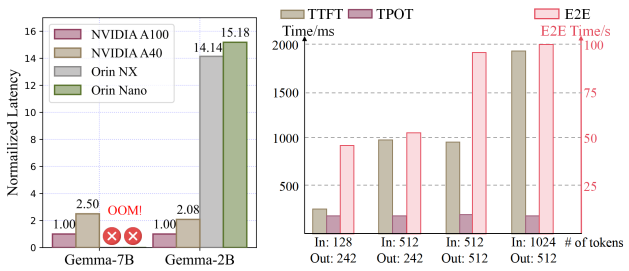
Table 1 lists specifications for server-level and edge-level processors commonly used for ML workloads, highlighting resource collapse. Despite the potential benefits, including privacy preservation and instant responses without depending on a stable internet connection [42, 105], deploying LLMs on the edge faces the following critical bottlenecks.

1) High Memory Footprint. The main contributors of "billion-parameter" LLMs are model weights (memory is occupied by the model parameters) and KV cache (memory is occupied by the caching of self-attention tensors to avoid redundant computation). For example, Llama-7B in 16-bit precision requires approximately 14GB memory ($7B \times$ sizeof(FP16)). Its architecture with 32 layers, 32 heads per layer, and a head dimension of 128 incurs a memory cost of 0.5MB per token, accounting for K and V matrices. Consequently, processing 4096 tokens demands 2GB, limiting the size of models that can be deployed on edge devices with 4–12GB memory [125] and often causing Out-of-Memory (OOM) errors.

Table 1: Popular ML hardware specifications.

GPU Types	Peak Perf.	Memory	Bandwidth	Peak Power
Server-level				
NVIDIA A100	312 TFLOPS	80GB	1935 GB/s	300W
NVIDIA A40	149.7 TFLOPS	48 GB	696 GB/s	300W
Edge-level				
Jetson Orin NX	100 TOPS	16GB	102.4GB/s	25W
Jetson Orin Nano	40 TOPS	8GB	68 GB/s	15W

2) High Inference Latency. Inference latency is a crucial metric for mobile optimization because if the latency of a service exceeds the human-acceptable thresholds (e.g., 33.3 ms for a 30 FPS video frame rate [28, 161] or 50 ms for interactive applications [29, 92]), end-users will abandon the service [161]. To evaluate inference QoE for LLMs, there are three main metrics: 1) *Time To First Token (TTFT)* latency from input to the output of the first token (prefill). Low TTFT means fast response, which is essential for user experience in real-time interactions. 2) *Time Per Output Token (TPOT)* latency to track the auto-regressive process of each token generated serially. TPOT refers to how each user perceives the "speed" of the model. 3) *End-to-end (E2E)* latency, the overall time it takes for the model to generate the full response for a user, denoted as: $E2E = (TTFT) + (TPOT) * N$, where N is the generated token number. Figure 2 (a) illustrates the latency across different processors running the same LLMs, representative Gemma-2B/7B [96], on the Wikitext2 [95] dataset. While Gemma-7B is OOM for edge device. For the same user request on Gemma-2B, the Orin Nano experiences 15.18× more latency than the NVIDIA A100, significantly impacting the Quality of end-user Experience (QoE) [53, 68, 69, 90]. Additionally, LLMs operate with an auto-regressive and probabilistic inference process [121]. Figure 2 (b) shows



(a) Server/edge latency. (b) Latency breakdown.

Figure 2: LLMs inference latency analysis. (a) Latency efficiency of two common LLMs (Gemma-2B/7B) inference use cases over server-level and edge-level processors. (b) Inference latency with different prompt and output tokens.

as prompt sizes increase (128 → 512 → 1024) inference Gemma-2B on Orin NX. We can observe that the number of pre-filled tokens increases significantly (255→1935ms) due to parallel processing capabilities. Conversely, the TPOT remains relatively stable (180∼200ms) due to serial decoding generation. However, the E2E is more than 100s, which fails to serve the end-user demands, indicating opportunities for optimizing practical inference performance.

3) High Energy Consumption. In server-level GPU deployments, it is typically assumed that these units are plugged into wall power due to the substantial energy demands of LLMs inference [4, 64, 74, 107, 111, 141]. However, this assumption does not hold for edge-level devices such as robots and autonomous vehicles, where energy availability is severely restricted [66]. In contrast to conventional on-device tasks, LLM inference consumes an order of magnitude more energy. For example, a Google search driven by a large AI model expends 8.9 watt-hours (Wh) of energy, approximately 30 times the 0.3 Wh required by a standard Google search [124]. Importantly, "Scaling Laws" [21, 63] suggest that as model parameters scale up, there is a corresponding increase in both performance and energy consumption. Transitioning from Gemma-2B to 7B, for instance, boosts accuracy from 42.3% to 64.3% on the MMLU benchmark [46]—a comprehensive evaluation platform—at the cost of tripling energy usage. Consequently, there is a pressing need to optimize the energy efficiency of LLM inference at edge to meet QoE.

3 Motivation

In this section, we present key observations from model-intrinsic dimensions (layer characteristics (§3.1)), stochastic I/O (§3.2)) and system factors (hardware and runtime variance (§3.3)) for practical LLM inference on edge devices. The design space is analyzed across three critical axes: generation quality, latency, and energy efficiency.

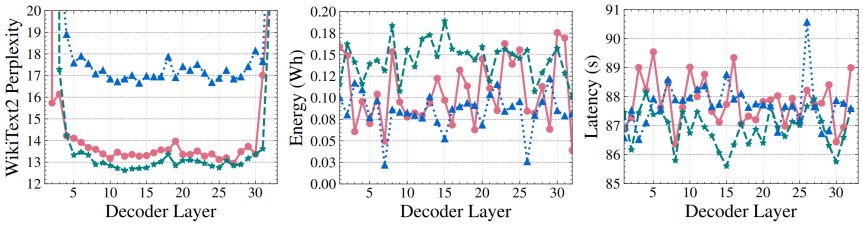
3.1 Heterogeneity of Model Characteristics

In order to investigate the contribution of different decoder layers, we conduct an in-depth analysis of the inherent sensitivity of the stacked transformer architecture across three critical dimensions: generative ability, energy efficiency, and latency. For general-purpose, we employ zero-shot perplexity (PPL) [14, 96, 132], a common metric, to evaluate generative abilities, lower PPL indicates higher model adeptness in predicting sequence tokens. Figure 3 (a) presents the PPL on the WikiText2 [95] dataset after removing specific decoder layers in the Llama-7B, Llama2-7B [133], and Vicuna-7B [160] models. The results show that the front and back layers have higher PPL values than the middle layers. Because the front layers play a critical role in feature extraction, while the back layers significantly influence output generation, both contribute markedly to model performance. while LLMs maintain a homogeneous layer structure, the generative impact varies by layer due to input and output data stream heterogeneity. To evaluate the system effectiveness, we infer LLMs on WikiText2, monitoring energy consumption and duration using CodeCarbon [24]. Figure 3 (b, c) shows that removing different decoder layers yields non-uniform changes in end-to-end energy and latency. This suggests that, beyond nominal parameter counts, each layer contributes heterogeneously to practical resource usage. We attribute this to (i) varying sequence-length–dependent workloads, (ii) hardware-level cache and parallel-sync effects, and (iii) non-linear inter-layer interactions typical of deep networks.

► *Motivation 1*: LLM layers contribute unevenly to effectiveness and efficiency, underscoring opportunities for model customization by pruning non-essential components and system optimization through fine-grained layer-wise tuning.

3.2 Heterogeneity of Stochastic Input/Output

As discussed at §2.1, inference serving systems exhibit significant non-deterministic due to the diversity of input prompts, and LLM auto-regressive output exhibit distinct execution behaviors. **Case study.** As shown in Figure 5 (a), we first illustrate the distribution of prompt input and generated output tokens on an Azure LLM inference services trace [111]. These long-tail patterns and the unpredictability of token generation lengths highlight the need for dynamic resource allocation to manage varying computational demands. **Performance impact.** To analyze the inherent patterns of mixed-task end-user requests, we visualized the task embedding similarities of the Flanv2 dataset [135] using a heatmap, as shown in Figure 4. Each axis enumerates the individual subtasks within the dataset, and each matrix cell quantifies the pairwise correlation between subtasks. The results reveal significant data heterogeneity across tasks. **System impact.** Otherwise, requests of different input and output lengths possess different compute and energy characteristics. As shown in Figure 5



(a) Generative-ability (b) Energy (c) Latency

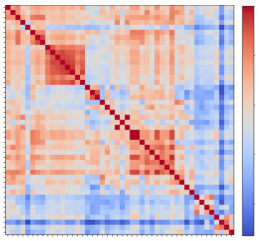

Figure 4: Task embedding similarity heatmap.

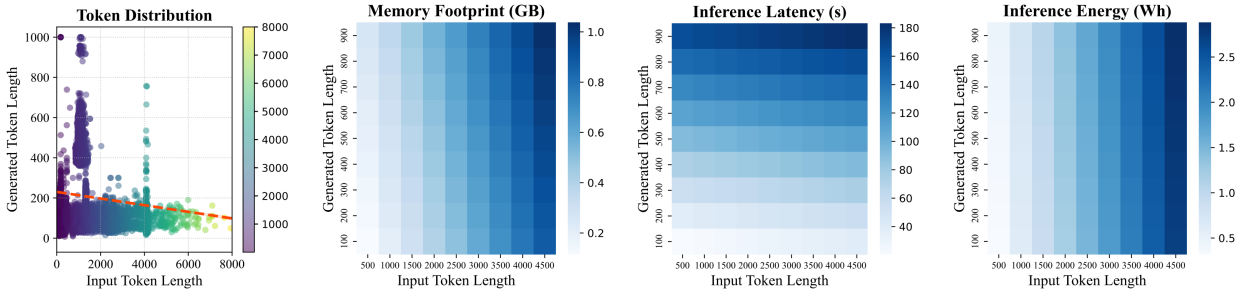

(a) Practical inference traces. (b) Memory consumption. (c) Latency analysis. (d) Energy consumption.

Figure 5: Comprehensive analysis of LLM inference system using Gemma-2B on NVIDIA Orin NX. (a) Analysis of practical LLM inference traces., while (b-d) highlight memory, latency, and energy consumption w.r.t. input and generated length.

(b-d), we measure Gemma-2B [96] on Nvidia Orin NX with different input and generated length to evaluate the memory footprint, latency and energy consumption. Memory consumption is influenced by both static model parameters and the dynamic KV cache, which grows as the number of tokens to be processed increases. E2E latency is primarily impacted during the decoding phase, as it is step-by-step, whereas the prefill phase computes all prompts in parallel. Consequently, an increase in generated tokens significantly impacts overall latency. Energy consumption is higher during the prefill phase due to large-scale matrix operations, while the decoding phase, processing one token at a time, has lower power demands. Inefficient system performance degrades QoE, making it critical to meet diverse LLM request demands without compromising output quality.

► *Motivation 2*: Stochastic I/O with mixed-task requests underscores the need for precise inference services to improve model performance. Similarly, significant resource slack suggests potential for fine-grained, LLM-specific system optimizations to improve utilization efficiency.

3.3 Heterogeneity of Runtime Platform

Practical system heterogeneity encompasses performance and energy variations arising from platform diversity (static heterogeneity, Table 1), diverse LLM application demands, and interference from co-running applications (dynamic heterogeneity). Table 2 lists LLM requests from various applications or tasks, each with distinct QoE demands [83, 130, 139, 140, 142, 147, 152, 161]. To investigate the impact of edge device hardware and concurrent running apps, we deployed the Gemma-2B model on two NVIDIA platforms—Jetson Orin NX and Orin Nano—and processed a workload comprising 128 prompt tokens and 242 generated tokens (the first scenario in Figure 2(b)). We profiled the resulting inference behavior, and Figure 6 reports the TTFT, TPOT, and E2E inference latency for both devices, alongside the corresponding performance degradation observed in a foreground web-search application [78, 161]. We find that 1) Due to the varying processing capabilities of different edge devices, the response time to the same end-user request can differ significantly. For instance, when both are in an idle state, the Orin NX, with its superior computational power, provides more timely feedback (TTFT: 255; TPOT: 198 ms) compared to the Orin Nano (TTFT: 268ms; TPOT: 231ms). 2) Resource contention caused by user interaction with the concurrent running app prominently slows down the model inference progress. For instance, the E2E inference latency on Orin NX is 42.6s when there is no user interaction in the foreground. However, it increases to 61.4s with a website searching application running in the foreground. This highlights the impact of latency on user experience, as service abandonment occurs when latency

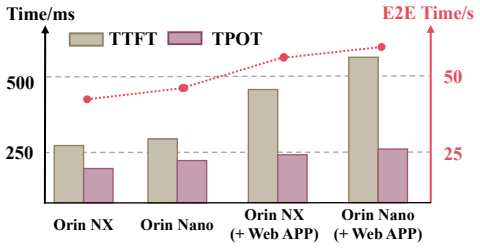

Figure 6: Impact of different hardware devices (Nano/NX) and concurrently running apps (web search) on edge LLMs inference.

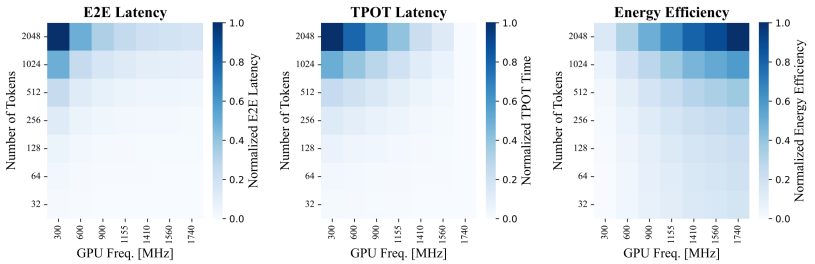

Figure 7: Impact of different token lengths and GPU frequencies on a) end-to-end (E2E) latency, b) time per output token (TPOT), and c) energy efficiency.

Table 2: SLOs of various LLM applications. Time To First Token (TTFT): refers to the latency from input to the first token output (prefill), while Time Per Output Token (TPOT) is the latency for each subsequent token (decode).

LLM Application	Service-Level Objective
Chatbot [5, 108]	Readable TTFT/TPOT
Search Engine [97]	Low TTFT, Medium TPOT
Event Logger [1, 58, 110]	Tolerable TTFT, Medium TPOT
Smart Reply [40, 98]	Low TTFT, Low TPOT
Code Generator [37]	Medium TTFT, High TPOT
Virtual Assistant [7, 39]	Low TTFT, Medium TPOT

exceeds the human-acceptable threshold [83, 161]. Figure 7 demonstrates that higher GPU frequencies reduce E2E latency and TPOT by accelerating token processing (a, b) while supporting energy-efficient control via frequency scaling (c). Dynamically adjusting processor frequencies based on workload size enhances efficiency with minimal performance impact, where the optimal frequency is determined by the LLM architecture and output length. Although DVFS [47, 48, 65] is commonly used to scale voltage and frequency for low-intensity workloads, existing schemes often rely on coarse-grained, black-box, workload-level adjustments with heuristic methods [10, 47, 48, 65, 112].

► ***Motivation 3:*** Hardware type and LLM application SLOs significantly impact end-user QoE, while resource preemption from foreground applications exacerbates runtime system heterogeneity. Accurate runtime estimation of application demands and device capabilities is crucial for guiding DVFS and optimizing LLM inference system efficiency.

4 CLONE: Design

4.1 System Overview

Figure 8 presents the architecture of CLONE which can be mainly divided into the following two phases: 1) offline device-specific tailor and 2) online latency-aware optimization. The overall workflow of CLONE can be represented as

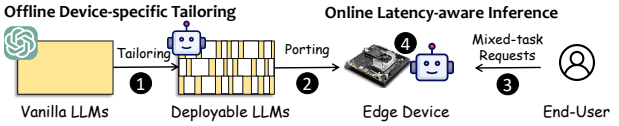

Figure 8: The overview of CLONE, including offline device-specific tailoring and online latency-aware inference.

the following main steps. ❶ CLONE leverages edge hardware profiles and LLM architecture using an encoder-evaluator-decoder framework to reframe LLM compression as a data-driven generative task. This approach addresses memory constraints, meets latency and energy requirements, and preserves generation performance. Plug-and-play LoRA adapters further fine-tune the tailored LLM for diverse edge applications. ❷ The deployable model is then ported onto the edge device. ❸ During runtime inference, to handle stochastic and mixed-task user requests, CLONE integrates a MoE router to dynamically select optimal LoRA adapters, enhancing model performance. ❹ At the system level, CLONE incorporates a learning-based DVFS controller to adjust device voltage (V_{DD}) and frequency ($Freq$) dynamically at layer boundaries during per-token autoregressive inference. This minimizes energy consumption while ensuring target latency is met. Furthermore, in order to fully leverage the synergistic advantages of these algorithms, we develop a specialized 28nm scalable hardware accelerator system designed to further boost energy efficiency through customized hardware integration.

4.2 Offline Device-specific Tailoring

According to *Motivation 1*, LLMs demonstrate considerable parameter redundancy, especially within their intermediate layers. This variance in contribution across layers not only affects performance but also system efficiency, facilitating tailored adaptations for edge deployment. To meet heterogeneous hardware constraints, CLONE redefines LLM pruning as a generative task, surpassing traditional manually designed discrete heuristic optimizations to identify and remove non-essential structures in a system-efficient manner. Specifically,

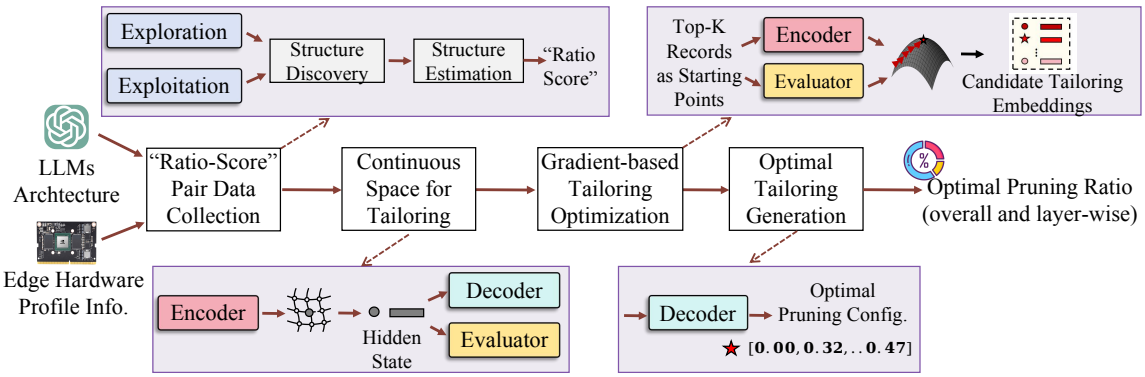

Figure 9: Hardware-aware tailor workflow. Four key components: "ratio-score" data collection, continuous space for tailoring, gradient-based tailoring optimization, and optimal tailoring generation.

it employs a data-driven tailor that identifies the optimal pruning configuration through gradient-based optimization within a continuous representation space. As illustrated in Figure 9, the generative tailor comprises four key modules:

1) *"Ratio-score" Data Collection.* Considering the memory constraints of the edge device and the dimensions of the model to be deployed, we initially establish the overall reduction ratio for the LLMs. For fine-grained optimization, we develop an exploration-exploitation strategy to determine layer-wise level pruning ratios r_i. This approach utilizes heuristic-based pruning methods [8, 30, 94] to produce high-quality ratios and incorporates random pruning ratios as part of the exploration process. In contrast to prior works [45, 55, 102] primarily focus on reducing the model size and computational overhead, CLONE integrates broader criteria including generation ability, inference latency, and energy cost. We define a holistic metric function f to characterize overall performance for a given r_i, aiming for optimization suitable for resource-constrained edge devices:

$$s_i = f(r_i) = \frac{1}{ppl_i} \times \left(\frac{E}{e_i}\right)^{\mathbf{1}(E<e_i)\times\alpha} \times \left(\frac{T}{t_i}\right)^{\mathbf{1}(T<t_i)\times\beta}, \quad (1)$$

where ppl is the zero-shot perplexity [14], quantifies the generative capabilities, with lower values indicating more precise model predictions. T and E denote the latency and energy budgets specific to edge, respectively. t_i and e_i represent the latency and energy consumption for a given ratio r_i. $\mathbf{1}(x)$ is an indicator that returns 1 if condition x holds, and 0 otherwise. Thus, configurations that exceed the thresholds T and E are penalized by developer-specified factors α and β, both set to 2 in our implementation. Finally, we obtain comprehensive ratio-score pairs, denoted as $\mathcal{P} = (r_i, s_i)$.

2) *Continuous Space for Tailoring.* Traditional approaches [8, 30, 94] often employ discrete pruning spaces, resulting in heuristic and incomprehensive pruning ratios. In order to characterize the continuous tailoring optimization space of edge devices, we implement an encoder-evaluator-decoder framework. This architecture includes a single-layer LSTM network [49] functioning as both encoder and decoder, alongside a feed-forward neural network serving as the evaluator. This setup effectively embeds ratio-score pairs (r_i, s_i) into a continuous representation space Θ.

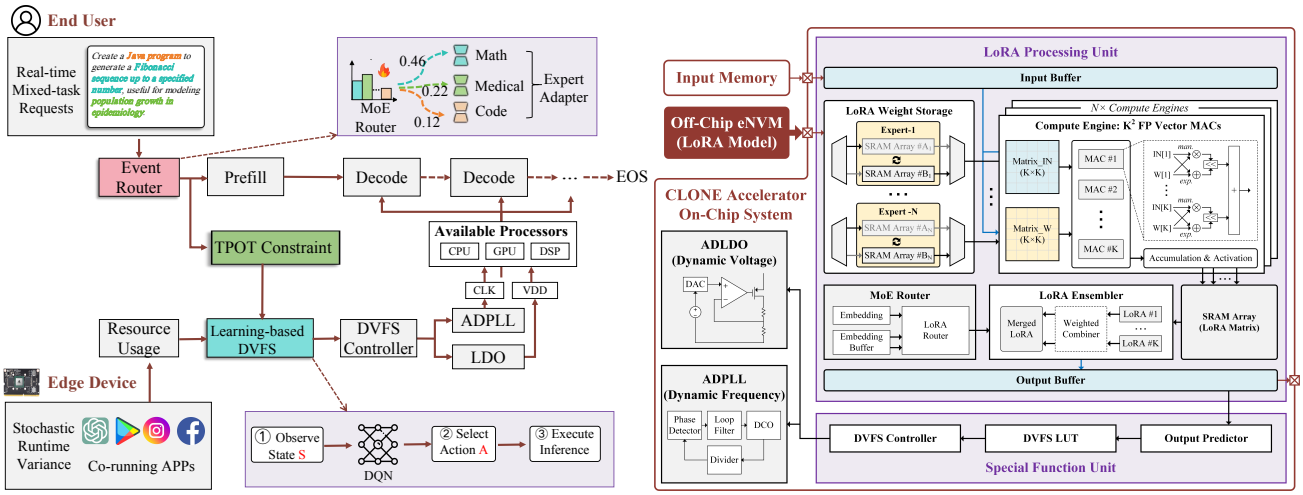
3) *Gradient-based Tailoring Optimization.* With the well-trained representation space Θ, we utilize a gradient-based optimization method to identify the optimal pruning configuration. We select top-K collected pairs serving as starting points to ensure effective initialization. Denoting such starting points as $\mathcal{E}r$, we initiate the optimization process along the gradient direction driven by the evaluator π:

$$\mathcal{E}_r^* = \mathcal{E}_r + \eta \frac{\partial \pi(\mathcal{E}_r)}{\partial \mathcal{E}_r}, \quad (2)$$

where $\mathcal{E}_r^*$ denotes the optimal pruning configuration representation, and η is step size used in the gradient update.

4) *Optimal Tailoring Generation.* Based on the optimal pruning representation $\mathcal{E}_r^*$, the optimal pruning configuration r^* is identified by the trained decoder ξ, denoted as $r^* = \xi(\mathcal{E}_r^*)$. To generate r^* iteratively without pre-specifying the ratios, we employ a beam search strategy [33], allowing for a systematic exploration of potential configurations to achieve the best possible performance. The generation process continues until the stop token $\langle$EOS$\rangle$ is encountered, enhancing the adaptiveness of the model configuration. Finally, remove non-essential groups through structural pruning, guided by the generated optimal pruning ratio.

According to *Motivation 2*, the patterns of user application usage and the inter-dependencies among tasks offer opportunities for optimization in downstream tasks, which can reduce the costs of fine-tuning and improve model performance. Therefore, plug-and-play LoRA adapters are utilized to enhance the tailored LLM generalization capabilities across diverse downstream applications. For n downstream applications, a set of LoRAs, $\Phi = \{\phi_1, \phi_2, \ldots, \phi_n\}$, is initialized, where each LoRA $\phi_i = BA$ is trained per task. The forward computation is:$y' = y + \Delta y = \mathbf{W}_0 x + BAx$, where $y' \in \mathbb{R}^d$ is the output, $x \in \mathbb{R}^k$ is the input, $B \in \mathbb{R}^{d\times r}$, $A \in \mathbb{R}^{r\times k}$ with



(a) Software (b) Hardware

$r \ll \min(d,k)$, and $\mathbf{W}_0$ are frozen LLM parameters. B is initialized to zero and A with Gaussian values.

4.3 Online Latency-aware Inference

Motivation 2 & 3 reveals that current approaches to real-time inference are constrained to workload-level resource adjustments, resulting in energy wastage. It identifies a crucial potential for system optimization via fine-grained management of performance and energy. While offline device-specific tailoring effectively reduces memory constraints and enhances downstream performance, the achieved latency can fluctuate significantly due to diverse user requests and runtime variability, potentially violating real-time latency constraints and increasing energy consumption. As shown in Figure 10, at the model level, a MoE-based router dynamically selects the optimal LoRA adapter based on stochastic user prompts, improving the accuracy of LLM-powered application responses. At the system level, CLONE integrates a token predictor to estimate the output token count, guiding a learning-based DVFS controller to adjust frequency and voltage for each token at layer boundaries. This minimizes per-request energy consumption while adhering to real-time latency targets. Additionally, CLONE embeds these efficient algorithmic enhancements into a 28nm on-chip accelerator architecture.

Request-wise MoE-based Router. In practice, end-user requests cover a diverse range of prompts, each associated with different tasks. Consequently, as shown in Figure 10 (a), an MoE (Mixture-of-Experts) [59, 117] router has been developed to dynamically and effectively merge LoRA modules for each mixed-task prompt. This development significantly extends the plug-and-play capabilities of CLONE. A set of experts $\mathbf{E} = (E_1, E_2, \ldots, E_N)$, where each expert E_i represents a tuned LoRA module. For input x_i, the output y_i:

$$y_i = \mathbf{W_o} x_i + \sum_{j=1}^{N} \omega_{ij} \cdot E_j(x_i), \tag{3}$$

where ω_{ij} modulates the contribution weights of each expert. Unlike traditional methods [131, 150] that incur extra computation and storage from trainable gate functions, we propose a parameter-free soft MoE method leveraging dynamic prompts. Using a sentence-embedding model, Γ (here adopting BGE [17]), the input embedding is formulated as $\Gamma(x)$. For each LoRA module ϕ, the embedding is obtained from randomly selected domain-specific samples k, expressed as $\Gamma(\phi) = \frac{1}{k}\sum_{i=1}^{k}\Gamma(k_{i\cdot\phi})$. To measure the similarity between the LoRA module ϕ and the prompt x, we leverage the cosine similarity, denoted as σ, as follows:

$$\sigma(x,\phi) = cos(\Gamma(x),\Gamma(\phi)), \tag{4}$$

Followed by a softmax function which takes an intermediate token representation as input and combines the output of each expert based on the gating weight $\Omega = (\omega_1, \ldots, \omega_N)$:

$$\Omega = \text{softmax}(\mathbf{s}_x), \tag{5}$$

Learning-based DVFS Controller. To further improve system effectiveness for LLM inference at the edge, a learning-based DVFS is developed to reduce per-generated token energy consumption while satisfying the real-time latency target at the layer-wise level. Among various reinforcement learning

(RL) methods [18, 62, 79, 85, 101], CLONE employs a simple two-layer MLP to efficiently learn policies within an episodic Markov decision process, ensuring minimal latency overhead. RL involves three core components:

State: Edge inference efficiency is heavily influenced by the processor intensity of co-running applications, denoted as S_{pro}. For runtime SLO constraints, inference efficiency is tightly coupled with frontend prefill time TTFT (T_{PRE}) and per-token decoding latency TPOT target (T_{DEC}).

Action: In RL, actions represent the adjustable control parameters of the system. For LLM inference at the edge, we define these actions as the selectable execution settings, specifically the energy-optimal supply voltage (V_{DD}) and the optimal running frequency (F_{req}) for each layer. Provided that the QoS constraints are met, it is feasible to lower the processor frequency, thereby conserving energy.

Reward: In RL, a reward models the optimization objective of the system. We encode energy optimization within the execution target as the reward, $\mathbb{R}_{energy}$, which is calculated using the power model [67, 70]:

$$\mathbb{R}_{energy} = \sum_{f} (P^{f}_{DEC} \times T_{DEC} + P^{f}_{PRE} \times T_{PRE}) \tag{6}$$

where P^{f}_{PRE} and P^{f}_{DEC} , representing the power consumption of the CPU/GPU at each frequency during the prefill and decoding states respectively, are determined through power measurements. These values are subsequently stored in a lookup table (LUT) within CLONE for efficient retrieval.

4.4 Hardware Accelerator System.

As illustrated in Figure 10 (b), acknowledging the limitations inherent in purely software-based approaches, CLONE introduces a scalable 28nm hardware accelerator specifically designed for edge-based LLM inference, effectively translating software optimizations into concrete performance improvements. This system integrates a LoRA Processing Unit (LPU) for dynamic adapter hot-swapping, enabling adaptive model performance optimization via dedicated data paths. Complementing this, a Special Function Unit (SFU) is equipped to perform continuous, fine-grained DVFS adjustments. The LPU executes a request-wise MoE router algorithm to efficiently manage stochastic requests, mitigating the limitations of general-purpose processors and enhancing computational throughput. Unlike conventional LoRA weight stored in on-chip SRAM, which either require frequent reloads from DRAM during wake-up cycles or keep SRAM active, wasting leakage power [73, 77, 90], we utilize an embedded non-volatile memory (eNVM) buffer to retain LoRA modules, eliminating reload overhead upon power-on. Simultaneously, the SFU employs a learning-based DVFS mechanism to adapt to runtime variability, ensuring rapid convergence to the desired voltage (V_{DD}) and frequency (F_{req}) settings. The SFU employs a lightweight predictor and DVFS model implemented as lookup tables (LUTs) for efficient hardware operation and action determination. The generated voltage (V_{DD}) and frequency (F_{req}) are realized using a fast-switching low-dropout (LDO) voltage regulator [9, 16] and an all-digital phase-locked loop (ADPLL) [2, 51], ensuring rapid runtime adjustments. Communication between the LPU and SFU is facilitated via a custom-built bi-directional streaming channel. An AXI splitter arbitrates the control flow of instructions and data bound for the LPU and SFU AXI-slave partitions.

5 EVALUATION

5.1 Experimental Setup

Infrastructure. In order to comprehensively evaluate the efficiency and effectiveness of CLONE, We perform our experiments on two heterogeneous edge devices: Orin Nano [104] and Jetson Orin NX [106]. Table 1 summarizes their specifications. To emulate heterogeneous deployment models, we utilize Llama-7B [132], Llama2-7B [133], Llama2-13B and Vicuna-7B [160] as baseline models. To simulate the heterogeneous performance requirements of multiple tasks at the edge, we employ the Flanv2 [135] dataset, which comprises 46 tasks across 10 domains, serving as the edge downstream dataset. Devices run stochastic web-search to simulate runtime variance. CodeCarbon [24] is utilized to measure runtime duration and the power consumption.

Baselines. To evaluate the effectiveness of CLONE, we compare CLONE with 7 representative approaches, including: ***A. Vanilla:*** (1) *Vanilla* assess the effectiveness of the original LLMs as the baseline criterion. ***B. Model compression:*** (2) *Random* randomly selects certain groups for pruning. (3) *LLM-Pruner* [30] removes connected structures of dependent multi-head attention from LLMs based on gradient information. (4) *ShortGPT* [94] defines the Block Influence metric to guide redundant subset removal. (5) *SliceGPT* [8] replaces each weight matrix in the network with a smaller, dense matrix, thereby reducing the network embedding dimension. ***C. Computation optimization:*** (6) *FlexGen* [118] retains all model parameters on CPU DRAM. During inference, the demand weights are loaded from the CPU to the GPU. ***D. Small size model:*** (7) OpenLLaMA-3B [35], an open reproduction of Llama with 3B parameters, trained on 1T tokens.

Evaluation Metrics. In order to comprehensively evaluate the efficiency and effectiveness of CLONE, we conduct evaluations from three perspectives. ***A.Generation ability.*** We measure the zero-shot perplexity (PPL) analysis on WikiText2 [95] and PTB [93], two of the most commonly used evaluation datasets, to evaluate the generation capabilities of the customized model. Lower PPL values signify stronger generation ability. ***B. General-purpose task solving ability.*** To demonstrate the world knowledge and problem-solving skills of the customized model, we utilize three benchmarks:

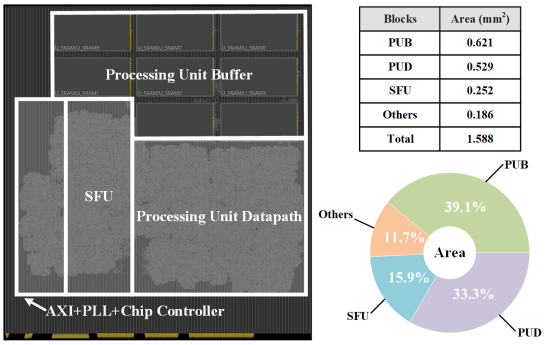

Figure 11: 28nm physical layout and area breakdown of the energy-optimal CLONE accelerator system.

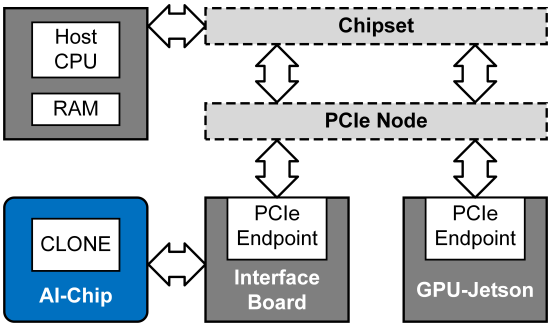

Figure 12: Test system. Integration of the CLONE accelerator into the Jetson platform via a PCIe interface to facilitate high-performance data exchange.

1) BBH [123], which includes 23 challenging tasks such as Q&A, natural language reasoning, and sentiment analysis. 2) MMLU [46], covering 57 tasks across diverse domains like mathematics, history, law, and ethics. 3) Commonsense reasoning tasks used in Llama paper [132], featuring BoolQ [22], PIQA [12], OBQA [100], ARC-c [23], ARC-e [23], WinoGrande [116], and HellaSwag [151]. ***C. System effectiveness.*** We evaluate the system effectiveness of CLONE from two perspectives: latency and energy consumption, which are defined as the duration and energy cost to infer the WikiText2 [95].

Hyperparameter and Reproducibility. For offline device-specific tailoring, we first execute classic approaches for 100 epochs to collect training data, and use 25× randomly shuffled client selection as data augmentation for tailoring training. Both Encoder and Decoder use a single-layer LSTM configuration, while the Predictor has a dual-layer feed-forward setup. Hidden state dimensions are 64 for Encoder and Decoder, and 200 for the Predictor, with all layers having an embedding size of 32. The hyperparameters include a batch size of 1024, a learning rate of 0.001, and $\eta = 0.8$. For optimization, we start with the top 25 model pruning ratio records. The LoRA rank r and the scaling hyperparameter α are set to 8 and 16, respectively, with 3 training rounds.

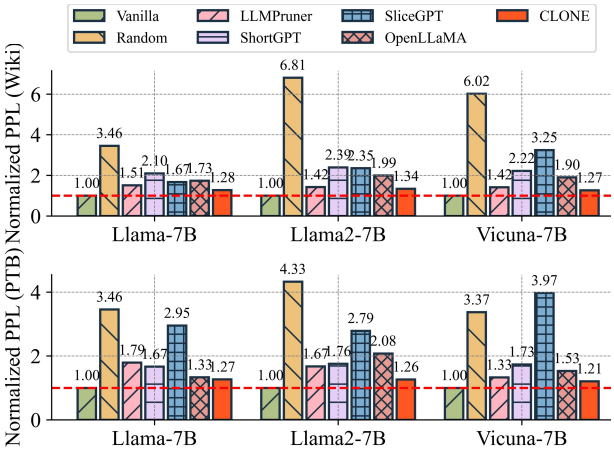

Figure 13: Generation ability comparison of various schemes on WikiText2 and PTB dataset across 3 representative LLMs.

5.2 Test System

Figure 11 presents the layout of the energy-optimal 28nm CLONE accelerator system. After place-and-route, the core footprint is only 1.588 mm^2; the figure also delineates module boundaries and reports the post-layout power- and area-breakdowns. Due to the high cost and time requirements of a full tape-out, the CLONE accelerator was validated through post-layout simulation. The physical layout was generated from Cadence Innovus synthesis results, following a complete design flow: behavioral modeling, RTL design, synthesis, P&R, and physical verification, ensuring simulation fidelity to actual fabrication. Figure 12 illustrates the integration of the CLONE accelerator into the Jetson platform via a PCIe interface to facilitate high-performance data exchange. The data flow initiates with the AI-Chip (CLONE), which interfaces with the Jetson GPU through a PCIe connection. An interface board bridges the PCIe endpoints of the CLONE accelerator and the Jetson GPU. This architecture is supported by the host CPU and RAM, where the CPU handles top-level data flow control, ensuring that requests are efficiently managed and routed. The CLONE is responsible for executing tasks based on user inputs, such as selecting the most efficient LoRA group and performing edge real-time DVFS control to optimize performance. By bypassing system software dependencies, this hardware-centric setup ensures seamless communication and data transfer between the CLONE and the Jetson device, achieving high levels of performance and energy efficiency.

5.3 Evaluation Results and Analysis

Generation Ability. To evaluate the customized model generation ability, we use the WikiText2 and PTB datasets to measure the zero-shot PPL (lower values correspond to stronger text generation capability) across different models on the

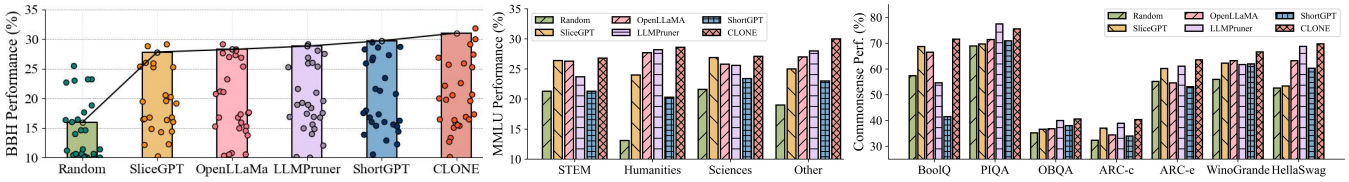

Figure 14: Downstream task performance of different customization approaches of Llama-7B on 3 representative benchmarks, including BBH (zero-shot), MMLU (3-shot), and Commonsense (zero-shot).

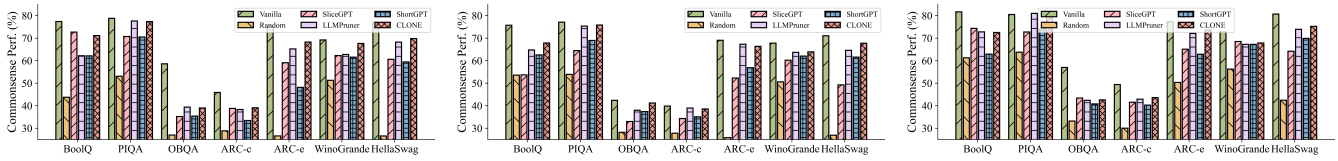

(a) Llama2-7B (b) Vicuna-7B (c) Llama2-13B

Figure 15: Zero-shot performance (commonsense) of Llama2-7B, Vicuna-7B and Llama2-13B.

Orin NX. Figure 13 shows the zero-shot PPL values that compare CLONE with the baselines. In order to effectively demonstrate the characteristics of different schemes, we normalize the measured PPL values to the vanilla model. Compared to baselines, CLONE preserves the most generation ability, achieving up to 5.1× generating capacity of *Random* on WikiText2 and up to 3.4× on PTB. This can be attributed to CLONE using PPL as a pruning metric to construct a continuous pruning selection space. It then utilizes gradient-based optimization to identify the optimal pruning configuration that minimally impacts generation ability.

Downstream Task Performance. Figure 14 illustrates the downstream task performance of CLONE across three representative benchmarks (BBH, MMLU, and Commonsense), covering 87 tasks. We observe that CLONE significantly outperforms other baselines across various domains and tasks. Specifically, for BBH, CLONE improves the average accuracy by 15.1% over Random and by 2.37% over others on average; for MMLU, it increases average accuracy by 6.0% over Random and by 2.96% over others on average; for commonsense tasks, CLONE enhances average accuracy by 10.1% over Random and by 6.1% over others on average. The principle as discussed in §3, CLONE implements task-aware tailoring for specific devices by considering end-user usage patterns and task specificity and relevance. It selects appropriate types and quantities of LoRA for fine-tuning. Moreover, we note that baseline performance varies across different downstream tasks. For instance, in BBH, ShortGPT is the sub-optimal model, whereas in Commonsense, LLMPruner is the sub-optimal. This variability stems from the heuristic and incomplete nature of baseline approaches. In contrast, CLONE utilizes a request-wise MoE-based router to effectively manage the properties of diverse real-world requests, resulting in superior LoRA module fusion. Overall, this experiment demonstrates CLONE's practical and robust ability to scale to complex workloads and applications.

Robustness and Scalability. Figure 15 details the zero-shot performance of the pruned model across a variety of downstream tasks, as well as its zero-shot perplexity on the WikiText2 and PTB datasets, utilizing diverse pruning configurations. Our observations confirm that CLONE consistently outperforms established baselines across all metrics.*1) Different types of models*: Comparing Llama2-7B and Vicuna-7B, the results indicate that CLONE exhibits a strong generalization capability, outperforming baselines by an average of 23.85%. *2) Different model sizes*: Evaluating Llama2-7B and Llama2-13B, it is evident from Figure 15 that CLONE maintains 91.13% of the performance of the unpruned (vanilla) models, underscoring its scalability. These results collectively affirm that CLONE is scalable to different LLMs in general, not limited to specific LLMs, so it is not a one-off "software-ASIC".

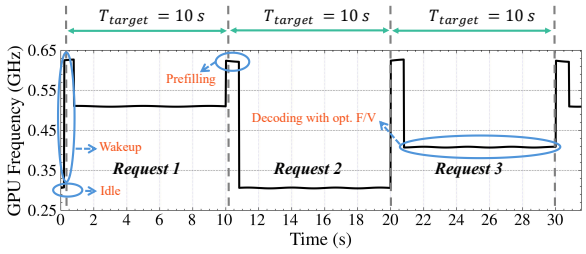

Figure 16: Simulations of LDO dynamic V_{DD} adjustments.

System Effectiveness. Then, we evaluate the system efficiency of CLONE from latency and energy consumption during the LLMs inference process on the WikiText2 dataset at the off-the-shelf devices Orin NX and Nano. As shown

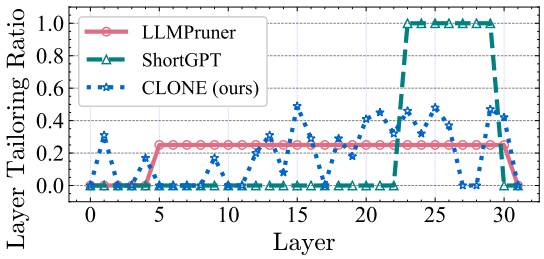

Figure 17: Comparison of the model pruning configuration.

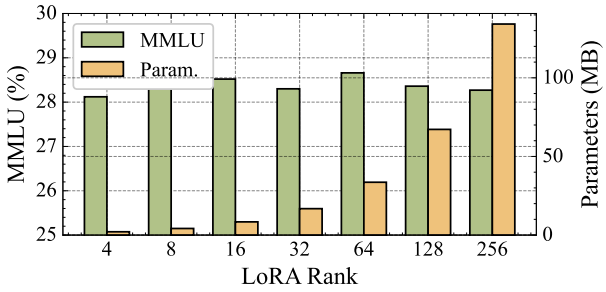

Figure 18: MMLU performance and parameter size across LoRA ranks.

in Table 3, we can see that CLONE effectively speeds up the inference process up to 11.92×, and achieves significant energy saving up to 7.36×. Figure 16 shows the spice-level simulation of the DVFS for runtime inference. There are two possible reasons 1) As shown in Equation 1, CLONE jointly considers the latency and energy budgets as metrics to generate optimal pruning configuration. 2) CLONE decouples prefill and decoding phases, applying request-level DVFS to boost effectiveness. In contrast, FlexGen trades high latency and energy for full-parameter LLMs, while methods like LLMPruner and ShortGPT focus on static, one-off compression without considering system-level optimization.

Table 3: System efficiency (latency and energy) comparison of various schemes to inference WikiText2 dataset.

Method	Energy (Wh)		Latency (s)	
	Jetson NX	Jetson Nano	Jetson NX	Jetson Nano
Random	7.27	8.26	842.40	1145.07
SliceGPT	5.47	7.54	661.65	929.39
OpenLLaMA	5.67	7.70	506.73	662.73
LLMPruner	6.01	6.91	622.92	1023.51
ShortGPT	5.67	8.56	555.14	698.02
FlexGen	21.12	26.04	3166.27	4674.42
CLONE^{-HW}	4.81	5.56	462.72	552.18
CLONE	**3.46**	**3.54**	**322.76**	**392.15**

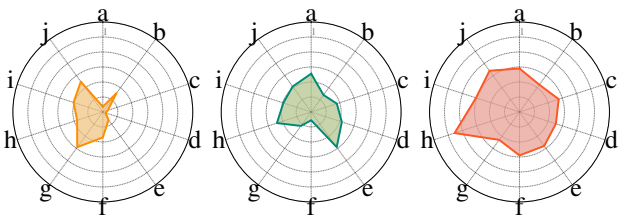
Study of the Generative Pruning Configuration. To examine how CLONE adaptively generates the optimal model pruning configuration, we compare the generative pruning approach to the layer-wise method used by ShortGPT and the uniform direct average method employed by LLMPruner on Llama-7B to illustrate the strategic disparities in their decision-making processes. As presented in Figure 17, LLMPruner remains static from the 5th to 30th layer. In contrast, ShortGPT uses only binary values of 0 or 1. We note that the layer-level pruning configuration determined by CLONE dynamically varies across layers. This adaptability reflects a more nuanced decision-making process, where the contributions of individual layers are recognized as heterogeneous, as discussed in *Motivation 1*. This indicates that CLONE's generative decision-making is more adaptive and tailored to the specific contributions of each layer.

Effectiveness of the Hardware Accelerator. The accelerator boosts efficiency by exploiting dedicated hardware resources; it does not itself alter generation quality or task-specific accuracy. Disabling it forces the workload onto general-purpose compute units, eliminating these hardware-level gains. As Table 3 shows, energy rises from 3.46Wh to 4.81Wh and end-to-end latency from 322.76s to 462.72s without the accelerator CLONE^{-HW}. Even in this regime, our offline, metric-guided generative pruning (Eq. 1) still surpasses all baselines, underscoring its robustness.

Effectiveness of Request-wise MoE Router. Figure 19 illustrates the performance of different LoRA adapter fusion methods during runtime inference for dynamic end-user requests. *w/o MoE* indicates direct averaging of all LoRA modules for all requests, which typically results in suboptimal performance due to the fact that not all stochastic multi-tasks benefit each other. *MoE (Top-1)* means based on the request to select the most similar LoRA for LLM inference. However, from Figure 19, we can see that *w/o MoE* Simply combining LoRAs results in worse performance because not all stochastic multi-tasks are beneficial to the others. Though *MoE (Top-1)* signifies that the most similar LoRA is selected based on the request for LLM inference. Although this approach enhances overall performance, it can still be sub-optimal in practice, as even a single request may involve multiple tasks, and merely considering task differences is insufficient. This observation highlights the critical importance of both the request-wise MoE router in maintaining CLONE performance within diverse data and task demands.

Impact of the Rank of LoRA Adapters. The rank r controls the number of trainable parameters, where larger values of r provide greater adapter capacity at the expense of increased training overhead. As illustrated in Figure 18, performance initially improves with higher ranks but eventually saturates, offering diminishing returns despite the rapidly growing parameter size.

Overhead Analysis. Offline tailoring utilizes a single-layer LSTM encoder-decoder and a dual-layer feed-forward network, adding minimal overhead and enhancing accuracy without affecting online inference. During online inference, the soft MoE router introduces no additional trainable parameters and performs a single probabilistic routing computation.



(a) w/o MoE (b) MoE (Top-1) (c) CLONE

Figure 19: Performance magnitudes of w/o MoE, MoE (Top-1) and CLONE. a-j represent different downstream tasks.

Implemented as a two-layer MLP with under 1K parameters, the DVFS controller imposes negligible overhead relative to billion-parameter LLMs. Both modules first execute concurrently (< 10ms) with the prefill stage (> 100 ms; see Figure 2), then the DVFS decision for token $t+1$ is generated while token t is being decoded, keeping the controller off the critical path. Meanwhile, the incremental energy cost of CLONE is on the milliwatt-hour scale, rendering it negligible compared with the watt-hour-level consumption of full-model inference.

6 Related Work

LLMs are highly memory-, compute-, and energy-intensive [5, 19, 96, 109, 132, 133], driving most "billion-parameter" inference to the cloud [6, 34, 81, 122, 124, 145, 149]. However, as edge devices become more powerful, there is increasing interest in executing LLM inference on the edge [4, 6, 34, 57, 74, 81, 107, 111, 122, 145, 149], which enhances data privacy and enables real-time service delivery. To address edge resource constraints, techniques such as model architecture search [54, 60, 88], quantization [26, 55, 57, 91, 143], pruning [27, 32, 91, 103], and knowledge distillation [41, 71] have been proposed. However, most approaches focus solely on model-level optimization, neglecting system-level trade-offs like storage and weight efficiency. Advances in LLM compilers and software stacks [56, 99, 113, 128] have enabled integration with co-processors and near-sensor processing [4, 43, 57, 74, 107, 111, 118, 122, 148, 155–158], but these often add computational and communication overhead, reducing edge device longevity and hindering concurrent application execution. Existing model customization methods [82, 126, 127, 153, 154] cannot directly address task-agnostic LLMs, where generalization is crucial. The unique characteristics of LLM decoder layers and stochastic outputs present untapped opportunities for hardware optimization. For system-level optimization, DVFS [10, 47, 48, 65, 112] has been widely used to dynamically adjust processor voltage and frequency. However, most DVFS strategies are designed for discriminative models like CNNs and RNNs, treating networks as black boxes. Generative LLMs, with their auto-regressive inference and stochastic prompt variability, remain underexplored in this context.

Edge–cloud collaboration offers a pragmatic middle ground between fully local and fully cloud-based inference. In practice, the edge should remain the first line of execution for latency-critical or privacy-sensitive workloads, running compact SLMs that fit the device's power and memory envelope. When a request exceeds local capacity—e.g., requires deeper reasoning, broader context, or larger knowledge—CLONE can transparently escalate the call to a cloud-resident LLM. This selective offloading preserves real-time responsiveness, keeps private data on-device whenever possible, and amortizes bandwidth and compute costs by invoking the cloud only for the fraction of tasks that truly need it.

7 Conclusion

CLONE integrates offline generative pruning and online latency-aware optimization to enhance edge deployment of LLMs. Offline, it dynamically generates device-specific pruning configurations via a generative framework. Online, CLONE employs a layer-wise DVFS strategy to optimize energy efficiency within latency constraints, using an MoE router with multiple LoRA adapters to support diverse tasks. Supported by a dedicated 28nm hardware accelerator, including specialized units for rapid LoRA adapter switching and fine-grained DVFS control, benchmarks confirm that CLONE significantly improves inference speed and energy efficiency while maintaining robust task performance, ideal for latency-sensitive, energy-constrained edge scenarios.

WEAVER: Efficient Multi-LLM Serving with Attention Offloading

Shiwei Gao, Qing Wang, Shaoxun Zeng, Youyou Lu and Jiwu Shu*

Tsinghua University

Abstract

LLM serving platforms typically provide services for tens to hundreds of different models, where a small number of hot models receive the majority of the requests, while most other models remain cold. Yet, current serving systems can not efficiently handle such workloads: Using dedicated instances for hot and cold models makes the GPU memory underutilized, and multiplexing different models with model parallelism introduces communication overhead.

We propose a mechanism called *workload weaving*, which offloads attention operators of hot models to *running* cold models, achieving high GPU memory utilization with low communication cost. To mitigate the blocking caused by running cold models, we propose WEAVER with two key techniques: (i) GPU-driven dynamic control flow, which delegates the control logic of offloading to GPUs, letting the offloaded operators bypass pending kernels in the GPU hardware queue; (ii) operator splitting, which carefully divides the large kernels of cold models into smaller ones to mitigate the head-of-line blocking. Our evaluation using real-world LLM trace demonstrates that WEAVER improves the throughput of hot models by up to 77% while maintaining the same or lower TPOT. For the cold model, WEAVER incurs a modest overhead (3-5ms).

1 Introduction

Large Language Models (LLMs) [1, 16, 18, 29, 30] have transformed numerous industries, leading to rapid adoption and innovation. As LLMs continue to evolve, serving platforms (e.g., Hugging Face [5], Together.ai [11]) now commonly host dozens or even hundreds of models, creating a new paradigm of *multi-LLM serving*. Multi-LLM serving features a skewed access pattern [17], where a small number of hot models receive the majority of requests, while most models remain rarely accessed (i.e., cold). This skewed pattern is also demonstrated by our analysis of a popular MaaS platform (§2.2).

However, through analysis and experiments, we find that existing methods can not efficiently handle the skewed workloads in multi-LLM serving (§2.3). A simple method is allocating dedicated GPU instances for hot and cold models respectively. Yet, it leads to poor GPU memory utilization for cold models due to their low request load. Another method is multiplexing, which shares GPUs between hot and cold models using model parallelism. Examples include AlpaServe [22], which employs model parallelism to share GPUs across models, and MuxServe [17], which enhances model parallelism with NVIDIA MPS [7] for improved spatial-temporal sharing. While these multiplexing methods can improve GPU utilization, they introduce non-negligible communication overhead, thus impacting overall system performance.

We observe that the inefficiency of existing multiplexing methods stems from the lack of exploiting LLM structures: they are designed for general DNN models. Motivated by it, we propose *workload weaving*, a mechanism that offloads a portion of attention, which are non-parameterized parts in LLMs that can be efficiently remotely executed, to GPUs running cold models. By doing so, we can allow hot models to harvest the underutilized GPU memory of cold models, enabling larger batch size and thus higher throughput. Besides, workload weaving has lower communication overhead compared to multiplexing methods.

However, making workload weaving practical is challenging. Different from offloading attention to dedicated computing devices [13, 19, 20, 23, 24], in workload weaving, the destination of attention offloading, i.e., the cold instance, is also responsible for serving its model. This makes the offloaded attention operators experience head-of-line blocking from *pre-issued kernels* and *long-running kernels*. First, existing LLM serving systems typically pre-issue hundreds of kernels to the GPU hardware queue. Therefore, when an offloaded attention operator arrives at the cold instance, it can only run on the GPU if all the pre-issued kernels are drained. Second, even if we could prioritize the execution of the offloaded attention operator, it might still be blocked when the GPU is being occupied with a long-running kernel.

We design WEAVER, a multi-LLM serving system that achieves efficient workload weaving while overcoming the above challenges. We guarantee that offloaded attention operators will wait for *at most one small running kernel* to finish, which ensures the efficiency of WEAVER. This is achieved by two techniques we propose:

1) GPU-driven dynamic control flow. WEAVER delegates the control logic of issuing offloaded attention operators to GPUs. Specifically, WEAVER leverages cross-GPU shared memory capabilities to dispatch offload tasks. The GPU in the cold instance continuously polls new offload tasks and executes them immediately, bypassing pre-issued kernels in the GPU hardware queue.

2) Operator splitting. WEAVER addresses the long-running kernel problem by splitting a large kernel into smaller ones, so

*Jiwu Shu is the corresponding author (shujw@tsinghua.edu.cn).

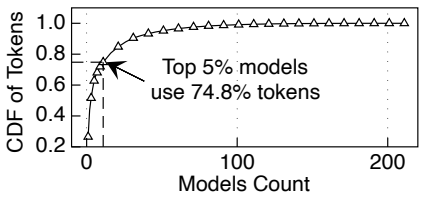

Figure 1: Model Workload Statictic of a MaaS Platform.

that the offloaded attention can be executed on GPUs within a bounded time. To mitigate the kernel fragmentation caused by splitting, we adopt a priority-based algorithm based on queuing theory analysis to generate the splitting plan.

We evaluate WEAVER on two real-world LLM traces (Azure-Conv, BurtGPT) and two hardware platforms (A100, L40S). Our results show that WEAVER improves the throughput of hot models by up to 77% against dedicated serving and 60% against multiplexing-based methods while maintaining the same or lower TPOT. For the cold model, WEAVER incurs a modest overhead (3-5ms) on average in the TPOT compared to dedicated serving.

2 Background and Motivation

2.1 Operators in LLM Serving

Due to the unique architecture of the Transformer, the LLM serving mainly involves two types of operators: parameterized *projection* and non-parameterized *attention*.

Projection operators. These operators include fully connected feed-forward networks (FFNs) and specialized linear transformations, such as query, key, value, and output projections in the multi-head attention mechanism. As a parameterized component, they rely on a fixed set of learned parameters to process input tokens or their intermediate representations.

Attention operators. Attention operators dynamically compute relationships between input tokens to capture contextual dependencies. Unlike projection operators, the attention mechanism is non-parameterized. Therefore, the attention computation does not require model parameters, but depends on the KV tensors of previous tokens. These KV tensors are typically saved in the form of *KV cache*, to avoid duplicated compuation in future token generation.

2.2 Multi-LLM Serving

LLMs have become popular across various industries, driving innovation and adoption at an unprecedented pace. As a result, the variety of available LLMs has grown rapidly, and thus LLM serving platforms now usually host tens to hundreds of LLMs, presenting the paradigm toward *multi-LLM serving*.

For instance, Model-as-a-Service (MaaS) platforms, such as Hugging Face [5], Together.ai [11], and OpenRouter [9], provide services of a broad range of models, catering to users with different requirements and use cases. Even single-model providers, e.g., OpenAI [8] and Gemini [3], host a family of models with varying capabilities, model sizes, and release versions, enabling users to select the most appropriate model for their specific tasks: OpenAI alone provides APIs for more than 20 variants of its chat family LLMs [8].

Batch Size	2 × Seperate (Token/s)	TP 2 (Token/s)	Slowdown
16	2024	1487	26.6%
32	3343	2645	20.9%
64	5392	4443	17.6%
128	8011	6606	17.5%

Table 1: Tensor Parallelism Overhead. *The results are tests on two A100-40GB with NVLink, Llama-3-8B, input 1024, output 128.*

Multi-LLM serving systems feature skewed access patterns [17]. We analyze a one-week multi-LLM serving statistic of a popular MaaS platform OpenRouter [9], which includes 209 models and more than 200 billion tokens. Figure 1 shows the CDF of request tokens: the top 5% models consume 74.8% tokens, exhibiting a skewed distribution. In other words, in multi-LLM serving, a small subset of hot models (e.g., Llama-3 or OpenAI's latest release) receives the majority of traffic, but many models are cold and see sparse usage; they receive a low but consistent request rate most of the time.

2.3 Existing Methods and Limitations

By analysis and experiments, we find that existing methods can not efficiently handle workloads with mixed hot and cold models, a remarkable feature of multi-LLM serving (§2.2).

Using dedicated instances. This method uses dedicated instances for hot and cold models respectively. For example, service providers can deploy hot models on dedicated GPUs [10], while dynamically allocating GPUs for cold models (e.g., leverage serverless). However, during processing requests for cold models, the associated GPUs suffer from low GPU memory utilization. We conduct an experiment, where a hot model (15 QPS, Llama-3-8B) and a cold model (1 QPS, Llama-3-8B) run on an A100-40GB GPU *each*, and measure their GPU memory utilization. While the hot model already utilizes all the GPU memory, the GPU memory utilization of the cold model remains at 43%.

Multiplexing. Another method is multiplexing GPUs for cold and hot models. AlpaServe [22] uses model parallelism for statistically multiplexing GPUs for multiple models. MuxServe [17] further improves it by incorporating NVIDIA MPS [7], thus achieving flexible temporal-spatial sharing. Micro-batching causes redundant LLM weight access [14], making pipeline parallelism less efficient and less commonly used for models that can fit on a single multi-GPU node. Both MuxServe and our work mainly focus on tensor parallelism as the primary model parallelism strategy. While tensor parallelism improves the GPU utilization, it also introduces overhead caused by communication and smaller (thus less efficient) operators. In Table 1, we evaluate the token generation throughput of the Llama-3-8B model with 2 separate instances and TP degree of 2 setting on the 2× A100-40GB GPU connected with NVLink. Results show that naively using TP can introduce up to 26% overhead even on a high

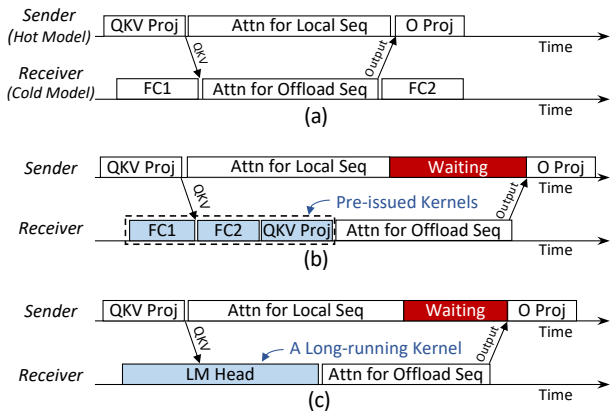

Figure 2: Workload Weaving and Challenges. *(a) Ideal case. (b) Blocked by pre-issued kernels. (c) Blocked by long-running kernels.*

interconnect bandwidth platform.

3 Approach and Challenges

Opportunity: attention offload. Attention offload is a technique that delegates attention operators to *dedicated* auxiliary computing devices [13,19,20,23,24], such as GPU, CPU, PIM, or CSD. The primary device (e.g., GPU) executes projection operators, and stores the sequence's KV cache on auxiliary devices. Attention offload provides a way to offload part of the computation and storage usage of LLM inference with low communication and memory overhead, this is because 1) for each attention computation, only the QKV tensor of the latest token needs to be transmitted to the auxiliary device, 2) the auxiliary device does not need to store model parameters (recall attention operators are non-parameterized, §2.1).

Our approach: workload weaving. Inspired by attention offloading, we propose *workload weaving* to handle multi-LLM serving workloads and overcome limitations of existing methods (§2.3). Workload weaving harvests the unutilized GPU memory of running cold models by offloading a portion of attention operators to them, and Figure 2a shows its workflow. During inference, the sender (i.e., a GPU running hot models) transmits the QKV tensor of the offloaded sequences's new tokens to the receiver (i.e., a GPU running hot models). The sender executes attention operators for the non-offloaded portion, while the receiver handles the offloaded portion and then returns results to the sender for final merging. The receiver also maintains the KV cache for the offloaded portion.

Workload weaving offers two advantages for multi-LLM serving. First, it can improve the throughput of hot models by utilizing the unused GPU memory of cold models, thereby enabling larger batch sizes. Second, it achieves lower communication overhead compared to model parallelism used in the multiplexing method.

3.1 Challenges

In the ideal case of workload weaving, the cold instance (i.e., receiver) can immediately execute the attention operators from the hot instance (i.e., sender), as shown in Figure 2a. Yet, realizing it is challenging, because the cold instance is also responsible for serving its model, making the offloaded attention operators suffer from head-of-line blocking from 1) pre-issued kernels and 2) long-running kernels.

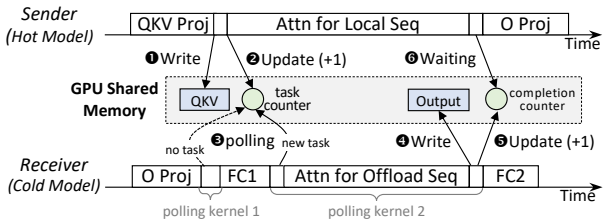

Figure 3: GPU-driven Dynamic Control Flow.

Blocked by pre-issued kernels. In existing LLM serving systems, CPUs perform the control flow logic, mainly including issuing kernels to the GPU. They typically pre-issue many kernels to the GPU (e.g., 387 kernels per iteration of Llama-3-8B in vLLM), each representing an operator. When these kernels enter the GPU hardware queue, the GPU hardware will execute them sequentially. Therefore, when an offloaded attention operator is launched by the receiver CPU, *there is no guarantee that it will be the next kernel to be executed*. For example, in Figure 2b, the offloaded operator is blocked by `FC2` and `QKV Proj`, two unexecuted but issued kernels.

Blocked by long-running kernels. Even if we can guarantee the offloaded attention operator is the next kernel to execute, it may still be blocked for a long time. This is because the receiver GPU may be executing a long-running kernel, as shown in Figure 2c. Long-running kernels are common in LLM serving: for example, the LM head of Llama-3-8B takes up to 961µs on an A100 GPU.

4 Design and Implementation

We propose WEAVER, a multi-LLM serving system that achieves efficient workload weaving while overcoming the associated challenges (§3.1).

WEAVER incorporates two key techniques, *GPU-driven dynamic control flow*(§4.1) and *operator splitting* (§4.2). The former delegates the control logic of attention offloading to the GPU, so that offloaded attention operators can bypass pre-issued kernels in the GPU hardware queue. The latter splits large operators into small ones using a priority-based algorithm backed by queueing theory, avoiding head-of-line blocking from a long-running kernel. Combining the two techniques, WEAVER can guarantee that offloaded attention will wait for at most one small running kernel to finish.

4.1 GPU-driven Dynamic Control Flow

To avoid the offloaded attention operator being blocked by pre-issued kernels, one strawman approach would be to issue kernels in a blocking manner: only when a kernel is complete, the receiver CPU will issue the next kernel (prioritize issuing the offload attention operator, if it exists). However, this

approach significantly impacts the receiver GPU's computational throughput. WEAVER proposes GPU-driven dynamic control flow to avoid the blocking problem of pre-issued kernels, while minimizing the impact on GPU performance. It delegates the control logic of issuing offloaded attention operators to the receiver GPU, and leverages cross-GPU shared memory capabilities [2, 4] for synchronization.

With GPU-driven dynamic control flow, the process of offloading an attention operator is shown in Figure 3. When the sender needs to offload an attention operator, it writes the latest token's QKV tensor to shared memory using one-sided writes (❶), and atomically increments a task counter (❷). The receiver GPU polls the task counter (❸). Upon detecting an increment, indicating a new task, the receiver GPU executes the attention operator, then writes the result tensor to shared memory (❹), and finally increments a completion counter (❺). Once the sender realizes that the completion counter has changed (❻), it obtains the result tensor from shared memory and then continues with the subsequent computation.

All the above operations of the receiver GPU, including polling, counter updates, data transfers, and attention execution, are encapsulated in a GPU kernel, which we call *polling kernel*. The receiver CPU pre-issues many kernels as in today's LLM serving systems to saturate the GPU hardware queue, but *each kernel is followed by a polling kernel*. In this way, the offloaded attention will only be blocked by the kernel that is executing, not other pre-issued kernels.

Of note, the updates of attention metadata (e.g., sequence page tables) are still executed on the CPU due to their complexity. These updates are infrequent (i.e., only one time per iteration) and thus do not create performance bottlenecks.

4.2 Operator Splitting

To avoid head-of-line blocking resulting from a long-running kernel, WEAVER introduces operator splitting. Its key idea is to split the kernel of a large operator into smaller ones, so that the offloaded attention can be executed on GPUs within a bounded time. However, it is non-trivial to generate a good splitting plan, considering that 1) the operators in LLM serving have diverse execution time, 2) excessive fragmentation due to operator splitting will induce performance overhead. To this end, we first employ queuing theory to model the sender's wait time, then adopt a priority-based algorithm to generate the splitting plan.

Modeling. We model the receiver as a polling system [28] with two logical queues. The first queue accommodates attention operators offloaded from the sender, arriving at intervals of M_i time units, each requiring a service time of N_i. The second queue accommodates the receiver's LLM operators, assumed to have an infinite backlog, with each operator requiring a service time of T_i. For the non-offloaded portion of the attention, the processing time in the sender is K_i.

Our objective is to minimize the conditional expected wait time experienced by offloaded attention operatiors in the first queue (i.e., W_i). Specifically:

$$\min E(W_i \cdot \mathbf{1}_{\{K_i < W_i + N_i\}})$$

Here, the condition $K_i < W_i + N_i$ means that: if the execution time of non-offloaded attention is less than the sum of receiver-side wait time and the execution time of offloaded attention, the sender will be blocked. To simplify the problem, we assume that the K_i and N_i remain constant (term as K and N), which can be obtained by periodic profiling. Based on statistical analysis, the completion position of each offloaded operator can be treated as a random variable uniformly distributed in $[0, T_i]$. Under this assumption, the wait time caused by each operator is:

$$W_i = \frac{\max\{T_i - (K-N), 0\}^2}{2T_i}$$

The probability of an operator being at the queue head is proportional to its time density in the system. Thus, the overall objective becomes:

$$min \frac{\max\{T_i - (K-N), 0\}^2}{2\sum T_i}$$

Priority-based operator splitting. The above formulation reveals that large operators contribute quadratically to the receiver's expected wait time. According to it, we propose a priority-based operator splitting algorithm, as described in Algorithm 1. We maintain a priority queue of all operators in the receiver and iteratively split the operator with the longest execution time into two halves. If the split operator still exceeds the $(K-N)$, it is reinserted into the queue. This process continues until the wait time is reduced below a pre-defined threshold $WT_{threshold}$ (we set it to 5% of the sender's average iteration time). With this algorithm, we can alleviate head-of-line blocking without generating many small kernels.

WEAVER executes the algorithm on the receiver-side CPU. WEAVER splits parameterized operators in the parameter dimension, and non-parameterized operators in the sequence dimension. Note that currently WEAVER fixes the proportion of offloaded attention. K and N are periodically updated via workload profiling.

4.3 Implementation Details

We implement WEAVER based on vLLM v0.6.0 [21]. We use the CUDA IPC for cross-GPU shared memory communication and FlashAttention [15] to execute the offloaded attention.

Request scheduling. The hot instance distributes the task of processing input sequences to itself and the cold instance, using a fixed offload ratio. After completing the prefill stage, the KV cache of each hot model's request is randomly assigned to either the hot or cold instance, where it remains until the request is complete. Since our work focuses on developing an efficient mechanism for serving multiple models, we leave the design of a cluster-level scheduler for future work. For instance, using request rate metrics, one could dynamically

while Estimated wait time $> WT_{\text{threshold}}$ **do**
    $OP_{\max} \leftarrow Q$.front();
    if $T_{\max} > K - N$ **then**
        $OP_1, OP_2 \leftarrow$ split($OP_{\max}$);
        Q.pop();
        Q.push(OP_1, OP_2);
    else
        break
return Q

adjust the offload ratio, reducing the offload ratio when the cold model's load is high and increasing it when the load is low, to enable dynamic harvesting of cold model resources.

KV cache management. In WEAVER, the GPU memory of the cold model's instance holds both KV cache blocks for offloaded sequences from the hot model and ones for its own sequences. Following prior work [17], we build a unified KV block allocator that supports models with different numbers of layers and KV heads.

4.4 Discussion

Influence of the model size. For larger models, GPU memory, especially for the KV cache, becomes a more significant constraint, often limiting the maximum batch size. In such a situation, WEAVER allows the hot model to leverage the memory resources of the cold model's GPU instance. This enables larger effective batch sizes for the hot model, leading to higher maximum throughput. For small language models, its benefits could be less significant. WEAVER can not speed up the FFN part of the model. For small language models and larger batch sizes, the projection part could be more dominant for the end-to-end performance. We leave the exploration of workload offloading for the FFN part as future work.

5 Evaluation

Workloads and test models. We evaluate our system using two widely-used LLM workload traces: BurstGPT [31] (ChatGPT-4 split) and Azure-Conv [25]. We filter out sequences exceeding 2048 tokens, since some baselines do not support running such lengths. BurstGPT represents a balanced workload, with an average input length of 575 tokens and an output length of 340 tokens. In contrast, Azure-Conv represents an input-heavy workload, with an average input length of 749 tokens and an output length of 232 tokens. All experiments use the Llama-3-8B model by default. Following prior work [21], we sample the arrival time of requests with the Poisson distribution from the above traces. Unless otherwise stated, we set the request rate of the cold model to 1 request per second and the offload ratio of WEAVER to 45%.

Baselines. We compare WEAVER to the following baselines. ❶ Dedicated Serving, which uses dedicated GPUs to serve cold and hot models respectively, each running unmodified vLLM. ❷ MuxServe [17], which supports two modes: 1) spatial-temporal multiplexing with NVIDIA MPS enabled and 2) temporary multiplexing only (i.e., Mux-Temporal). For a fair comparison with MuxServe, we do not enable CUDA Graph in WEAVER and dedicated serving. Moreover, we also replace the attention kernel of MuxServe with more efficient FlashAttention, which is the same as WEAVER.

Testbeds. We used two test platforms with different interconnect bandwidths: (i) 4× A100-40GB with NVLink; (ii) a cloud server containing 4× L40S with PCIe as the interconnect. Following popular disaggregation serving design [34], each model (hot and cold) uses the 1p1d setup. We only multiplex the workload between decoding GPUs. On the L40S

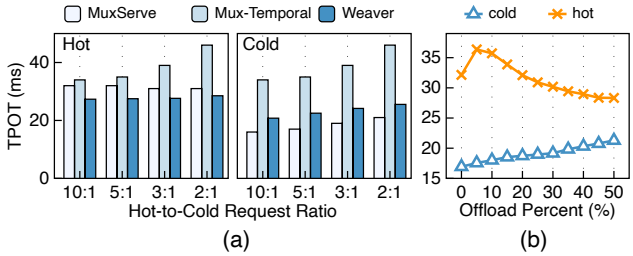

Figure 5: Sensitivity Analysis (I). *(a): Varying hot to cold request rate. (b): Varying the offload sequence percentage.*

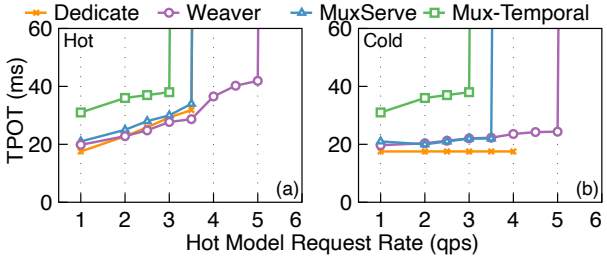

Figure 6: Sensitivity Analysis (II). *Results with longer output.*

testbed, we did not have root access, preventing NVIDIA MPS from being enabled. Therefore, we evaluated MuxServe using only the temporal multiplexing mode on this platform.

Metrics. Since in the evaluation WEAVER and baselines perform workload multiplexing only in the decode instance, the TTFT is out of the optimization scope of these systems (we present it in §5.3). Thus, we mainly report the TPOT (Time Per Output Token) of different models, which is crucial for the user experience.

5.1 Overall Performance

We evaluate the overall performance of WEAVER against baselines by varying the request rate of the hot model, ranging from low loads up to its maximum sustainable QPS (its saturation point), and respectively reporting the mean TPOT of the hot and cold model. Figure 4 shows the results.

Hot model (Figure 4a-d). WEAVER primarily aims to improve hot model performance. Compared to dedicated serving, WEAVER increases maximum throughput by up to 60%. This is because WEAVER utilizes available memory on GPUs of cold models, enabling larger batch size and thus higher throughput. At low request rates (less than 5 QPS), WEAVER shows slightly higher TPOT due to communication overhead. However, at higher request rates, WEAVER reduces the TPOT by up to 39%. When compared to multiplexing serving approaches, WEAVER achieves up to 22% higher maximum throughput for hot models on A100 GPUs. The improvement is more significant on L40S GPUs with lower interconnect bandwidth, where WEAVER achieves up to 77% higher maximum throughput, as tensor parallelism in multiplexing approaches introduces larger overhead on such platforms.

Cold model (Figure 4e-h). While improving the hot model's throughput, WEAVER has an acceptable impact on the cold model's performance. When load of the hot model is low, WEAVER achieves a 1.04× higher TPOT for the cold model compared to dedicated serving. Under the high load of the hot model, where more workload is offloaded, WEAVER incurs modest overhead and the TPOT increases 3-5ms on average. MuxServe shows slightly lower TPOT since it uses tensor parallelism with 2 GPUs for the cold model during inference, which comes at the cost of lower hot model throughput. Moreover, since each offloaded attention operator is small, it does not significantly interfere with the cold model's execution. As a result, the P99 TPOT of the cold model is not influenced: for example, 19-22ms on the A100 platform, which is 1-2 ms higher than the mean case.

Batch size and memory utilization We analyze the advantages of WEAVER in terms of memory utilization, using serving Azure-conv trace on A100 as an example. Under dedicated serving, at its maximum throughput of 15 QPS, the hot model achieves an average batch size of 118. This nearly saturates the KV cache memory of the hot GPU, reaching 88.9% utilization. In contrast, at the same QPS of 15, WEAVER significantly alleviates memory pressure on the hot GPU, reducing its KV cache utilization to 46.9%. This is achieved by actively leveraging the KV cache memory of the cold GPU, which exhibits 36.7% utilization. Furthermore, when the QPS is increased to 22, the maximum throughput supported by WEAVER, the average batch size of the hot model rises to 231. This effectively doubles the batching capacity compared to the dedicated serving approach.

5.2 Sensitivity Analysis

We analyze the sensitivity of WEAVER under two different configurations on the A100 platform with the BurstGPT trace.

Hot-to-cold request ratio. We evaluate the WEAVER's benefits with varying hot-to-cold request ratios, the request rate of the hot model is fixed at 10. As shown in Figure 5a, across all kinds of hot-to-cold request ratios, WEAVER shows consistently 15% lower TPOT than MuxServe and 20%-40% lower than Mux-Temporal for the hot model. For the cold model, MuxServe's TPOT is slightly lower than WEAVER, because it uses model parallesim. The Mux-Temporal suffers more from inefficient interleaved execution caused by temporal sharing, and the TPOT of WEAVER can be 56% lower than it.

Offloaded sequence ratio. We evaluate WEAVER's performance by varying the percentage of offloaded attention operators, with the hot model's request rate fixed at 15. Figure 5b shows the results. The cold model's TPOT increases almost linearly with the offload percentage, which is expected due to the proportionally increased workload. At low offload ratios (5%-10%), the hot model's performance slightly degrades due to communication overhead. When the offload ratio increases to 50%, the hot model's TPOT decreases by 13% while adding a 3.7ms TPOT overhead to the receiver's processing time. Our experiments show that in our workloads, a 45% offload ratio achieves optimal hot model's TPOT by

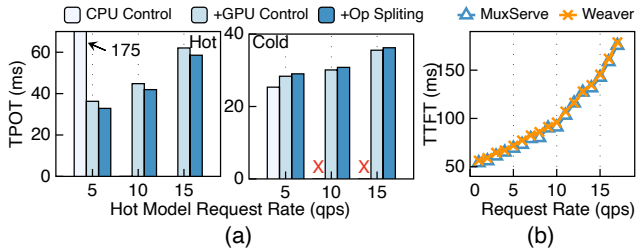

Figure 7: Ablation Study. *(a): Ablation of different techniques in* WEAVER. *(b): Ablation of different serving frameworks.*

providing a small grace period (i.e., $K-N$ in Algorithm 1) for possible blocking caused by a single small kernel.

Longer output length. We further evaluate WEAVER's performance on synthetic data featuring longer output sequences. The requests are synthesized with 512 placeholder tokens as the input and enforce the LLM to generate exactly 1024 tokens by setting max output length to 1024 and enabling ignore_eos. Experiments were conducted on the A100 testbed, with the cold model's QPS fixed at 1. Figure 6 presents the results. WEAVER achieves up to 42% higher max throughput compared to MuxServe. This improvement is more pronounced than observed with the Azure and BurstGPT datasets, primarily because WEAVER's attention offloading facilitates effective workload interleaving. With extended output lengths, the batch size is limited by the KV cache size. By offloading attention computation, which constitutes a larger portion of execution time, to the cold model instance, WEAVER increases the maximum possible overall batch size, and thus enables the hot model to achieve higher throughput with the same resources. Meanwhile, since the offloaded workload is heavier, the cold model's TPOT increases by up to 8ms than dedicated serving.

5.3 Ablation Study

Ablation of different techniques in WEAVER. We evaluate WEAVER's individual optimizations using the Azure-Conv dataset on L40S GPUs. Figure 7a shows our results. In the baseline (i.e., *CPU Control* in the figure), the CPU performs the control flow logic, which leads to significant blocking from pre-issued kernels. This blocking delays the offloaded attention computation, resulting in a high TPOT of 175ms for the hot model. After implementing GPU-driven dynamic control flow (i.e., *+GPU Control*), we observe a 4.83× reduction in the sender's TPOT, with only a minor 1.8ms increase in TPOT of the cold model due to the additional polling kernel. Adding operator splitting (i.e., *+Op Spliting*) further reduces the hot model's TPOT by up to 9.5% while increasing the cold model's TPOT by just 0.7ms. Together, these optimizations add only 2.5ms overhead to the cold model's original TPOT, representing less than a 10% increase — a reasonable trade-off given the performance improvements for the hot model.

Ablation of different serving frameworks. We compare the TTFT of MuxServe and WEAVER on the A100 platform, running the BurstGPT trace at various request rates. Figure 7b shows our results. The TTFT between WEAVER and MuxServe remains consistently close. The TTFT of WEAVER is slightly higher (at most 5.7%) due to more complex Python logic in our vLLM version. The results demonstrate that the performance comparison between the two frameworks is fair and the TTFT is not influenced.

6 Related Work

Multi-model serving. In the era of DNNs, numerous approaches have been proposed to support multi-model serving, such as TGS [33], PipeSearch [12], AlpaServe [22], MPS [7], and MIG [6], among others. They focus on achieving efficient model switching and spatio-temporal multiplexing with minimal overhead. These approaches mostly treat the model as a black box and omit the opportunity to take advantage of the model structure to serve multiple models.

For multi-LLM serving, several studies have explored scalable and efficient solutions. Llumnix [27] migrates KV cache to achieve load balancing across the LLM-serving system. The most closely related to ours is MuxServe [17], which employs tensor parallelism and leverages spatial-temporal multiplexing to concurrently serve multiple LLM requests.

Attention offloading. Prior work [13, 19, 20, 23, 24] has explored offloading attention operators in LLMs to different computing devices, including CPUs, GPUs, and PIM. LoongServe [32] speeds up inference of long sequences by splitting attention operators across multiple servers. Our work differs from these approaches: instead of using dedicated hardware, we offload attention to GPUs that are *running* cold models. This unique approach requires careful design to mitigate the blocking caused by the ongoing cold model serving.

7 Conclusion

This paper presents WEAVER, a multi-LLM serving system that introduces workload weaving to improve GPU memory utilization with low communication overhead. Our experimental results demonstrate its performance gain.

Abstract

Serverless computing offers a compelling cloud model for online inference services. However, existing serverless platforms lack efficient support for GPUs, hindering their ability to deliver high-performance inference. In this paper, we present `Torpor`, a serverless platform for GPU-efficient, low-latency inference. To enable efficient sharing of a node's GPUs among numerous inference functions, `Torpor` maintains models in main memory and dynamically swaps them onto GPUs upon request arrivals (i.e., late binding with model swapping). `Torpor` uses various techniques, including asynchronous API redirection, GPU runtime sharing, pipelined model execution, and efficient GPU memory management, to minimize latency overhead caused by model swapping. Additionally, we design an interference-aware request scheduling algorithm that utilizes high-speed GPU interconnects to meet latency service-level objectives (SLOs) for individual inference functions. We have implemented `Torpor` and evaluated its performance in a production environment. Utilizing late binding and model swapping, `Torpor` can concurrently serve hundreds of inference functions on a worker node with 4 GPUs, while achieving latency performance comparable to native execution, where each model is cached exclusively on a GPU. Pilot deployment in a leading commercial serverless cloud shows that `Torpor` reduces the GPU provisioning cost by 70% and 65% for users and the platform, respectively.

1 Introduction

The remarkable advances in machine learning (ML) and its widespread adoption in various domains have fueled a surging demand for cloud-based ML inference services [24, 32, 49, 65, 66]. Severless computing offers a compelling cloud model for inference serving [20, 58, 61]. In a serverless cloud, users publish ML models as inference functions, and delegate resource provisioning and scaling responsibilities to the cloud platform. Serverless computing is also economically appealing as users only pay for the resources consumed by their functions (i.e., pay-per-use billing), eliminating resource idling costs.

However, today's serverless computing platforms, such as AWS Lambda [6] and Alibaba Function Compute [1], lack efficient support for GPUs. They typically run an ML model in a container (or a microVM) and early bind it to a GPU before starting to serve requests. To avoid considerable startup overhead of on-demand GPU function provisioning (e.g., tens of seconds as shown in Table 1), an inference function is maintained as a long-lived, provisioned instance on a designated GPU to handle future requests [4, 7]. This approach essentially follows the "serverful" inference serving practice [47, 49, 65], requiring users to pay for the occupied GPUs even during function idling. Furthermore, our analysis in a production cloud demonstrates that inference functions exhibit varying request rates, with 85% functions being invoked no more than once per minute (Fig. 2). Early binding these functions to GPUs results in low utilization and imbalanced load across GPUs, making it inefficient for cloud providers.

We believe that an efficient serverless inference platform should provide four desirable properties. First, it should enable *pay-per-GPU-use billing* for users, with charges incurred only when the functions are invoked and running on GPUs. Second, the platform should achieve optimal GPU utilization through efficient *GPU sharing* for concurrent inference functions, minimizing resource provisioning costs for cloud providers. Third, the platform should be aware of the user-specified *latency SLOs* and strive to meet them for all inference requests, if feasible. Lastly, the platform should achieve the aforementioned three properties *without requiring detailed knowledge about inference models* due to intellectual property and business-critical confidentiality reasons. We notice that there have been several relevant systems developed in recent years [23, 32, 34, 36, 46, 47, 49, 58, 63], none of which, however, provide all of these properties for serverless inference. They often suffer from cost inefficiency, SLO violations, or necessitate model-specific knowledge (see §2.2 and §9).

In this paper, we present `Torpor`, a GPU-efficient serverless inference platform that achieves all four desirable properties and is readily-deployable onto real-world serverless platforms without intrusive changes. `Torpor` follows a late binding de-

sign principle, whereby idle inference models are maintained in host memory and dynamically swapped to GPUs upon request arrivals. Compared to GPU memory, host memory is less expensive and has a much larger capacity, making it an ideal storage for holding numerous idle functions. This approach naturally supports pay-per-GPU-use billing, as idle functions no longer occupy GPU resources. Furthermore, by dynamically swapping models from host to GPUs, it enables fine-grained GPU sharing among concurrent inference functions, substantially improving GPU utilization and load balancing across GPUs. Model swapping can also be efficiently performed through pipelined loading, yielding significantly lower latency compared to function cold starts. All these are achieved without detailed knowledge about inference models – a must-have in a commercial environment for intellectual property and confidentiality protection. These techniques, combined with intelligent request scheduling, enable the platform to optimize the SLO attainment for users.

Specifically, to realize late binding while being readily-deployable on real-world serverless platforms, `Torpor` leverages a GPU pooling architecture. In this design, each worker node manages a pool of local GPUs and allows its inference functions to access any of these GPUs freely through CUDA API redirection. This enables seamless model swapping within a GPU pool and is transparent to users. However, this approach also presents three key challenges.

First, GPU pooling and model swapping incur high communication overhead compared to native execution (i.e., executing a model directly on a GPU). To address this challenge, `Torpor` proposes *asynchronous API redirection* to avoid frequent synchronizations between the inference functions and the GPU pool, eliminating the high communication overheads for model inference. `Torpor` further utilizes *pipeline execution* to overlap the host-to-GPU model swapping and the inference execution, thereby reducing end-to-end latency. It also utilizes high-speed NVLink for fast model swapping between GPUs whenever feasible and beneficial. Combined with low-latency API redirection, `Torpor` can efficiently execute models on any available GPUs. `Torpor` is intentionally designed to be model-agnostic to meet the confidentiality requirements while being generally applicable to various models, including even large generative models where runtime states (e.g., KV cache) can be managed as part of the model.

The second challenge is that GPU pooling and model swapping necessitate an efficient GPU memory management system. `Torpor` designs such a system that automatically tracks the addresses of models as they are swapped across multiple GPUs and adjusts each memory access of CUDA APIs accordingly during inference execution. It also efficiently organizes and shares memory blocks to avoid high memory allocation overheads, improving the overall performance of model swapping. Additionally, `Torpor` offers two GPU runtime management modes—runtime sharing and runtime isolation—to meet various needs for resource efficiency and cross-model isolation.

The third challenge is that the platform should meet the latency SLOs for inference functions while maintaining low GPU costs. `Torpor` proposes three policies to achieve this objective. First, `Torpor` designs a request scheduling algorithm that minimizes model swapping overheads, resulting in reduced end-to-end inference latency. It categorizes models into two groups, heavy or light, based on whether these models incur high overhead during swapping via PCIe. `Torpor` then prioritizes NVLink over PCIe for transferring heavy models across GPUs, effectively reducing concurrent PCIe traffic. Second, `Torpor` globally manages GPU memory in the pool and leverages model heaviness to guide eviction. Together with request scheduling, this approach significantly minimizes model swapping overhead. Third, `Torpor` proposes an SLO-aware request queuing policy that prioritizes requests to functions that have a higher likelihood of meeting SLOs, effectively improving the SLO attainment.

We have implemented and evaluated `Torpor` through a pilot deployment in Alibaba Cloud [1], one of the world's largest commercial serverless platforms. Evaluation results show that `Torpor` achieves low-latency model inference, comparable with native executions. `Torpor` can share a single GPU across hundreds of inference functions and load-balance GPUs with model swapping, resulting in over 10× cost reduction compared with current GPU offering in Alibaba Cloud. With its efficient SLO-aware scheduling and queuing policies, `Torpor` can serve 480 functions on a 4-GPU worker node while achieving low tail latency and satisfying millisecond-scale SLOs for all functions. Cluster experiments further demonstrate that `Torpor` scales well with the number of inference functions at low resource cost and meets per-function latency SLOs for thousands of functions. `Torpor` has been beta-released in a pilot production cluster in Alibaba Cloud, saving 70% of user costs on average and 65% of GPU provisioning costs for Alibaba Cloud.

2 Background and Motivation

In this section, we first give an overview of serverless inference. We then describe the inefficiency of existing solutions to enabling GPUs in serverless platforms, and highlight four key requirements in this regard.

2.1 Serverless Inference

As a leading serverless platform with a global presence, our Alibaba Cloud has observed a growing adoption among enterprise customers who opt to deploy their inference services using serverless functions, known as *serverless inference*. In comparison to existing inference services based on a "serverful" cloud model, such as AWS SageMaker [5], serverless

[1] We have open-sourced `Torpor`'s single-node prototype at https://github.com/FCSLab/torpor.

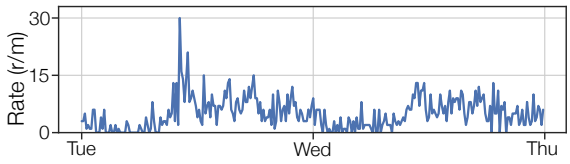

Figure 1: A two-day request trace of a typical GPU inference function in Alibaba Cloud.

inference significantly alleviates the burden of server management for cloud users. Specifically, the serverful approach requires users to manually configure various system-level parameters (e.g., VM types, GPUs, CPU cores, etc.) and manage resource provisioning (e.g., scaling the number of VMs up or down according to demand changes). In contrast, serverless inference enables users to simply publish models with inference code as functions, and then cloud providers automatically handle resource provisioning, autoscaling, scheduling, and fault tolerance. Furthermore, compared with the serverful approach, serverless inference also offers substantial cost savings as users do not pay for idle resources under the pay-per-use pricing model [20, 58, 61, 65]. In Alibaba Cloud, the requests to a function typically exhibit dynamic, bursty arrival patterns as shown in Fig. 1, consistent with previous research findings [24, 25, 32, 33, 41, 42, 47, 49, 67]. By leveraging the high elasticity of a serverless platform, inference functions can quickly scale in response to the changing workload, while users are billed based on the actual function runtime at a fine granularity, such as 1 ms [6, 8].

2.2 GPU Support in Serverless Platforms

Despite the benefits of the serverless inference model, existing serverless platforms, including Alibaba Cloud and other leading platforms, currently lack efficient support for GPUs, which impedes their ability to achieve high-performance serverless inference. Alibaba Cloud users also have expressed a compelling need to execute their models in GPU-enabled functions.

Existing solutions and their inefficiency. A number of recent systems have been proposed to support GPUs in serverless platforms [1, 27, 29, 58]. They, however, still follow the approach of existing serverful model serving systems (e.g., Nexus [49] and INFaaS [47]), and deploy inference models as long-running containers where each container, when created, is bound to a specific GPU (i.e., early binding). The deployed model remains in the memory of a designated GPU to handle future requests, and the occupied GPU resources can only be reclaimed after the model serving terminates.

However, the early-binding approach deviates from the serverless paradigm and is costly for both cloud users and providers. First, binding inference functions to GPUs occupies resources for extended duration, even when idling. Thus, users are obligated to pay for the allocated GPUs regardless of actual usage [3], leading to high expenses that undermine

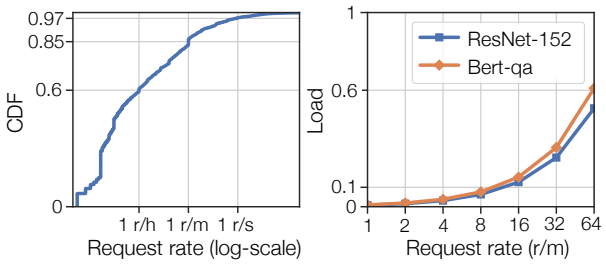

Figure 2: CDF of average function request rates from a one-week production trace (left) and the GPU load under various per-function request rates when running multiple functions on a `V100` GPU to saturate its 32 GB memory (right).

Table 1: Model startup times (s) under `Torpor` (runtime isolation mode in §4.5) and cold-starts. `Torpor`'s startup time is broken down into model loading and runtime resumption.

Model	Torpor		Cold-start	Mem. footprint
	Model	Runtime		
ResNet-152 [17]	0.03	0.26	8	1.6 GB
Bert-qa [26]	0.14	0.19	11	2.4 GB
Stable Diffusion [18]	0.24	1.5	25	5.1 GB
Llama3-8B [11]	1.6	1.4	48	13 GB
Qwen-14B [16]	2.1	1.5	57	20.1 GB
Llama2-13B [10]	2.5	1.9	61	24.5 GB

the cost-saving benefits of serverless inference. Second, this approach results in severe GPU underutilization, considering the low average request rates of most inference functions and the cross-GPU load imbalancing. Fig. 2 (left) depicts the distribution of the average request rates of Alibaba Cloud functions in a one-week trace, revealing that 85% (97%) of functions were invoked only once per minute (second) on average[2]. These findings align with the observations from other production traces [8, 48]. Fig. 2 (right) further illustrates that consolidating multiple models to fill GPU memory can still lead to low GPU load. Meanwhile, packing models into a GPU can cause temporary overloading due to the bursty request patterns (Fig. 1), thus inevitably leading to hotspots and load imbalancing in a multi-GPU setting. The impact of load imbalancing will be shown in Fig. 9 in §7.2.

To reduce costs, current systems need to frequently reclaim GPU resources when functions are inactive, avoiding charges for unused GPUs and allowing other functions to utilize idle resources. Unfortunately, this approach leads to frequent function cold starts, leading to significant overhead for model inference. Table 1 shows model startup times under cold starts, which need tens of seconds for GPU container setup, ML framework startup, GPU runtime creation, and model initialization[3]. Therefore, the cold-start overhead far exceeds the

[2]For confidentiality reasons, we depict the request rates of both CPU and GPU functions, which exhibit similar patterns (see Fig. 1).

[3]We exclude the delay of fetching a remote container image or a model file for cold starts, which can take extra seconds to minutes to complete [54]. A detailed discussion of `Torpor`'s performance is provided in §8.

Table 2: A comparison of Torpor and existing solutions that offer GPU support on serverless platforms.

Solution	GPU pay-per-use	GPU efficient	SLO compliant	Model agnostic
Alibaba Cloud [1]	×	×	×	✓
Molecule [27]	×	×	×	✓
DGSF [29]	×	×	×	✓
INFless [58]	×	×	*	×
Torpor	✓	✓	✓	✓

typical SLO requirement of model inference.

Requirements of serverless inference. Table 2 summarizes key requirements of serverless inference and compares Torpor with other existing solutions. Serverless users should be billed only when their functions are invoked and running on GPUs to achieve substantial cost savings (***pay-per-GPU-use***)[4]. Serverless platforms like Alibaba Cloud should serve as many inference functions as possible using a minimum number of GPUs, thereby attaining high GPU utilization (***GPU efficient***). The platform should allow users to specify their latency SLOs and strive to meet the latency SLOs for all functions (***SLO compliant***). For confidentiality reasons, the serverless platform should avoid inspecting detailed model structure, which can be of high business value (***Model agnostic***).

Compared with Torpor, none of existing solutions can meet all desired requirements. Alibaba Cloud and Alibaba Function Compute [1] are leading commercial serverless platforms with GPU supports; Molecule [27] introduces a serverless platform that supports GPUs and other hardware devices; DGSF [29] enables serverless functions to access GPUs in a remote cluster. These systems employ the early-binding approach as previously discussed, failing to enable pay-per-GPU-use billing and achieve high GPU efficiency. Moreover, they are oblivious to the semantics of model inference and unable to meet latency SLOs. INFless [58] presents a serverless inference system that early-binds functions to GPUs. While INFless proposes function scheduling and keep-alive schemes aimed at low-latency inference, it still leads to function cold starts and SLO violations (details in §7.3). Furthermore, INFless requires model knowledge for operator-level profiling. We leave more discussions on related work to §9.

3 Key Insight and Challenges

Key insight. As described in §2.2, the current early-binding approach of retaining inference models in GPU memory leads to high idling costs and underutilized resources. Therefore, an efficient serverless inference platform should enable *late binding*, where GPUs are managed as a resource pool and idle inference models reside in host memory, dynamically swapping into any available GPUs upon request. This approach should also be *easily deployable* on real-world serverless platforms without requiring intrusive changes. Late binding offers several key advantages in meeting the requirements in §2.2. **First**, keeping models in host memory eliminates GPU memory usage during idle periods, enabling pay-per-GPU-use billing and cost savings for cloud users. **Second**, host memory is significantly larger than GPU memory (e.g., a few TB vs. tens of GB), allowing for consolidation of multiple low-frequency functions onto a single GPU with improved GPU utilization. Late binding also facilitates load-balancing across multiple GPUs in a pool. **Third**, model swapping provides an efficient method to resume function execution compared to cold starts in the early-binding approach, thereby facilitating SLO compliance. **Finally**, late binding can be performed transparently to users within the GPU pool, which holds a holistic view of memory usage without requiring detailed model-specific knowledge.

Challenges. Implementing GPU pooling and late binding in the serverless platform presents three challenges. ***C1: Efficient GPU pooling and model swapping***. GPU pooling requires inference functions to synchronize with a remote GPU pool [28, 31], which introduces additional communication overhead compared to local executions and presents challenges in achieving low-latency inference. ***C2: GPU memory management.*** To enable seamless late binding, the platform should automatically monitor and manage memory usage without detailed model knowledge. This requires a unified and efficient GPU memory management system across the GPU pool. ***C3: SLO compliance and resource efficiency***. The platform should provide efficient request scheduling and model placement algorithms that effectively utilize the late binding mechanism to meet latency SLOs and enhance resource efficiency.

In the following sections, we present Torpor, a GPU-enabled serverless platform that addresses the aforementioned challenges and, importantly, is readily-deployable onto real-world serverless platforms without intrusive changes.

4 Torpor System Design

4.1 Architecture overview

Fig. 3 provides an overview of the architecture of Torpor, which comprises two main components: the cluster manager and worker nodes. The cluster manager handles cluster-level tasks, including request routing, node allocation, and resource scaling. It dynamically schedules function instances and routes inference requests to maintain load balancing across worker nodes and ensure fault tolerance (§ 4.5). At each worker node, Torpor employs GPU pooling, where a GPU server manages all local GPUs as a pool and allows functions to dynamically access any available GPUs. Within the GPU

[4] In our experiences, enterprise customers are willing to pay a nominal fee to retain idle functions in host memory for substantially improved performance (§8), similar to the function keep-alive charge meant to avoid cold starts [3, 7, 37].

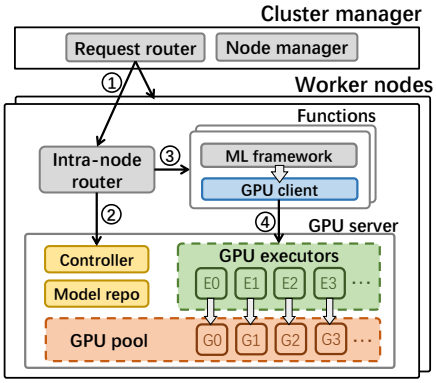

Figure 3: Architecture overview of Torpor. A request arriving at a Torpor cluster is first routed to a worker node hosting its target function ①. The router in the worker node synchronizes with the GPU server to query the executor for this request ②, and then routes it to the function instance with the target executor ID ③. The function instance next processes the request and uses a GPU client to automatically redirect CUDA API calls to this executor ④, and finally returns the result to the user after request completion.

server, a model repository manages models in host memory; GPU executors handle CUDA execution, perform necessary model swapping, and manage GPU memory on the associated GPUs; the controller maintains a global view of GPU memory and executor status, and decides how to schedule requests to executors. Additionally, each worker node runs an intra-node router to signal the GPU server about request arrivals and route requests to local inference functions. Once the target function receives a request, it interacts with the scheduled executor through a GPU client by remoting CUDA API calls. All components within the worker node—the GPU server, intra-node router, and functions—are deployed as containers.

Key to Torpor is to develop an efficient GPU server that enables low-latency model inference and addresses the challenges discussed in §3. Specifically, we will elaborate upon Torpor's designs to address the following questions: 1) how Torpor achieves low-latency GPU pooling (§4.2) and model swapping (§4.3); 2) how Torpor tracks the memory footprint of functions and manages GPU memory (§4.4); 3) how Torpor ensures isolation and handles failures (§4.5).

4.2 GPU Remoting

Asynchronous API redirection. Existing GPU remoting solutions [28, 45] introduce high communication overhead due to synchronizations for individual API calls during model inference (details in §7.1). Leveraging the computing pattern of model inference, Torpor proposes *asynchronous* API redirection to reduce synchronizations. Specifically, we observe that the intermediate steps in an inference execution are typically performed asynchronously on the GPU, where intermediate data is generated and consumed in GPU memory without requiring data transfer to the host until the execution completes. Consequently, a function can redirect intermediate CUDA calls to the GPU executor asynchronously without waiting for their results, and only perform synchronizations for the final output. This approach preserves the execution order of CUDA APIs, ensuring the correctness of the inference results.

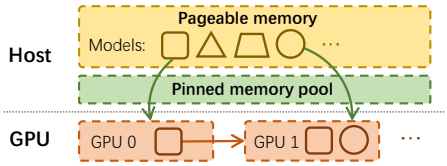

Figure 4: An example of model swapping. Models can be swapped from host to GPU through PCIe (green arrows), or across GPUs through NVLink (red arrow).

Following this insight, Torpor categorizes CUDA APIs into two groups based on their semantics: 1) *synchronous, blocking* APIs that require the host to await their completion before proceeding, such as cudaMalloc; and 2) *asynchronous, non-blocking* APIs that do not alter the host's runtime state, such as cudaLaunchKernel, which allows for asynchronous API redirection. Most APIs issued during inference fall into the asynchronous category, presenting opportunities to mitigate the synchronization overhead. Torpor can further batch consecutive CUDA API calls to enhance asynchronous API redirection (see APIs and batching details in our technical report [62]).

4.3 Model Swapping

As serverless platforms are constrained from examining the detailed model structures, it poses challenges to achieve seamless and efficient model swapping. Torpor overcomes the problem by leveraging two insights: 1) tracking general memory footprint of model inferences is feasible within a GPU pool, and 2) the memory access pattern of a model—the addresses and access order of model parameters—generally remains consistent across requests. Therefore, Torpor only tracks the first function execution (i.e., cold start), and applies the pattern to future request executions (see memory tracking in §4.4). Torpor performs model swapping on demand at the request level, and enhances performance through pinned memory pool and pipeline execution.

Model swapping and pipeline execution. Fig. 4 illustrates the model swapping in Torpor, where it utilizes pinned memory to enhance the host-to-GPU model loading and supports fast, cross-GPU model swapping via high-speed NVLink. Torpor's swapping can be generally applied to various types of models, including those that require maintaining runtime states (e.g., KV cache in LLMs) by treating these states as part of the model itself. Torpor further employs pipeline execution to enhance swapping performance, which is particularly effective for models computed in one forward pass, allowing the transmission of subsequent layers to overlap with the

computation of previous layers.

Key to pipeline execution is to judiciously group model parameters for swapping. Grouping too few parameters triggers a large number of transmissions and high synchronization overhead; conversely, grouping too many parameters impairs pipeline efficiency. Pipeline strategies in previous systems like PipeSwitch [22] and DeepPlan [36] do not suit serverless inference as they assume model structure is provided and require extensive model profiling. `Torpor` employs a model-agnostic approach to determine the group size for model pipelining. We observe that the transmission performance experiences an "elbow point" concerning group sizes: increasing the group size improves overall transmission throughput, but the improvement becomes marginal after a certain point. We therefore select this elbow point as the group size, which can achieve good swapping performance without substantially compromising pipeline efficiency. This group size depends only on hardware configurations such as PCIe, and can be easily determined by profiling various-sized data (e.g, about 2 MB in our testbed). This approach requires no detailed model knowledge and can be directly applied to various models.

Model eviction. We observe that model unloading from GPUs to host can result in considerable overhead and can interfere with concurrent inference executions. Therefore, `Torpor` always maintains a copy of the model in the host, and only invalidates its GPU memory region during eviction.

4.4 Memory Management

`Torpor` presents two key requirements for GPU memory management, as compared with other systems [12, 23, 44]. First, late binding requires a pool of GPUs to share the same logical memory space. This is because the inference functions do not recognize backend GPUs, and consistently access models using identical memory addresses even across different GPUs. Second, model swapping triggers frequently GPU memory (de)allocation, which leads to substantial overhead when using native methods like `cudaMalloc` (see Fig. 13). We therefore design a GPU memory management system that can effectively hide memory address differences between various GPUs and provide low-latency memory (de)allocations.

Memory address management. We observe ML frameworks like PyTorch typically organize data into blocks, each containing multiple parameters. `Torpor` leverages such memory layout to perform memory mapping at the block level. In particular, `Torpor` monitors memory blocks for each function and maintains a mapping to their actual physical addresses after model swapping. Since the internal data layout within each block remains unchanged (e.g., parameter offsets), `Torpor` can easily obtain the physical address of a parameter using its associated block address and offset. This approach eliminates the need for extensive metadata maintenance for individual data pointers, enabling the efficient address translation with low management overhead.

Memory block allocation. To mitigate the high overhead of native GPU memory allocation, `Torpor` reserves all GPU memory at bootstrap and internally manages memory blocks. This provides a shim layer to service memory requests from functions, without needing the native method. Key to this approach is to avoid memory fragmentation, which can decrease available GPU memory and harm overall efficiency. `Torpor` effectively addresses this issue by extending the Buddy memory allocation scheme [40] and leveraging unique characteristics of inference. It consolidates memory blocks from the same models to minimize fragmentation and enables sharing of common-sized blocks across different models (see details in our technical report [62]).

4.5 Isolation and Fault Handling

Resource isolation and GPU runtime management. `Torpor` provides container-level isolation for CPU and memory resources[5], similar to existing serverless platforms [1, 52, 60]. For GPUs, `Torpor` executes only one function on a GPU at a time and isolates GPU memory regions across functions. This is achieved through `Torpor`'s GPU server, which has full control over CUDA API execution and GPU memory access.

`Torpor` offers two isolation modes for GPU runtime: 1) runtime sharing, which runs a single runtime on a GPU for multiple models, for instance, in a more trusted environment, and 2) runtime isolation, which maintains a dedicated runtime for each model and suits better for a more untrusted environment. By default, `Torpor` employs runtime sharing to improve resource efficiency. When stricter isolation is necessary, `Torpor` can switch to runtime isolation mode. Indeed, in our pilot deployment (§8), `Torpor` runs in the runtime isolation mode. The overhead incurred by runtime isolation is generally acceptable, e.g., hundreds of milliseconds to 1.5 seconds as shown in Table 1, which is still over one order of magnitude latency improvement compared with cold starts.

Fault handling. `Torpor` sustains various system component failures. In case of function failures, `Torpor` restarts them to resume the execution. For executor failures or GPU runtime errors, `Torpor` migrates the affected models to other working GPUs (executors) via swapping, and then restarts the failed ones. When runtime isolation is employed, `Torpor` can ensure that buggy function executions do not affect others, achieving stronger fault isolation. The GPU server also persists runtime states (e.g., models and metadata) in local storage to allow fast recovery from an entire failure of the GPU server.

At the cluster level, `Torpor` persists metadata of individual nodes in a database, which enables the cluster manager to retain these states and recover from failures, aligning with current practices in Alibaba Cloud. It also keeps periodic health checks with the router on each worker node, and handles node

[5] `Torpor` makes no assumption on function sandboxes and can also support microVMs [19, 53].

Table 3: Latency (ms) of model pipelining execution when concurrently swapping other models through PCIe. The diagonal values indicate the latencies without concurrent models.

Model	DenseNet-169	ResNet-152	Bert-qa
DenseNet-169	**27**	27 (+0%)	27 (+0%)
ResNet-152	31 (+7%)	**29**	43 (+48%)
Bert-qa	166 (+11%)	240 (+61%)	**149**

failures by launching a new node and migrating all relevant functions.

5 Torpor Policy Design

We present how Torpor meets the latency SLOs and delivers resource efficiency (i.e., Challenge *C3* in §3). We start with the design overview, followed by individual policies.

5.1 Design Overview

Objective. The objective of Torpor's policy design is to meet latency SLOs for inference functions while minimizing the resource cost. We define a function to comply with latency SLOs if its tail request latency is not longer than a user-specified deadline, and meter the resource cost by the number of worker nodes. Key to achieving this goal is to *maximize the number of SLO-compliant functions* at each worker, such that Torpor can efficiently exploit per-worker GPU resources to host as many functions as possible, which in turn reduces the total number of workers required.

Challenges. Previous systems have proposed various schemes to meet latency SLOs [32, 58, 65, 67]; however, their policies do not apply to Torpor for two reasons. First, previous systems like INFless [58] and Shepherd [67] assume sufficient GPU memory and employ early binding, so they schedule model serving instances to GPUs and then batch and route requests to them. In contrast, Torpor focuses on late-binding the often lower-frequency or varying-demand functions to a pool of memory-constrained GPUs, requiring a joint design of model management (i.e., model swapping and eviction) and request scheduling. Second, previous systems assume a stable model inference latency [32, 47, 58, 65, 67] which, however, does not hold in our setting — model swapping can cause unpredictable performance due to PCIe bandwidth contention [21, 38]. For instance, as show in Table 3, concurrently swapping two models through PCIe increases individual model inference latency compared with running them alone, especially for large models (e.g., Bert-qa).

We propose three policies to address the aforementioned challenges. First, considering that packing many functions together can cause short-term overloading and request queueing, Torpor introduces a request prioritization policy to maximize the number of SLO-compliant functions (§5.2). Second, Torpor designs a request scheduling and model swapping policy to reduce bandwidth contention across concurrent models, thereby improving overall inference performance (§5.3). Lastly, by leveraging the characteristics of model swapping, Torpor proposes an effective model eviction policy to reduce bandwidth footprint in model swapping; combined with the request scheduling policy, Torpor minimizes the interference among concurrent model executions (§5.4).

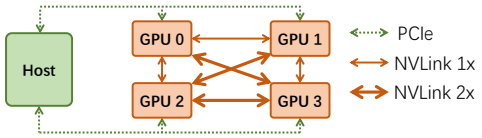

Figure 5: Topology of a 4-GPU worker node in Alibaba Cloud.

5.2 Request Queueing

To maximize the number of SLO-compliant functions, Torpor needs to monitor the SLO compliance of individual functions to determine their request executions. Intuitively, Torpor prioritizes functions with a higher probability to comply with SLOs. However, realizing this approach requires answering two questions: 1) how to quantify the likelihood of SLO compliance for a function, and 2) how to determine function execution order for improved SLO compliance.

Torpor proposes a metric, *required request count* (RRC), to measure the "degree of needed effort" to meet SLOs. RRC represents the expected request number that a function needs to successfully serve in order to satisfy SLOs. Let n be the current number of requests to a function, and m be the number of requests served within deadlines out of n. The RRC of this function is defined as $\frac{pn-m}{1-p}$, where p is the tail percentile specified in SLOs such as 98%. This is derived from the equation: $\frac{m+RRC}{n+RRC} = p$. Smaller RRC values indicate a higher likelihood of SLO attainment. Hence Torpor divides functions into high- and low-priority groups based on their RRCs, and prioritizes their requests accordingly. We develop an effective strategy to determine the boundary (i.e., RRC threshold) between the two groups that can dynamically adjust function prioritization based on the current load at a worker, thereby improving the overall SLO compliance (see details in our technical report [62]).

5.3 Scheduling and Model Swapping

While model execution latency is often stable, model swapping can incur unpredictable overhead due to PCIe bandwidth contention [21, 38]. Fig. 5 shows the topology of a worker node in Alibaba Cloud, where each pair of GPUs shares a PCIe switch and GPUs are inter-connected via NVLinks with various bandwidths[6]. The performance slowdown caused by

[6]Despite the presence of other GPU interconnects (e.g., NVSwitch in DGX A100), inter-GPU PCIe bandwidth sharing continues to necessitate interference mitigation.

Algorithm 1 Interference-Aware Request Scheduling

```
1:  function SCHEDULE(req r)
2:      A ← set of available GPUs                    ▷ A ≠ ∅, otherwise queueing r
3:      M ← set of GPUs hosting the target model
4:      if M ≠ ∅ then
5:          G ← M ∩ A
6:          if G ≠ ∅ then
7:              g ← any GPU in G
8:              Execute r on g                       ▷ No swapping
9:          else
10:             (g, m) ← GPU pair with fastest NVLink, g ∈ A, m ∈ M
11:             Execute r on g; Swap model from m    ▷ GPU-to-GPU
12:     else
13:         g ← a GPU whose neighbor is not loading models, g ∈ A
14:         if g not found then
15:             g ← a GPU whose neighbor is loading a light model, g ∈ A
16:         if g not found then
17:             g ← any GPU in A
18:         Execute r on g; Swap model from host     ▷ Host-to-GPU
```

bandwidth contention can vary among models as shown in Table 3, where larger models require more intensive data transmission and exhibit more pronounced performance degradation. Hence we propose interfere-aware scheduling to minimize PCIe contention, thereby reducing request latencies.

Interference-aware scheduling. `Torpor` exploits the direct NVLink connections between GPUs to reduce PCIe contention whenever possible. It prioritizes GPU-to-GPU over host-to-GPU model swapping to enable faster model transmission and avoid interference with concurrent PCIe traffic. When concurrent host-to-GPU swapping is unavoidable, `Torpor` avoids loading bandwidth-intensive models (e.g., Bert-qa in Table 3) simultaneously to minimize the impact of PCIe contention. Therefore, models are categorized as heavy or light based on their bandwidth requirements (see Table 4).

Algorithm 1 shows `Torpor`'s scheduling and swapping mechanisms. `Torpor` first checks whether the target model is loaded on an available GPU, and if so, directly executes it without swapping (line 8). If the model is hosted by busy GPUs, `Torpor` then schedules the request to perform GPU-to-GPU swapping, as the source and target GPUs should have a fast NVLink connection (line 11). Otherwise, `Torpor` resorts to the host-to-GPU swapping and prioritizes target GPUs whose neighbors are idle or running light models to reduce PCIe contention (line 18). Altogether, `Torpor` minimizes the interference and overhead of model swapping for each request, thus providing low inference latency.

5.4 Model Eviction Policy

Model eviction plays a critical role in reducing bandwidth contention and enhancing the overall inference performance, in conjunction with `Torpor`'s request scheduling policy. Unlike traditional cache eviction strategies which primarily aim to minimize the miss rates, `Torpor`'s model eviction policy considers the performance implications of model swapping for different models to facilitate future model loading.

We notice that swapping light models leads to negligible overhead for end-to-end performance compared with heavy ones (Table 3 and Table 4). Therefore, we tend to evict models that have little or no impact on performance when swapping. We employ two mechanisms following this insight. First, `Torpor` manages memory of all GPUs as a pool to globally optimize model placement, which ensures that each model can have up to one replica among GPUs when GPU memory is full. This allows for more efficient model caching and reduces host-to-GPU data transmission. Second, `Torpor` prioritizes light models in eviction, as swapping them leads to negligible or no PCIe bandwidth contention. When only heavy models remain, `Torpor` adopts Least-Recently-Used (LRU) policy to determine their eviction order.

6 Implementation

We have implemented `Torpor` for Alibaba Cloud, one of the world's leading commercial serverless platforms. `Torpor`'s GPU server and GPU client were implemented in 4k and 1.5k lines of C++ code, respectively. Intra-node router and cluster manager were implemented atop the relevant components in Alibaba Cloud. `Torpor`'s late-binding mechanism imposes no intrusive changes to standard cluster management logic, enabling the reuse of Alibaba Cloud's existing manager with minimal changes. In fact, `Torpor` has been successfully deployed in a real-world production environment of Alibaba Cloud (§8). We provide a container image as a function template based on PyTorch, where the original CUDA libraries (e.g., `libcudart.so`) are replaced by our GPU clients to enable GPU remoting. This requires no modification to the PyTorch framework.

7 Evaluation

In this section, we evaluate `Torpor` with the runtime sharing mode using production traces from Alibaba Cloud. We intergrate `Torpor` with runtime isolation mode into Alibaba Cloud's real-world production environment and report the results in §8.

Settings. We deploy `Torpor` at Alibaba Cloud following the realistic production specification of its serverless platform. `Torpor` runs in a cluster with up to 6 workers. Each worker node has 48 vCPU cores, 384 GB memory, and 4 NVIDIA V100 GPUs each with 32 GB memory. We use 8 popular ML models for evaluation, as shown in Table 4, and distribute them across inference functions in a round-robin manner. All functions are warmed up before running the test workloads. We compare `Torpor` against Native execution—the default approach in Alibaba Cloud—and INFless [58], a state-of-the-art serverless inference system.

Metrics. We focus on the ratio of functions meeting SLOs and

Table 4: Various models and their latencies (ms) with GPU remoting and model swapping. Underlined are heavy models where swapping via PCIe slows down the inference (see §5.3).

Model	Native	GPU remoting	Swap-PCIe	Swap-NVLink
DenseNet-169	30	25	27	26
DenseNet-201	36	28	30	30
Inception-v3	19	14	17	16
EfficientNet	17	12	13	13
ResNet-50	11	9	13	11
ResNet-101	20	14	22	16
ResNet-152	25	17	25	20
Bert-qa	42	43	144	45

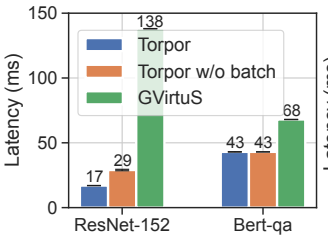

Figure 6: Inference latency with Torpor and other GPU remoting techniques.

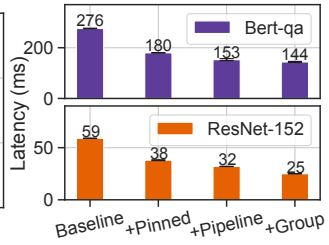

Figure 7: Performance breakdown of Torpor's model swapping via PCIe.

the GPU load in the evaluation. A function complies SLOs if its tail request latency is within a deadline. By default, we use 98^{th} tail latency, and set deadlines for CV models and Bert-qa to 80 ms and 200 ms, respectively. The GPU load is measured by the proportion of time during which the GPU is processing inference requests.

7.1 Overhead of Torpor's Late Binding

Table 4 compares the performance of 8 popular models under Native execution and Torpor with its GPU remoting (§4.2) and model swapping (§4.3). For GPU remoting, Torpor adopts efficient, asynchronous API redirection, leading to comparable performance to Native, or even better for CV models. This is because serving these models requires configuring many cuDNN descriptors where the relevant CUDA APIs are executed on the CPU side and do not require GPU resources; thus, redirecting these APIs effectively distributes CPU-side workloads across functions and the GPU server, enabling functions to access more CPUs and perform parallel computation. Note that, CPU resources are not the bottleneck in this scenario. According to our measurements, the CPU utilization of Torpor (native execution) for ResNet-152 and Bert-qa remains at 27.4% (8.8%) and 17.2% (9.2%), respectively. For model swapping, Torpor supports efficient pipeline execution through PCIe, and leveraing NVLink further improves performance.

Performance of Torpor's GPU remoting. To show the advantage of Torpor's GPU remoting, we compare it with GVirtuS [9, 31], a leading solution among publicly available GPU

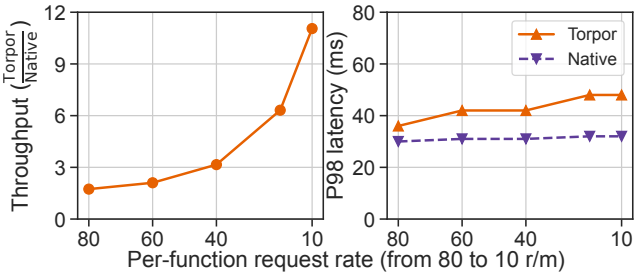

Figure 8: Performance of executing multiple ResNet-152 functions on a single GPU with Torpor's late binding (Torpor) and Native execution. We show the throughput of Torpor normalized to Native (left) and the tail latencies under varying per-function request rates (right).

remoting techniques. GVirtuS adopts a synchronous approach to API redirection. We also evaluate a variant of Torpor that disables call batching in asynchronous API redirection, i.e, "Torpor w/o batch". Fig. 6 shows the inference performance under various approaches. Torpor significantly outperforms GVirtuS and reduces latencies by 88% and 37% for ResNet-152 and Bert-qa, respectively. ResNet-152 triggers a large number of API calls during each inference, leading to high synchronization overhead for GVirtuS. Asynchronous API redirection (Torpor w/o batch) dramatically reduces the latency by 79%; with API call batching, Torpor further reduces the latency by 41%. Compared with ResNet-152, Bert-qa requires less communication in GPU remoting; therefore, the improvement from asynchronous API redirection is less but still quite significant.

Performance breakdown of model swapping. To illustrate how each of Torpor's model swapping designs contributes to performance improvement, we break down the inference performance of ResNet-152 and Bert-qa, as shown in Fig. 7. Specifically, "Baseline" directly performs model swapping and then executes inference; "Pinned" uses a pinned memory pool for improved swapping performance; "Pipeline" overlaps model swapping and execution at the granularity of individual model parameters; "Group" groups parameters for efficient pipeline execution. We note that enabling pinned memory reduces overall latencies by around 35%; parameter-level pipeline execution further reduces the latency by 15%. By grouping model parameters, Torpor achieves up to 22% performance improvement over "Pipeline", especially for ResNet-152 that consists of many small-sized parameters.

7.2 Benefits of Torpor's Late Binding

GPU efficiency for low-frequency functions. With late binding, Torpor substantially reduces per-function memory footprint, thereby enabling the consolidation of many low-frequency functions for improved GPU efficiency. We stress-test its performance by executing multiple ResNet-152 functions on a single GPU, varying request rates between 80

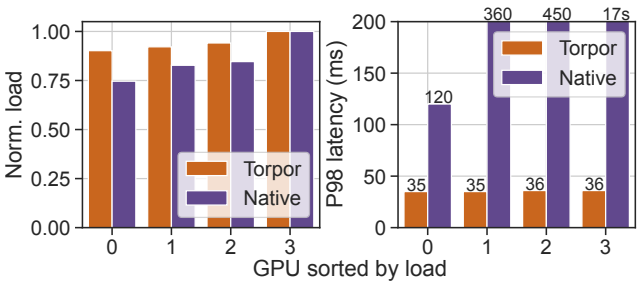

Figure 9: The normalized per-GPU load and the tail request latency with Torpor's late binding (Torpor) and Native.

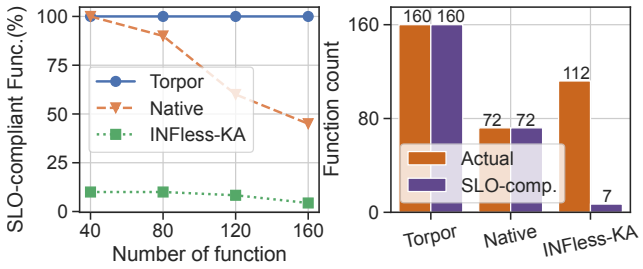

Figure 10: Performance comparison in terms of SLO compliance between Torpor, Native, and INFless-KA.

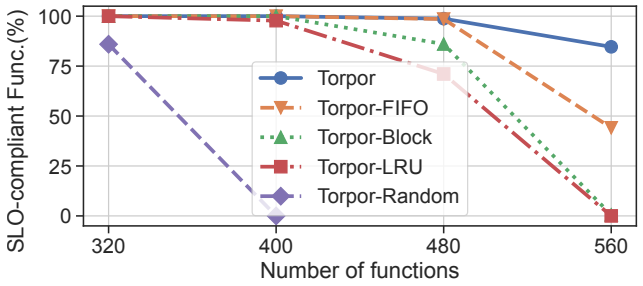

Figure 11: Ratio of SLO-compliant functions with the full Torpor and various different policies.

and 10 requests per minute (r/m)—a typical range of low-frequency functions in production traces (Fig. 2). In this setup, we execute sufficient concurrent functions on a GPU node to saturate GPU memory and ensure a high overall load. Fig. 8 compares normalized throughput and latency under Torpor and Native executions. Native's throughput declines as the per-function request rate decreases, due to its limited capacity to host many functions. In contrast, Torpor leverages host memory to accommodate many more functions, maintaining high throughput with efficient, request-level GPU sharing. For example, Torpor achieves over 10× higher throughput than Native at 10 r/m. Furthermore, even when model swapping is required, Torpor still keeps the tail latency below 50 ms.

Cross-GPU load balancing for high-frequency functions. We run 40 high-frequency ResNet-152 functions on a 4-GPU worker, where the average request rate is around 200 r/m. Fig. 9 shows the normalized per-GPU load and the tail request latency with Torpor and Native. Unlike Native, where GPUs hosting high-frequency functions can easily become overloaded due to bursts of requests, Torpor enables on-demand model migration for efficient load balancing. Therefore, Torpor achieves much less load variance across GPUs compared with Native, as shown in Fig. 9 (left). Moreover, Fig. 9 (right) shows the tail latency of requests executed on each GPU, where Native leads to extremely long tail latency (e.g., multi-seconds) due to high queueing delays. In contrast, Torpor consistantly delivers fast model inference, achieving a tail latency of around 35 ms on all GPUs.

7.3 Torpor at A Node

We next evaluate the performance of Torpor at a node. We use real-world workloads sampled from production traces (Fig. 2), where function request rates range from 5 to 30 r/m.

Performance comparison. We compare Torpor with two baselines, Native execution and INFless [58] — a state-of-the-art serverless inference system. INFless introduces a function keep-alive policy to set the lifespan of individual functions based on historical traces, denoted as INFless-KA. For a fair comparison, we implement the keep-alive policy of INFless (INFless-KA) in the Native system. Fig. 10 (left) shows the ratio of functions meeting SLOs in Torpor, Native, and INFless-KA. Fig. 10 (right) shows the numbers of functions being actually executed and being SLO-compliant, when hosting 160 functions. With fast model swapping, Torpor executes all 160 functions and also meets SLOs for all functions. In contrast, due to limited GPU memory, Native can only execute 72 out of 160 functions. INFless-KA can reclaim GPU memory via cleaning up idle functions, thereby enabling the execution of more functions (i.e., 112 functions) than Native; however, INFless-KA inevitably incurs function cold starts and results in only 7 functions being SLO-compliant.

Benefits of Torpor's policies. To understand the benefits of Torpor's policy designs, we compare the full Torpor with four baselines. 1) *Torpor-FIFO* uses a FIFO policy in request queueing rather than our SLO-aware policy (§5.2). 2) *Torpor-Random* disables our interference-aware scheduling and model swapping (§5.3), and randomly schedules a request to an idle GPU if the target model is not loaded, and then triggers model swapping. 3) *Torpor-LRU* adopts a LRU policy in model eviction rather than prioritizing models according to swapping overheads (§5.4). 4) *Torpor-Block* disables our block management policy (§4.4), and caches the released memory blocks in a single pool; when a new block is required, it directly returns a cached one in the pool if the requested size can be satisfied, otherwise it frees multiple blocks until the required memory space is available.

Fig. 11 shows the ratio of SLO-compliant functions. In particular, Torpor-FIFO is oblivious to SLOs and unable to properly prioritize functions, leading to serious SLO violations when the number of functions is large. Torpor-Block cannot reuse various-sized blocks and forces frequent memory allo-

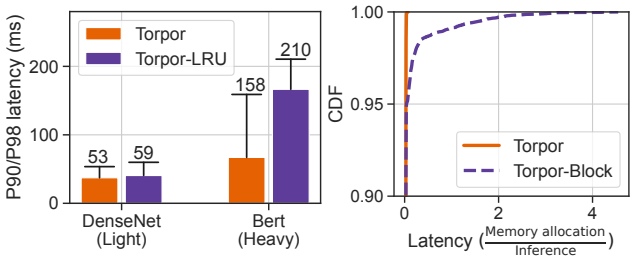

Figure 12: 90^{th} (bars) and 98^{th} (whiskers) tail latencies in `Torpor` and `Torpor`-LRU.

Figure 13: Latency CDF of memory allocation in `Torpor` and `Torpor`-Block.

cation via CUDA APIs, which incurs long delay in block allocation and harms overall performance. `Torpor`-LRU evicts heavy models often, leading to PCIe bandwidth contention during future model swapping. `Torpor`-Random leads to the worst performance due to its inefficient scheduling and model swapping policy, which does not exploit NVLink across GPUs and is oblivious to model heaviness. Compared with these baselines, `Torpor` successfully supports over 80% functions even with 560 functions, maximizing the number of SLO-compliant functions.

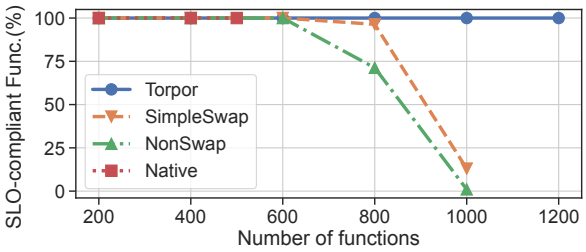
Efficiency of model heaviness. We evaluate the efficiency of model heaviness with `Torpor` and `Torpor`-LRU, using DenseNet-201 and Bert-qa as light and heavy models, respectively. Fig. 12 shows tail latencies of DenseNet-201 and Bert-qa in a mixed workload, where Bert-qa instances account for 60% of overall memory footprint. `Torpor`-LRU is agnostic to model heaviness and can evict heavy models frequently, leading to high tail latencies for Bert-qa that fail to meet its SLOs (200 ms). In contrast, `Torpor` effectively reduces tail latencies of Bert-qa without compromissing performance for DenseNet-201, achieving SLOs for both models.

Efficiency of memory allocation. Fig. 13 shows the distribution of the latencies of per-request memory allocation normalized to inference time, under `Torpor` and `Torpor`-Block. Due to efficient memory allocation and sharing (§4.4), `Torpor` incurs only negligible overhead. In contrast, `Torpor`-Block leads to high allocation overhead (e.g., over 4× than the actual inference time), harming the end-to-end performance.

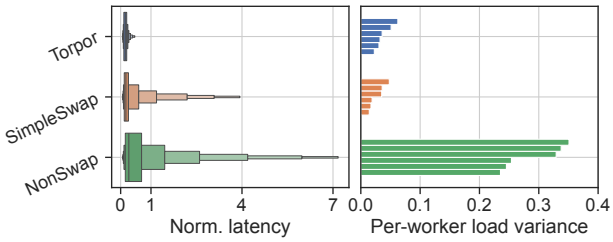
7.4 `Torpor` in A Cluster

We next evaluate `Torpor` in a cluster deployment with 6 GPU worker nodes. As running `Torpor` in a Alibaba Cloud cluster incurs additional system overhead, we set the SLOs for CV models and Bert-qa to 150 ms and 250 ms, respectively.

Baselines. We exclude INFless-KA from our cluster deployment due to its poor performance (see Fig. 10). We use three baselines: 1) *Native* uses native GPU containers bound to specific GPUs, which is the current practice in Alibaba Cloud. 2) *NonSwap* allows GPU remoting similar to `Torpor`, but disables model swapping, reducing memory footprint compared with Native. 3) *SimpleSwap* enables model swapping



(a) Ratio of SLO-compliant functions under `Torpor` and baselines.



(b) Distribution of per-request latencies normalized to deadlines (left) and the per-worker variance of GPU load normalized to the maximum (right), when running 1k functions. Boxes (left) depict the $1/128, 1/64, \ldots, 1/2, \ldots, 63/64, 127/128$ quantiles.

Figure 14: Cluster evaluation of `Torpor`.

compared with NonSwap. This approach only supports simple strategies as discussed in §7.3, including FIFO request queueing, random scheduling, and LRU model eviction.

Cluster evaluation. Fig. 14 compares `Torpor` with these three baselines. We first show the ratio of SLO-compliant functions under various number of functions. As shown in Fig. 14a, only `Torpor` can consistently meet per-function latency SLOs even with a large number of functions (e.g., over 1000). Native quickly saturates all GPU memory and only supports up to 500 functions, thus low GPU utilization. Compared with Native, NonSwap relaxes the constraint of GPU memory and enables more functions; however, it still fixes the binding between functions and GPUs, and causes GPUs overloaded by requests and leads to long tail latency. Moreover, while SimpleSwap outperforms NonSwap with model swapping, it still suffers from severe SLO violations with a large number of functions (e.g., 1k).

Fig. 14b compares the behaviors of `Torpor`, SimpleSwap, and NonSwap under 1k functions. We show the distribution of per-request latencies normalized to corresponding deadlines (left). In `Torpor`, almost every request can be served within its deadline, leading to a normalized latency less than 1. However, SimpleSwap and NonSwap suffer from long tail latency — over 4× and 7× of the respective deadlines. We also compare the per-worker GPU load of the three systems. For each worker node, we normalize the loads of its four GPUs to the maximum, and calculate the variance. Lower variance indicates better load balancing. Fig. 14b (right) plots the per-worker load variances of three solutions, each with 6 workers in total. Compared with NonSwap, `Torpor` and SimpleSwap

Table 5: Overview of Torpor's pilot production.

Metric	Value	Metric	Value
# of users	> 150	Users' cost savings	70% on avg.
# of GPUs	> 350	GPU savings	65%
# of daily requests	up to 465k		

can effectively balance GPU load across workers with model swapping, thus achieving much less load variance.

8 Torpor in Pilot Production

Torpor has been deployed in a pilot production cluster in Alibaba Cloud for beta testing. In this section, we present the testing results and our observations.

Overview of the pilot production. In the deployment, we employ a cost-efficient billing scheme in which users are charged only 10% of the GPU cost when their functions are inactive and retained in the host memory. This billing scheme aligns with Torpor's late binding mechanism and has attracted a variety of real-world inference workloads to Alibaba Cloud, including image processing, text generation, and image generation. Table 5 provides an overview of our pilot production system and the achieved savings. Currently, Torpor serves over 150 users in a cluster with more than 350 GPUs, handling up to 465k requests everyday. The system achieves an average cost savings of 70% for users compared to the previous approach of Alibaba Cloud that kept functions long-running on GPUs and billed users for the entire GPU time. Moreover, Torpor enables Alibaba Cloud to consolidate various functions for improved GPU utilization, resulting in a 65% reduction in the total number of required GPUs and cost savings for Alibaba Cloud.

Startup latency. Table 1 shows the performance of Torpor in the pilot production across various models, ranging from CNNs such as ResNet to LLMs like Llama. In the production environment, Torpor prioritizes user isolation and manages a dedicated GPU runtime for each function. Hence we also provide a detailed breakdown of the time required for model loading and runtime resumption in Table 1. Compared to cold starts in Alibaba Cloud, Torpor reduces model startup latencies by over an order of magnitude, e.g., cutting Llama2-13B's startup time to 4.4 seconds—a delay that is acceptable considering that generating all output tokens for a query can take tens of seconds [30, 68].

Case study. We next present a case study of a realistic GPU function in our pilot production, which involves text generation from input images. This function is invoked several thousands times per day and follows a request arrival pattern similar to Fig. 1. Without Torpor, this function would need to be kept long-running on a GPU for low inference latency, resulting in high GPU costs. Fig. 15 depict latency distribution and user cost of this function. For confidentiality reasons, we normalize the latency of model (and runtime) loading to the

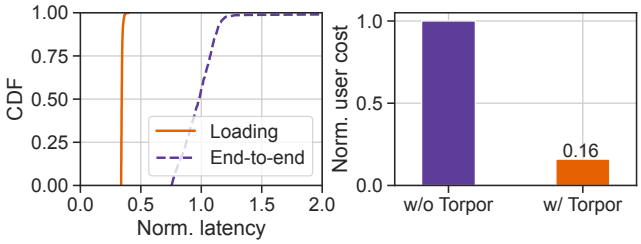


Figure 15: Latency distribution and user cost of a realistic GPU function in Alibaba Cloud.

mean of end-to-end times, and the cost to that of long-running GPU functions (i.e., w/o Torpor). The loading duration is consistent, as shown in Fig. 15 (left), which accounts for only ∼30% of the overall latency. Fig. 15 (right) illustrates the user cost, where Torpor reduces the total cost by 84% compared to the previous approach in Alibaba Cloud. Based on this real-world use case, Torpor achieves significant cost savings without compromising end-to-end performance, proving to be an effective solution for serverless inference.

Discussion. We have identified three challenges that require further investigation based on our experiences with the production cluster. *(1) Extremely infrequent functions:* We have observed that some functions are invoked extremely infrequently (e.g., a few requests per hour). However, these functions still result in substantial user costs due to their host memory usage. To address this, we plan to explore the utilization of cheaper storage for low-demand functions and investigate a multi-tier storage architecture that dynamically adapts to request patterns for improved resource and cost efficiency. *(2) Very large models:* While Torpor's late–binding design is versatile and has been applied to large models (Table 1), it currently does not support model-parallel execution across multiple GPUs. To accommodate very large models spanning multiple GPUs or nodes, it is crucial to enable efficient model partitioning and parallelization that integrates with Torpor's model-swapping mechanism. Therefore, we intend to extend Torpor to leverage various interconnects, including PCIe and NVLink (Fig. 5), for enhanced model parallel and pipeline execution. *(3) Highly bursty workloads:* While Torpor is primarily designed for efficient resource sharing among many low-frequency functions (Fig. 2), some functions may experience highly bursty workloads with short periods of extensive request arrivals. To handle such spikes, Torpor can proactively maintain host-memory-cached model replicas across multiple nodes, mitigating cold starts at the cost of increased memory usage. We plan to explore high-speed inter-node networks (e.g., RDMA) for efficient model loading between nodes, which can reduce memory footprint while maintaining low-latency model startup.

9 Related Work

Serverless Inference. In addition to the serverless platforms discussed in §2.2, there are several recent works on serverless

inference. StreamBox [56] and Dilu [43] support spatial GPU sharing for concurrent model execution; FaaSTube [55] improves data sharing within inference workflows. These works are orthogonal to Torpor and can be integrated for enhanced performance. ServerlessLLM [30] and Medusa [64] propose cold-start optimizations specialized for large language models, which is complementary to Torpor and can be used to accelerate those specific models.

Host-to-GPU data swapping. Many other systems have leveraged host-to-GPU data swapping in general deep learning and GPU workloads [23, 32, 34, 39, 46, 50, 57, 63]. For example, vDNN [46], Salus [63] and SwapAdvisor [34] leverage host memory for deep learning jobs with large GPU memory footprints; Batch-aware [39] and HUVM [23] optimize GPU memory access for general-purpose workloads; POS [35] supports efficient GPU checkpointing and restoring. Compared with Torpor, these systems are not specifically designed for model inference and do not account for its SLO attainment. Inference systems such as PipeSwitch [22] and DeepPlan [36] improve host-to-GPU model loading for fast switching. Unlike Torpor, these systems require detailed model-specific knowledge and do not target meeting model-level SLOs in a shared, multi-tenant serverless environment.

GPU remoting. GPU remoting techniques have been employed in different layers for GPU virtualization [28, 31, 45, 59]. Existing solutions like GVirtuS [31] and rCUDA [28] primarily focus on general-purpose workloads. Torpor applies GPU remoting in serverless inference, leveraging its characteristics for asynchronous, low-latency API redirection.

Spatio-temporal GPU sharing. Existing techniques have investigated the spatial and temporal GPU sharing to improve overall utilization [2, 13–15, 24, 33, 51, 56]. These techniques are orthogonal to Torpor and can be directly applied, which allow partitioning a physical GPU into multiple virtual instances to late-bind more functions.

10 Conclusion

This paper introduces Torpor, a serverless platform for SLO-aware and GPU-efficient model inference. Torpor employs a late binding approach, managing inference functions in host memory and dynamically swapping them to a pool of GPUs upon request arrivals. This approach enables pay-per-GPU-use billing and maximizes resource utilization. Additionally, Torpor proposes request scheduling and model management policies to meet latency SLOs for inference functions while minimizing resource costs. Torpor has been beta released in a large commercial serverless platform, successfully serving up to 465k requests per day and achieving 70% and 65% GPU cost savings for users and the platform, respectively.

Abstract

Low-Rank Adaptation (LoRA) is a popular approach that adapts a base large language model (LLM) to domain-specific tasks by adding lightweight trainable adapters. In this paper, we present TOPPINGS, a system that efficiently serves many LoRA adapters derived from a common base LLM. TOPPINGS pins the base model on GPUs and dynamically loads the requested LoRA adapters from host memory as new requests arrive. In view of the high GPU loading overhead, which not only delays the time-to-first-token of the newly arrived request but also *interrupts* the ongoing decoding of *all* inflight queries when continuous batching is in use, TOPPINGS proposes a *CPU-assisted* LoRA serving approach. It simultaneously uses CPUs to compute the lightweight adaption for prefilling as the requested LoRA adapter is being loaded onto GPUs; it then switches to the GPUs after loading completes to resume the remaining computation. TOPPINGS develops a highly optimized synchronization mechanism and pipeline loading scheme to efficiently coordinate LoRA computation on the CPUs and GPUs. TOPPINGS further designs a *rank-aware scheduling algorithm* that optimally schedules heterogeneous LoRA requests to maximize the SLO attainment. Compared with the state-of-the-art LoRA serving systems, TOPPINGS improves the average request serving latency by up to 1.7× and achieves an SLO attainment of up to 99%.

1 Introduction

Large language models (LLMs) are making significant strides in generative AI [50, 60]. Deploying LLMs for domain-specific tasks requires specialization [3, 4, 12, 33, 34], which involves adapting a pre-trained base model to different downstream tasks. Low-Rank Adaptation [7, 12, 22] (LoRA) has emerged as a popular parameter-efficient fine-tuning (PEFT) approach. It preserves the base model's parameters and adds small trainable rank decomposition matrices to each Transformer layer, allowing the creation of numerous lightweight LoRA adapters from a single base model. As LoRA gains popularity, efficiently serving them with LLMs in a multi-tenant cloud becomes critically important [6, 34, 42, 46, 54].

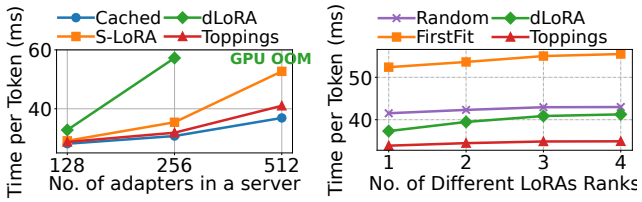

Figure 1: Time per token (TPT) performance on Llama2-7B. CACHED: the ideal case. **Left**: server node performance of existing works. **Right**: cluster-wide performance under different scheduling methods.

Typical LoRA serving systems maintain thousands of LoRA adapters on inference servers, offering APIs for end users to access specialized LLM inference [6, 35, 42, 46, 54]. Critical to the serving efficiency is *multiplexing a single base LLM* to facilitate multi-tenant LoRA serving [6, 42], where an inference server can serve requests to different LoRAs in a batch using one LLM. *Within a server*, the base LLM runs on GPUs and a stock of LoRAs reside in host memory. The server node takes two steps to serve new requests, adhering to the *continuous batching* paradigm [24, 26, 31, 56]. First, it interrupts the inference of running batch, loads demanded LoRA adapters onto GPUs, and executes the *prefill* computation for the new requests. Second, it includes the new requests into the running batch and executes the *decoding* computation for the entire batch. *At the cluster scale*, a scheduler receives users' requests and routes them across server nodes to maximize throughput [6] or ensure load balancing [54].

Despite the capability of batch serving and request orchestration, existing systems overlook two fundamental challenges in large-scale multi-tenant LoRA adapter serving [6, 42, 54].

First, on-demand loading LoRA adapters onto GPUs for new requests introduces high latency overheads. Specifically, when the desired LoRAs for new requests are not present on GPU, they must be fetched from host memory before *prefill* can commence, which can take tens of milliseconds

[*]Equal contribution

depending on the adapter size and PCIe bandwidth [15]. Consequently, this *delays* not only the time-to-first-token of the arriving request, but also the ongoing decoding of *all inflight requests*. Notably, LoRA loading is more than one-off overhead. As new requests keep arriving, the decoding of inflight requests frequently interrupts, *cumulatively* delaying token generations by 49% on average in our experiments (§2.3).

Second, in multi-tenant LoRA serving, users often request heterogeneous LoRA adapters with varying LoRA ranks [7, 12, 42]. Though heterogeneous adapters can be batched together to multiplex one base LLM using specialized CUDA kernels [6, 42], disregarding the heterogeneity and batching LoRAs blindly can increase the batch decoding latency by up to 1.5×. This increase is due to the high GPU memory I/O overheads introduced by large-rank LoRAs, which also impact the low-rank LoRAs computation in the same batch [6, 42]. Therefore, at the cluster level, the system should judiciously schedule requests of heterogeneous LoRAs to ensure that the heterogeneity does not compromise SLOs in latency. This necessitates the scheduler to accurately model the inference latency for a given batch of heterogeneous adapters, which is challenging due to the combinatorial complexity of batching heterogeneous adapters.

We introduce TOPPINGS[*], a new multi-tenant LoRA serving system to address these challenges. Compared to previous practices in LoRA serving, TOPPINGS improves efficiency and scalability of multi-tenant LoRA serving: it effectively scales to serve more LoRAs within a server and accommodate higher heterogeneity in a cluster (Fig. 1). TOPPINGS achieves this with two novel designs, which we elaborate as follows:

CPU-assisted LoRA serving. Similar to the existing LLM-multiplexing solutions [6, 42], TOPPINGS maintains the base LLM on GPUs and all adapters in host memory. When a new request arrives, TOPPINGS dynamically loads the desired adapter onto the GPU with a *loading pipeline* (§4.1). Meanwhile, it *concurrently* utilizes CPUs to compute *the LoRA adaption* to early-start the *prefill* computation. As a PEFT approach, LoRA computation is lightweight, with computational load in the order of 1 GFLOPs, making it feasible to run on CPUs. Once adapter loading completes, TOPPINGS switches to the GPU to handle adaption and the remaining prefill computation, if not finished. It then proceeds to decoding, together with other inflight requests that were previously interrupted by the new arrival under continuous batching [24, 26, 31, 56].

Nevertheless, implementing CPU-assisted LoRA serving poses several challenges. LLMs are constructed using the Transformer architecture, which consists of multiple attention layers [52]. During inference, the computed output of the base LLM needs to be synchronized with that of the LoRA models at each layer. Since these computations are split between the CPU and GPU, efficient layer-wise synchronization between the two processors is crucial to performance. Also, the frequent triggering of LoRA computations (e.g., 32 times per prefill in Llama2-7B [50]) leads to high invocation overheads, such as inter-process communication (IPC) and data transfer, increasing inference latency by 79.4% in our experiment. Moreover, CPUs' constrained parallel processing capabilities may create a new bottleneck when computing adaption for long prompts, especially in comparison to GPUs.

We address these challenges with a series of optimization designs. To efficiently coordinate on-GPU LLM computation and on-CPU LoRA computation, TOPPINGS develops a specialized CUDA operator that optimally overlaps the two computations by means of asynchronous memory copy and signaling. It also uses shared memory for fast data exchange between the base LLM process and multiple CPU LoRA processes without data copying and (de)serialization, reducing the LoRA invocation overhead to less than 1 ms. Furthermore, TOPPINGS designs a profiling-guided parallelization scheme to scale out LoRA computations across multiple CPUs, so as to eliminate the potential bottleneck. Together, TOPPINGS accelerates the request serving by 1.7× on average (§7.2).

Rank-aware request scheduling. We observe significant performance variations in decoding when batching different sets of heterogeneous LoRA adapters (§2.3). This highlights the need for intelligent request scheduling that takes into account the *rank heterogeneity* and its impact on decoding. To this end, we construct a performance model based on kernel profiling and characterization [6, 42]. This model can accurately predict the decoding latency for a given batch of heterogeneous adapters, despite the combinatorial complexity of batching heterogeneous adapters. With the performance model, we design a *rank-aware scheduler* to enhance cluster-wide serving performance and meet latency SLOs. Specifically, when a new request arrives, the scheduler examines all inference servers that possess the desired LoRA adapters and evaluates a *cost score* for each server using the performance model. This score measures the additional latency cost and SLO violation risk on the current ongoing requests if the new request were to be served on that server. The scheduler then routes the request to the server with the minimum cost score.

We have implemented TOPPINGS based on LightLLM [31] and evaluated its performance using Llama2-7B/70B [50] with requests generated from real-world and synthetic traces [40, 61]. Evaluation results show that TOPPINGS outperforms S-LoRA [42] and dLoRA [54], the state-of-the-art solutions, improving the average serving latency of inference requests by up to 1.7×. Even compared to the ideal, yet non-implementable baseline that caches all adapters on GPUs (no loading), TOPPINGS incurs only 7% overhead. We further tested TOPPINGS with long prompts of 2k to 30k tokens and observed consistent advantages. Additionally, we evaluated the rank-aware scheduling algorithm through testbed experiments and large-scale simulations. Compared to the popular scheduling policies used in existing systems [6, 54], TOP-

[*]"Topping" is a layer of food added to another food base to enhance flavor. Here, it metaphorically refers to a LoRA that adapts a base LLM's outputs.

PINGS reduces the average time per token by up to 57% and achieves an SLO attainment of 99%.

2 Background and Motivation

In this section, we give a primer to LLM inference and low-rank adaptation (LoRA). We also discuss the key challenges that arise when serving LoRA models in a multi-tenant cloud.

2.1 LLM Inference

Generative LLM inference. LLM inference is a process that involves generating a sequence of output tokens in response to an input prompt. This process consists of two phases: *prefill* and *decoding*. During the prefill phase, the LLM processes the prompt to generate the first response token and the key-value cache (KV cache) for each token; the decoding phase then uses the previous KV cache to generate new tokens iteratively and appends the KV cache accordingly. The decoding phase continues until a specified condition is met, such as emitting an end-of-sequence (<eos>) token.

LLM adaption. Parameter-efficient adaptation of LLMs enhances their performance for domain-specific tasks [33,34,46]. One popular approach is Low-Rank Adaptation or LoRA [22], which introduces an *adapter* to modify the intermediate LLM inference results while keeping the original LLM parameters unchanged. Specifically, given a pre-trained LLM weight matrix $\mathbf{W} \in \mathbb{R}^{H_1 \times H_2}$, an adapter consists of two low-rank matrices $\mathbf{A} \in \mathbb{R}^{H_1 \times r}$ and $\mathbf{B} \in \mathbb{R}^{r \times H_2}$, where r is the LoRA rank. LoRA adapts this weight matrix to $\mathbf{W}' = \mathbf{W} + \mathbf{AB}$. Let $\mathbf{y}$ be the original output of this layer given by $\mathbf{y} = \mathbf{xW}$. With LoRA adaption, the updated computation becomes

$$\mathbf{y}' = \mathbf{xW} + \mathbf{xAB} = \mathbf{xW}'. \quad (1)$$

The LoRA adapter is highly efficient in terms of parameter space because the rank $r \times (H_1 + H_2) \ll H_1 \times H_2$. Therefore, LoRA adaption is widely applied in the attention modules of transformer-based LLMs [22, 42]. When deploying LoRA-adapted models for inference, the computation load required by the LoRA adapter (**xAB**) is orders of magnitude smaller than that of the original weights **xW** in terms of floating-point operations, if we compute these two parts separately [6].

2.2 Multi-Tenant LoRA Serving

The need of LLM-multiplexing. A naive way to serve a LoRA adapter [22] is to *merge* its weights into the weights of the base LLM. However, this approach does not scale to multi-tenant LoRA serving: because one base model can only merge with one adapter at a time, serving n different LoRAs requires duplicating n copies of the base LLM, wasting GPU memory and missing opportunities for batch inference [26].

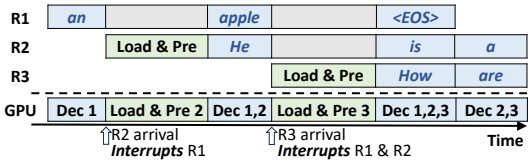

Figure 2: Continuous batching in which the decoding phase (Dec) is preempted to perform prompt processing upon a request arrival, which involves loading the requested LoRA adapter (Load) and prefilling (Pre).

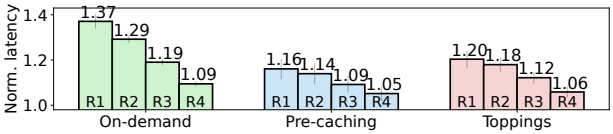

Figure 3: The normalized serving latency of first four identical LoRA requests (rank=128, 128 input tokens, 32 output tokens) with inter-arrival of 200ms under different approaches.

In practice, many LoRA adapters are developed based on common LLM series (e.g., Llama2 [50]), and multiple LoRA adapters originating from the same LLM can multiplex that LLM for GPU-efficient inference. This can be achieved by computing LoRA adaption **xAB** on the fly and adding this result back to the intermediate results **xW** before subsequent computations. As the computation of **xAB** is lightweight, multiple LoRA computations can be batched during inference.

Continuous batching. Existing LLM serving systems employ the *continuous batching* strategy optimized for LLM's iterative auto-regressive generation process [1, 24, 26, 31, 56]. Continuous batching operates at the iteration level, where completed requests are immediately removed from the running batch after each iteration and new requests can join the running batch in just one iteration, without waiting for the entire batch inference to complete. Continuous batching significantly improves the token generation throughput while minimizing the request queuing delays. Fig. 2 illustrates this batching process used in existing systems [24, 26, 31], where the decoding and prefill phases interleave as new requests arrive. Upon a request's arrival, the decoding phase (Dec) is preempted by prompt processing, which involves loading the requested LoRA adapter (Load) and prefilling (Pre). During this period, all the inflight requests are suspended, resulting in a decoding interruption. Once prompt processing completes, the new request joins the running batch, and the system combines them together to continue the decoding process.

Underutilized CPUs. LLM inference highly demands GPUs while CPUs are often underutilized. Recent LLM cluster analysis reveals that the median GPU utilization is 99%, whereas the CPU utilization is less than 10% for 75% nodes [23].

2.3 Challenges

However, simply enabling LLM-multiplexing and continuous batching is insufficient to achieve optimal performance for

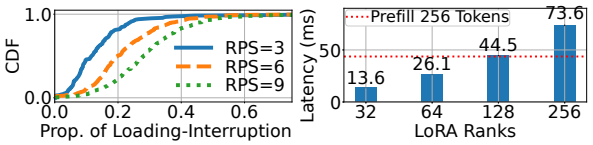

Figure 4: Left: The proportion of decoding-interruption overhead during the entire token generation of each request. Right: The latency of loading a single adapter of different ranks. The adapter applies to the projection matrices of a Llama2-7B. Prefilling 256/1k tokens takes 44ms/90ms, respectively, longer than 90%/99% of prompts in the real-world dataset [61].

multi-tenant LoRA serving, as it imposes two challenges.

C1: High cumulative decoding-interruption overhead. To save GPU memory, existing systems only cache the base LLM on GPU while keeping all its LoRA adapters in host memory [6, 42]. When a new request arrives, the corresponding adapter is loaded from the host to the GPU, initiating an adapter loading that must complete before the prefill phase can begin (Fig. 2). This results in a severe cold-start problem, where adapter loading can take between a few to tens of milliseconds depending on the adapter size* (Fig. 4-Right). Cold-start delays the time-to-first-token of the prefill request and becomes even more detrimental under continuous batching, where the arrival of a new request interrupts the ongoing decoding of all inflight queries (e.g., R3's arrival interrupts R1 and R2 in Fig. 2). Consequently, the cold-start latency adds to the decoding-interruption overhead, delaying all inflight requests. To illustrate this problem, we set up a simple experiment where five identical LoRA requests sequentially arrive, with the i-th arrival interrupting the decoding of the ongoing $i-1$ requests. Fig. 3 illustrates the output generation latency of the first four requests normalized by that of the last one with different serving approaches. Compared to pre-caching all adapters on GPU, the cold-start introduced by on-demand loading cumulatively extends the decoding interruption: earlier requests observe longer latency as they are delayed by more cold starts of late arrivals.

In a scenario where new requests keep arriving, the decoding of inflight requests is frequently interrupted, resulting in a significant *cumulative delay* in token generation. We empirically validate this by multiplexing a Llama2-7B model with 512 LoRA adapters (rank=64). These adapters have skewed popularity (Fig. 12-Left) following the Microsoft Azure Function (MAF) trace [40]. We configured Poisson request arrivals with various aggregate loads. Fig. 4-Left shows the proportion distribution of the cumulative decoding-interruption overhead, which, on average, accounts for 13%, 22%, and 29% of the entire request serving time when the aggregate load is 3, 6, and 9 requests per second (RPS), respectively. The median number of interruptions per request is 4 when RPS=3 and increases to 10 and 25 as the RPS increases to 6 and 9, respectively.

*Larger adapters are increasingly common as they usually allow LLMs to generate better response [7, 12, 51, 55].

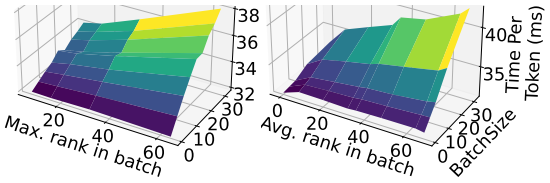

Figure 5: The decoding latency variation of batching heterogeneous LoRA adapters. Left: `BGMV`. Right: `MBGMV`.

To avoid adapter loading, a simple approach is to pre-cache all LoRA models in GPU. However, this approach is expensive: a single rank-64 adapter that adapts attention projection weights $\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_V$ of the Llama2-7B demands approximately 100 MiB, equivalent to the size of a KV cache of 200 tokens. Pre-caching all adapters will swallow up GPU memory, degrade system throughput significantly [26], and cause GPU out of memory (OOM) errors (§7.2). A recent production trace [27] reveals that LoRA invocations follow a long-tailed distribution. Achieving a 50% hit rate requires caching over 200 LoRAs, which consumes more than 20 GiB of GPU memory for Llama2-7B. This is not well justified as most GPU memory should be reserved for KV-cache to maximize throughput [26].

C2: Cluster-level request scheduling for heterogeneous LoRA serving. In multi-tenant LoRA serving, users often request to use heterogeneous LoRA adapters with varying ranks [7, 42, 51, 55]. These heterogeneous adapters can be batched together to multiplex one base LLM using specialized kernels, such as the Batched Gather Matrix-Vector Multiplication (`BGMV`) kernel in Punica [6] or the Multi-size Batched Gather Matrix-Vector Multiplication (`MBGMV`) kernel in S-LoRA [42]. Rank heterogeneity in a batch of adapters directly affects their serving performance. Specifically, when batching a set of heterogeneous LoRA adapters, `BGMV` pads adapters of smaller ranks to the highest rank to perform batch operations, while `MBGMV` does not use padding [42]. As a result, `BGMV`'s performance is determined by the maximum rank in the batch, whereas `MBGMV`'s performance depends on the average rank. We measure the decoding latency of batch serving heterogeneous LoRAs using these two kernels with various batch configurations, and depict the results in Fig. 5. We observe significant performance variations when batching different sets of heterogeneous adapters. With the same batch size, rank heterogeneity can increase batch decoding latency by 28%. This highlights the need for *intelligent request scheduling* that considers the impacts of rank heterogeneity on performance to satisfy SLO.

To illustrate this point, we refer to a toy example shown in Fig. 6, where Instance 1 handles 24 requests with LoRA rank=32, and Instance 2 runs 16 requests with rank=64. Using Punica's `BGMV` kernel, the decoding latencies are 34.8 ms and 35.8 ms for Instances 1 and 2, respectively. With S-LoRA's `MBGMV`, the latencies are 35.3 ms and 35.9 ms for Instances 1 and 2, respectively. Assume a decoding latency SLO of 36ms,

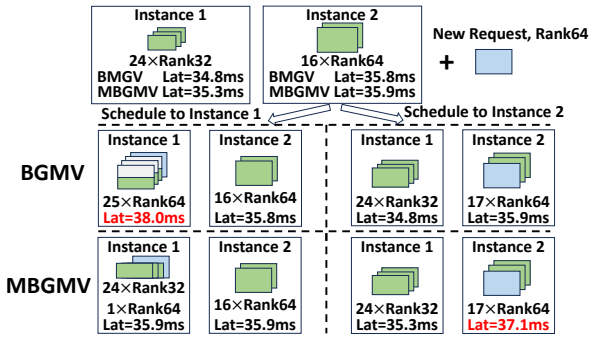

Figure 6: An toy example illustrating performance variations when scheduling a single request. With a decoding latency SLO of 36 ms, the new request should be routed to Instance 2 with BGMV, while Instance 1 with MBGMV.

System	Cumulative **loading** overhead	**(un)merging** overhead	Multi-LoRA **computation**	Cluster-wide **scheduling**
Punica [6]	High	Zero	Fast	Rank-agnostic
S-LoRA [42]	High	Zero	Fast	Rank-agnostic
dLoRA [54]	Zero	High	Slow	Rank-agnostic
TOPPINGS	Low	Zero	Fast	Rank-aware

Table 1: Comparison of existing systems on server efficiency (LoRA loading, merging, computing) and cluster scheduling.

and we need to determine the optimal schedule for a new request with rank=64. With the BGMV kernel, assigning the request to Instance 2 would meet the SLO, while sending it to Instance 1 would increase the maximum rank of the batched requests to 64, resulting in an SLO violation due to the processing of 25 higher-rank requests on Instance 1. However, with MBGMV, where latency is proportional to average LoRA ranks, scheduling the request to Instance 1 preserves the SLO, while routing it to Instance 2 leads to a violation.

However, modeling serving latency based on the rank heterogeneity is challenging due to the combinatorial complexity. With a common *maximum* serving batch size $B = 64$ and a small number of $N = 5$ different LoRA types, there are a total of $\sum_{b=1}^{B} \binom{N+b-1}{b} \approx 1.1 \times 10^7$ different rank combinations.

2.4 Concurrent Work and Their Inefficiency

Model serving system design primarily aims optimizing serving efficiency within a server and request scheduling across a cluster [20, 54, 59]. In Table 1, we compare concurrent adapter serving systems [6, 42, 54] in terms of adapter loading and computing within a server, and scheduling at the cluster scale.

Adapter loading. By default, both Punica [6] and S-LoRA [42] load adapters on demand, leading to high cumulative decoding-interruption overhead (**C1**), which we elaborate in evaluation (§7). Though S-LoRA suggests using predictive prefetching, it does not provide details, and frequent mispredictions are expected given the bursty inference request workloads [54, 59]. dLoRA [54] pre-caches all LoRA adapters into GPUs. Though pre-caching avoids loading overhead, it fall shorts in serving a large number of adapters, causing GPU OOM or degraded performance in our evaluation (§7.2).

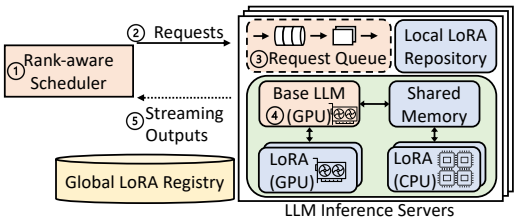

Figure 7: An architecture overview of TOPPINGS.

Multi-LoRA computation. Critical to the inference efficiency is LLM-multiplexing. Notably, Punica [6], S-LoRA [42], and TOPPINGS adopt efficient GPU kernels for the on-the-fly LoRA computation (§2.2). dLoRA [54] proposes a *dynamic batching* approach, which dynamically merges adapters with the base model to serve requests of the same adapter in a batch and unmerges adapters to serve requests of different adapters. However, deciding when to merge and unmerge adapters during inference introduces additional overhead [54] and results in slow computation, as evident in §7.2.

Scheduling. Despite the impact of heterogeneous LoRA adapters on request scheduling, the cluster scheduling policy in concurrent systems [6, 42, 54] are rank-agnostic, resulting in significant delays that violate SLOs (§7.4).

3 TOPPINGS Overview

In this section, we provide a high-level overview of TOPPINGS, a LoRA serving system that efficiently tackles the two challenges mentioned earlier. Within a server, TOPPINGS uses a *CPU-assisted* approach to hide the long cold-start latency. It uses CPUs to simultaneously execute the requested LoRA adapter while loading it onto the GPU, effectively overlapping the adapter loading with the *prefill* computation (§4) to mitigate the cumulative decoding-interruption overhead. At the cluster scale, TOPPINGS optimizes the scheduling of requests to heterogeneous LoRA adapters using a *rank-aware* scheduling algorithm, significantly enhancing cluster performance and SLO compliance (§5). Fig. 7 illustrates the system architecture, which consists of a cluster of LLM inference servers, a scheduler, and a global LoRA registry.

LLM inference server. Each LLM inference server maintains a long-running service of the base LLM on the GPU. It also stores a set of heterogeneous LoRA adapters in an in-memory *local LoRA repository*. During inference, the server coordinates LoRA computations on the CPU and GPU. Specifically, it adapts the BGMV kernel from [6] to perform LoRA computation efficiently on the GPU. For CPU-based LoRA execution, it utilizes four techniques to enhance its efficiency: 1) pipelined adapter loading, 2) asynchronous invocation, 3) shared memory data transfer, and 4) profiling-guided parallelization, which we elaborate in §4.

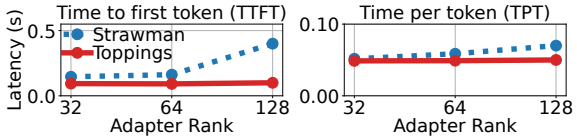

Figure 8: Performance of Llama2-7B on A100. The strawman solution increases TTFT by up to 4× and TPT by up to 1.4×.

Rank-aware scheduler. The scheduler receives requests and routes them to the appropriate servers to meet SLOs. To make informed scheduling decisions, it uses a performance model to predict the latency cost by considering the rank heterogeneity of the serving batch, which we explain in §5.

Global LoRA registry. It stores the metadata of all adapters, such as the LoRA ranks, the path to their weights file, etc.

Workflow. As illustrated in Fig. 7, new requests arrive at the scheduler (①), which uses the rank-aware scheduling algorithm described in §5 to route them to appropriate inference servers (②). Following the continuous batching strategy [56], the LLM inference server fetches requests from the request queue (③) and provides generative inference services using the corresponding LoRA adapters (④). New tokens generated by the LLM are then streamed back to the users (⑤).

4 CPU-Assisted LoRA Serving

In this section, we present TOPPINGS's design of CPU-assisted LoRA serving to address the high cumulative decoding-interruption overhead (§2.3). We start with a strawman solution. Then, we proceed to describe LoRA computation on GPU and CPU and discuss the challenges of efficiently combining the two executions to reduce the decoding-interruption overhead (§4.1). We then present optimization techniques that address these challenges (§4.2).

Strawman Solution. To reduce the cumulative decoding-interruption overhead, a strawman solution is to overlap adapter loading with ongoing decoding. That is, when a new request arrives, the system asynchronously loads its adapter onto the GPU without interrupting the ongoing decoding of inflight requests. When the adapter is fully loaded, the system then switches to the prefilling computation of the new request. Though the strawman solution can avoid decoding interruptions, it makes new requests suffer from longer loading overhead and degrades serving performance (Fig. 8), especially the time-to-first-token (TTFT), which is the time required to generate the first output token and is critical to user experience [11]. The strawman solution motivates TOPPINGS to early-start the *prefill* with LoRA computation on the CPU.

4.1 LoRA Computation on GPU and CPU

A parameter-efficient adapter, LoRA requires lightweight computation (§2.1) and can run on either GPU or CPU.

GPU LoRA. As the base LLM is "pinned" on GPU, running LoRA adapters on the same device saves the communication overhead and is usually more efficient than running them on CPU. To maximize the token throughput, LoRA computations (i.e., **xAB** in Eq. (1)) are batched in each attention layer during base LLM inference. This can be achieved with a specialized CUDA operator [6, 42]. In TOPPINGS, we adapt the Batched Gather Matrix-Vector Multiplication (`BGMV`) operator [6], which parallelizes the LoRA weight gathering and computation for efficient execution. The LoRA output is then added to the base output in the self-attention computation, following in Eq. (1). For an efficient implementation, we incorporate the operators of GPU LoRA computation into the base LLM inference process, as shown in Fig. 9.

CPU LoRA. LoRA computation, which is highly lightweight at approximately 1 GFLOPs (§2.1), can also be executed using CPUs. However, computing LoRA on CPUs requires *layer-wise synchronization* with the base LLM inference running on the GPU. Specifically, at each attention layer, the base inference process transfers the input tensor **x** in Eq. (1) from the GPU device memory to the host memory (Fig. 9). The CPU LoRA process then performs computation and transfers the result **xAB** back to the GPU device. Meanwhile, the base inference process proceeds to compute **xW**, which is finally adapted with the received LoRA output following Eq. (1). Though CPU LoRA requires synchronization, it can start immediately as the LoRA weights are already in memory. We hence utilize it to mitigate cold start and the cumulative decoding-interruption overhead in GPU LoRA.

CPU-assisted LoRA serving with pipeline loading. When a new request arrives and the corresponding adapter is not available on the GPU, the server fetches it from host memory and, in the meantime, early-starts its *prefill* computation using the CPU LoRA instead of waiting for the adapter loading to complete. As an adapter has a layered structure as the base LLM, we design a *pipeline loading* scheme to overlap communication and computation [5]. Given an adapter with N layers, we divide it into M layer groups. TOPPINGS uses the CPU to compute the first layer group, while in the meantime loading the second layer group onto the GPU. TOPPINGS carefully determines the group size to ensure that CPU computation and GPU loading of one layer group complete at around the same time by profiling the latency of CPU LoRA computation, adapter loading and GPU LoRA computation. Starting from the second group, the GPU pipeline is established, allowing TOPPINGS to parallelize GPU computation of the m-th group and GPU loading of the $(m+1)$-th group, where $m = 2, 3, \ldots, M-1$. In case of latency variations in LoRA loading and LoRA computation, Toppings can dynamically decide where to execute LoRA computation during inference. If the weight of the LoRA model layer has been loaded, Toppings executes the LoRA computation on the GPU; otherwise, it executes it on the CPU. Pipeline loading is particularly ef-

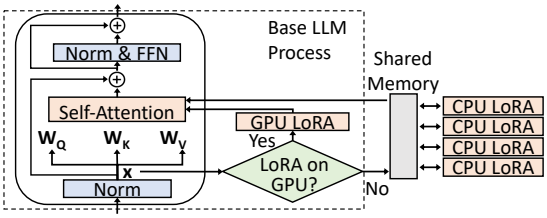

Figure 9: Illustration of coordinated LoRA computation on GPU and CPU per transformer block's attention layer.

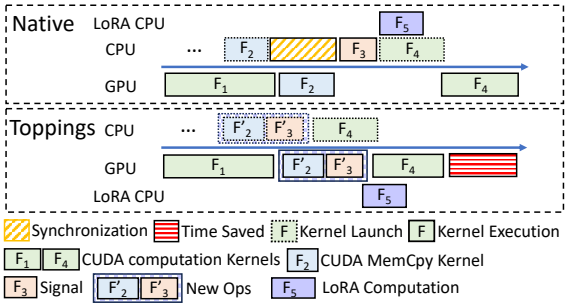

Figure 10: Execution timeline of Native LoRA Invocation using default CUDA synchronize primitives and LoRA Invocation with TOPPINGS's operator in base LLM process.

fective when serving large adapters (e.g., rank > 64), reducing the prefill latency by up to 15% compared with no pipelining ($M = 1$), as shown in §7.3.

Fig. 9 shows the orchestrated CPU and GPU LoRA computations, where CPU LoRAs run as isolated, concurrent processes for resource/failure isolation and better performance.

Challenges. Hosting LoRA computation in isolated CPU processes poses three challenges to system implementation. First, running LoRA in CPU processes requires *layer-wise synchronization* between the GPU-based LLM inference to ensure data validity. Second, frequent triggering of LoRA computation in each attention layer leads to high invocation overhead, such as inter-process data transfer. Third, using CPU to compute adaptation can be slow given its limited parallelization capability, especially when the prompt is long.

4.2 Efficient GPU-CPU LoRA Coordination

In this subsection, we tackle the system challenges mentioned earlier with three optimization techniques.

Sync-free CPU LoRA invocation. Most LLM serving systems achieve low latency through asynchronous GPU computation in PyTorch-like frameworks [26, 31, 42, 50]. By default, GPU operations (e.g., CUDA kernels) are executed asynchronously. They are first launched on CPU and enqueued to the GPU device queue, but not necessarily executed until later. For example, in Fig. 10, CUDA kernel F_2 is first launched on CPU, and then executed on GPU asynchronously. The order in which the kernels are added to the stream dictates their execution order. Hence, adapter serving requires careful coordination between base LLM inference running on GPU and LoRA invocation running on CPU to ensure correctness and good performance.

In native PyTorch, having the base LLM process invoke CPU LoRA requires explicit synchronization, which *blocks* subsequent kernels from launching. To illustrate this problem, we refer to Fig. 10-Top, which depicts the native PyTorch invocation timeline from the base LLM process's perspective. The CUDA kernel F_1 computes the input matrix $\mathbf{x}$. Meanwhile, the base LLM process launches F_2 on CPU, a CUDA `MemCpy` kernel to transfer the input matrix $\mathbf{x}$ to the host memory for CPU LoRA's access. After F_1 execution completes on GPU, the GPU executes the enqueued F_2 kernel. Once the data transfer completes, the base process uses a *signaling operator* F_3 to notify CPU LoRA processes to compute $\mathbf{xAB}(F_5)$. It then launches the next CUDA kernel F_4. This implementation requires explicit synchronization (shown as a yellow block with slashes) to ensure that the memory copy (F_2) completes before the signaling (F_3). However, the synchronization blocks the subsequent F_4 from launching, resulting in significant inference delay and GPU underutilization.

To address this issue, we introduce a customized operator that eliminates explicit synchronization by fusing an asynchronous `MemCpy` kernel with a CUDA signaling kernel. The CUDA signaling kernel writes a semaphore variable in host shared memory* to achieve signaling. As shown in Fig. 10-Bottom, instead of relying on synchronization, we fuse F_2 and F_3 into an *asynchronous* CUDA kernel $[F_2', F_3']$, where F_2' performs asynchronous `MemCpy` and F_3' asynchronously signals the intended CPU LoRA processes through changing the semaphore in the shared memory. As a result, the fused kernel $[F_2', F_3']$ can be added to the GPU device queue without waiting for the completion of F_1. Note that data validity and consistency is preserved in this case because CUDA device queue follows a sequential, strict first-in-first-out execution ordering. The semaphore variables employed will synchronize and ensure the correctness of memory read and write operations. Since the new operator requires no explicit synchronization, subsequent base model kernels, such as F_4, can launch without being blocked, eliminating unnecessary synchronization overhead. In §7.3, we show that our kernel can reduce the *prefill* latency by 15% compared to implementation with explicit synchronization. The design of the sync-free operation is not limited to LoRA computation and can be adapted to other workloads if necessary.

Shared memory data transfer. Transferring data and signals between the base LLM process and the isolated CPU LoRA processes requires inter-process communication (IPC). This is a one-to-N communication involving one base LLM inference process and multiple CPU LoRA processes. (We explain why multiple CPU LoRA processes later.) We create shared memory blocks in the host memory, i.e, DRAM, for fast inter-process signaling and data transfer, eliminat-

*The term "shared memory" refers to the shared memory in host memory.

ing the need for data copying and (de)serialization (Fig. 9). The CPU processes periodically poll from the semaphore in the shared memory. Once it changes, LoRA processes start reading the input matrix **x** from the shared memory and perform the computation **xAB**. They then write **xAB** back to the shared memory and notify the LLM inference process to incorporate the adaptation results (Eq. 1). Micro-benchmark evaluations (§7.3) demonstrate that the use of shared memory reduces data transfer overhead to less than 1 ms (Fig. 12-Right), substantially outperforming the message passing IPC employed by existing LLM frameworks [31].

Profiling-guided LoRA parallelization. Given that the CPU has lower computing power and limited parallelization capability compared to the GPU, performing LoRA adaptation using a single CPU is not scalable. Therefore, we propose a profiling-guided parallelization scheme to accelerate LoRA adaptation using multiple CPU cores. As discussed in §2.1, the adaptation computation is **xAB**, where $\mathbf{x} \in \mathbb{R}^{B \times L \times H}$ is the input matrix for B requests with L tokens, totaling $B \times L$ tokens. We first profile the performance achieved by a single core under varying workloads (Fig. 17-Left) and set the maximum number of tokens for a single CPU core to handle for computation. For example, if one core can handle c tokens, we allocate $\lceil \frac{L}{c} \rceil$ cores for computing the adaptation results of each request with weight matrix **W**. Each core is dedicated to an isolated CPU process to avoid interference. Specifically, the CPU process reads a slice of **x** from the shared memory region, performs the computation, writes the results back to the shared memory, and notifies the base LLM process accordingly. Compared to PyTorch's native multi-threading module [14], this approach achieves 1.4× speedup when using 16 CPUs for the same workload (Fig. 17-Right).

Putting it altogether, our design, as demonstrated in §7.2, can accelerate the request serving by 1.7× on average.

5 Rank-Aware Scheduling

In a multi-tenant LoRA serving system, user requests can trigger the use of heterogeneous LoRA adapters with varying ranks. As discussed in §2.3, the rank heterogeneity directly affects the performance of multi-tenant LoRA serving systems. Therefore, the scheduling strategy for handling these requests is crucial for enhancing system efficiency (**C2**): a sub-optimal strategy can drive the adapter heterogeneity in a server to a non-ideal setting that slows down token generation for both new and ongoing requests. An effective scheduler needs to be aware of the *heterogeneity-performance model* to make *rank-aware* request scheduling decisions and meet SLOs.

Performance modeling. TOPPINGS employs performance models to guide the scheduler in making informed decisions, ensuring that SLOs are met by mapping LoRA rank heterogeneity to serving performance. However, performance modeling is challenging (**C2**). Under continuous batching, when new requests are routed to a server, the server's running batch size increases, and the batch's rank heterogeneity changes as well, making the number of possible LoRA rank combinations in a batch grow exponentially.

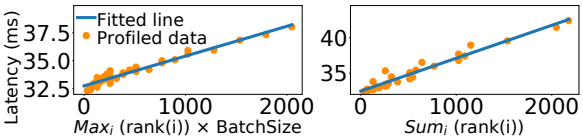

Figure 11: Performance models for BGMV (Left) and MBGMV (Right) kernels. Both linear regression models achieve a high coefficient of determination (R^2) of 0.96.

To address the challenge, TOPPINGS builds performance models based on the characterizations of the LoRA computation kernels, e.g., BGMV and MBGMV. We profile the kernels using Nvidia Nsight Compute [13] and observe that their performance is bounded by the GPU memory bandwidth, which is dominated by transferring adapter weights into L2 cache. Based on the insights, we develop generic performance models to predict the latency of a *prefill* or *decoding* iteration for a specific batch of heterogeneous adapters. These models are created through lightweight serving performance profiling, involving varying batch sizes and heterogeneous adapters on a specific GPU. We present the performance models tailored for both BGMV [6] and MBGMV [42]. For the padding-based BGMV kernel, where lower-ranked LoRAs require padding to match the highest rank, we observe that the serving performance of decoding latency is almost linear to the product of batch size and the *maximum* rank encountered in the batch (see Fig.11-Left). On the other hand, MBGMV [42] modifies the BGMV kernel to eliminate padding, improving performance with highly heterogeneous LoRA ranks but introducing additional performance overhead for computing homogeneous ranks. Through profiling, we find that under MBGMV, the serving performance scales linearly with the *sum* of LoRA ranks in a batch of heterogeneous adapters (Fig. 11-Right). Denoting the adapter rank of request i as $rank(i)$, we present performance models for these two kernels on a batch of requests $\mathcal{S}$ as two linear functions with parameters α and β, inspired by [29]:

$$\begin{aligned} \text{PERF}_{\text{BGMV}}(\mathcal{S}) &= \alpha_B \cdot |\mathcal{S}| \cdot \text{Max}_{i \in \mathcal{S}} rank(i) + \beta_B \\ \text{PERF}_{\text{MBGMV}}(\mathcal{S}) &= \alpha_M \cdot \text{Sum}_{i \in \mathcal{S}} rank(i) + \beta_M \end{aligned} \quad (2)$$

As shown in Fig. 11, our linear performance models accurately fit the profiled data. Both models achieve a high coefficient of determination (R^2) of 0.96, *suggesting the models can predict performance almost perfectly*: R^2=1 indicates a perfect fit.

The parameters α and β are specific to the hardware and LLM models. When the model or hardware changes, re-profiling is required to adjust these parameters. To construct the performance models in Fig. 11, we collect the data by profiling the serving of 7,618 requests with batch sizes of 4, 8, 16, and 32, and LoRA ranks of 8, 16, 32, and 64, which can complete in minutes. Besides, the model inference incurs

a negligible overhead in the order of 0.001ms.

Scheduling requests across inference servers. Using the established performance models, we develop a *rank-aware* scheduling algorithm (Algo. 1) for heterogeneous LoRA requests. Upon receiving a new request, the scheduler gathers information about ongoing requests from all available LLM inference servers. The scheduler identifies potential candidate servers by matching the base LLM, adapter, and GPU memory availability. If multiple candidates are found, the scheduler calculates a total cost score for each candidate server based on the performance model. This cost score measures the impact of the new requests on the performance of the server's ongoing requests. If serving the new request would cause a violation of the SLO, the cost score is assigned a large penalty. The scheduler then selects the server with the minimum cost score to handle the new request.

Algorithm 1: Rank-aware Scheduling Policy

Input: Performance models for *Prefill* and *Decoding*: $PrePerf(\cdot)$, $DecPerf(\cdot)$; average response length: avg_resp_len;

```
while True do
    Request i arrives;
    candidates ← available LLM inference servers
    for instance in candidates do
        running_batch, queue = instance.GetStats()
        cost = CalcCost(i, running_batch, queue)
        requests = len(running_batch) + len(queue)
        instance.total_cost = cost * requests
    best = min(candidates, key=lambda x: x.total_cost)
    best.serve(i)
Function CalcCost(req, running_batch, queue):
    exists = running_batch + queue
    # calculate additional prefilling time
    Δ_prefill = PrePerf(queue + req) - PrePerf(queue)
    # calculate additional decoding time
    Δ_decode = DecPerf(exists + req) - DecPerf(exists)
    cost_score = (Δ_prefill / avg_resp_len) + Δ_decode
    if DecPerf(exists + req) > SLO then
        penalty_score = float('inf')
        cost_score += penalty_score
    return cost_score
```

6 Implementation

LLM inference server. We implemented TOPPINGS's LLM Inference Server on top of LightLLM [31], an LLM serving framework based on PyTorch [37] and Triton [48]. We extended its Llama2 inference module to incorporate our LoRA adapters. This allows for easy integration with different LLMs and other popular LLM inference frameworks such as vLLM [26]. We implemented GPU LoRA adapters by adapting the `BGMV` kernels [6]. Regarding CPU LoRA, we implemented the custom CUDA kernel (§4.2) as a PyTorch Extension using `PyBind11`. Each CPU LoRA adapter runs as an isolated process, binding to one CPU core using the `numactl` command. To enable efficient batch inference, we utilize the request queue in LightLLM, which facilitates the continuous batching mechanism [26, 56].

We employ tensor parallel techniques [45] to support base LLMs that require multiple GPU devices. Tensor parallelism involves partitioning a weight matrix into multiple chunks, and each GPU device holds only one chunk to perform a portion of the computation in parallel [28]. To enable tensor parallelism for LoRA computation, TOPPINGS partitions the LoRA adapter weights (**B** in Eq.1) using the same strategy as that of the base LLMs. It performs the computation and incorporates the adaptation results into the inference intermediates in place, causing no extra communication overhead.

Scheduler & global LoRA registry. We implemented the scheduler with Algo. 1 using Python Flask. For the global LoRA registry, we utilized SQLite.

7 Evaluation

We evaluate TOPPINGS regarding the efficiency of an LLM inference server (§4) and the scheduler performance across multiple servers (§5). Our evaluation highlights include:

- TOPPINGS achieves efficient multi-tenant LoRA serving on Llama2-7B/70B, outperforming state-of-the-art baselines, e.g., S-LoRA [42] and dLoRA [54] (§7.2).
- TOPPINGS's optimizations in CPU LoRA execution are effectively illustrated by various micro-benchmarks (§7.3).
- TOPPINGS's scheduler achieves high SLO attainment and improves the performance as a cloud service (§7.4).

7.1 Experimental Setup

Model and server configs. We adopt Llama2 [50] with 7B and 70B parameters where LoRA adapters are applied to $\mathbf{W}_Q$, $\mathbf{W}_K$, and $\mathbf{W}_V$ in LLM's attention layers following the standard settings* [12, 22, 42]. We serve Llama2-7B with a single NVIDIA A100 GPU and Llama2-70B with four A100 GPUs using tensor parallelism, following [6, 32, 54].

Metrics. We use following metrics, which are considered essential in user-facing LLM serving [1, 11, 38, 42].

- ***Time-to-first-token (TTFT)*** measures how quickly users start getting the model's output after entering their prompts. It reflects the time required to process the prompt and then generate the first output token. Low waiting times for a response are essential in real-time interactions.
- ***Time-per-token (TPT)*** measures the time on average to generate an output token for each user. This metric corresponds with the perceived "speed" of the model. We calculate TPT by accounting for all tokens, including those from both the prefill and decoding phases.

*Following the setting in [6, 42], we use dummy weights (not zeros) for LoRA models, which do not affect system performance.

- ***E2E Latency*** measures the end-to-end time it takes for the model to generate the full response for a request.

Baselines. We consider the following baselines.

- CACHED represents an *ideal but impractical* method where all required LoRA adapters are *pre-cached* in *unlimited* GPU memory. It has no adapter loading overhead, thus achieving performance upper bound.
- S-LORA [42] represents a state-of-the-art multi-tenant LoRA serving framework, which is also built on top of LightLLM [31]. It loads LoRA adapters on demand and uses an adapted CUDA kernel for GPU LoRA computation.
- dLORA [54] is another LoRA serving system based on vLLM [26]. It pre-caches all LoRA adapters into GPU memory and dynamically merges/unmerges LoRAs with the base model during inference. It uses PyTorch's general matrix multiply (GEMM) kernel for LoRA computation.

Note that CACHED and TOPPINGS are built on top of LightLLM [31], the same as S-LORA [42]. We equip CACHED and TOPPINGS with the `BGMV` kernel [6] to perform GPU LoRA computation for a fair comparison. S-LORA and dLORA use their own kernels.

Workloads. We use both scaled production and synthetic workloads in our evaluation.

- ***Scaled production workload.*** We use the MAF trace [40] to generate a scaled production workload, which is widely used to emulate model serving workloads [30, 54, 59]. The trace contains invocation traffic of different functions, and we regard each function as one adapter. We randomly group adapters. Each inference server hosts a group of adapters and receives the aggregated request traffic from all the adapters it hosts. Within a group, adapters have varying probabilities of being invoked shown in Fig. 12-Left, proportional to their invocation frequency in the original trace.
- ***Synthetic workload.*** The aggregate request traffic to an LLM server follows Poisson processes with varying intensities, widely used in approximating simulated invocations [6,59]. Similar to [6,42], each request targets a distinct adapter and hence undergoes the adapter loading phase. Following [42], we place 200 adapters in an inference server.

Datasets. We refer two datasets to set each request's prompt and output length. The first is LMSYS-CHAT-1M [61], which contains input and output texts of one million real-world conversations. The second is QMSum [46, 62], which has prompts with lengths ranging from 2k to 30k tokens. QMSum comprises transcripts from real-world meetings, focusing on query-based summarization with long detailed answer [62].

7.2 LLM Inference Server Performance

In this section, we evaluate the performance of a *single* LLM inference server, which is subject to adapter loading and computing. For a fair comparison, we employ homogeneous LoRA ranks in this section, eliminating the potential performance differences that result from the way different LoRA computation kernels handle heterogeneous ranks [6, 42].

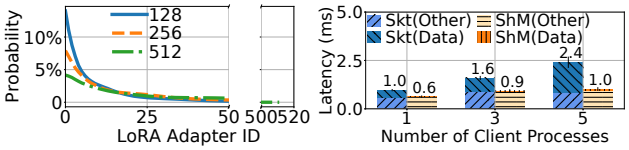

Figure 12: Left: LoRA invocation probability. X-axis: adapter ID sorted by invocation probability. Right: CPU LoRA computation time. Each process receives data of 16 tokens. *Skt*: Domain socket for inter-process communication (IPC). *ShM*: Shared memory for IPC. *Data*: Time for transfering data to other process via IPC. *Other*: Time for all other operations.

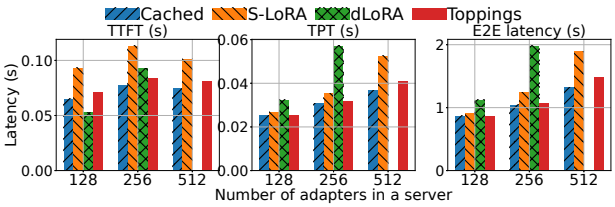

Figure 13: Performance with varying number of adapters under the scaled MAF workloads. dLORA causes GPU OOM when there are 512 adapters in the server.

Scaled production workloads. We first evaluate TOPPINGS on the scaled production workload. Fig. 12-Left illustrates the skewed distribution of adapter popularity. We evaluate each baseline with an increasing number of LoRAs served in an inference server. With more LoRA adapters, the server will receive higher request loads, and each new request is more likely to invoke a new LoRA adapter that needs to be loaded onto GPU on demand (Fig. 12-Left). Therefore, a larger number of LoRAs manifests higher cumulative loading overhead. The average aggregate *RPS* for 128/256/512 adapters is 1.5/3.6/7.7, scaled from the original trace. We set the LoRA *rank* = 64 in this setting.

We measure serving performance using the metrics defined in §7.1. See Fig. 13. When 128 LoRA adapters are in a server, the impact of cumulative adapter loading overhead is negligible because the request traffic is low, and most new requests do not require adapter loading. Compared to CACHED, S-LORA increases TTFT by 43%, TPT by 7%, and E2E latency by 5% on average, mainly due to the one-off adapter loading overhead introduced by new requests. dLORA achieves better TTFT as it pre-caches all LoRA adapters into GPU and dynamically merges LoRAs with the base LLM to accelerate *prefill* computation [54]. However, its frequent LoRA (un)merging operations impact the *decoding*, increasing the TPT by 29% and E2E latency by 29% compared to CACHED. TOPPINGS outperforms by only increasing TTFT by 9%.

However, as the number of LoRA adapters increases to 512, adapter loading incurs prohibitively high cumulative overhead, which can hinder S-LORA from scaling to efficiently serve

Setup	Model Size	Datasets	No. of LoRAs	Rank	RPS
S1	7B	LMSYS	200	32	9
S2	7B	LMSYS	200	64	6
S3	7B	LMSYS	200	64	9
S4	7B	QMSum	50	256	3
S5	70B	LMSYS	200	32	3
S6	70B	LMSYS	200	64	3

Table 2: Evaluation setups with the synthetic workload.

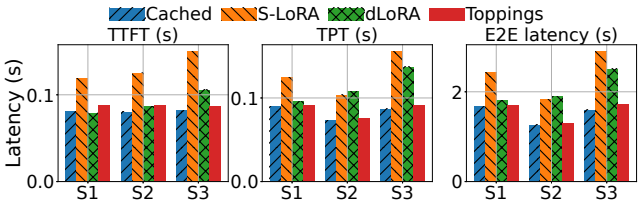

Figure 14: Serving performance. Setup: S1, S2, S3 in Tab. 2.

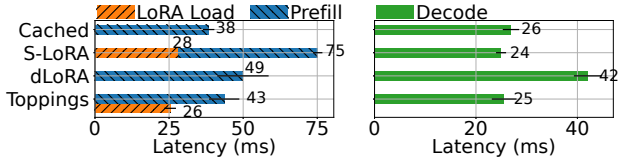

Figure 15: Prefill and decoding latency at LLM server.

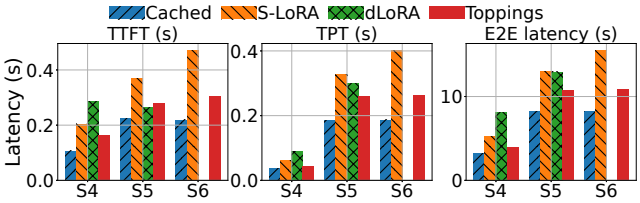

Figure 16: Serving performance. Setup: S4, S5, S6 in Tab. 2. dLoRA causes GPU OOM in S6.

a large number of adapters. Compared to the CACHED, S-LORA increases TPT by 43%, and E2E latency by 43% on average. Nevertheless, TOPPINGS can rival CACHED, accelerating S-LORA by 1.25×, 1.29×, 1.28× in terms of TTFT, TPT and E2E latency, respectively.

dLORA falls short in serving numerous LoRA adapters in a server. When 256 adapters are in a server, dLORA incurs significant computation overhead, increasing TPT/E2E latency by 86%/90%, due to its LoRA computation operator. Worse, deploying 512 adapters in a server can cause GPU OOM and the server cannot spin up (Fig. 13).

Synthetic workloads. We evaluate each baseline with various setups using the synthetic workloads, as shown in Tab. 2.

1) Setup S1, S2, and S3. We explore different LoRA ranks and request traffic in these three settings. As discussed in §2.3, two factors affect TOPPINGS's advantages (§2). The first is LoRA rank, which determines the size of a LoRA adapter: smaller rank leads to shorter loading latency. The second is the workload traffic, which determines the frequency of adapter loading (decoding interruption).

As shown in Fig. 14, TOPPINGS achieves the most performance advantage in **S3**, which has the largest LoRA rank and highest RPS. TOPPINGS rivals the performance of CACHED by introducing tolerable overheads, slightly increasing the TTFT by 6%, TPT by 6%, and the E2E latency by 7%. Compared to the CACHED baseline, S-LORA introduces high overhead due to the cumulative loading interruption, increasing TTFT by 82%, TPT by 80%, and E2E latency by 81% on average. dLORA incurs no adapter loading overhead as it preloads all adapters but falls short in calculating LoRA adaption (Eq. 1), degrading the computation performance. Besides, dLORA decides online whether to merge/unmerge the LoRA adapters with the base model to provide service [54], further increasing prefill latency when RPS is high. Compared to the CACHED baseline, dLORA increases TTFT by 29%, TPT by 58%, and E2E latency by 57% on average. We further evaluate TOPPINGS's performance under conditions of reduced CPU availability, where each CPU LoRA computes 4× more tokens. Despite the constrained CPU resources, TOPPINGS maintains consistent performance advantages over the baseline systems thanks to the pipeline loading design (§4.1). Compared to the CACHED baseline, TOPPINGS increases the TTFT by 17%, TPT by 11%, and E2E latency by 10%. The pipelined loading design allows TOPPINGS to promptly switch to GPU for LoRA computation, effectively mitigating the impact of reduced CPU availability.

S1 and **S2** represents less challenging settings, with smaller LoRA ranks or lower request traffic. As shown in Fig. 14, S-LORA/dLORA incurs smaller overhead than that in **S3** while TOPPINGS rival the performance of CACHED.

Fig. 15 explains TOPPINGS's advantage from the LLM inference server's side. The latencies of *decoding* iterations achieved by CACHED, S-LORA, and TOPPINGS are similar, while S-LORA have a long *prefill* iteration due to the adapter loading overhead. TOPPINGS leverages the CPU-assisted design (§4) to avoid the loading overhead. dLORA incurs no loading overhead as it pre-cache all adapters but slows down LoRA computing, leading to the long *decoding* latency.

Resource Utilization. Throughout the request serving in **S3**, the average GPU utilization of S-LORA/dLORA/TOPPINGS is 46%/81%/56%. dLORA's GPU utilization is much higher due to its LoRA (un)merging overhead and computation whereas S-LORA and TOPPINGS use high-performance kernels adapted from BGMV [6]. The average CPU utilization of S-LORA/dLORA/TOPPINGS is 4%/4%/46%, respectively, with each request consuming an average of 27ms for CPU-assisted LoRA computation. TOPPINGS exploits the underutilized CPUs [23] to accelerate adapter serving, which is overlooked by S-LORA and dLORA.

2) Setup S4. We stress test each baseline using the long prompts from the QMSum dataset [46, 62] that have lengths ranging from 2k to 30k tokens. We adopt Lloco's workflow [46] that serves these prompts with LoRA adapters. Given a lengthy prompt, Lloco first processes the prompt into token embeddings using the AutoCompressor [8, 46]. Subsequently, Lloco sends a request with the embeddings to query

the LLM and a designated LoRA adapter. As larger ranks contribute to higher response quality for long prompts [7], we use adapters with *rank* = 256. As shown in Fig. 16, TOPPINGS maintains superior with minimal overhead compared to CACHED. dLORA's slow LoRA computation is more salient with the long prompts in this setting.

3) Setup S5,S6. In these two settings, we evaluate each baseline with Llama2-70B using tensor parallelism [32]. We re-implement S-LORA by adapting CACHED since existing works [6, 42] have not released code in multi-GPU settings. We also emulate dLORA by importing its LoRA computation into CACHED to avoid the performance differences resulted from different backends (vLLM [26] v.s. lightLLM [31]), which are evident in the multi-GPU settings [10, 49, 64]. See Fig. 16. In **S5**, S-LORA/dLORA/TOPPINGS increases TTFT by 65%/18%/24%, TPT by 65%/59%/30%, and E2E latency by 61%/61%/33%. compared to CACHED. In **S6**, dLORA fails due to GPU OOM and TOPPINGS achieves consistent benefits, accelerating TTFT by 1.6×, TPT by 1.5×, and E2E latency by 1.4×, compared to S-LORA.

7.3 Microbenchmark Evaluations

We further evaluate the effectiveness of the CPU LoRA optimizations (§4) at the microbenchmark level.

Pipelined adapter loading. Pipelined adapter loading allows TOPPINGS to promptly prefill prompts on GPU instead of waiting for the adapter to be fully loaded (§4.1). To show its effectiveness, we measure the *prefill* performance w/ and w/o pipelined adapter loading, where the pipelined adapter loading accelerates the *prefill* computation by 1.2× and 1.1× when using adapter with *rank=128* and *rank=64*.

Sync-free CPU LoRA invocation. To analyze the performance of our optimized CPU LoRA invocation kernel (§4.2), we compare the *prefill* latency using PyTorch's native implementation and our optimized kernels. While *prefilling* 64 tokens, TOPPINGS's kernel gains a 10% speedup, reducing the latency from 67ms to 61ms. While *prefilling* 256 tokens, TOPPINGS's kernel gains a 15% speedup, reducing the latency from 145ms to 126ms.

Shared memory data transfer. We compare the latency of computing CPU LoRA with different IPC methods: shared memory and UNIX domain socket. We measure the time it takes to perform LoRA computation and the data round trip cost. Fig. 12-Right shows that as the number of receiver processes increases, the domain socket approach suffers from linear time increase in data transmission, whereas the shared memory approach obtains near-constant performance.

Multi-CPU computation. We first profile the LoRA computation performance in a *prefill* phase with a single CPU. We profile it with different workloads (number of tokens to process). We run the profiling on a Llama2-7B model with a A100 card using Intel Platinum 8369B CPU. As shown in Fig. 17-Left, the CPU has limited parallelism and does not scale to fit high workloads. We observe similar results using AMD EPYC 7R32 CPU. Fig. 17-Right illustrates the performance of *prefilling* a prompt of 256 tokens with TOPPINGS's multi-CPU design (§4.2) or the native multi-core utilization of PyTorch multi-threading module [14]. TOPPINGS's design achieves up to 1.4× speedup.

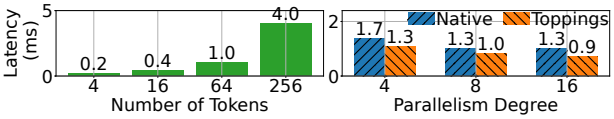

Figure 17: Left: CPU computation time of **xAB** in the *prefill* phase. Right: CPU computation for 256 tokens with different parallelism. Native: PyTorch native multi-threading [14].

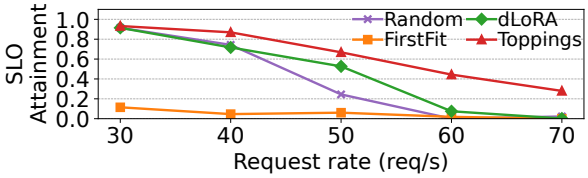

Figure 18: Scheduler performance under varying RPS.

7.4 Cluster Scale Performance

Following [59], we run cluster scale experiments in two settings: an 8-instance real-world testbed and a large-scale simulation. We use four different LoRA ranks in this section.

Baselines. Upon the arrival of new requests, we consider the following scheduling baselines for comparison:

- dLORA [54] enables reactive request migration to balance the workloads among servers.
- FIRSTFIT scheduler picks a server following the first-fit bin-packing strategy, which is also adopted by Punica [6].
- RANDOM scheduler randomly picks an inference server.

Performance model. The performance model can predict performance almost perfectly with a high R^2 of 0.96 (§5). Besides, the model takes 0.005ms for one inference.

Testbed evaluation. We set up a cluster testbed consisting of 8 Llama2-7B models to evaluate each scheduler under varying Poisson request traffic. TOPPINGS's LLM inference server is used as the LoRA serving backend. The SLO is set regarding TPT, as it reflects the perceived "speed" of the inference service. The SLO is set to be 1.5× higher than that achieved by LLM inference without LoRA. See Fig. 18. TOPPINGS's rank-aware scheduler outperforms other baselines by achieving the highest SLO attainment across all settings. When the request rate is low (RPS=30), the RANDOM and dLORA perform well as they tend to scatter the requests across servers, mitigating the impacts of rank heterogeneity. In contrast, the FIRSTFIT degrades as it tends to consolidate requests to heterogeneous LoRAs on a few servers, exacerbating rank heterogeneity. As the request rate increases, the performance of rank-agnostic

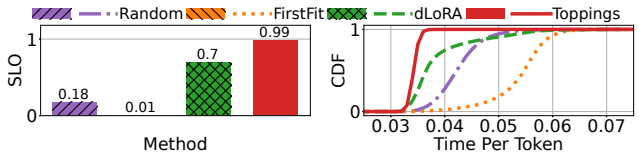

Figure 19: Scheduler performance across 60 instances.

schedulers, e.g., dLoRA, plummets, while Toppings maintains consistent advantages, improving SLO attainment by 21% and 26% when the RPS is 40 and 50, respectively.

Large-scale simulation. To ensure the fidelity of the simulator, we reuse the code from the LightLLM [31] and maintain the same serving logic. We obtain the *prefill* and *decoding* latency for the simulator by extensive profiling. We include all 40,000 functions from the MAF trace [40], with an aggregated RPS≈340, and use 60 server instances. The SLO is set regarding TPT, which is 1.5× higher than that of LLM inference without LoRA. Fig. 19 compares the SLO attainment of each scheduler and the CDF of requests' TPT. Toppings's rank-aware scheduler achieves the highest SLO attainment and speeds up the average TPT by 22/23/57% compared to dLoRA/Random/FirstFit. We see similar results in the simulation if replacing the `BGMV` in Toppings with `MBGMV`.

8 Related Work and Discussion

LLM inference. Optimizing LLM inference is the target of recent studies [2,16–19,21,25,30,38,47,57]. Orca [56] proposed iteration-level continuous batching to improve the throughput of LLM serving. Further, vLLM [26] addressed the issue of the GPU memory fragmentation resulting from LLM's KV Cache, improving serving throughput by high GPU efficiency. Sarathi-Serve executes chunked-prefills, which combines *prefill* and *decoding* computation to maximize serving throughput [1]. DeepSpeed-Ulysses enables efficient LLM training and inference for long prompts using sequence parallelism [25]. FlexGen [44] supported LLMs with limited GPU memory, maximizing serving throughput by efficiently processing tensors. Toppings is compatible with these optimizations, has already supported continuous batching and optimized GPU memory management mechanism [31].

Multi-tenant LoRA serving. In addition to the works discussed in §2.4, PetS [63] proposed a unified framework for serving various adapters in discriminative language models. However, it lacks iterative decoding and is orthogonal to Toppings. Recent works [43] have also explored the fairness issues in multi-tenant LLM serving, where some users may receive more resources than others. The primary goal of Toppings's rank-aware scheduling algorithm is to address performance variations caused by heterogeneous LoRA ranks, while not explicitly tackling fairness concerns. A straightforward approach to ensuring fairness is to limit the number of requests a user can make within a specified time frame, a strategy also adopted by OpenAI [36]. It is worth noting that fairness in LLM serving is not a challenge unique to LoRA serving. For instance, the Virtual Token Counter (VTC) scheduling algorithm [43] guarantees fairness not only for general LLM serving but also for adapter-based serving. Importantly, Toppings does not introduce additional unfairness to the system and is fully compatible with fairness strategies like VTC.

Multi-model inference serving. A series of systems optimize multi-model inference serving, including Clipper [9], MArk [58], Nexus [41], INFaaS [39], Clockwork [20], Shepherd [59], and AlpaServe [28]. They optimize batching, caching, and model placement of serving multiple models. However, they do not specially support generative LLMs and heterogeneous LoRA adapters, leading to optimization gaps.

Discussion. Toppings's design is versatile, supporting various LLM series and not restricted to a specific framework, as most LLMs share a backbone of Transformer blocks and utilize the attention mechanism [52]. The CPU-assisted design is compatible with existing GPU servers, which are typically equipped with abundant CPUs but have low CPU utilization [23, 53]. For example, the AWS g5.48xlarge instance has 192 vCPU cores. Besides a recent analysis of production traces from GPU clusters reveals significant underutilization of CPU resources [23]. This observation suggests that spare CPU cycles are readily available to support a CPU-assisted design without impacting overall cluster performance. For fault tolerance, our current implementation isolates CPU processes, with each bound to a specific CPU. Additionally, running redundant CPU processes enhances fault tolerance.

9 Conclusion

This paper presents Toppings, an efficient multi-tenant LoRA serving system. In a nutshell, Toppings multiplexes base model to serve many LoRA adapters in a batch, coordinates LoRA computation on CPU and GPU to avoid cold-start, and employs a rank-aware scheduler to meet SLOs. Compared to existing systems, Toppings significantly improves serving efficiency by reducing the request serving latency by up to 47% and achieves an SLO attainment of 99%.

QFactory: Accelerating Quantized Large Language Model Serving with Qtile Graphs

Qihao Zhang Mingshu Zhai Rui Sun Jidong Zhai

Tsinghua University

Abstract

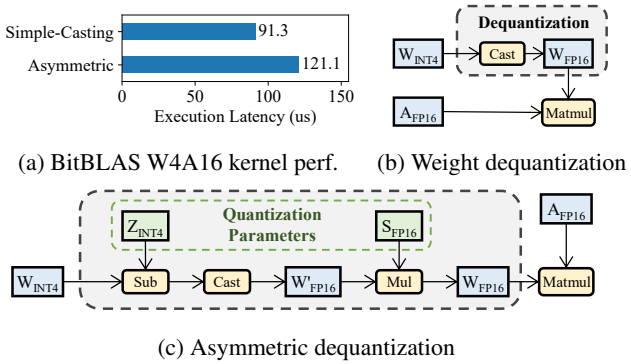
Quantization is a critical technique for accelerating large language models. To achieve tangible speedups, weight dequantization must be performed on-the-fly, necessitating tailored quantized kernels for various quantization algorithms and precision formats. Existing methods typically rely on a static eager execution paradigm for dequantization operations, which overlooks a broader range of potential optimizations, leading to suboptimal performance.

In this paper, we present QFactory, an efficient compilation framework designed to generate high-performance quantized kernels. QFactory introduces a novel Qtile abstraction that facilitates the representation of quantized tensors, transforming the traditional tensor computation graph into a Qtile-graph (Qgraph). Leveraging this QGraph abstraction, QFactory first explores graph-level Qtile computation transformations to generate equivalent QGraphs, thereby expanding the search space for optimizations. Subsequently, QFactory employs operator-level Qtile scheduling to identify optimal memory loading strategies for each Qtile within the QGraph before generating the final code. Experimental results demonstrate that QFactory achieves an average performance improvement of 1.66× over existing systems and delivers 1.23× end-to-end generation speedup when integrated into state-of-the-art large language model serving systems.

1 Introduction

Quantized large language model (QLLM) serving is increasingly promising, as it facilitates the deployment of powerful and effective LLMs within limited resource environments. Many quantization techniques [6, 10, 11, 14, 22, 23, 42, 43, 47] have been proposed to reduce the deployment cost of leading LLMs [1, 2, 32, 34–36].

The core of quantization techniques is eliminating memory pressure in LLM serving. Due to the autoregressive nature of LLMs, the decoding phase exhibits memory-bound computational characteristics. The computational bottleneck



(a) BitBLAS W4A16 kernel perf. (b) Weight dequantization

(c) Asymmetric dequantization

Figure 1: Quantized kernels for serving QLLMs.

mainly lies in the loading of model parameter matrices from GPU memory [14, 20]. To address this problem, quantization algorithms compress model parameters and store them in low-precision formats (e.g., from 16-bit FP16 to 4-bit INT4), significantly reducing DRAM memory requirements. Additionally, the quantized computation kernels [23, 30, 42] only load the compressed weights and dequantize them to higher precision before performing computations with the activation tensor, as shown in Figure 1b. Thus, the decoding speed is boosted because of the reduced memory access.

As the model bit-width becomes extremely low, **fine-grained quantization** algortihms [17, 30, 47] have been proposed to better preserve model accuracy, which typically applies an **asymmetric** and **group-wise** method. A representative fine-grained quantization algorithm is GPTQ [10]. It performs *asymmetric* quantization by compressing model weights with two auxiliary quantization parameters, *zero point Z* and *scaling factor S*. Compared to the simple type-casting dequantization in Figure 1b, asymmetric dequantization in Figure 1c introduces extra computation and memory overhead. Additionally, it is a *group-wise* quantization algorithm since these auxiliary parameters are shared among a small group of parameters within a weight tensor.

Although fine-grained quantization algorithms hold promis-

ing in preserving model capability at extremely low bit-width, the inefficient execution of dequantization hurts their effectiveness. The issue stems from the use of custom kernels that incorporate on-the-fly dequantization operations [12, 23], namely quantized kernels, which are poorly supported by the current deep learning compilers [4, 31, 39]. For instance, as shown in Figure 1a, the state-of-the-art low-precision deep learning compiler BitBLAS [39] experiences a significant performance degradation when compiling asymmetric quantized kernels. Compared to the simple type-casting W4A16 kernel, asymmetric quantized kernel compiled by BitBLAS exhibits 30% higher latency. Even worse, the performance issue becomes more pronounced when scaling to lower bit-widths. As the bit-width of weight parameters decreases and more complex quantization algorithms are adopted, the additional memory access introduced by dequantization becomes relatively significant, emerging as a new performance bottleneck.

Existing systems fail to process the extra dequantization in quantized kernels efficiently due to their **eager execution paradigm** for dequantization operations. Upon encountering quantized values during execution, this static approach rigidly converts them immediately according to the quantization algorithm's definition, limiting the potential for optimization. In contrast, our insight is that a **deferred execution paradigm** of dequantization can improve end-to-end performance. The dequantization operations can be deferred to the following tensor in the computation graph instead of applying to the original quantized tensor. Compared to this novel deferred paradigm, the conventional eager paradigm has two following limitations.

Limited Searching Space Quantized programs introduce new dequantization operations, which alter the original computation graph. These changes increase the graph's complexity and create additional opportunities for graph-level transformations. Our investigation reveals that exploring this transformation space can yield improved kernel performance. However, existing approaches remain unaware of these changes in the computation graph and eagerly execute dequantization operations on the original graph, thereby failing to exploit this potential optimization space.

Underutilized Memory Bandwidth Quantization algorithms introduce additional quantization parameters associated with weight parameters that are computed during dequantization. These quantization parameters are often shared across a certain scope of weight parameters. However, existing approaches fail to leverage this shared property and instead perform dequantization independently for each weight parameter, leading to underutilized memory bandwidth. Our findings show that by differentiating the data loading for various tensor tiles, overall bandwidth utilization can be improved.

To address these challenges, we propose QFactory, an efficient compilation framework for generating high-performance quantized kernels. The core design of QFactory is Qtile, an annotated tensor expression for quantized tensors. With this abstraction, QFactory discovers that Qtiles can be propagated along the computation graph from operator inputs to operator output. In this way, tensor dequantization is deferred to later computation, enabling a more flexible placement of dequantization operations.

To compile a quantized kernel, QFactory first transforms the user-specified quantized program into a Qtile-graph (Qgraph) by replacing the quantized tensors in computation graph with Qtiles. Then QFactory optimizes the kernel generation of quantized programs at two levels. Firstly, QFactory applies *Qtile Computation Transformation* to deduce mathematically equivalent Qgraphs, exploring a wider range of graph transformation opportunities. Subsequently, QFactory takes all discovered Qgraph candidates and generates code for them. QFactory identifies data reuse as a crucial key factor of kernel performance, and performs *Differentiated Qtile Scheduling* to maximize the overall data reuse possibilities. Finally, QFactory employs a template-based kernel generation and a machine learning based hyperparameter selector for efficient auto-tuning.

To evaluate the effectiveness of QFactory, we conduct experiments on GPUs across different generations, ranging from NVIDIA V100 to newest NVIDIA H100 GPU. Our evaluation shows that QFactory outperforms state-of-the-art low-precision deep learning compiler by 1.66× on single kernel performance, and can accelerates end-to-end decoding speed of various scale QLLMs by 1.23× when integrated into the popular LLM serving framework vLLM [21].

2 Background

2.1 Quantization of Large Language Models

While the advancements in large language models have yielded impressive results, their substantial resource consumption presents a significant challenge for model serving. Current LLMs generate tokens in an autoregressive manner, resulting in low batch sizes and leading to a memory-bound computational scenario [30, 42].

Researches have found quantization as a promising solution for reducing the large memory footprints and accelerating LLM decoding, particularly in resource-constrained circumstance such as edge devices. To maintain good accuracy with lower bit-widths, various quantization algorithms [10, 11, 30] have been developed. These algorithms propose the use of various custom data types for storing compressed weight, such as x-bit integers [17], NormalFloat [7], and even arbitrary fixed bit-width types defined by lookup tables [29]. They also introduce additional data storage, such as scaling factors and zero points, as quantization parameters to help recover the

original weight magnitude.

Take asymmetric W4A16 quantization as an example, which is the quantization format adopted in GPTQ [10]. To quantize a half-precision weight tensor w in model, $\min(w)$ and $\max(w)$ are mapped to the lower and upper bound of destination data range, namely -8 and $+7$ in INT4 data type, respectively. The remaining values in tensor w are mapped linearly. Specifically, the quantization procedure can be formulated as:

$$scale = \frac{\max(w) - \min(w)}{2^4 - 1}$$

$$zero = C_{F2I}\left[\frac{0 - \min(w)}{scale}\right]$$

$$Q_{FP16 \to INT4}(w)[i] = C_{F2I}\left[\frac{w[i] - \min(w)}{scale}\right]$$

where *scale* is a half-precision scaling factor and *zero* is an INT4 zero point. They are auxiliary parameters associated with tensor w. The C_{F2I} function represents the type casting from a half-precision real value to integer, which is often implemented with round-to-nearest method.

When inference on a quantized LLM, the quantized model weights need to be dequantized back to the original data type for computation. The dequantization process of above quantization method can be formulated as:

$$DEQ_{INT4 \to FP16}(w_{INT4})[i] = C_{I2F}(w_{INT4}[i] - zero) \times scale$$

It is straightforward to verify that the above equation is capable of recovering the original weight values, except for the precision loss that occurs during the casting between real and integer data types.

To balance between model accuracy, compression rate, and algorithm complexity, researchers have proposed a spectrum of quantization methods with changeable configurations including symmetric/asymmetric quantization (with or without zero point), quantized data types and quantization granularity (the scope of data sharing same quantization parameters). This wide range of diversity poses great challenges to efficient quantized kernel generation.

2.2 Compiling Deep Learning Models

Deep learning compilers have been proposed to accelerate model execution through optimizations on different levels. We conclude existing works to the following two categories:

Graph-level Transformation Deep learning models can be represented as tensor computation graphs, where vertices correspond to operators and edges represent the flow of tensor data between these operators. Previous works [16, 18, 25, 37, 45] explore the transformation space on the computation graph to find optimal kernel mappings. These systems focus primarily on algebraic transformations at the graph level, and attain better performance through kernel fusion or selection of kernels with higher utilization. They leverages lower-level tensor program compilers like TVM [4] for code generation.

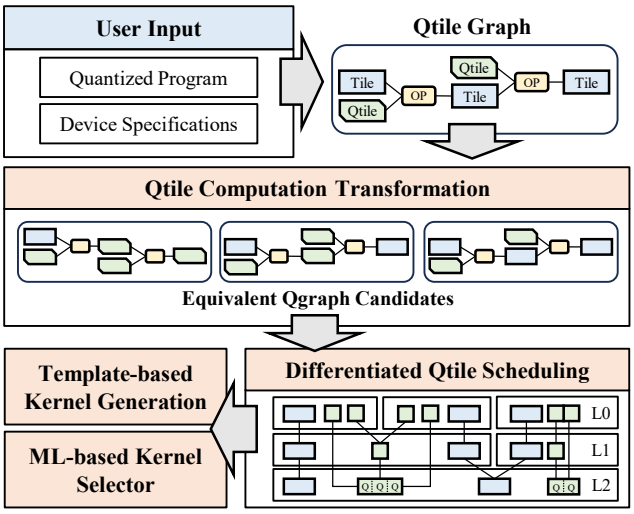


Figure 2: QFactory overview.

Operator-level Memory Scheduling Other compilers [31, 46] focus on efficient operator fusion and kernel generation through a tensor tile abstraction and apply memory scheduling to improve memory efficiency. BitBLAS [39] extends this tile abstraction to support low-precision data formats, enabling the compilation of quantized deep learning models. However, these approaches apply scheduling optimizations solely to model weight tensors and eagerly execute dequantization. As a result, they struggle to effectively handle the unique requirements of quantized models with auxiliary parameters, where more flexible dequantization strategies and finer-grained memory optimizations are necessary for optimal performance.

3 Overview

3.1 QFactory Framework

Figure 2 provides an overview of the QFactory framework. At the entry point, QFactory accepts a user-provided quantized program as input, which are subsequently transformed into a Qtile-graph by replacing certain tensors in the computation graph with the newly designed Qtile abstraction (§3.2). For common quantization algorithms, QFactory provides skeleton templates of Qgraphs, requiring users to define only key settings, such as bit-width, data type, and quantization algorithm. Alternatively, users can directly provide a Qgraph constructed with a combination of Qtiles and standard tensor tiles for greater flexibility.

Thereafter, QFactory performs *Qtile Computation Transformation* (§4) to explore the Qgraph transformation space by propagating Qtiles along operators in Qgraph, generating Qgraph candidates with guaranteed mathematical equivalence. QFactory then analyzes these candidate graphs, and inserts dequantization operations as needed. Afterward, lower-level code is generated for each Qgraph. To optimize overall memory bandwidth utilization, QFactory employs *Differentiated Qtile Scheduling* (§5) to determine the best data placement and loading strategy for Qtiles, maximizing data reuse. Finally, QFactory applies template-based kernel generation (§6.1) to enable instruction-level parallelism and develops a ML-based kernel selector (§6.2) to speedup the selection of optimal kernel configurations.

3.2 Qtile Design

QFactory proposes a novel abstraction for quantization programs, called Qtile, which serves as a critical bridge between quantized program and efficient kernel implementation. Essentially, Qtile is a tensor extended with annotations of quantization attributes. The term "Qtile" is used instead of "Qtensor" because tensors on parallel devices, such as GPUs, are computed in smaller slices, or data tiles. This terminology aligns with the tile-graph abstraction introduced in Welder [31].

Qtile extends tensors with two types of annotations: mapping function and group pattern, representing the quantization algorithm and the scope within which quantization parameters are shared, respectively.

Mapping Function with Quantization Parameters The mapping function encodes all detailed information required for dequantization, including quantization algorithm and its auxiliary parameters. It specifies the storage format of compressed weights (e.g., 4-bit integers for W4A16 quantization), the compression methods (e.g., simple type-casting or asymmetric quantization), and the storage format of any additional quantization parameters. Rather than viewing these quantization parameters as separate data tiles, Qtile incorporates them directly into its extended annotations. This allows QFactory to utilize the relationship between weight tensor and its associated quantization parameters, enabling data reuse opportunities. Theoretically, Qtile can represent arbitrary quantization formats by defining the mapping function as a lookup table. This flexibility allows Qtile to handle unconventional quantization methods, ensuring compatibility with diverse application schemes.

Quantization Group Pattern Quantization is often performed with specific granularity. Tensor elements are divided into groups where scaling or other operations are applied independently. This fine-grained approach enables better approximation and preserves tensor's values. Within each quantization group, the quantization parameters are shared, making group pattern critical for enabling data reuse. Qtile includes the group pattern information in its annotation and provides four commonly used group pattern attributes, ranging from coarse-grained to fine-grained: tensor (t), channel (c), block (b), and individual (i).

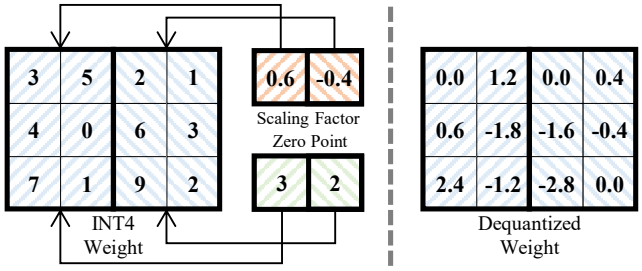

Figure 3: Qtile example of asymmetric INT4 quantization with a group pattern of 3×2 blocks.

Qtile Example We illustrate a Qtile for asymmetric 4-bit quantization with a block group pattern in Figure 3. In this example, the quantized weight tensor is divided into blocks of 3×2, with each block associated with a pair of quantization parameters: a 4-bit integer zero point and a 16-bit half-precision scaling factor. To dequantize a value in the weight tensor, the computation $(W - zero) \times scale$ is performed. For instance, the element in the second row and third column of the weight matrix is dequantized as $(6-2) \times (-0.4) = -1.6$.

Through Qtile, QFactory provides users with a unified interface to define existing quantization algorithms or design new ones. By embedding quantization information directly into the tensor, Qtile balances versatility and efficiency, facilitating wider compilation optimizations to improve kernel performance.

4 Qtile Computation Transformation

With the Qtile abstraction, QFactory replaces certain tensors in the computation graph with quantized tensors, thereby forming a Qtile-graph (Qgraph). As a result, operators within the graph may now receive both Qtiles and normal tensor tiles as input. In existing approaches, such operators are executed eagerly, with dequantization operations performed immediately whenever a quantized tensor is encountered. This strategy leads to a rigid, static translation of Qgraph, limiting the potential for further optimizations.

In contrast, QFactory introduces a compilation procedure for Qgraphs, deferring dequantization operations to later stages by performing *Qtile computation transformations*. Through the transformation rules, Qtiles can actively participate in operator computations, generating new Qtiles as output. As a result, Qtiles are propagated throughout the graph, creating equivalent Qgraphs.

Algorithm 1: Qtile Propagation Search

Input: G^Q: Initial Qtile-graph of quantized program.
Output: S: Set of equivalent Qgraphs discovered.

```
1  Function QtilePropagate(G^Q):
2      S ← ∅ ;
3      Q ← List() ;
4      Q.Push_Back(G^Q) ;
5      while Q.Size() > 0 do
6          g^Q ← Q.Pop_Front() ;
7          S.Insert(g^Q) ;
8          for Op ∈ g^Q do
9              ITiles ← Op.GetInputTiles() ;
10             OTile ← Op.GetOutputTile() ;
11             if ! OTile.IsQtile() and ITiles.hasQtile()
                and CanCompute (Op, ITiles) then
12                 NTile ← ComputeQtile(Op, ITiles) ;
13                 g'^Q ← Replace(g^Q, OTile, NTile) ;
14                 if g'^Q ∉ S and g'^Q ∉ Q then
15                     Q.Push_Back(g'^Q) ;
16     return S ;
```

4.1 Qtile Propagation Search

QFactory proposes *Qtile Propagation Search* for graph-level optimization, generating all possible Qgraph candidates, as outlined in Algorithm 1. Given a Qtile-graph, QFactory enumerates all operators within the graph (Line 8) and determines whether Qtile computation transformation can be applied to each operator. If the input tiles (which may include both Qtiles and normal tiles) of the operator satisfy the transformation rules, they are processed by the *ComputeQTile* function to produce an output Qtile (Line 12). This output Qtile then replaces the original output tile in the graph, resulting in a new Qgraph. The propagation process is repeated on the newly generated Qgraph. QFactory employs a breadth-first search approach to iteratively explore all possible Qgraphs. Finally, a set containing all alternative Qgraphs is returned, which will be passed to subsequent optimization stages.

The key component of the algorithm is the *ComputeQtile* function, which takes the operator and its input tiles as arguments and produces a Qtile expression that is equal to the original output tile. Since Qtiles are quantized tensors with additional annotations, these annotations must be considered in computation. The Qtile computation involves two types of transformation: group pattern transformation and mapping function transformation, corresponding to the two types of annotation in the Qtile design.

4.2 Group Pattern Transformation

The computation on Qtiles leads to transformation in the group pattern. For instance, when an element-wise binary operator (e.g. add, mul) is applied to a normal tile and a quantized Qtile, the group pattern from the Qtile operand is broadcast to the other operand, causing the output Qtile to adopt the same group pattern as the input Qtile.

There are also cases where operators are applied to two Qtile inputs. In such circumstance, QFactory must check whether the group patterns of the input Qtiles can be transformed into a common one. For example, when two block-grouped Qtiles with different block strides (W_1, H_1) and (W_2, H_2) are added, QFactory calculates the greatest common divisor (gcd) of the block strides to determine a common group pattern to which both Qtiles can be converted. In this case, a finer-grained group pattern $(\gcd(W_1, W_2), \gcd(H_1, H_2))$ is identified. Then, QFactory modifies the group pattern of these Qtiles to the common pattern and broadcasts the associated quantization parameters correspondingly. This ensures that different Qtiles can be computed with same group pattern.

4.3 Mapping Function Transformation

Since the mapping function is closely tied to the dequantized value of Qtile tensors, the mapping function of Qtiles also evolves as Qtiles propagate through various operators.

Take the linear mapping function for example, where each element in Qtile is quantized with scaling factor and zero-point bias. The dequantized value in a linearly-quantized Qtile can be represented as $(X_z^s)_{i,j} = s \times X_{i,j} + z$, where $X_{i,j}$ is the compressed tensor value in low precision format, and s and z represent the scaling factor and bias, respectively, which are shared across the quantization group.

Table 1 demonstrates the output Qtile expression resulting from the element-wise addition operator applied to different types of Qtiles. The operands may include non-quantized normal tiles (X) or Qtiles with scaling factors (X^s), bias offsets (X_z), or both (X_z^s). The Qtile computation transformation extends conventional tensor computations to a broader domain of quantized tensor operations.

From Table 1, quantized parameters can be redistributed between different operands. For instance, adding A_{z_1} to a non-quantized tile B can be transformed to $A + B_{z_1}$, with the bias offset z_1 shifted from the quantization parameters of tile A to those of tile B. Furthermore, in the case of plus A_{z_1} with $B_{z_2}^{s_2}$, the result can be transformed to the sum of one Qtile ($B_{z_1+z_2}^{s_2}$) and one normal tensor tile (A). This transformation minimizes the number of dequantization operations required when generating code, offering potential performance improvements.

Next, we present the Qtile transformation table for the matrix multiplication operator in Table 2. The transformation rules for Matmul operator produces more complicated result

Table 1: Mapping function transformation for the element-wise tensor addition operator. Marker $\times$ indicates that no valid transformation exists for the given Qtile inputs.

+	A	A_{z_1}	$A^{s_1}_{z_1}$
B	$A+B$	$A+B_{z_1}$	$A^{s_1}+B_{z_1}$
B^{s_2}	$\times$	$A^{s_1}+B^{s_2}_{z_1}$	$A^{s_1}+B^{s_2}_{z_1}$
B_{z_2}	$A_{z_2}+B$	$A_{z_1+z_2}+B$	$A^{s_1}+B_{z_1+z_2}$
$B^{s_2}_{z_2}$	$A_{z_2}+B^{s_2}$	$A+B^{s_2}_{z_1+z_2}$	$A^{s_1}_{z_1+z_2}+B^{s_2}$

Table 2: Mapping function transformation for the matrix multiplication operator.
J_X denotes a matrix filled with all ones, with the same shape as matrix X. K is the reduction dimension size of the matrix multiplication.

MatMul	A	A_{z_1}
B	AB	$AB+(J_AB)^{z_1}$
B^{s_2}	$(AB)^{s_2}$	$(AB)^{s_2}+(J_AB)^{s_2z_1}$
B_{z_2}	$AB+(AJ_B)^{z_2}$	$AB+(J_AB)^{z_1}+(AJ_B)^{z_2}+(J_{AB})^{z_1z_2K}$
$B^{s_2}_{z_2}$	$(AB)^{s_2}+(AJ_B)^{s_2z_2}$	$(AB)^{s_2}+(J_AB)^{s_2z_1}+(AJ_B)^{s_2z_2}+(J_{AB})^{s_2z_1z_2K}$

expressions due to the incorporation of reduction along the K dimension. Matrix J_X, which represents a matrix filled with all ones and has the same shape as X, is introduced in the result.

To illustrate the potential benefits brought by these transformations, consider the multiplication of Qtiles A_{z_1} and B_{z_2} as an example. The output is the summation of four Qtiles, as shown in the table. The first component, AB, is a normal tile that does not require dequantization. The second and third components involve matrix multiplications with J matrices. While these components are Qtiles requiring dequantization, the all-one property of J matrices reduces the Qtile shape. Since all rows in J_A matrix are identical, the product J_AB inherits this property. Consequently, the dequantization can be performed solely on the first row of $(J_AB)^{z_1}$, and the resulting values can be broadcast to the remaining rows. As a result, the dequantization overhead is reduced because of the reduction property of J matrices. The final component $(J_AJ_B)^{z_1z_2} = (J_{AB})^{z_1z_2K}$ is a matrix with all identical values, which can be efficiently represented and computed as a single scalar. In summary, the number of computationally expensive dequantization operations is significantly reduced, leading to improved performance.

Additionally, Qtile computation transformation allows for shifting between different quantization formats. In the matrix multiplication of A and $B^{s_2}_{z_2}$, the resulting Qtile expression consists solely of symmetrically quantized Qtiles (without zero points). Since distinct mapping functions may incur varying dequantization overheads, Qtile transformations provide an expanded optimization space by replacing heavy dequantization operations with more lightweight alternatives.

5 Differentiated Qtile Scheduling

After the graph-level Qtile transformation, the generated Qgraphs are executed by inserting dequantization operations. When performing dequantization, Qtiles need to be loaded from the lowest GPU memory to the highest registers. Previous DNN compilers solely focus on the memory access of model weight tensors, overlooking the overhead brought by the associated quantization parameters introduced in quantized models. When it comes to Qtiles, the scheduling needs further consideration to ensure full reuse of quantization parameters.

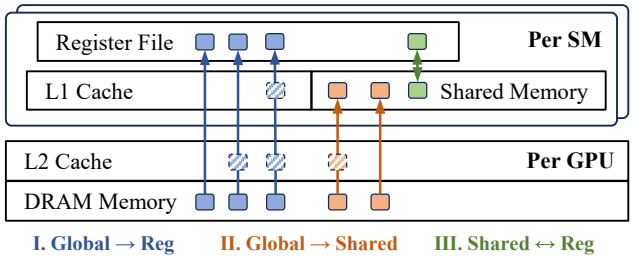

Figure 4: GPU memory hierarchy.

5.1 Diverse Data paths in Memory Hierarchy

Modern GPUs are equipped with hierarchical and multi-path data loading mechanisms in memory system. As illustrated in Figure 4, GPUs typically feature at least four distinct levels of memory hierarchy, ranging from the lowest DRAM memory to the highest register file. Memory resources are allocated across various scopes of processing units, with each layer offering a different visibility. The GPU memory and L2 cache are globally visible and shared across the entire GPU, whereas the upper two layers are specific to each Streaming Multiprocessor (SM). The user-configurable L1 cache, referred to as shared memory, is visible to all threads within a thread block, while registers are private to individual threads.

To perform computations on GPUs, data must be transferred from DRAM to registers, passing through intermediate memory layers. The thread-block-level shared memory allows for explicit control of data at L1 level, creating two categories of data paths, namely global-shared path and shared-register path, as depicted in Figure 4. Other intermediate cache layers remain transparent to programmer. However, CUDA provides a mechanism for controlling the cache eviction policy of certain data through PTX-level attributes called cache operators [27]. Specifically, .cg cache operator allows load instructions to bypass L1 cache, while .cs operator sets an evict-first policy for data in both L1 and L2 caches. This evict-first pol-

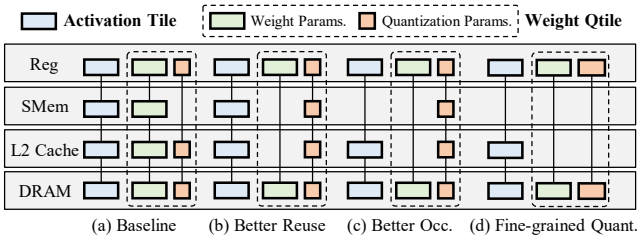

Figure 5: Qtile scheduling examples.

icy prioritizes the eviction of data from cache, minimizing memory pollution in cache, forming a data path bypassing the transparent cache layers. As a consequence, a wider range of distinct data loading paths from global memory to register are explored, as shown in blue lines in Figure 4.

Recent generations of NVIDIA GPUs (since Ampere) have introduced new asynchronous data movement instructions, enabling deeper software pipelining. The Hopper-series GPUs further introduces an independent hardware component specialized for data transfer and address calculation called Tensor Memory Accelerator (TMA). These advanced features are compatible with QFactory and can be passed as device specifications by users, enabling full utilization of these new hardware capabilities.

5.2 Scheduling Qtiles on Memory Hierarchy

With these various data loading paths, QFactory differentiates the mapping of tensor tiles to different data paths for maximizing overall memory utilization, generating strategies tailored to specific scenarios.

To illustrate, we demonstrate the data loading of a non-quantized activation tile and a quantized weight Qtile, which consists of low-precision weight parameters and their associated auxiliary quantization parameters. Figure 5 presents possible Qtile loading schedules discovered by QFactory.

Schedule (a) in Figure 5 represents the static strategy employed by previous compilers. In this approach, activation tensor tiles and weight tensor tiles are cached in shared memory before fetched into registers, enabling data reuse for both tiles. However, this strategy fails to optimize the quantization parameters in Qtiles, as it rigidly executes the dequantization operation, overlooking the overhead introduced by quantization parameters.

Beyond this conventional scheduling, QFactory proposes schedule (b) for better data reuse. By being aware of the group structure within Qtiles, QFactory enables the reuse of quantization parameters with shared memory. Moreover, QFactory applies the evict-first cache operator and bypasses intermediate cache levels for weight tiles. Since the decoding phase involves matrix-vector multiplication, weight values loaded are never reused across computation units. Bypassing intermediate cache levels frees up cache resources, increasing the cache hit rate for other kernel inputs.

In scenarios where GPU occupancy is critical for achieving optimal memory bandwidth utilization, QFactory trades off cache hit rate for improved occupancy, further eliminating caching of activation tiles in shared memory, as shown in schedule (c). This tradeoff is particularly effective on modern GPUs like H100, which provides massive number of LD/ST units for memory access. Allocating excessive shared memory to each thread block can restrict maximum occupancy, leading to underutilization of memory units and a degradation in overall memory bandwidth.

Finally, if an extremely fine-grained quantization algorithm is used or in the circumstance of lower bit-width, one thread may be assigned the workload of computing a whole weight group. In such case, QFactory switches to schedule (d), disabling shared memory usage for quantization parameters and directly reuse them at the register level.

6 Implementation

In this section, we introduce other necessary details of implementing QFactory, including the code generation method and kernel auto-tuning.

6.1 Template-based Kernel Generation

Inspired by CUTLASS [33], QFactory constructs CUDA code templates to implement various data loading paths on GPUs for moving data between memory hierarchy layers. This approach not only facilitates efficient code generation but also promotes automated tuning for performance optimization.

Given that type conversion instructions often have limited computational throughput compared to standard floating-point instructions [26], QFactory incorporates efficient type casting methods from previous works [12, 39]. Specifically, QFactory implement template functions for fast converting different formats of low-bit integers to half-precision real values in a unified manner.

To address the inefficiency caused by unaligned matrix sizes, which is a common issue in quantized kernels due to the increased alignment requirements of lower bit-width data types, QFactory eliminates unnecessary conditional jump instructions through templates. This is achieved by passing matrix shapes and other tuning parameters as compile-time constants, allowing most program constants to be deduced at compile time.

Finally, with the help of CUDA compiler, QFactory enables loop unrolling and instruction reordering to leverage instruction level parallelism (ILP) for overlapping memory overheads. While our approach is orthogonal to techniques such as double buffering and software pipelining, we observe that ILP is already efficient to deliver near-optimal performance in most LLM decoding scenarios.

6.2 ML-based Kernel Selector

As QFactory expands the search space for kernel optimization, efficiently determining the best kernel candidates and other hyperparameters in kernel tiling becomes a critical challenge.

To address this, QFactory employs a machine learning-based approach to quickly identify the optimal configuration of tunable parameters. Rather than directly training a model to output the best configuration, QFactory trains a lightweight multi-layer perceptron (MLP) model to predict the efficiency of given kernel configurations. We choose the achieved memory bandwidth utilization rate as regression goal instead of latency as it provides a limited value range. Kernels with different quantization settings do not share prediction models, but the kernels with the same quantization config for different matrix shapes share the same prediction model. We concatenate input matrix shapes and kernel hyperparameters (e.g., tiling block sizes, threadblock size) into a vector as input data and use the ratio of the kernel's achieved bandwidth to the device's maximum bandwidth as label. Training data is collected through offline profiling, where the real execution latencies of a small subset of kernels with randomly generated configurations are measured.

During the online compilation of a new quantized program, QFactory uses the trained model to estimate the latencies of all possible kernel configurations. QFactory then selects a few kernel configurations with the lowest estimated latencies for code generation and benchmarking. Therefore, a significant portion of inefficient kernel implementations are excluded, significantly accelerating the tuning process.

7 Evaluation

In this section, we present a comprehensive evaluation of QFactory across three different generations of NVIDIA data center GPUs: V100 (PCIe, 32GB), A100 (PCIe, 40GB), and H100 (PCIe, 80GB). We use CUDA 12.4 for evaluation on A100 and H100 GPUs, and CUDA 12.1 for V100 GPUs.

Evaluated Workloads We conduct experiments of two types of workloads to assess the overall performance of QFactory. We first evaluate the performance of the generated quantized kernels across different matrix shapes. These matrix shapes are categorized into two groups: one consisting of square matrices of varying scales, and the other comprising matrix shapes derived from actual LLM models. Next, we integrate QFactory into the popular LLM serving framework vLLM [21] to test the end-to-end model inference speedup. The evaluated LLM models include Llama-2 [35] and Qwen-2.5 [32] series with different scales, and can serve as a representative benchmark for a boarder range of LLMs. All workloads include different quantization bit-widths ranging from 8-bit to 2-bit.

Baselines For kernel-level benchmark, we compare QFactory to BitBLAS [39], which is the state-of-the-art deep learning compiler for low-precision linear kernels. We also compare QFactory to Marlin [12], which is a manually optimized kernel library for 4-bit quantized kernels on NVIDIA Ampere-series GPUs. For end-to-end evaluation, we compare QFactory to BitBLAS, Marlin and llama.cpp [13]. llama.cpp is a popular LLM inference framework with support of multiple quantization bit-widths and formats. For model inference with BitBLAS and Marlin, we leverage their integration with vLLM for fair comparision.

Methodology For kernel analysis, latency is measured with 200 warmup runs and 100 measurement runs. L2 cache is flushed between runs, and timing is recorded using CUDA events. No synchronization is invoked during the 300 runs to exclude CPU launch overhead, which can significantly affect measurements for small kernels. For end-to-end inference, we use the benchmarking scripts of vLLM for fairness. Generation speed is reported in tokens per second.

7.1 Kernel Overall Performance

NVIDIA H100 GPU Figure 6 demonstrates the performance of quantized kernels compiled by QFactory compared to BitBLAS and Marlin on NVIDIA H100 GPU. The evaluated quantization method is asymmetric weight-only quantization, with a group pattern of 128×1 blocks. Since Marlin is originally supported only on Ampere-series GPUs, we made necessary source code modifications for running it on H100.

The figure shows the relative speedup of different quantization bit-widths, including 8-bit (W8), 4-bit (W4), and 2-bit (W2), against the half-precision (W16) cuBLAS kernel as the baseline. The x-axis represents different weight matrix shapes. The shapes from M0 to M2 are square matrices of size 4096, 8192, and 16384. The matrix shapes from M3 to M8 are derived from Llama2-13B and Qwen2.5-72B models. We also demonstrates the geometric mean speedup of all test cases in the figure. The batch size of input activation is set to 1, indicating the common decoding scenario where weight-only quantization could gain most benefits.

As shown in the figure, QFactory consistently outperforms BitBLAS across most quantization configurations and matrix shapes. For quantization bit-width of 8, 4 and 2, QFactory achieves average speedups of $1.17\times$, $1.52\times$, and $1.66\times$, respectively. The performance gap becomes more pronounced at lower bit-width settings due to the changes in data volume of weight parameters. Specifically, as the bit-width decreases, the data volume of weight parameters loaded from memory is reduced, while the data volume of quantization parameters remains unchanged. As BitBLAS is unaware of this change, its kernel is hindered by the overhead associated with loading and processing quantization parameters, leading to significant performance degradation at lower bit-widths.

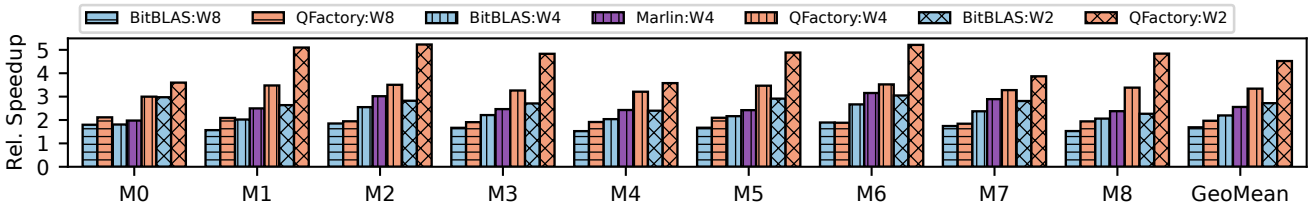

Figure 6: Relative kernel performance compared to FP16 cuBLAS kernel on NVIDIA H100 GPU.

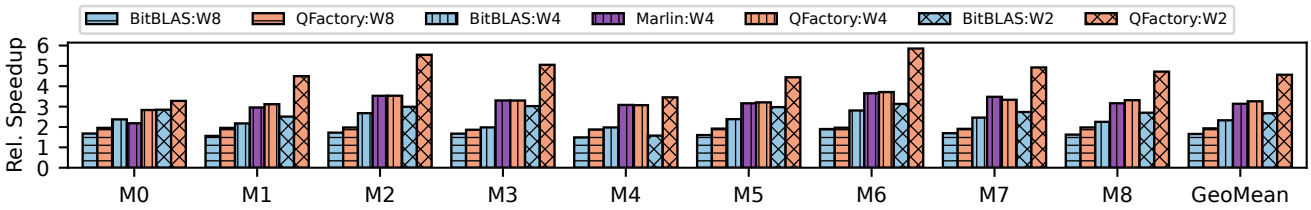

Figure 7: Relative kernel performance compared to FP16 cuBLAS kernel on NVIDIA A100 GPU.

It is noteworthy that QFactory also outperforms the heavily optimized Marlin kernel in 4-bit quantization on H100 GPU by 1.30×. This suggests that simply applying optimizations designed for Ampere-series GPUs results in suboptimal performance on Hopper-series GPUs. To achieve optimal performance across different GPU generations, it is essential to develop general-purpose compilers.

NVIDIA A100 and V100 GPUs We also evaluate kernel performance on NVIDIA A100 and V100 GPUs. Figure 7 and Figure 8 show the relative kernel performance on these GPUs. On A100, QFactory achieves an average speedup over BitBLAS of 1.17× for 8-bit, 1.40× for 4-bit, and 1.71× for 2-bit quantization. The Marlin library performs well on A100, significantly outperforming BitBLAS. Nevertheless, compared to the heavily optimized Marlin library, QFactory still delivers a comparable performance with 1.04× speedup.

On V100, QFactory achieves an average speedup of 0.99× for 8-bit, 1.17× for 4-bit, and 1.41× for 2-bit quantization compared to BitBLAS. Marlin is not supported on V100 due to its reliance on specific hardware characteristics, such as asynchronous data copy instructions, which are unavailable on this older GPU. The relative speedup against cuBLAS shown in Figure 8 appears significantly higher than on other GPUs, likely because the cuBLAS library on V100 has not been fully optimized for certain matrix shapes commonly encountered in recent LLM inference workloads.

7.2 Memory Bandwidth Analysis

Quantized linear kernels are memory-bound at low batch sizes, so achieved memory bandwidth is a strong proxy for kernel efficiency. The bandwidth metric also allows us to better evaluate GPU bandwidth utilization by comparing it with hardware specifications. Below, we conduct an in-depth analysis of the kernel's memory bandwidth utilization by scaling various matrix sizes and different quantization methods.

Scaling Matrix Sizes We evaluate the achieved kernel memory bandwidth utilization of QFactory, BitBLAS, and Marlin in 4-bit quantization on the NVIDIA H100 GPU. To provide a point of comparison, we also include the FP16 cuBLAS kernel. The evaluation uses square matrices of varying sizes. To align with different storage precision between 4-bit weight and 16-bit weight (in cuBLAS), we plot the achieved memory bandwidth as a function of the matrix storage size rather than its shape.

Figure 9 presents the memory bandwidth achieved by the simple-casting W4A16 and asymmetric quantized W4A16 kernels across different matrix sizes. In all cases, the achieved bandwidth increases as the size of the weight matrix grows. This trend can be attributed to the improved utilization of GPU's hardware load units with larger matrices.

The Marlin kernel achieves strong performance, comparable to cuBLAS, with little to no difference observed between simple and asymmetric workloads. This is due to Marlin's well-designed software pipeline, which effectively hides memory loading latencies of both weight parameters and quantization parameters. However, Marlin fails to fully utilize the memory bandwidth of H100 hardware due to its static execution paradigm.

BitBLAS also demonstrates comparable performance in the simple-casting W4A16 kernel but suffers from a significant performance degradation in the asymmetric kernel. This is primarily due to its inability to handle the overhead introduced by additional quantization parameters.

In contrast, QFactory consistently achieves higher bandwidth, particularly for medium-sized weight matrices. Al-

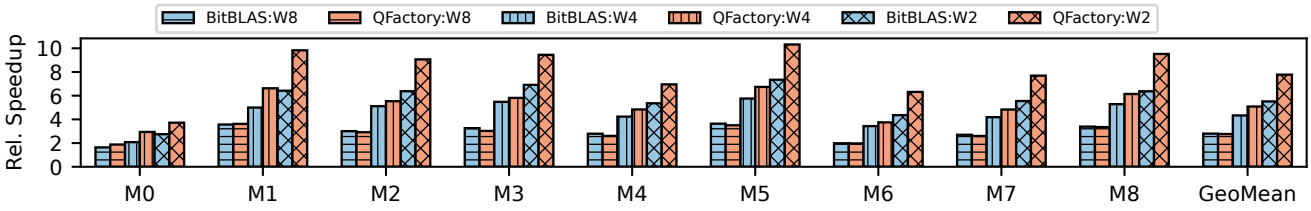

Figure 8: Relative kernel performance compared to FP16 cuBLAS kernel on NVIDIA V100 GPU.

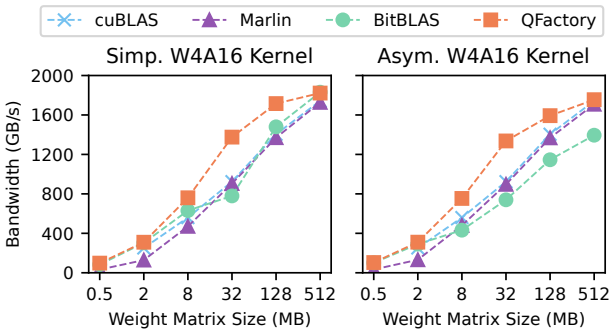

Figure 9: Achieved memory bandwidth on NVIDIA H100 GPU across varying weight matrix sizes for 4-bit kernels. Simp. and Asym. in the figure title stands for Simple-Casting and Asymmetric, respectively.

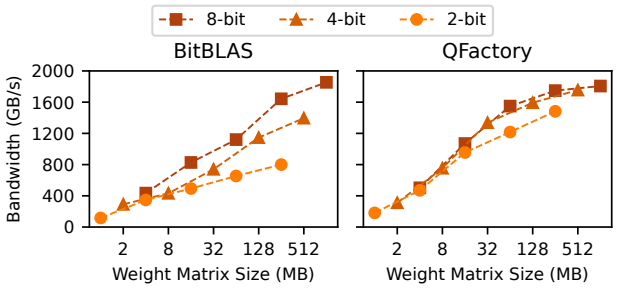

Figure 10: Achieved memory bandwidth on NVIDIA H100 GPU for Asymmetric WxA16 quantized kernels across varying bit-widths.

though the asymmetric kernel achieves slightly lower bandwidth compared to its simple-casting counterpart, QFactory still outperforms other baselines, highlighting its efficiency in managing memory load overhead introduced by quantization parameters.

The speedup advantage of QFactory diminishes with larger matrix sizes as all baseline methods approach the hardware's peak memory bandwidth (approximately 90% of 2TB/s on H100 GPUs). However, extremely large matrices are rarely encountered in practical LLM serving scenarios. For instance, the largest weight matrix in Llama2-70B (found in the gate/up projection layer) measures only 28,672 × 8,192 (112MB in FP16 format). The memory footprint becomes even smaller when employing weight quantization to lower bit-widths.

Consequently, real-world inference workloads primarily operate on medium-sized matrices, where QFactory demonstrates substantially superior performance compared to baseline approaches.

Scaling Bit-Widths We further analyze kernel memory bandwidth by scaling the bit-widths of weight matrices. Figure 10 illustrates the achieved memory bandwidth of QFactory and BitBLAS under 8-bit, 4-bit, and 2-bit asymmetric quantization settings on H100.

As shown in Figure 10, the memory bandwidth utilization for BitBLAS decreases significantly as the bit-width is reduced from 8-bit to 2-bit. This decline is primarily attributed to the increasing dominance of additional quantization parameters, including scaling factors and zero points, which introduce more overhead and reduce effective memory bandwidth utilization in lower-bit-width settings.

In contrast, QFactory demonstrates significantly better scalability across different bit-widths. Although there is a minor reduction in bandwidth when moving from 4-bit to 2-bit quantization, QFactory consistently outperforms BitBLAS across all quantization levels. This advantage becomes particularly pronounced as the matrix size increases, highlighting QFactory's ability to fully utilize H100's ample memory bandwidth by delivering higher occupancy and more efficient resource usage.

7.3 End-to-end Inference

To evaluate the effectiveness of QFactory in accelerating model serving, we conduct end-to-end performance tests using real models and measure the generation speed in tokens per second during the decoding stage. The tests are performed on both 4-bit and 2-bit quantization levels. All models are quantized with GPTQ algorithm [10], which is widely adopted for quantized model deployment. The quantization format follows group size 128 with symmetric quantization, a common configuration in HuggingFace [41] model repositories.

For Marlin, BitBLAS, and QFactory, we use the vLLM framework integration to ensure consistency and fairness. For llama.cpp, which uses a custom GGUF format for quantiza-

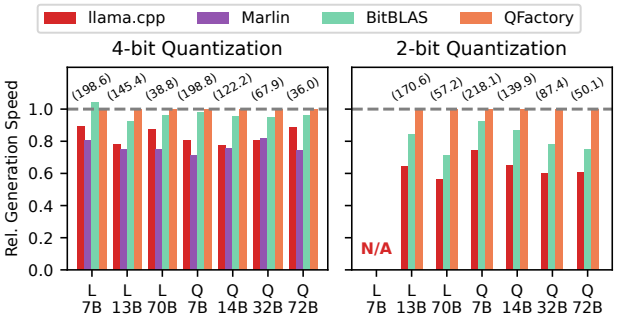

Figure 11: End-to-end model inference performance on NVIDIA H100 GPU. All generation speeds are normalized to QFactory. "L" denotes Llama models, while "Q" denotes Qwen models. The number in parentheses indicates the absolute generation speed of QFactory in tokens per second (tokens/s).

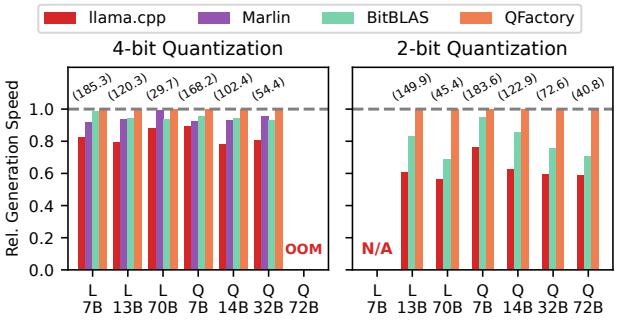

Figure 12: End-to-end model inference performance on NVIDIA A100 GPU.

tion and tensor storage, we apply the Q4_0 format for all linear layers in 4-bit quantization and Q2_K format for 2-bit quantization to ensure comparable computation workloads with GPTQ quantization. The inference tests are conducted with a batch size of 1, a prompt length of 16 tokens, and a generation length of 128 tokens. We use the decoding stage generation speed (tokens/second) as the primary metric. As our optimizations do not involve mathematically non-equivalent transformations, we have verified that QFactory could produces identical model output tokens.

NVIDIA H100 GPU Figure 11 presents the end-to-end inference results on NVIDIA H100 GPU across seven models, including models from Llama-2 and Qwen-2.5 series with different model size ranging from 7B to 72B. All generation speeds are normalized to QFactory for clarity, with absolute generation speeds (in tokens/s) displayed in parentheses for reference.

On 4-bit quantization, QFactory demonstrates robust performance, achieving a geometric average speedup compared to llama.cpp, Marlin, and BitBLAS by 1.21×, 1.32×, and 1.03×, respectively. The speedup is particularly significant for larger models, such as Llama-2-70B and Qwen-2.5-72B, as the relative impact of overheads, such as kernel launches and non-linear-layer operations, is more effectively amortized in larger models.

For 2-bit quantization, Marlin is not supported. Additionally, Llama-2-7B is excluded because its intermediate hidden size (11008) is not divisible by 128 (quantization group size) × 4 (alignment requirement for packing 2-bit data into 1 byte). QFactory exhibits superior performance on 2-bit quantization, with an average speedup of 1.58× and 1.23× compared to llama.cpp and BitBLAS, respectively. Notably, llama.cpp performs poorly in 2-bit quantization, showing no significant latency reduction compared to 4-bit quantization. This is primarily due to the lack of optimizations in its 2-bit kernel implementation.

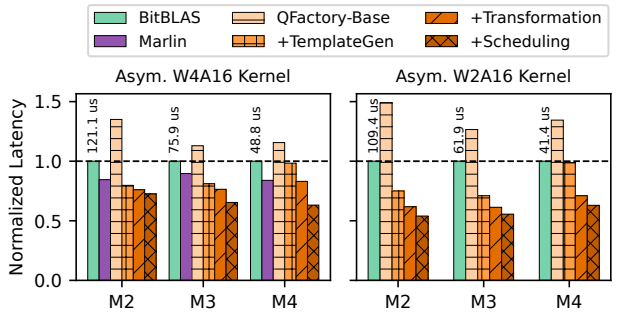

Figure 13: Kernel performance breakdown. All kernel latencies are normalized to BitBLAS. The number above bar shows the absolute latency of BitBLAS kernel in us.

NVIDIA A100 GPU Figure 12 shows the end-to-end inference performance on NVIDIA A100 GPU. Qwen-72B runs out of memory (OOM) on A100 due to its limited 40GB memory capacity. Across the remaining models, QFactory demonstrates consistent speedups, highlighting its adaptability to different GPU architectures.

Specifically, on 4-bit quantization, QFactory achieves average speedups of 1.21×, 1.06×, and 1.05× compared to llama.cpp, Marlin, and BitBLAS, respectively. On 2-bit quantization, QFactory achieves speedups of 1.61× and 1.26× over llama.cpp and BitBLAS, respectively. On A100, Marlin shows significantly better performance than on H100, as it has been fully optimized for this GPU architecture. Nevertheless, QFactory remains competitive, delivering comparable performance to Marlin while maintaining its robust efficiency across all tested models and quantization levels.

Table 3: Average kernel speedup over cuBLAS baseline on varying batch size.

Batch Size	1	2	4
BitBLAS	2.19	1.46	0.87
Marlin	2.56	2.54	**2.53**
QFactory	**3.44**	**3.18**	2.52

7.4 Optimization Breakdown

Figure 13 illustrates the kernel performance as optimization steps are progressively applied during the compilation of quantized kernels. We select three representative matrix shapes from Figure 6 for ablation study. For clarity, all kernel latencies are normalized to BitBLAS, with the absolute latency of BitBLAS indicated above bar.

The optimization process starts with the QFactory-Base implementation. The naive kernel shows degraded performance for 2-bit kernels, primarily due to the increased overhead caused by severe data alignment mismatches inherent in low bit-width computations.

The template-based kernel generation (+TemplateGen) introduced in §6.1 delivers substantial performance improvements. By leveraging instruction-level parallelism to overlap memory access and computation, and aligning memory layouts with hardware cacheline size, QFactory achieves marked reductions in latency. Specifically, QFactory surpasses all baselines in M2 and M3, while achieving comparable performance to BitBLAS on M4.

The Qtile computation transformation (+Transformation, proposed in §4) and Qtile scheduling (+Scheduling, introduced in §5) further unlock additional performance gains by exploring a broader range of transformation spaces. Together, these techniques enable QFactory to achieve better overall performance than all baselines across the evaluated matrix configurations.

7.5 Scaling Batch Size

Table 3 compares the geometric average speedup of asymmetric W4A16 kernel over the FP16 cuBLAS baseline across nine selected kernels same with Figure 6 on H100 GPU.

All baselines achieve highest speedup at batch size 1, as weight-only quantization provides the greatest benefit in memory-bound scenarios. From Table 3, QFactory consistently outperforms BitBLAS across all batch sizes but is surpassed by Marlin at larger batch sizes. This is because Marlin leverages manually optimized MMA instructions to take advantage of Tensor Core capabilities in high-batch-size scenarios. However, this optimization is orthogonal to QFactory and can be integrated with additional engineering efforts.

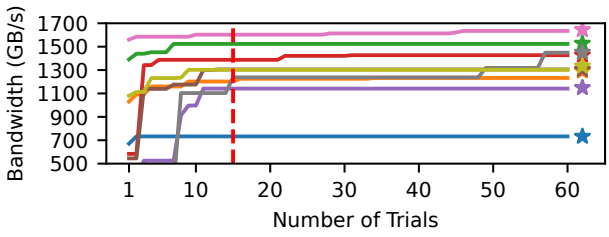

Figure 14: Prediction performance of kernel selector.

7.6 Kernel Selector

In the offline profiling stage of auto-tuning, QFactory randomly chooses 50 configurations for each kernel and collect data through profiling. The trained model is than utilized for prediction. We use the same nine matrices from §7.1 for evaluating the effectiveness of kernel selector. QFactory enumerates candidate kernels in the order of shorter predicted execution time and selects best kernel configurations by benchmarking. Figure 14 illustrates the achieved memory bandwidth as a function of the number of trials. The star markers in the figure represent the optimal kernel performance of each matrix shape in the whole search space. It is shown that the optimal kernel configuration can be identified within 15 trials in most matrix shape cases.

Since kernel latency is measured in microseconds, the tuning overhead primarily comes from compilation. Compared to evaluating the full search space, which could contain thousands of candidate kernels, testing just 15 candidates achieves a practical balance between tuning time and performance.

Users can increase the number of trials or conduct exhaustive offline profiling to obtain better kernel performance. In our experiments, full parameter enumeration takes a few hours for a single LLM model. As the results are reusable, even exhaustive tuning is feasible for production deployment.

8 Related Work

Quantization of LLMs Quantization methods for LLMs can be broadly categorized into Quantization-Aware Training (QAT) and Post-Training Quantization (PTQ), both aiming to reduce the bit-width of model weights while maintaining performance.

QAT integrates quantization into the training process, requiring retraining or fine-tuning of the model. While this incurs significant computational and memory overhead, it enables much lower bit-widths, with some methods achieving extreme cases such as 1-bit quantization. Examples of QAT methods include LLM-QAT [24], QLoRA [7], BitNet [38], BitDistiller [9], and OneBit [44].

In contrast, PTQ avoids the need for retraining by directly quantizing pre-trained weights, often using a calibra-

tion dataset to guide the quantization process. Due to its efficiency, 4-bit PTQ methods including GPTQ [10], AWQ [23] and SpQR [8] have gained widespread adoption, particularly in resource-constrained scenarios. Recent works, including QuIP [3], SqueezeLLM [19], and OmniQuant [30], have extended PTQ to explore even lower bit-widths.

System for Deploying Quantized LLMs Systems such as bitsandbytes [5], TensorRT [28], llama.cpp [13], vLLM [21], and Marlin [12] provide fast kernels for popular quantization formats. However, these systems are limited in application scope, supporting only a few specific cases, and often exhibit less portable performance across different hardware devices. Consequently, researchers frequently resort to manually implementing custom kernels for advanced quantization formats, such as those used in AWQ [23], FP6-LLM [42], and SqueezeLLM [19]. LUT-GEMM [29], FLUTE [15], and T-MAC [40] focus on optimizing lookup table based quantization, which is particularly useful in low-bit-width scenarios. BitBLAS [39], which builds on normal-precision deep learning compilers including TVM [4], Roller [46], and Welder [31], provides support for low-precision quantization. Nonetheless, it does not adequately address the complexities of advanced quantization formats or group-wise quantization, limiting its effectiveness in more sophisticated quantization workflows.

9 Limitation

As batch size increases, weight-only quantization fails to consistently deliver theoretical speedups because the kernel shifts from memory-bound to compute-bound, diminishing the benefits of reduced memory footprint. To address this limitation, joint activation-weight quantization introduces additional compression for activations and employs low-precision computation, enabling sustained speedups even at large batch sizes.

While QFactory currently supports only weight-only quantization, its core methodology can be extended to activation-weight quantization for further kernel acceleration. We leave this direction as future work.

10 Conclusion

We present QFactory, an efficient compilation framework for accelerating quantized LLM serving. QFactory addresses the inefficiency of existing systems by introducing a novel Qtile abstraction, enabling the exploration of a broader optimization space through Qtile computation transformations and differentiated memory scheduling. Extensive evaluations across a range of GPUs demonstrate that QFactory outperforms state-of-the-art compilers and manually optimized libraries. As a scalable solution for deploying quantized LLMs, QFactory not only enhances model efficiency but also facilitates the exploration of new quantization algorithms by alleviating the significant human effort required for custom kernel implementation.

Abstract

Machine learning (ML) compilers are effective solutions for deploying diverse Deep Neural Network (DNN) workloads on various hardware platforms automatically. However, there is a notable lag in existing ML compilers when it comes to supporting emerging optimization techniques like recent attention optimizations. These compilers lack the requisite flexibility to support expert-driven subgraph optimizations timely, resulting in suboptimal performance compared to manually optimized libraries. Conversely, template-based compilers lack the ability to abstractly express subgraphs, thereby reducing their adaptability to subtle changes in model architectures.

In this paper, we present PluS, an end-to-end ML compiler that facilitates the deployment of expert-optimized subgraph implementations while still preserving compiler flexibility. We rethink the encapsulation of ML compiler and decouple the burdensome embedded graph transformation process. PluS provides a lightweight loop-centric subgraph abstraction for experts to manage a flexible pattern warehouse, and employs a pattern identification approach for subgraph generation. As a result, PluS can deploy efficient subgraph implementations with minimal manual efforts, making it outperform the state-of-the-art rule-based embedded compilers (up to 4.04× speedup) on popular ML models.

1 Introduction

Deep neural networks (DNNs) have achieved remarkable success in various ML tasks [16, 25, 29, 33, 34, 41, 50]. In recent years, key DNN architectures have exhibited the trend of convergence. For instance, notably, the attention mechanism [43] has become a staple in state-of-the-art DNN designs. Even so, they continue to evolve with the introduction of novel local changes over time, e.g., RMSNorm normalizing function [48] and SwiGLU activation function [37]. Besides the above trends of model evolving, new tensor graph optimization techniques emerge rapidly, e.g., FlashAttention [13, 14] and fused Matmul-LayerNorm-Matmul [40]. The partially convergent model architectures and the rapidly evolved graph optimizations lead to a new demand for ML compilers.

ML compilers [10, 22, 30, 36, 57] play a crucial role in generating efficient kernel implementations for deploying ML models on various hardware platforms automatically. Typically, ML compilers translate ML models into computational graphs of operators and leverage graph transformation techniques like operator fusion to enhance performance. However, many ML compilers [22, 30, 36, 57] rely on predefined rules hard-written in the compilers for graph transformation. This approach cannot meet the growing demands of quickly supporting emerging novel and high-performance optimization techniques, as adjusting the compilers often requires significant effort. Consequently, ML compilers often lag behind the state-of-the-art performance due to the need for heavy modifications to predefined rules and code bases.

Simultaneously, template-based methods have been proposed to optimize computational graphs by matching predefined templates with specific operator compositions. Compared with the compilers with hard-written predefined rules, these methods allow users to support emerging optimizations more easily, without the need to modify the compiler implementation itself. However, this approach often struggles to support diverse model structures. For instance, the current AITemplate [45] codebase fails to support models like T5 due to the absence of fused `T5LayerNorm` composition, even though the `T5LayerNorm` consists of very basic operators. To support this model, users need to define the `T5LayerNorm` graph pattern and code generation (codegen) template.

Given the limitations of existing works, ML compilers face significant demands and challenges in swiftly supporting emerging graph optimization technologies, especially as ML model architectures exhibit a convergent yet evolving trend.

In this work, we introduce PluS, a highly efficient and

*Work was done when Ruofan and Zaifeng interned at Microsoft, advised by Zhen.

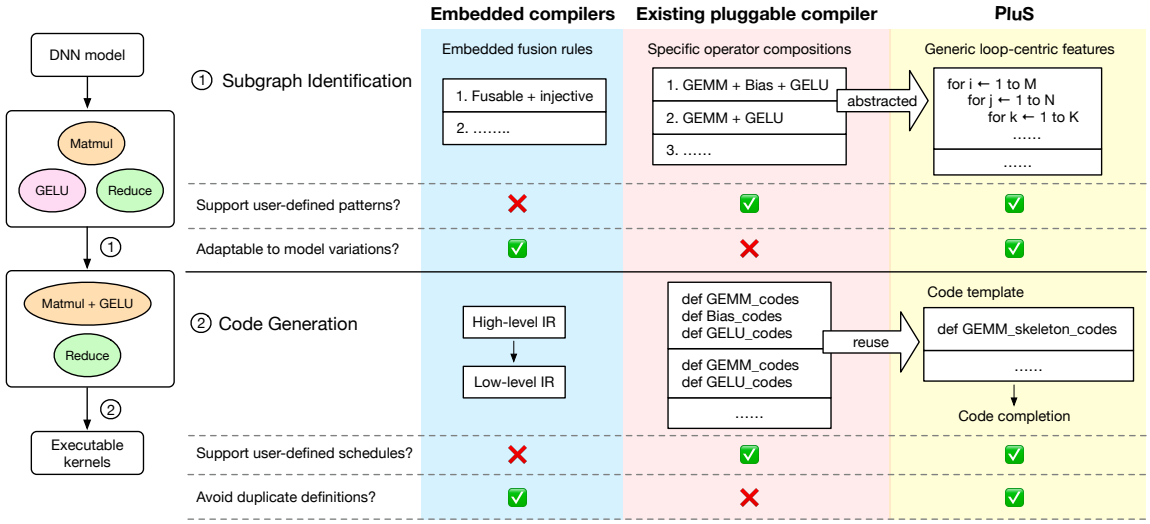

Figure 1: Workflow of ML compilers and a comparison between embedded compilers, existing pluggable compilers, and PluS.

expandable ML optimizing compiler with pluggable graph schedules. PluS decouples the graph transformation and codegen schedule definition from the compiler implementation itself based on the following insights. First, rather than relying on cumbersome graph transformation rules hard-written in the compiler itself, PluS offers a pluggable graph transformation module, which allows domain experts to maintain a warehouse of subgraph patterns. This approach facilitates the seamless deployment of emerging high-performance optimization techniques. Second, PluS recognizes that the optimized schedules for a subgraph are usually determined by the loop structure of key operators, such as `MatMul` and `Reduce`. For instance, substituting an `Add` operator with a `Sub` operator does not alter the loop structure of a graph, making it unnecessary to regenerate the entire schedule for such modifications. Therefore, instead of matching the exact graph of operators, PluS employs a loop-centric pattern matching method for graph transformation, wherein a pattern represents operators or subgraphs with similar underlying loop-centric features.

Building upon these insights, PluS proposes *+Graph*, a lightweight subgraph abstraction based on the loop-centric feature (named *+Loop*) (Sec. 4.1). PluS employs a novel graph transformation approach by generically matching a set of predefined subgraph patterns (with *+Graph*) from the expert-driven pattern warehouse (Sec. 4.2). Subsequently, PluS generates code for the subgraph pattern using the predefined code template (Sec. 4.3).

We have implemented PluS on top of PyTorch and conducted evaluations using five mainstream ML models on NVIDIA A100 GPU and RTX 4090 GPU. In comparison with TorchInductor [8] and TensorRT [22], PluS demonstrates an average end-to-end performance improvement of 4.04× and 1.77×, respectively. These performance gains are attributed to PluS's ability to integrate high-performance subgraph optimization techniques from various vendors and select optimal schedules for different shapes. When compared to the template-based ML compiler AITemplate [45], PluS excels in supporting newly developed DNN architectures while still maintaining a slight performance advantage (approximately 7.8%) on those AITemplate-supported models.

In summary, we make the following contributions:

► We pioneer the concept of pluggable graph schedules, enabling the effortless integration of expert-driven subgraph optimizations within an ML compiler. This innovation facilitates the decoupling of subgraph code generation iteration from the burdensome compiler infrastructure.

► We introduce a novel subgraph abstraction based on the underlying loop-centric features, providing a robust representation of subgraph patterns. Leveraging this abstraction, we devise a novel pattern-matching strategy for graph optimization.

► We develop PluS, an ML compiler supporting the pluggable graph schedule definition, and establish a subgraph pattern warehouse leveraging optimization schedules from state-of-the-art vendors. Extensive evaluation demonstrates the efficacy, portability, and flexibility of PluS.

2 Background and Motivation

2.1 Embedded and Pluggable Compilers

Given a DNN model, an ML compiler typically lowers it into a computation graph composed of a set of fine-grained tensor operators. The common workflow of ML compilers usually involves two key modules: subgraph identification and code generation (codegen), as shown in the left half of Fig. 1. The subgraph identification is to identify subgraphs within the computation graph that can be further optimized. For example, it identifies groups of operators that can be fused into a single subgraph, allowing for the generation of higher-performance code. Codegen is responsible for generating

codegen schedules for the identified subgraphs, which define how to map data computation onto hardware [56].

We categorize the optimizing compilers into two types: embedded and pluggable, based on whether the subgraph identification process supports user-defined functions or not. Embedded compilers implement the subgraph identification within the compiler so that users cannot customize this behavior. In contrast, pluggable compilers empower users to customize the process without modifying the compiler itself. Fig. 1 shows the characteristics of the embedded compilers and the existing pluggable compilers.

Embedded mode. Many of the ML compilers adopt embedded mode, such as XLA [36], TorchInductor [8], BladeDISC [56], DNNFusion [31] and TensorRT [22]. These compilers utilize predefined fusion rules to generate subgraphs. Users cannot modify the fusion rules without changing the compiler implementation. For example, TVM [10] has a set of embedded fusion rules not customizable by users. It categorizes operators into complex-out-fusable, injective, and reduction, and proposes three fusion rules: injective can fuse after complex-out-fusable, injective can fuse before reduction, and injective can fuse with injective. After generating the subgraphs, these compilers lower the high-level graph representations into target-specific code using a low-level intermediate representation (IR). For example, BladeDISC [56] employs the MLIR dialects [26], which encodes computations as loop constructs that map closely to the underlying hardware.

However, embedded compilers are not friendly to adopting the emerging subgraph optimizations. This stems from the complete reliance on compiler predefined rules for graph transformation, making it challenging to harness the innovations of the new optimizations fast. To catch up the new optimizations, it usually requires to modify the cumbersome graph transformation module in the compiler, demanding substantial effort and time.

We utilize the subgraph and the corresponding optimized kernels depicted in Fig. 2 to elucidate the limitations of embedded graph transformation. This subgraph comprises a matrix multiplication (Matmul) followed by a softmax function (Softmax), and the Softmax is decomposed into several basic operators by the ML compiler. Existing manually-written libraries (CUTLASS [40]) can optimize this pattern into 3 kernels as shown in Fig. 2. However, embedded-mode ML compilers face challenges in leveraging these optimizations. First, it requires modifying the fusion and codegen rules to support such subgraphs, which is usually labor-intensive and cannot be timely. Second, given that the high-level operators (Softmax) are usually decomposed into smaller and basic operators in the modern ML compilers, it is hard for the existing compilers to match the intricate subgraph adequately based on simplistic rules.

Pluggable mode. Some tensor compilers allow users to customize the subgraph identification. Users do not need to rewrite the compiler itself to add new fusion or codegen rules. For example, AITemplate [45] employs operator-level subgraph matching to optimize ML models. Users can define desired subgraphs during model definition, and AITemplate identifies specific operator-composed subgraphs for code generation. For instance, AITemplate currently supports 18 types of matrix multiplication-based subgraphs, such as `gemm_rcr_bias_gelu`. This particular subgraph represents a General Matrix Multiply (GEMM) with inputs in row major and column major, followed by Bias and GELU operations, with the output in row major.

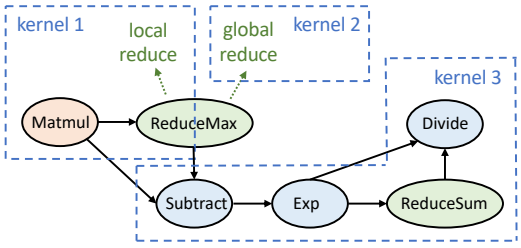

Figure 2: A subgraph formed by basic operators consisting of matrix multiplication followed by the softmax function, and the corresponding kernel implementation in CUTLASS.

However, the existing pluggable mode ML compiler relies on operator-level pattern matching to identify subgraphs and lacks proficiency in handling subtle changes in model architectures. Users are required to provide corresponding implementations for the specific operator composition and specify it during the model definition. For instance, in the case of AITemplate, it currently supports `gemm_rcr_bias_gelu` but not `gemm_rcr_gelu`. This implies that if a user opts to exclude the Bias operation, a new backend template and frontend definition must be added to AITemplate. Furthermore, AITemplate lacks the design for compiling models with dynamic shapes, limiting its flexibility in real-world scenarios. These shortcomings significantly reduce adaptability of pluggable ML compiler and hinders its ability to generalize for broader use cases.

2.2 Opportunities and Insights

We recognize the pressing need for ML compilers to alleviate manual burdens and overcome the inflexibility of embedded graph transformations. In this work, we introduce the concept of pluggable graph transformation to decouple the intricate graph transformation process from the ML compiler implementation. By providing a pluggable and flexible approach to subgraph identification and optimization, we empower users to define graph transformation patterns flexibly.

Given the limitations of existing pluggable compilers that rely on operator-level pattern matching for subgraph optimization, our insight is to use a general pattern with fundamental characteristics to map different operator compositions into the same underlying codegen schedule. We address several key issues with PluS in Sec. 4.1, Sec. 4.2 and Sec. 4.3 respectively:

► How is the general pattern defined, and how does it express the fundamental characteristics of a subgraph?

► How does PluS match or identify subgraph patterns?

► How do users provide codegen schedules for subgraph patterns, and how does PluS generate code accordingly?

First, operators and subgraphs can be expressed through only the loop skeleton of several key operators, which dominate the codegen schedules [56, 57]. PluS introduces a lightweight subgraph abstraction, +*Graph*, to define subgraph patterns with the loop-centric characteristics of key operators while ignoring trivial operators.

Unlike low-level loop abstractions designed for code generation like MLIR dialects [26], which are complex and generally inaccessible to ML optimization experts, +*Graph* is specifically designed for subgraph pattern matching, offering users the concise and necessary representation of a subgraph's essential structure.

Second, PluS employs a novel subgraph pattern identification method based on +*Graph*, rather than relying on fusion rules or matching specific operator compositions. PluS starts identification from the key operators and iteratively matches the subgraphs with user-predefined subgraph patterns.

Compared to the operator-by-operator matching approach employed by AITemplate [45], PluS's subgraph identification algorithm applies a generic matching on subgraph loop skeletons, which allows subgraphs with the same underlying loop-centric features but different operator compositions to be matched to the same +*Graph*.

Third, PluS offers an interface called +*Code* for users to provide the codegen template for any +*Graph*. The code templates define the schedules for the loop skeleton of the key operators, and PluS generates code for other trivial operations in the subgraph according to the data and computation information maintained by the compiler.

With this mechanism, PluS can reuse the codegen schedules for subgraphs with identical +*Graph*, eliminating the need to repeatedly define code implementations for every operator composition like in AITemplate (Fig. 1).

3 System Overview

Building upon the motivation and insights elaborated in Sec. 2, we introduce PluS to address the challenge of flexible subgraph optimization integration with a pluggable graph transformation solution based on loop-centric pattern matching. The core insight is to map different subgraphs with the same loop skeleton to a unique identifier and share the same codegen schedules for these subgraphs. PluS first designs +*Graph* (Sec. 4.1) to serve as an identifier for subgraph pattern matching, which encapsulates the loop-centric characteristics of subgraphs. PluS develops a pattern warehouse to decouple the subgraph identification and codegen process from compiler internals. Users are empowered to manage these processes by providing mappings of +*Graph*s to their corresponding

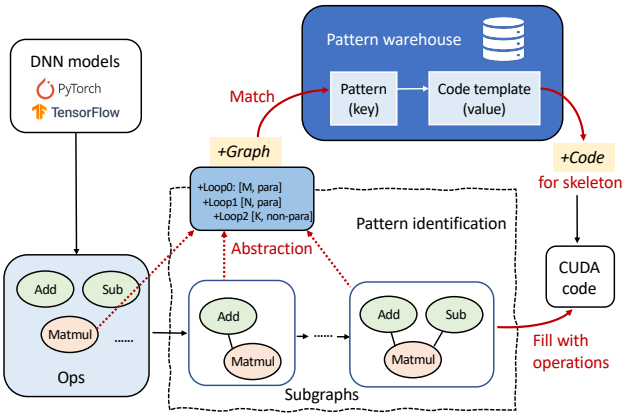

Figure 3: System Overview of PluS.

code templates using PluS's interface +*Code* (Sec. 4.3). The code template defines the codegen schedules for the skeleton operations in the subgraphs.

Figure 3 shows the system overview of PluS. To begin the compilation process, PluS ingests a DNN model from the framework (e.g., PyTorch). It then automatically translates the model into a computational graph comprised of operators. Each operator is essentially expressed as a +*Loop* (Sec. 4.1), which serves as the building block of +*Graph*. Subsequently, PluS employs a pattern identification methodology to identify subgraphs that match the pre-defined subgraph patterns in the pattern warehouse, as detailed in Sec. 4.2. Specifically, PluS adopts a greedy extension policy to expand the subgraph scope, obtaining the +*Graph*s of subgraphs and iteratively querying the pattern warehouse to determine whether the +*Graph* matches the pre-defined patterns. Finally, PluS generates code for the identified subgraphs using the code templates in the pattern warehouse and specific information within each subgraph, filling in the trivial operations, as detailed in Sec. 4.3.

4 Design Methodology

4.1 Subgraph Identifier: +Graph

In this section, we introduce +*Graph*, a subgraph representation designed to serve as an identifier in the subgraph identification process. +*Graph* abstracts DNN computation to its loop structure and key operations. This allows subgraphs with different operator compositions but similar loop-centric features to be mapped to the same +*Graph*, and share the same codegen schedule. This enhances PluS's adaptability to varying model structures. The +*Graph* consists of multiple levels of +*Loop*s. Typically, computations on a tensor can be expressed as nested loops. +*Loop* is an abstraction of such loops, with the nested loops of tensor computations corresponding to the nested +*Loop*s.

As a subgraph identifier for pattern identification, +*Graph* must possess two key features: it encapsulates the underlying characteristics of loops and computations, and it maintains

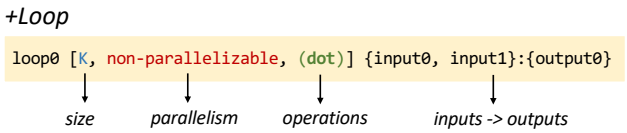

Figure 4: The +*Loop* representation.

uniqueness—each subgraph has a distinct +*Graph*. In the following content, we first introduce the key properties of +*Loop*, which succinctly express essential information of a loop for the pattern abstraction. We then present a comprehensive list of transformation primitives of +*Loop*. When multiple operators are grouped into a single subgraph, the +*Loop*s are interconnected and undergo transformations based on these primitives, forming the unique +*Graph* of the subgraph.

Properties. As shown in Fig. 4, +*Loop* is characterized by three main properties: *size*, *parallelism*, and *operation*.

Size describes the size of a +*Loop*, encompassing two types: *integer* and *symbolic*. When the size is known at the compile time, it will be a constant integer, otherwise it will be represented symbolically (i.e., dynamic shape).

Loop-level Parallelism assumes paramount significance for mapping +*Loop* computations onto hardware execution units. It can be classified into two categories: *parallelizable* and *non-parallelizable* +*Loop*. A *parallelizable* +*Loop* indicates that there are no data dependencies between consecutive loop iterations, allowing for parallel execution. Conversely, in the *non-parallelizable* +*Loop*, statements in an iteration of the +*Loop* depend on statements in another iteration of the +*Loop*, which necessitates serial execution or synchronization efforts. For instance, the innermost +*Loop* of a reduction operator (ReduceOp) is non-parallelizable, while each level of the +*Loop* in an elementwise operator is parallelizable.

Operation is an optional property that records computational operations within a +*Loop*. When users provide +*Graph* in the pattern warehouse, they need to specify only the crucial operations that determine codegen schedules in the subgraph pattern, such as dot product, reduce-max, etc., rather than specifying all trivial operations. PluS will identify subgraph patterns by leveraging the information within the *Operation* property. If an operation is defined in a +*Graph*, only subgraphs whose corresponding +*Loop* contains this operation will match the pattern (detailed in Sec. 4.2). Other trivial operations not specified by users will be ignored in the subgraph's +*Loop*. For instance, users can specify the permutation (transpose) operation in +*Graph* to determine whether the permutation operator can be included in a subgraph.

In addition to the three properties mentioned above, +*Loop*s in a subgraph also carry *input and output tensors*. However, this information does not affect pattern matching as this does not affect the underlining codegen schedule design. This means that subgraphs with different inputs and outputs might still map to the same +*Graph*, depending on the key operations within the subgraph. We will discuss the input and output features in the code generation section in Sec. 4.3.

Transformation primitives. As an identifier of a subgraph, the +*Graph* representation should be deterministic and unique for a given subgraph. Our insight is to merge the loops in a graph as much as possible while maintaining correctness to simplify the representation of the subgraph, making pattern identification easier. To achieve this, we design three primitives to guide the transformation of +*Loop*s across different operators when forming a subgraph. After the +*Loop*s of the subgraph are transformed, a fourth primitive collapses nested +*Loop*s for final standardization.

Assuming operator B follows operator A, i.e., B's input corresponds to A's output, we define the tensor connecting these two operators as the *hub tensor*. The +*Loop* associated with this hub tensor in operator A is referred to as *prev_loop*. The corresponding loop of operator B is denoted as *cur_loop*.

Primitive 1: Merge without Altering Properties. This primitive involves merging prev_loop and cur_loop when they share identical sizes and are both parallelizable.

For example, consider merging MatmulOp [M, N, K] and AddOp [M, N] into a +*Graph*, where axes M and N can be seamlessly merged without altering their properties. Before the merge, the computation of MatmulOp is illustrated in Fig. 5(1)(a). After the merge, the computation of MatmulOp and AddOp is depicted in Fig. 5(1)(b). The final +*Loop* structure of the subgraph is determined as shown in Fig. 5(1)(c).

Primitive 2: Merge with Parallelism Modification. In cases where prev_loop and cur_loop share identical sizes, and prev_loop is parallelizable while cur_loop is non-parallelizable, when merging the two loops, the *Parallelism* property is adjusted to non-parallelizable.

For instance, consider the fusion of AddOp [M, N] and ReduceOp [M, N], where the reduction axis is N. Since the N axis of AddOp is parallelizable while the N axis of ReduceOp is non-parallelizable, these +*Loop*s can be merged into a non-parallelizable +*Loop*. The computation of AddOp and this fused subgraph, and the +*Loop* structure of this subgraph are shown in Fig. 5(2).

Primitive 3: Transition to a New Loop. If the prev_loop is non-parallelizable, cur_loop cannot be merged and instead forms a distinct new +*Loop*, irrespective of the size and parallelism of cur_loop.

For instance, consider the fusion of ReduceOp [M, N] and AddOp [M, N], shown in Fig. 5(3)(a) and (b). Given that the N axis of ReduceOp is non-parallelizable, it results in the creation of a distinct new +*Loop* for the N axis of AddOp in Fig. 5(3)(c). This subgraph is represented as Fig. 5(3)(d).

Primitive 4: Nested loops collapsing. After the +*Loop*s in different operator are transformed, PluS collapses consecutive nested +*Loop*s that belong to the same categories within the subgraph to achieve the simplest representation under equivalent conditions. For instance, a BatchMatmulOp [B, L, M, N, D] can be simplified to BatchMatmulOp [B x L, M, N, D] because axes B and L both represent batch dimensions in this

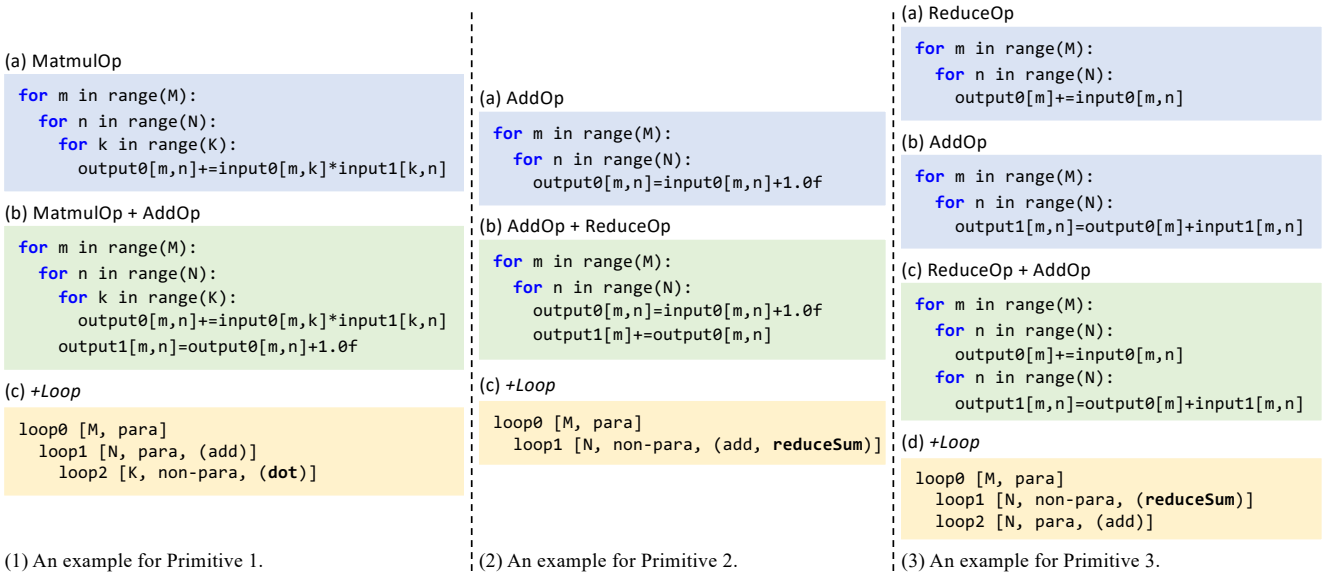

Figure 5: Examples for transformation primitives of +*Loop*.

scenario and can be collapsed.

Specifically, PluS determines the collapsibility of a +*Loop* and its next +*Loop* sequentially, adhering to three conditions for collapsing: First, the next +*Loop* must be the only +*Loop* nested inside the current +*Loop*. Second, the next +*Loop* must possess the same parallelism as the current +*Loop*. Third, the input tensors involved in both the next +*Loop* and the current +*Loop* must be exactly the same. For instance, consider the BatchMatmulOp [B x L, M, N, D]. Here, axes B and L are both parallelizable and present in all input tensors, whereas the parallelizable M axis exists only in the first input tensor, and the parallelizable N axis exists only in the second input tensor. The D axis is non-parallelizable.

4.2 Subgraph Identification

Based on the subgraph identifier +*Graph*, PluS employs a pattern identification method to generate subgraphs. This process is guided by two key insights. First, PluS begins subgraph identification with a skeleton operator. The concept of a *skeleton operator*, as proposed in [57] and [56], denotes a crucial operator that determines the data layout and codegen schedule within the computational graph, such as MatmulOp and ReduceOp. Most advanced optimized subgraphs are now built around these skeleton operators.

Second, PluS uses a greedy extension strategy to expand the subgraph scope when identifying subgraph patterns. This approach aims to match the largest possible range of subgraph patterns, including the maximum number of operators. Through subgraph extension, PluS iteratively matches the subgraph with pre-defined +*Graph*s in the pattern warehouse. The greedy extension strategy provides users with the greatest flexibility in code planning to decide the best implementation of the subgraphs. Unlike conventional ML compilers that map each subgraph into a single kernel, PluS allows users to freely determine the number of kernels in the code template of a +*Graph*. By expanding the range of subgraphs from the skeleton operator, PluS can identify most of the current mainstream subgraph optimizations.

In this section, we first present the steps of PluS's pattern identification method, which continually expands the subgraph and queries the pattern warehouse to match +*Graph*s. We then propose the match conditions to determine whether to continue or stop the extension.

Algorithm 1: Main steps of subgraph identification.

```
Input  : unfused_ops initialized by the computational graph of operators
Output : computational graph of fused subgraphs
1 while unfused_ops.IsEmpty() ≠ True do
2     skeleton_op = FindSkeletonOp(unfused_ops);
3     if skeleton_op then
4         MatchFromSkeletonOp(skeleton_op);
5     else
6         root_op = FindRootOp(unfused_ops);
7         MatchFromSkeletonOp(root_op);
```

Subgraph identification process. The main steps of PluS's subgraph identification are outlined as Algo. 1. The variable *unfused_ops* denotes the operators that have not yet been fused into a subgraph and is initialized by the computational graph. When the list of unfused operators is not empty (line 1), PluS attempts to identify a skeleton operator from unfused operators (line 2) and initiates pattern matching from that point (line 4). In PluS, we define the skeleton operator as the operator possessing at least one non-parallelizable +*Loop*, including MatmulOp and ReduceOp. If there is no skeleton operator in the unfused operators, PluS will start pattern matching from the root operator (lines 7-8), defined as the operator without a producer operator in the list in this paper.

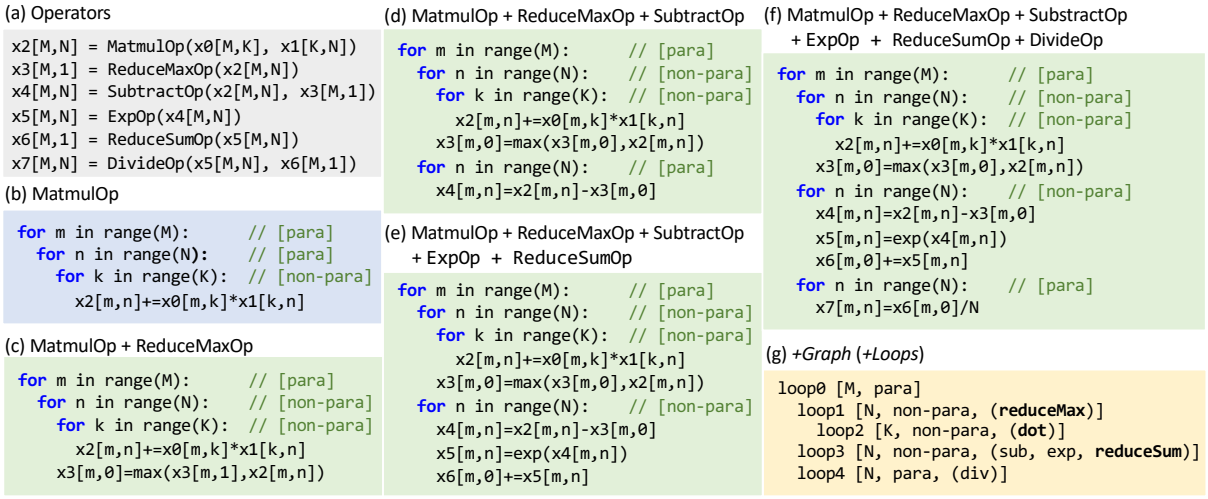

Figure 6: Case study for the subgraph identification workflow of PluS.

Algorithm 2: The steps of MatchFromSkeletonOp.

```
   Input : subgraph initialized by skeleton operator
   Input : Boolean flags: allow_prologue, allow_epilogue
1  if allow_prologue then
2      while prologue = FindPrologueOp(subgraph) do
3          if Matching(subgraph, prologue) then
4              FusePrologueOp(subgraph, prologue);
5  if allow_epilogue then
6      while epilogue = FindEpilogueOp(subgraph) do
7          if Matching(subgraph, epilogue) then
8              FuseEpilogueOp(subgraph, epilogue);
9              while producer = GetProducerOp(epilogue) do
10                 if Matching(subgraph, producer) then
11                     FusePrologueOp(subgraph, producer);
```

The steps of *MatchFromSkeletonOp* are outlined in Algo.2. First, PluS initializes the current *subgraph* with a skeleton operator. Each skeleton operator has two boolean properties predefined by experts in the pattern warehouse: *allow_prologue* and *allow_epilogue*, which determine the fusion direction of the skeleton operator. Specifically, if the skeleton operator allows prologue fusion (line 1), PluS continuously attempts to find a prologue operator of the current subgraph (line 2), which produces one of the input tensors of the current subgraph. PluS then assesses whether the subgraph meets the match conditions if the prologue operator is fused (line 3). If the conditions are met, PluS fuses this prologue operator into the subgraph (line 4). The criteria for determining whether the subgraph meets the match conditions will be detailed later.

Additionally, if the skeleton operator allows epilogue fusion (line 5), PluS continuously attempts to find an epilogue operator of the current subgraph that utilizes the output tensor of the current subgraph (line 6). PluS then evaluates whether the subgraph meets the match conditions if the epilogue operator is fused (line 7). If the conditions are met, PluS incorporates this epilogue operator into the subgraph (line 8). Moreover, unlike prologue operators, after an epilogue operator is fused, PluS endeavors to find the producer operator of this operator that is not in the subgraph (line 9) and assesses whether it can be fused (lines 10-11). For instance, after fusing a MatmulOp and a binary AddOp, PluS will also fuse the producer operator of another input tensor in the AddOp, such as the DivideScalarOp.

PluS applies the following prioritization to avoid ambiguity in subgraph matching. First, if an operator can serve either as an epilogue to a skeleton operator or as a prologue, PluS prioritizes epilogue fusion. This is because prologue fusion sometimes introduce redundant computations due to repeated input loading across multiple thread blocks, whereas epilogue operations do not, as the output is computed and written only once, such as the data processing in MatMul. Second, if an operator A produces two outputs, and each output could be fused with different downstream operators (B and C), but not both together, PluS does not enforce a fusion priority between them. PluS applies a greedy matching strategy: if B is encountered first during traversal, PluS fuses A with B, saves A's intermediate output, and computes C separately using that output. From a performance standpoint, fusing A with either B or C yields comparable efficiency, as the key benefit—avoiding redundant memory accesses and kernel launches—is achieved in both cases.

PluS fuses operators only to generate *+Graph*s as identifiers to match the pre-defined patterns and corresponding codegen schedules in the pattern warehouse. This approach differs from conventional compilers, which use hard-written fusion rules to generate code of subgraphs.

Case study for subgraph identification. We use Fig. 6 to illustrate how the *+Graph* of a subgraph is transformed during subgraph identification based on the transformation primitives. It is assumed that at each step the subgraph satisfies the match conditions. To exemplify, we consider the subgraph shown in Fig. 6, which consists of a subgraph comprising a GEMM operation followed by a Softmax operation. This subgraph

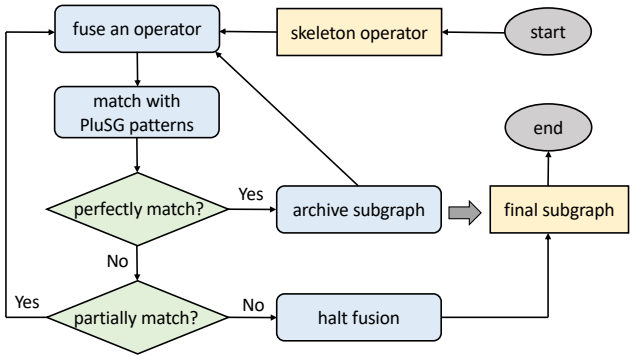

Figure 7: Workflow of match conditions.

encompasses six basic operators, as shown in Fig. 6(a).

Initially, PluS identifies a skeleton operator, MatmulOp [M, N, K], within the *unfused_ops*. The MatmulOp permits epilogue fusion while disallowing prologue fusion. The +*Loop* of MatmulOp [M, N, K] is shown in Fig. 6(b), where the M axis and N axis are parallelizable +*Loop*s, while the K axis is a non-parallelizable +*Loop*.

Subsequently, PluS identifies an epilogue operator, ReduceMaxOp [M, N], and attempts to incorporate it into the subgraph. During the fusion of MatmulOp and ReduceMaxOp, the properties of the M axis remain unaltered, following Primitive 1. However, the N axis is modified to be non-parallelizable in accordance with Primitive 2. The results are shown in Fig. 6(c).

Following that, PluS identifies an epilogue operator, SubtractOp [M, N]. The M axis can be merged according to Primitive 1 since the M axis in the subgraph and SubtractOp are both parallelizable. However, the N axis in the subgraph is non-parallelizable, while in SubtractOp, it is parallelizable. Hence, after fusing SubtractOp based on Primitive 3, the subgraph requires a new N axis, depicted in Fig. 6(d).

Similarly, as depicted in Fig. 6(e), PluS fuses injective ExpOp [M, N] where axes M and N are merged following Primitive 1, and ReduceSumOp [M, N] where M axis is merged following Primitive 1 and N axis is merged following Primitive 2. Additionally, a new N axis emerges within the subgraph during the fusion of DivideOp [M, N], according to Primitive 3. Finally, the computation of the resulting subgraph is depicted in Fig. 6(f), and can be represented by Fig. 6(g).

Match conditions. During the pattern matching process, PluS generates subgraphs represented by +*Graph* and evaluates them against match conditions with the patterns stored in the pattern warehouse to determine whether to extend further. Fig. 7 shows the workflow of this assessment process in PluS. Initially, it verifies whether each pattern in the warehouse perfectly aligns with the +*Graph* of the subgraph. If there is a complete match, PluS archives the subgraph as the most recently successfully matched subgraph corresponding to that skeleton operator and proceeds with the extension. This aligns with the principle of PluS, which is to expand subgraphs within the broadest scope possible.

In cases where there's no perfect match, PluS investigates whether the current subgraph represents a partial or intermediate state of a +*Graph* pattern in the warehouse. This involves determining if the current subgraph could potentially evolve into a specific +*Graph* pattern in the future. PluS accomplishes this by recursively traversing the multi-level +*Loop* tree, considering the following criteria for each +*Loop*: First, if the +*Loop* in the warehouse pattern is non-parallelizable, the corresponding +*Loop* in the current subgraph can be either parallelizable or non-parallelizable, as parallelizable +*Loop*s might transform into non-parallelizable ones in subsequent extension as per Primitive 2. Second, if the +*Loop* in the warehouse pattern is parallelizable, the corresponding +*Loop* in the current subgraph must also be parallelizable. Third, the number of +*Loop*s nested within one +*Loop* in the warehouse pattern must be greater than or equal to the number of +*Loop*s nested within the corresponding +*Loop* in the current subgraph, as subsequent extension operations might introduce new +*Loop*s. Fourth, if the warehouse pattern includes an operation, such as dot product and max-reduction, the subgraph must match it exactly.

Finally, two outcomes emerge: First, if the current subgraph doesn't align with any +*Graph* pattern in the pattern warehouse in its partial or intermediate state, the pattern matching process for the current skeleton operator is halted. The last archived subgraph, i.e., the most recently matched subgraph corresponding to a warehouse pattern, becomes the final subgraph for the current skeleton operator. Second, if the current subgraph represents the partial or intermediate state of a specific pattern in the pattern warehouse, the pattern matching process continues.

Case study for match conditions. Taking the subgraph in Fig. 6(d) as an example, which includes MatmulOp, ReduceMaxOp, and SubtractOp, its +*Graph* (+*Graph0*) can be represented as follows.

```
loop0 [M, parallelizable]
  loop1 [N, non-parallelizable, (reduceMax)]
    loop2 [K, non-parallelizable, (dot)]
  loop3 [N, parallelizable, (sub)]
```

While this subgraph does not perfectly match the +*Graph* pattern in Fig. 6(g) (+*Graph1*), it can be identified as a partial state of that pattern. First, loop0 in +*Graph1* is parallelizable, and loop0 in +*Graph0* is also parallelizable. Second, loop3 in +*Graph1* is non-parallelizable, whereas loop3 in +*Graph0* can be parallelizable. Third, the number of +*Loops* nested within +*Graph1*-loop0 (loop1, loop3, loop4) is greater than those nested within +*Graph0*-loop0 (loop1, loop3). Finally, the skeleton operations involving in +*Graph0*, specifically `reduceMax` and `dot`, are the same as those in +*Graph1*.

4.3 Code Generation

In this section, we describe how PluS generates code for subgraphs. Subgraph optimization experts first provide mappings between a +*Graph* and the code template in the pattern

```
loop0 [M, para] {x0,x1}:{x7}
  loop1 [N, non-para, (reduceMax)] {x2}:{x3}
    loop2 [K, non-para, (dot)] {x0,x1}:{x2}
  loop3 [N, non-para, (sub, exp, reduceSum)] {x2,x3}:{x6}
  loop4 [N, para, (div)] {x6}:{x7}
```

Figure 8: An example for loop bodies.

warehouse. The +*Graph* encapsulates the loop skeleton of the subgraph with key operations, while the code template defines the codegen schedules for this skeleton, leaving the code for trivial operations to fill by compiler. PluS compiler will maintain every detailed information during subgraph identification and generate the remaining code for the subgraph.

PluS compiler. During actual compilation, PluS retains information about all the data dependencies and operations of each +*Loop*, including the input tensors, output tensors, and computations involved in each loop. When the PluS compiler fills the code template of the +*Graph* with specific code, it traverses from the leaf nodes of the +*Loop* tree and generates the corresponding data and operation code, because the +*Loop* body of each leaf node can be implemented as an independent code segment. For instance, consider the subgraph in Fig. 6(g). PluS compiler will generate code for four +*Loop* bodies in turn: loop0-loop1-loop2, loop0-loop1, loop0-loop3 and loop0-loop4. The inputs, outputs, and operations involved in each of these +*Loop*s are illustrated in Fig 8.

+*Code* interface. Each matched subgraph pattern has a expert-provided code template in the pattern warehouse. Experts can create these templates by adding +*Code* statements in the code. +*Code* includes three types: data placeholder, compute, and data write-back, as shown in Fig 9. A *data placeholder* can represent any number of input and output tensors in the code. The compiler will complete the code for pointers to the data at this position based on the specific +*Loop* information. *Compute*-type statement tells the compiler where the data computation occurs in the code. If the data has not been loaded before computation, the compiler will automatically generate the code to load the data based on the addressing information in the +*Loop*, followed by the corresponding computation code. *Data write-back* usually occurs after all +*Loop* body computations are completed, indicating to the compiler to generate code that writes the computation results back to global memory. Typically, the compiler needs to address computations and write-backs. PluS has also implemented a compilation path compatible with CUTLASS, which is widely used by many ML compiler backends. Since CUTLASS provides a wrapper for implementing high-performance linear algebra on CUDA, PluS's compiler does not need to handle those details in code generation.

Case study for code generation. Continuing with the subgraph from Fig. 6 as an example, an expert might want to define a codegen schedule for subgraphs with this skeleton. First, they would define the pattern of this subgraph, or +*Graph*, in the pattern warehouse, retaining only the skeleton operations in the pattern. This allows the compiler to reuse the codegen

```
// data placeholder
plus::InputList input_list;
plus::OutputList output_list;
// compute
plus::compute</*DataType*/float>(input_list,
              /*Result*/local_out);
// data write-back
plus::writeback(local_out, output_list);
```

Figure 9: +*Code* statements.

schedule for any subgraph that matches the same structure.

Then, in the code template, the expert defines the code design for the loop0-loop1-loop2 structure, which corresponds to a matrix multiplication pattern. The expert has the flexibility to use a simple cuBLAS interface, the Matmul templates from CUTLASS, or even custom handwritten code. Since MatmulOp is a skeleton operator that allows epilogue fusion, the expert uses the *compute* statement in the code to reserve a placeholder for epilogue operations. Next, the expert implements the schedule logic for loop0-loop1 and loop0-loop2, handling the reduction logic by designing parallel execution and synchronization operations as needed. They can also decide whether to integrate this logic with the previous `dot` operation to achieve the most efficient schedule. Similarly, *compute* placeholders for prologue operations are reserved before reduction operations. Finally, since the loop0-loop4 loop body does not contain skeleton operations, the expert only needs to reserve a placeholder with a *compute* statement for this loop body. After all the loops are completed, a data write-back statement is added to the code.

Dynamic shape. PluS is capable of compiling models with dynamic shapes. It uses symbolic types to represent shapes during subgraph identification. These symbolic dimensions are carried through the compilation process, and the corresponding code templates treat shapes as runtime variables. Experts can then autonomously decide dynamic schedules based on the actual input sizes. PluS enables broad flexibility in handling dynamic shapes by allowing multiple implementations for the same subgraph pattern. For example, if different shapes require different fusion or scheduling strategies, experts can define a subgraph pattern with maximal scope, and encode shape-based routing logic within the code template.

5 Implementation

Recalling the overview of PluS outlined in Sec. 3, PluS has the capability to compile model representations compatible with various mainstream deep learning frameworks, and our current implementation is specifically based on PyTorch [32].

Pattern warehouse. PluS incorporates an expert-defined pattern warehouse that facilitates the dynamic insertion and deletion of patterns at any given time. This warehouse serves as a mapping between +*Graph*s and their corresponding kernel implementations. Users can define subgraph patterns through two methods. The first method allows them to deploy optimized code for a specific subgraph by providing a

torch.nn.Module and the corresponding code. For instance, deploying the FlashAttention optimization for the attention mechanism. In such cases, PluS automatically generates a *+Graph* and stores the provided code as a template in the pattern warehouse. Nevertheless, this approach may lack the desired flexibility and universality.

Meanwhile, PluS offers a second method where users can articulate the *+Graph*, as detailed in Sec. 4.1. Users also provide the associated code template to the pattern warehouse with *+Code* detailed in Sec. 4.3. Subgraphs with the same data layout share identical *+Graph*, minimizing the need for additional deployment efforts. PluS automatically generates codes for various operations.

Workflow. We implement a complete TorchDynamo-based backend. Initially, PluS takes a *torch.fx.GraphModule* as inputs and leverages Hidet [17]'s API to parse the graph module, resulting in a computational graph composed of low-level operators represented by the *+Graph* outlined in Sec. 4.1. Subsequently, PluS generates subgraphs through a pattern matching method explained in Sec. 4.2. Finally, PluS utilizes a code generation module detailed in Sec. 4.3 to produce codes for each subgraph. The code generation module maps the *+Graph* to codes using the templates stored in the pattern warehouse. In our current implementation, we seamlessly integrate kernels from CUTLASS, ByteTransformer, FlashAttention, and other sources.

Applicability discussion. PluS can support all DNN models, as all DNN computations are fundamentally loop-based computations involving multi-dimensional tensors. The subgraph abstraction introduced by PluS is built on this loop-based nature, which allows various types of operators to be supported through this abstraction.

6 Evaluation

6.1 Experimental Setup

Methodology. We compare PluS against mainstream DNN compilers and framework including TorchInductor [8] v2.4.0, TensorRT [22] v10.5.0 (in ONNX Runtime [15] v1.18.0), and AITemplate [45] v0.3.dev0. In our evaluation, we initially evaluate the end-to-end inference latency (Sec. 6.2). The effectiveness of PluS's *+Graph*-matching fusion strategies is demonstrated by presenting the layer count before and after fusion. Subsequently, we conduct several case studies to highlight the advantages of PluS in two aspects (Sec. 6.3). First, we report the subgraph inference latency to showcase PluS's ability to leverage efficient expert-optimized subgraph implementations. Second, we compare the size of code required by experts to add a new subgraph implementation against AITemplate, demonstrating that PluS can accommodate new subgraph implementations with minimal effort.

Platforms. We conduct experiments on two GPUs with different architectures: an NVIDIA A100 PCIe 80GB and an NVIDIA GeForce RTX 4090. The servers are equipped with AMD EPYC 7V13 CPUs and Intel Xeon Gold 5318Y CPUs, running Ubuntu 22.04 with CUDA 11.8 installed.

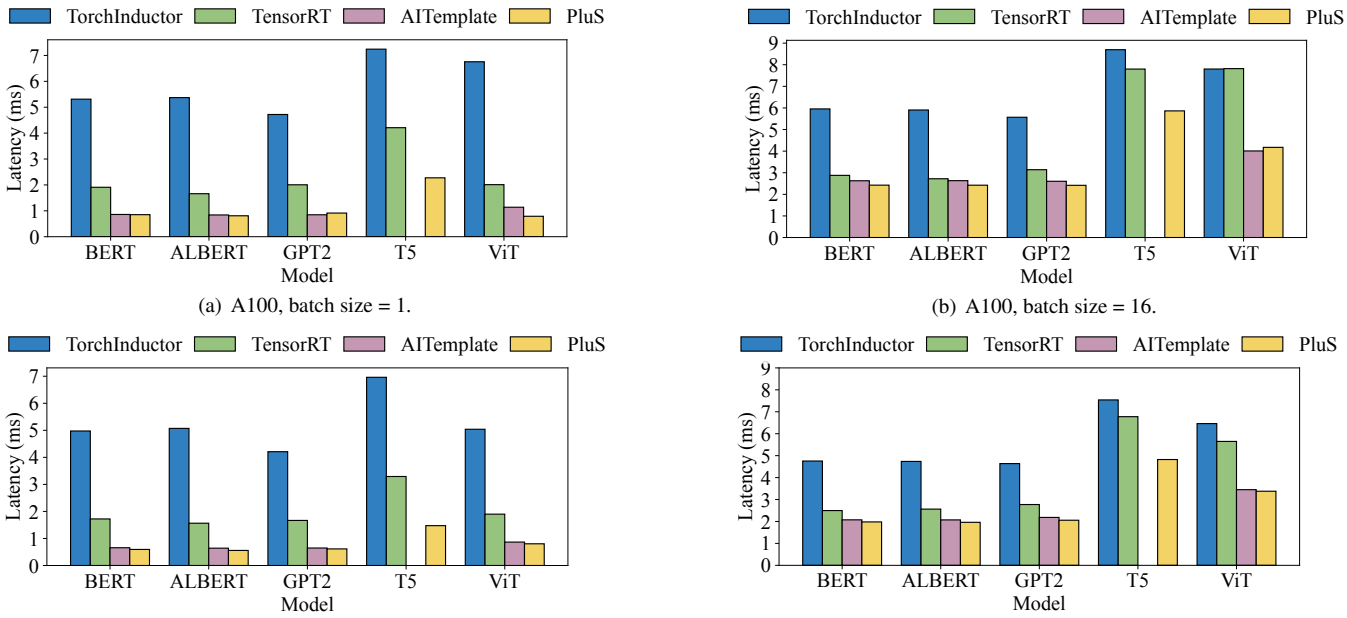
Workloads. We use five typical DNN models for evaluation, including BERT-base [16], ALBERT [25], GPT-2 [33], T5 [34] and ViT [18], encompassing popular transformer architectures in both natural language processing and computer vision. For the experiments, we set the batch sizes to 1 and 16, with a default sequence length of 128 for language models and an input image size of 224×224 for vision models.

6.2 End-to-End Evaluation

Performance. We first evaluate the end-to-end performance of PluS by comparing it against TorchInductor, TensorRT, and AITemplate. For TorchInductor, we employ the TorchInductor compiler provided by TorchDynamo to compile the PyTorch models, but dynamic shape support is disabled due to its poor performance. To evaluate TensorRT, we utilize the TensorRT provider in the Onnx Runtime with dynamic shape enabled, defining a batch size range of 1 to 32 and a sequence length range of 64 to 256 for the TensorRT engine. Furthermore, AITemplate does not support dynamic shape, whereas PluS supports the compilation of PyTorch models with dynamic shape. For each experiment, we measure the average end-to-end latency over 10 executions, repeated three times after 10 warm-up executions. One exception is that we observe unusually long GPU-to-CPU memory transfer time when running the T5 model in TensorRT, resulting in the end-to-end runtime exceeding 300 ms. Therefore, we perform additional profiling of the T5 model in TensorRT using Nsight Systems [1] and use the pure kernel execution time from the profiling data as the end-to-end runtime for the T5 model.

Fig. 10 shows the end-to-end inference latency on all workloads for batch sizes 1 and 16. PluS, when compared to state-of-the-art deep learning compilers with embedded graph transformation, outperforms TorchInductor by an average of 4.04× and TensorRT by 1.77× on A100 GPU. On the RTX 4090 GPU, it achieves an average speedup of 4.59× over TorchInductor and 2.01× over TensorRT. In Sec. 6.3, we delve into a subgraph performance analysis to showcase PluS's advantages in supporting highly optimized subgraph implementations.

Additionally, as a pluggable graph transformation solution, PluS demonstrates comparable end-to-end performance with AITemplate, even exhibiting an average 7.8% performance improvement on the A100 and 7.2% on the RTX 4090. This achievement stems from PluS's ability to leverage all subgraph optimization techniques available in AITemplate, alongside additional techniques from various vendors, such as ByteTransformer [47] and FlashInfer [46]. Notably, the performance of the T5 model in AITemplate is not reported, as we cannot define the `T5LayerNorm` module using the AITemplate interface. Meanwhile, AITemplate is designed solely for static shapes, limiting its flexibility in deployment. A case study in Sec. 6.3 further illustrates the portability of PluS in



(a) A100, batch size = 1.

(b) A100, batch size = 16.

(c) RTX 4090, batch size = 1.

(d) RTX 4090, batch size = 16.

Figure 10: End-to-end inference latency on different GPU platforms.

Table 1: Fusion rate evaluation. #Ops represents the number of fundamental operators comprising the DNN model, and #Layers denotes the number of layers after graph transformation within DNN compilers.

Model	#Ops	#Layers			
		TorchInductor	TensorRT	AITemplate	**PluS**
BERT	635	195	107	88	**87**
ALBERT	637	195	107	89	**88**
GPT2	630	171	126	89	**87**
T5	1460	364	247	-	**220**
ViT	655	201	105	90	**87**

comparison to AITemplate.

Fusion rate. In this section, we report the number of fundamental operators and the number of layers after subgraph identification (i.e., fusion) in PluS, TorchInductor, TensorRT, and AITemplate across all evaluated models. We define the fusion rate as the ratio of the original operator count to the fused layer count as [31]. As illustrated in Tab. 1, PluS demonstrates an average 2.08× and 1.25× fusion rate improvement compared to TorchInductor and TensorRT, respectively. This is due to PluS's capability to generate fused subgraphs with a larger scope, facilitated by its flexible pattern warehouse, in contrast to TorchInductor and TensorRT's rule-based embedded graph transformation module. Moreover, PluS exhibits subgraph fusion behavior similar to that of AITemplate, as both are ML compilers equipped with pluggable graph transformation modules, sharing advanced capabilities for deploying state-of-the-art subgraph optimizations. However, PluS can identify subgraphs with broader operator variations and leverage the reuse of codegen schedules, enabling it to support a wider range of models than AITemplate, such as T5.

Runtime overhead. We analyze the compilation time and memory overhead of PluS. PluS incurs a compilation overhead of 18 to 25 seconds when the model is cached, which is dominated by NVCC compilation. It takes 1 to 2 minutes to compile the model for the first time. The memory overhead of PluS includes the memory consumption of pattern warehouse and the intermediate representations, all of which reside on the CPU. After excluding memory consumed by other Python modules such as torch andtransformers, PluS introduces a memory overhead of 130 to 190 MB.

6.3 Case Studies

Subgraph optimization. In this section, we utilize the benchmark BERT on A100 GPU to dissect why PluS outperforms other frameworks. Tab.2 delineates the configurations of subgraphs that consume over 95% of end-to-end execution time, detailing the operators constituting each subgraph along with shape information. The final column specifies the implementation vendor PluS utilizes for each subgraph. PluS integrates highly optimized kernel implementations from CUTLASS [40], ByteTransformer [47], and FlashAttention [13, 14]. We dynamically select the optimal solution for different configurations during the pattern definition phase. It is noteworthy that we adopt the implementation from FlashAttention for multi-head attention in batch size 16 (S1) and the implementation from ByteTransformer for multi-head attention in batch size 1 (S6). Both implementations demonstrate optimal performance within their respective configurations during our evaluation.

We utilize Nsight Systems [1] to measure the latency of subgraphs. Comparisons of subgraph latency between PluS, TensorRT, and AITemplate are presented in Fig. 11. The results demonstrate that PluS achieves an average speedup of

Table 2: Dominant subgraph configurations in BERT.

Note	Operators	Configuration	PluS vendor
S0	Matmul+Bias	M=2048,N=2304,K=768	CUTLASS
S1	Split+Permute+Matmul+ Div+Add+Softmax+ Matmul+Permute	M0=2048,N0=128,K0=64 M1=2048,N1=64,K1=128	FlashAttention
S2	Matmul+Bias+ Add+LayerNorm	M=2048,N=768,K=768	ByteTransformer
S3	Matmul+Bias+Gelu	M=2048,N=3072,K=768	CUTLASS
S4	Matmul+Bias+ Add+LayerNorm	M=2048,N=768,K=3072	ByteTransformer
S5	Matmul+Bias	M=128,N=2304,K=768	CUTLASS
S6	Split+Permute+Matmul+ Div+Add+Softmax+ Matmul+Permute	M0=128,N0=128,K0=64 M1=128,N1=64,K1=128	ByteTransformer
S7	Matmul+Bias+ Add+LayerNorm	M=128,N=768,K=768	ByteTransformer
S8	Matmul+Bias+Gelu	M=128,N=3072,K=768	CUTLASS
S9	Matmul+Bias+ Add+LayerNorm	M=128,N=768,K=3072	ByteTransformer

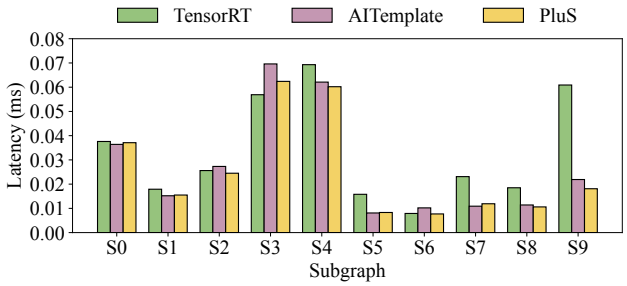


Figure 11: Subgraph latency.

1.53× over TensorRT and 1.07× over AITemplate. Moreover, PluS retains the ability to reduce their latency by incorporating superior optimizations subsequently.

Ablation study. We then compare PluS with a configuration that disables optimized kernel sources (i.e., CUTLASS, ByteTransformer, and FlashAttention), falling back to generic implementations. PyTorch eager mode is used as the default baseline. Experimental results on the ten subgraphs show that PluS achieves an average speedup of 4.79× and 13.27× over the baseline with batch size of 16 and 1, respectively.

We further analyze why flexibly supporting a variety of subgraph patterns is necessary. Take the subgraphs S1 and S6 as examples. If these subgraphs are executed in PyTorch's eager mode—where each operator is executed separately—the total runtime for S1 and S6 is 0.221 ms and 0.209 ms, respectively. This demonstrates the poor performance that results from a lack of operator fusion. Next, when using TorchInductor, it excutes three kernels for this subgraph, fusing the element-wise operators with MatmulOp and implementing SoftmaxOp as a whole. Under this mode, the runtime for S1 and S6 becomes 0.0183 ms and 0.0078 ms. Furthermore, TensorRT, AITemplate and our PluS go a step further by implementing S1 and S6 as a single subgraph, generating one large kernel to execute the entire subgraph [13, 14]. They achieve better performance due to the tighter integration, with execution times of 0.015 ms and 0.0077 ms in PluS. The results demonstrate that different graph optimization techniques can lead to significant changes in model performance.

Portability. In this section, we use the T5 model as an example to showcase the portability of PluS compared to AITemplate, which does not support T5. Assuming that both frameworks can already support models like BERT, ALBERT, and GPT2, it becomes evident that PluS exhibits superior adaptability to minor alterations in DNN models, thereby reducing deployment complexities when compared to other pluggable ML compilers.

First, we observe that all Linear layers utilized in the T5 model lack bias operations, leading to the emergence of numerous new subgraphs not present in models like BERT, ALBERT, and GPT2. Intuitively, this subgraph should share the same code generation schedule as the subgraph with bias operations found in BERT, ALBERT, and GPT2, given their shared loop structure and data layout. However, to accommodate this fused subgraph in AITemplate, a new template must be added. This entails a developer writing both frontend and backend code for the Matmul+Relu module, comprising over 250 lines of code (LoC), and registering it in the pipeline. As similar subgraphs continue to arise, programmers must repetitively perform this task. In contrast, leveraging the +Graph and code templates previously added by experts in the pattern warehouse, PluS can seamlessly generate code for these subgraphs without additional efforts.

```
x1[M,N] = Pow(x0[M,N])
x2[M,1] = ReduceMean(x1[M,N])
x3[M,1] = AddScalar(x2[M,1])
x4[M,1] = Rsqrt(x3[M,1])
x5[M,N] = Multiply(x1[M,N], x4[M,1])
x6[M,N] = Multiply(x5[M,N], c[1,N])
```

Another case arises with T5 introducing a novel layer normalization method, T5LayerNorm [49], leading to a distinct subgraph composition as depicted above. To support this subgraph in AITemplate, developers must invest additional effort in writing an end-to-end pipeline, including frontend and backend components, due to the lack of inheritable similar subgraphs defined previously. This process involves 1701 LoC to accommodate all components related to layer normalization, including 453 LoC for frontend registration and 1248 LoC for backend implementation. Similarly, in PluS, a new subgraph pattern must be incorporated into the pattern warehouse due to the absence of subgraphs sharing the same subsequent +Loop structure. In total, PluS requires 18 LoC to define the +Graph and an additional 129 lines to provide

the necessary code template. In contrast, when new variants of this algorithm emerge, such as adopting a zero-centered gamma, PluS supports them seamlessly without requiring any additional effort.

```
loop0 [M, parallelizable]
  loop1 [N, non-parallelizable]
  loop2 [N, parallelizable]
```

Sensitivity analysis. PluS is designed as a functional compiler, where subgraph matching and operator fusion does not change the computation semantics. The code generation process in PluS strictly follows the data dependencies between operations, ensuring correct implementation of the backend kernels. Therefore, accuracy degradation is not expected under correct pattern definitions.

To validate the correctness and robustness of PluS, we compare the accuracy of subgraph outputs between the optimized and unoptimized execution paths using randomly initialized inputs from a standard normal distribution. We use PyTorch eager mode as the baseline. Experimental results show that the maximum absolute difference between the outputs is 1.9e-3, and the average absolute difference is 3.57e-5.

7 Related Works

Graph-level optimization. Graph-level optimization techniques are crucial for enhancing model execution in ML compilers [8, 10, 19, 22, 23, 30, 31, 36, 39, 45, 51, 52, 56, 57]. ML compilers can be categorized into two classes based on the approach to graph transformation. Embedded mode ML compilers [8,22,23,30,31,36,39,51,52,56,57], such as TensorFlow XLA [36] and TorchInductor [8], employ a rule-based strategy for graph enhancement. In particular, FractalTensor [28] employs nested loops to express DNN operator, breaking the optimization boundaries of traditional operator functions. However, they often overlook opportunities for expert-driven subgraph optimizations due to the complexities of their embedded graph transformation modules. In contrast, pluggable mode ML compilers like AITemplate [45] utilize fixed operator patterns for graph-level optimizations, sacrificing adaptability to structure-similar subgraphs. PluS offers a novel approach supporting flexible integration of pluggable graph schedules with an adaptable pattern-matching strategy based on loop-centric features. Additionally, FlexAttention [20] supports the implementation of different attentions variants as FlashAttention optimizations; however, its scope is limited to attention-specific adaptations. While TVM [10] and TensorFlow Grappler [19] allow users to catch and modify the entire computational graph with customized passes, they require developers to define complicated graph transformation rules from scratch. In contrast, PluS allows users to define graph optimization easily, providing a mapping of loop-centric subgraph pattern with associated code templates. It is also possible for us to implement PluS on top of TVM and TensorFlow Grappler, and integrate FlexAttention in the future.

Kernel-level optimization. Many deep learning frameworks [4, 5, 32] rely on ad-hoc kernels libraries [2, 3, 7, 13, 14, 27, 40, 47] to efficiently execute specific operators or subgraphs. NVIDIA's libraries like cuBLAS [2], CUTLASS [40], and cuSPARSE [3] provide high-performance implementations for operators and subgraphs, and frameworks like ByteTransformer [47], FasterTransformer [4], xFormers [27] and FlashInfer [46] offer optimized GPU kernels for transformer-based models. FlashAttention [13, 14] is a novel attention kernel implementation with fewer memory accesses. Meanwhile, ML compilers [6,9,11,12,17,21,24,38,42,44,52–55,58] focus on different operator-level scheduling strategies to improve efficiency. TVM [10], for instance, leverages Halide [35]'s scheduling principles to map tensor expressions to low-level code. AutoTVM [11] and Ansor [54] employ heuristic algorithms to automatically search optimal configurations. Tiramisu [9], AKG [52], and Tensor Comprehensions [42] automate scheduling space exploration using polyhedral models. PluS is a compiler that supports pluggable graph schedules, making it compatible with these manually-optimized and auto-scheduled approaches, and capable of accommodating various tensor program scheduling within its pattern warehouse.

8 Conclusion

ML compilers encounter new challenges in the face of partially convergent model architectures and the rapid evolution of graph optimization techniques. PluS addresses this challenge by offering pluggable graph scheduling based on the *+Graph* abstraction, enabling rapid deployment of high-performance subgraph implementations. Unlike existing ML compilers burdened by cumbersome embedded graph transformation rules, or limited by matching fixed operator composition, PluS introduces a pioneering loop-centric pattern-matching solution. Consequently, PluS outperforms state-of-the-art embedded ML compilers, achieving up to a 4.04× speedup, owing to its superior expandability for graph optimizations. Moreover, it demonstrates improved adaptability to model evolution while still preserving minor performance benefits (about 7.8%) compared to template-based solutions.

Abstract

Pipeline parallelism has become a widely adopted strategy for training large language models (LLMs) by distributing computational workloads across multiple nodes. However, it faces a significant challenge in the form of memory bottlenecks at early stages. While recomputation can mitigate this issue, it incurs additional computational overhead.

To address this limitation, we propose Obscura, a computationally efficient pipeline training system designed to optimize recomputation overhead under the given memory constraints. Leveraging the observation that bubbles following backward passes can conceal recomputation overhead in pipeline parallelism, Obscura introduces a novel pipeline transformation to enhance overhead concealment. Furthermore, we integrate swapping techniques into the pipeline and model the execution time as an optimization problem to identify an optimal recomputation strategy. A partition adjustment algorithm is also implemented to balance computation across stages under the transformation. Evaluations on Llama-2 and GPT-3 models of various sizes demonstrate that Obscura achieves throughput improvements of up to 1.33× compared to widely used recomputation baselines.

1 Introduction

A new AI paradigm leveraging large language models (LLMs) has emerged, significantly improving performance across various domains [3, 4, 6, 21, 23, 25]. However, the lack of extensive GPU resources poses significant challenges for small and medium enterprises (SMEs) in adopting this trend to meet their specific needs. Fine-tuning a Llama-2 13B [23] model, for example, demands approximately 400GB of GPU memory to store model states, activations, and other operations. This far exceeds the 80 GB memory of a single A100 GPU, necessitating at least six A100 GPUs to complete the task.

To accommodate larger models, distributed training has become a standard approach, leveraging multiple devices for distributed computation and storage through various parallelism strategies [8, 13, 20]. Among these strategies, pipeline parallelism [5, 8] stands out due to its lower communication overhead, which enables efficient scaling across multiple nodes and supports the training of larger models.

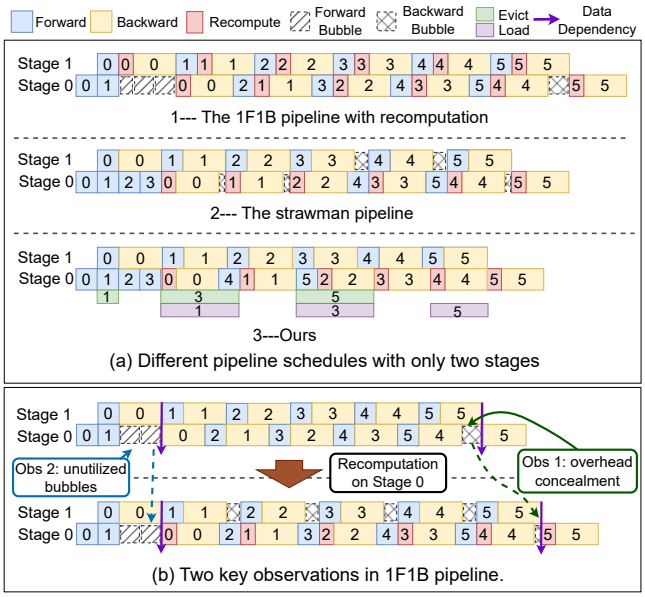

Figure 1: The timeline of three pipeline schedules.

The 1F1B (one-forward, one-backward) pipeline [5] is the most commonly used approach in pipeline parallelism, but it encounters a memory bottleneck in the early stages [10, 29]. Specifically, 1F1B pipeline alternates the scheduling of forward and backward pass across a large number of micro-batches. To maximize pipeline utilization, earlier stages execute more forward passes than later stages before initiating the first backward pass. This results in greater accumulation of micro-batch activations, leading to significantly higher memory usage in the early stages. For example, when training Llama 2-13B model using an 8-way 1F1B pipeline, memory usage in stage 0 surpasses that in stage 7 by 35 GB.

Recomputation [12], an effective technique for reducing

*Corresponding author: chenwuh@mail.sysu.edu.cn

memory usage caused by activations, involves discarding activations during the forward pass and recomputing them during the backward pass. In cases of out-of-memory (OOM) errors, as illustrated in Figure 1(a1), the conventional approach is to recompute all micro-batches across stages, discarding most activations to avoid OOM. However, this approach introduces substantial computational overhead and extends the pipeline duration due to the recomputation of each micro-batch. To alleviate this, several studies [11, 27] have proposed selectively recomputing cost-effective operators—those with high memory usage but low recomputation overhead—to minimize computational overhead. Nonetheless, under severe memory constraints, many non-cost-effective operators still need to be recomputed, which keeps the overhead substantially high.

In our exploration of integrating recomputation into pipeline parallelism, we apply recomputation only to stages experiencing memory bottlenecks, termed *On-Demand Recomputation*, achieving better performance than *All-Stage Recomputation*. Through an analysis of On-Demand Recomputation, we make the following key observations: **Backward Bubbles Can Conceal Recomputation Overhead:** *Backward Bubbles*, defined as bubbles between the first and last backward passes, are effectively utilized. As shown in Figure 1(b), in stage 0, backward bubbles are primarily filled by the recompute forward pass and the backward pass of micro-batch 4, which prevents delays in subsequent micro-batches. Moreover, **Forward Bubbles are Unutilized:** *Forward Bubbles*, defined as bubbles between the first forward pass and the first backward pass, are non-utilized. As they occur before the first backward pass, making them unavailable for recomputation.

Building on these findings, we propose a novel pipeline transformation: converting forward bubbles into backward bubbles to better conceal recomputation overhead. To achieve this, we introduce a strawman pipeline based on 1F1B pipeline through the following adjustments: First, stages that exceed memory constraints are identified as "adjusted stages," where recomputation is applied. Next, in adjusted stages, forward passes that occur after the first backward pass are migrated to execute before the first backward pass. This transformation converts forward bubbles into backward bubbles, enabling them utilization to conceal recomputation overhead. Therefore, the resulting pipeline, illustrated in Figure 1(a2), leverages the converted backward bubbles effectively conceal the recomputation overhead of micro-batches 0 and 1.

Although the strawman pipeline better conceals recomputation overhead to accelerate training, it still encounters three performance-related challenges: **1) How to Fully Utilize Backward Bubbles:** Due to tight data dependencies—where micro-batches are executed sequentially from the first stage to the last—each backward bubble can only conceal the recomputation of its preceding backward pass. This limitation leads to the underutilization of available bubbles. **2) How to Reduce Extra Memory Usage:** Compared to the 1F1B pipeline, adjusted stages in the strawman pipeline perform additional forward passes before the first backward pass. This results in the accumulation of more activations, increasing the likelihood of exceeding memory constraints. **3) How to Address the Computation Imbalance:** On-demand recomputation creates workload imbalances between adjusted and non-adjusted stages. While bubbles conceal some of the recomputation, their limited number and the increasing overhead with larger micro-batches leave some recomputation unconcealed, creating idle bubbles in non-adjusted stages.

To address these challenges, we propose Obscura, a computationally efficient pipeline training system for LLMs that leverages pipeline transformation to better conceal recomputation overhead, as illustrated in Figure 1(a3). Obscura enhances the strawman pipeline by introducing three key components to further improve performance:

Dependency Relaxation. To relax data dependencies, Obscura introduces a left-shifting method for the remaining unadjusted forward passes, strategically inserting them alternately between backward passes. This transformation forms the Obscura pipeline, ensuring that backward bubbles are fully utilized to effectively conceal recomputation overhead.

Swapping-Aware Recomputation. Obscura leverages activation swapping in adjusted stages to reduce activation footprints before the first backward pass. Furthermore, it models pipeline execution as an optimization problem to derive an optimal recomputation strategy that minimizes both communication and recomputation overhead.

Partition Adjustment. To address computation imbalance, Obscura introduces a stage partitioning adjustment algorithm that redistributes layers from adjusted stages to non-adjusted stages. For instance, adjusted stages are assigned fewer layers, while non-adjusted stages handle more, thereby balancing workloads and improving overall performance.

The primary contributions of Obscura are as follows:

- We identify a novel opportunity to conceal recomputation overhead by utilizing pipeline bubbles and propose a strawman pipeline to achieve overhead concealment.
- We introduce Obscura, which incorporates three key components—Dependency Relaxation, Swapping-Aware Recomputation, and Partition Adjustment—to improve pipeline training performance.
- We implement Obscura on DeepSpeed, demonstrating a throughput improvement of up to 1.32× compared to widely used recomputation strategies on NVIDIA GPUs.

2 Background and Related Work

2.1 Pipeline Parallelism

Pipeline parallelism [5, 8, 15] partitions model layers into distinct stages distributed across multiple GPUs. The input batch is divided into smaller micro-batches, which are processed sequentially in a pipelined manner. Communication between

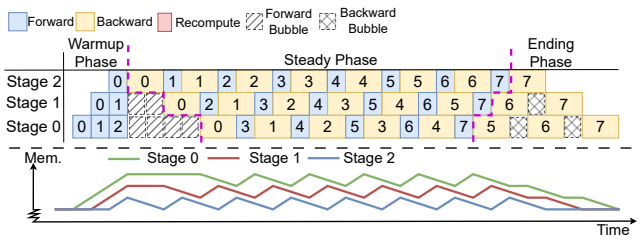

Figure 2: Scheduling of the 1F1B pipeline.

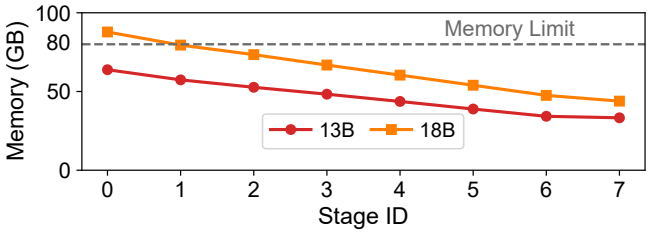

Figure 3: Memory usage across stages during the training of 13B and 18B Llama-2 models in the 1F1B pipeline. Results for the 18B model are estimated.

stages is required before and after each forward or backward pass to transfer activations and gradients.

GPipe [8] processes the forward passes of all micro-batches sequentially before initiating the backward passes. This scheduling approach requires storing activations for all micro-batches, resulting in significant GPU memory usage.

In contrast, the 1F1B pipeline [5] reduces memory overhead by initiating backward passes earlier, effectively avoid memory usage of activations accumulation from all micro-batches. Its schedule, shown in Figure 2, comprises three phases: warmup, steady, and ending. The warmup phase spans from the first forward pass to the start of the first backward pass, with memory usage rising linearly as only forward passes are executed. The steady phase, the core of 1F1B, alternates backward and forward passes, reusing memory freed by backward passes to store activations from forward passes, ensuring stable memory usage. The ending phase mirrors the warmup phase in reverse. Additionally, we define two types of bubbles: forward bubbles (diagonal blocks), occurring between the last forward and first backward passes, and backward bubbles (crossed-line blocks), occurring between the first and last backward passes.

To reduce pipeline bubbles, several scheduling strategies [1,14–16,26] based on the 1F1B schedule have been proposed, though they often increase memory pressure or affect convergence. For example, Chimera [14] reduces bubbles through bidirectional scheduling but at the cost of higher memory consumption. PipeDream [15] eliminates bubbles by overlapping the forward pass of the second micro-batch with the backward pass of the first, but it faces challenges with convergence.

Although the 1F1B pipeline offers better memory efficiency than GPipe, it faces a memory bottleneck in the early stages [10,29]. Specifically, stage s out of p stages must store activations for up to $p-s$ micro-batches. As a result, earlier stages ($s \to 0$) experience higher memory usage. As shown in Figure 3, for the 13B model, the memory usage in stage 0 is significantly higher than in stage 7, with a gap of up to 24 GB. For the 18B model, the memory usage in stage 0 exceeds the GPU memory limit (OOM), causing training failures.

2.2 Recomputation

A straightforward approach to reducing the memory usage of activations is the recomputation technique, which is incorporated into various parallel strategies in modern frameworks like DeepSpeed [18] and Megatron [20].

Formally, a pipeline stage consists of a set of operators, each producing and storing activations during the forward pass. The recomputation technique reduces memory usage by discarding a portion of these activations during the forward pass and recomputing them during the backward pass. Although this approach effectively lowers memory consumption, it introduces additional computation overhead, as the discarded activations must be generated by re-executing the corresponding operators in the backward pass.

Various studies [7,9,11,22,27] have investigated strategies to minimize recomputation overhead within specific memory constraints. These works leverage the varying computation and space complexities of operators to identify an optimal recomputation strategy, consisting of cost-effective operators with high memory usage but low recomputation overhead. However, relying solely on recomputation for memory savings is highly model-dependent and inevitably introduces substantial overhead, particularly under strict memory limits.

To address this limitation, several works [2,17,24,28] combine offloading with recomputation, utilizing tensor liveness analysis and dynamic memory states to decide whether to swap data out or discard it. While these techniques reduce recomputation overhead through swapping, they are constrained by PCIe bandwidth, often introducing significant communication overhead. Additionally, they may interfere with the communication required for pipeline parallelism [17] and, in some cases, incur extra CPU computation latency [19].

BPipe [10] introduces a pipeline-specific approach that leverages high-bandwidth inter-GPU connections to transfer activations from earlier stages to the spare memory of later stages, alleviating memory bottlenecks. Additionally, it incorporates selective recomputation [11] to further reduce memory usage. However, the limited spare memory available in later stages constrains the effectiveness of BPipe's swapping technique, necessitating a greater reliance on recomputation under stringent memory constraints. Due to its lack of optimized integration between inter-GPU swapping and recomputation, BPipe still incurs significant recomputation overhead.

In summary, recomputation overhead remains a significant challenge. Our work, Obscura, identifies an opportunity to

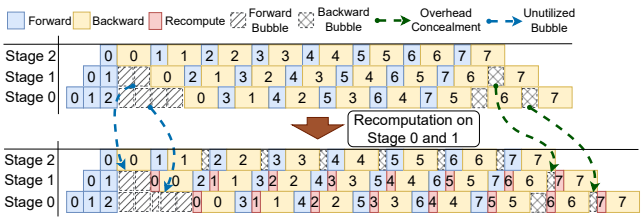

Figure 4: Observations in On-Demand Recomputation.

hide recomputation overhead within pipeline bubbles and introduces a novel pipeline schedule designed to better conceal this overhead. This approach also enables a more effective integration of recomputation and swapping, achieving efficient memory savings. To our knowledge, we are the first to explore reducing overhead by strategically concealing recomputation.

3 Motivation

3.1 Observations in 1F1B Pipeline Schedule

Existing works typically implement recomputation across all stages (referred to as *All-Stage Recomputation*) when the pipeline encounters OOM errors. However, as discussed in §2.1, the memory bottleneck is primarily concentrated in the early stages, where only a subset exceeds the memory limit while others remain underutilized. Therefore, recomputation should be selectively applied to the early stages that surpass the memory limit. We refer to this approach as *On-Demand Recomputation* and derive the following observations.

Observation 1: On-Demand Recomputation Achieves Better Performance than All-Stage Recomputation. We evaluate the execution time of various on-demand recomputation pipelines with four stages. The *Full* recomputation strategy discards nearly all activations and performs an extra forward pass during the backward pass. As shown in Figure 5(a), *Recomp-N* denotes recomputation applied to stages with $s \leq N$, *Recomp-All* represents recomputation applied to all stages, and *Recomp-Non* indicates no recomputation. By comparing stage 0 across all configurations, we observe that *Recomp-0* and *Recomp-1* increase execution time by 19% and 25%, respectively, compared to *Recomp-Non*, outperforming *Recomp-All*, which increases execution time by 33%.

To investigate the benefits of on-demand recomputation, we dive into the 1F1B pipeline schedule in Figure 4 with recomputation selectively applied to stages 0 and 1 (*Recomp-1*), leading to another critical observation.

Observation 2: Backward Bubbles Can Conceal Recomputation Overhead. As illustrated in Figure 4, after applying *Recomp-1*, the backward bubbles in stage 1 are largely filled by the time extension caused by the recomputation of micro-batch 6, preventing it from impacting subsequent executions. In contrast, micro-batches 0–5, which lack sufficient backward bubbles to absorb the recomputation overhead, cause the

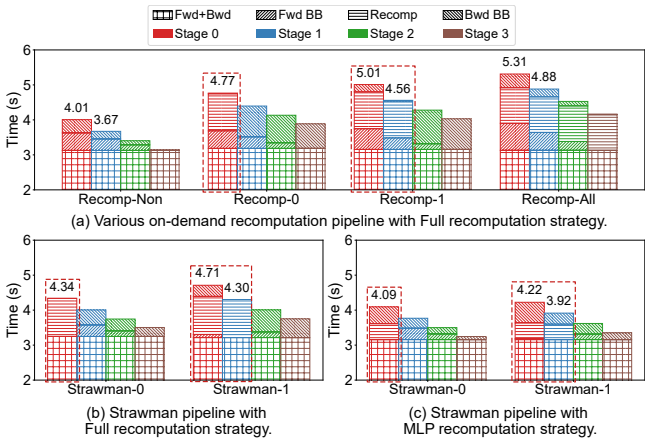

Figure 5: Computation and bubble times for a single iteration. *Fwd+Bwd* denotes the total forward and backward time; *Fwd BB* and *Bwd BB* represent forward and backward bubble times, respectively; and 'Recomp' indicates the recomputation time.

overall execution to shift rightward, extending the pipeline. A similar pattern is observed for the recomputation of both micro-batch 6 and micro-batches 0–5 in stage 0.

To validate this finding, we analyze the changes in computation and bubble times shown in Figure 5(a). Comparing *Recomp-Non* with *Recomp-0* in stage 0 reveals that backward bubbles are replaced by recomputation task. A similar phenomenon is observed in stages 0 and 1 of *Recomp-1*. In contrast, the backward bubbles in *Recomp-All* remain unaffected because the last stage lacks backward bubbles and all stages incur the same recomputation time, making the last stage the slowest. This delay then propagates through inter-stage dependencies, preventing earlier stages from utilizing their backward bubbles.

Although backward bubbles can partially conceal recomputation overhead, their limited availability allows them to hide only a small portion of it. To explore opportunity for increasing backward bubbles, we present the third observation.

Observation 3: Forward Bubbles Are Unutilized. As illustrated in Figure 4, forward bubbles remain unused in recomputation stages. This is because forward bubbles are generated before the first backward pass, whereas recomputation inherently occurs during the backward pass. Furthermore, the duration of forward bubbles is significantly longer than that of backward bubbles. In a p-stage pipeline, stage s contains $2(p-s-1)$ forward bubbles, which is double the number of backward bubbles $(p-s-1)$.

In Figure 5(a), compared to *Recomp-Non*, the forward bubbles in stage 0 of *Recomp-0* remain unchanged, with the bubble time being longer than the backward bubble time (0.50s vs. 0.37s, not a double relation due to synchronized communication between stages). Similar trends are observed in *Recomp-1* and *Recomp-All*, where the forward bubbles are slightly extended. This occurs because the recomputation in stage s delays the initiation of the first backward pass in stage

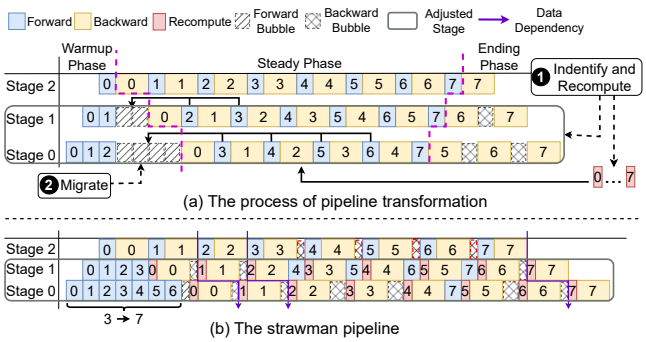

Figure 6: Pipeline transformation process (top) and the resulting strawman pipeline (bottom).

$s-1$, thereby increasing the duration of forward bubbles.

3.2 A Strawman Pipeline: Optimization Opportunity of Recomputation Overhead Concealing

Building on our three key observations, we propose converting forward bubbles into backward bubbles to more effectively conceal recomputation overhead. To implement this concept, we introduce a strawman pipeline, derived from the 1F1B pipeline using a pipeline transformation, as illustrated in Figure 6(a). This transformation consists of two key steps:

Step 1: Identify and Recompute. In the 1F1B pipeline, stages that exceed the memory limit are identified as "adjusted stages" and are subjected to recomputation. The remaining, referred to as "non-adjusted stages," are left unchanged.

Step 2: Migrate. For adjusted stages, the forward passes in the steady phase are migrated leftward into forward bubbles as much as possible, causing the forward bubbles to shift rightward and convert into backward bubbles.

Figure 6(b) illustrates the proposed strawman pipeline, whose performance is evaluated in Figure 5(b). The term *Strawman-N* corresponds to the same meaning as *Recomp-N*. Compared to *Recomp-0* and *Recomp-1*, the recomputation overhead in *Strawman-0* and *Strawman-1* is reduced to 8% and 17%, respectively. This is achieved by eliminating forward bubbles and replacing them with recomputation tasks.

In practice, instead of applying the *Full* recomputation strategy to the adjusted stage, a selective strategy that discards only partial activations to precisely meet memory constraints proves more effective. This approach results in reduced recomputation overhead and improved overhead concealment. However, it introduces three key challenges:

Challenge 1: How to Fully Utilize Backward Bubbles. The tight data dependency between adjusted and unadjusted stages—where micro-batches are executed sequentially in the forward pass and in reverse during the backward pass—restricts the ability of backward bubbles to conceal recomputation. Backward bubbles can only hide preceding recomputation, not subsequent ones. For example, as depicted in Figure 6(b), the recomputation for micro-batch 1 cannot utilize the preceding bubble because it must wait for the backward pass in stage 2 to finish. Furthermore, when a selective recomputation strategy is employed, the recomputation time per micro-batch becomes shorter than the bubble time, leading to underutilized backward bubbles. Using the *MLP* recomputation strategy, which discards only *MLP* activations, Figure 5(c) demonstrates that, compared to *Strawman-0* in Figure 5(b), a significant portion of the previously fully utilized backward bubbles is now left unused.

Table 1: Memory usage across stages in different pipelines.

	Recomp-Non	Recomp-0	Recomp-1	Strawman-0	Strawman-1
Stage 0	48.01	34.40	34.40	**46.18**	**46.18**
Stage 1	42.62	42.62	32.25	42.62	**39.58**
Stage 2	36.72	36.72	36.72	36.72	36.72
Stage 3	30.92	30.92	30.92	30.92	30.92

Challenge 2: How to Reduce Extra Memory Usage. Compared to the 1F1B pipeline, the adjusted stages in the strawman pipeline store activations for more forward passes during the warmup phase. As a result, the strawman pipeline exhibits higher memory usage, which can lead OOM errors. Table 1 presents the memory usage across stages under the *MLP* recomputation strategy. The results clearly show that the memory usage of the adjusted stages in the strawman pipeline is significantly higher than that of the 1F1B pipeline.

Challenge 3: How to Address the Computation Imbalance. On-demand recomputation introduces workload imbalances between adjusted and non-adjusted stages. While forward and backward bubbles can partially conceal recomputation, their limited availability and the growing overhead with larger micro-batches leave some recomputation unconcealed. This leads to the formation of additional backward bubbles in the non-adjusted stages, as clearly demonstrated in Figure 6(b). Specifically, as illustrated in Figures 5(b) and 5(c), backward bubbles caused by computation imbalance are evident in the non-adjusted stages.

4 Overview of Obscura

To address above challenges, we propose Obscura, a training system with an architecture illustrated in Figure 7. Obscura is composed of two primary modules: the Obscura Planner and the Obscura Runtime. The Obscura Planner transforms the original 1F1B pipeline into the Obscura pipeline and generates a deployment configuration for use by the Obscura Runtime. The Obscura Runtime manages distributed deployment and model training during execution.

The Obscura Planner comprises four submodules: Pipeline Transformation, which converts forward bubbles into backward bubbles to better conceal recomputation overhead; Dependency Relaxation, which relaxes tight data dependencies between stages to fully utilize backward bubbles; Swapping-

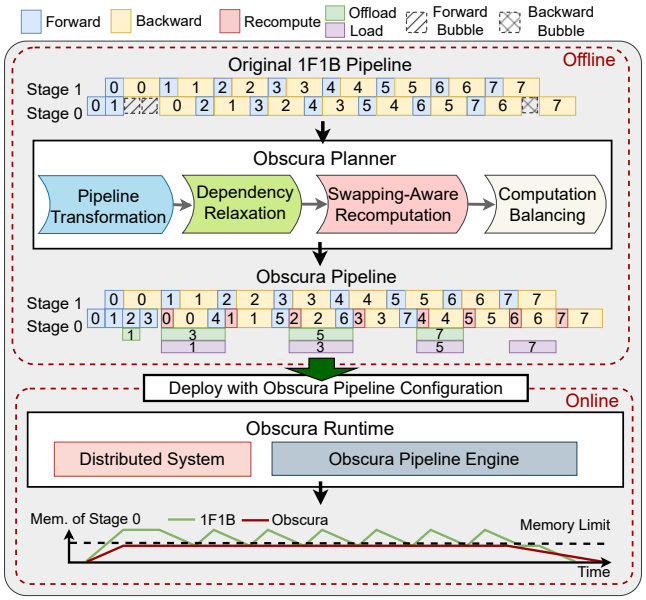

Figure 7: System Architecture of Obscura.

Aware Recomputation, which combines swapping and recomputation to efficiently adhere memory constraints; and Partition Adjustment, which refines the stage partition strategy to eliminate bubbles in non-adjusted stages. The Obscura Runtime consists of the Distributed System, which enables distributed training, and the Obscura Pipeline Engine, which implements the core runtime of the Obscura pipeline.

Notably, the Obscura Planner operates offline to generate the Obscura configuration using only a few training iterations. Specifically, the pipeline transformation submodule runs for several iterations to determine the adjusted stages and collect runtime profiling data, including the computation and memory costs of operators. The remaining submodules use this profiling data to solve small-scale optimization problems and execute lightweight algorithms, introducing negligible overhead. In addition, the Obscura Runtime operates online and manages system behavior during training.

5 Dependency Relaxation

To fully utilize backward bubbles, we first perform an in-depth analysis of computation and bubbles in adjusted stages. Based on this analysis, we propose dependency relaxation, which re-purposes unused backward bubbles for other computations. Additionally, we refine the migration of forward passes to minimize the additional activations footprints caused by unnecessary forward pass migrations.

5.1 Analysis of Computation and Bubbles

We illustrate the simplified steady phase of adjacent adjusted and non-adjusted stages in Figure 8. In Figure 8(a), the left side shows the underutilization of backward bubbles after migration, while the right side depicts the remaining forward passes. Due to tight data dependencies between the two stages, backward passes cannot shift leftward to utilize left-side bubbles. Specifically, the backward pass of micro-batch x in stage s must wait for the completion of the backward pass of the same micro-batch in stage $s+1$, preventing the use of preceding bubbles for recomputation. Forward passes encounter a similar trouble: they cannot shift rightward to utilize right-side bubbles (if any), as this would delay the forward passes of the same micro-batch in later stages, extending the pipeline.

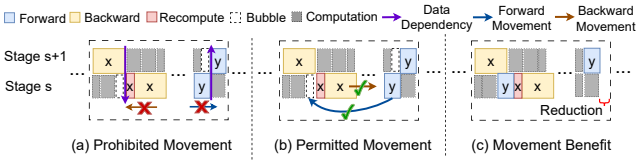

Figure 8: The simplified steady-phase schedule for adjacent adjusted and non-adjusted stages.

However, the opposite movements to exploit bubbles are allowed. As illustrated in Figure 8(b), the forward pass of micro-batch y in stage s can shift leftward to utilize the left-side bubbles without violating its data dependency. Similarly, the backward pass of micro-batch x can shift rightward. This observation provides a key insight: instead of relying solely on adjacent recomputation tasks to utilize unused backward bubbles, we can shift the remaining forward passes leftward to exploit these bubbles. Subsequently, the backward passes can be shifted rightward to take advantage of the bubbles created by the adjusted forward passes.

Figure 8(c) illustrates the outcome of this adjustment. The bubbles preceding the backward pass of micro-batch x in stage s are utilized, resulting in a reduction in execution time. This demonstrates that the previously unused backward bubbles are effectively utilized to conceal recomputation overhead.

5.2 Dependency Relaxing among Stages

Based on the analysis, we propose dependency relaxation to improve backward bubble utilization, as shown in Figure 9. The key adjustment involves shifting the remaining forward passes leftward and the backward passes rightward during the steady phase. To prevent excessive activation accumulation, the left-shifted forward passes are interleaved with the backward passes, similar to the 1F1B approach. For example, the forward passes of micro-batches 4–7 are shifted leftward and orchestrated in an interleaved manner with the corresponding backward passes, which are shifted rightward accordingly.

This adjustment relaxes the tight data dependencies between stages, ensuring that the execution of one stage no longer directly impacts another. As a result, underutilized backward bubbles are effectively leveraged, reducing overall iteration time, as shown in the middle of Figure 9.

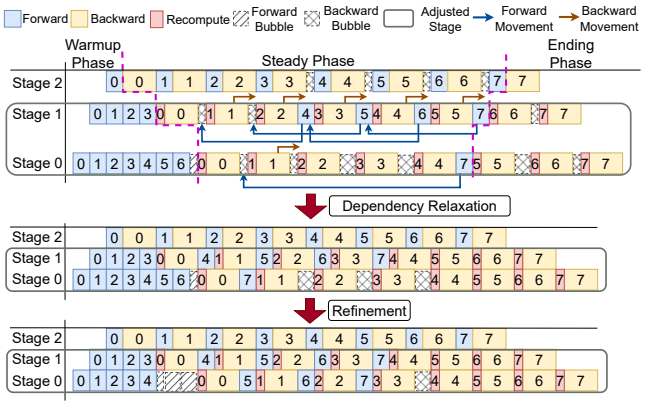

Figure 9: Two-step optimization process applied to the strawman pipeline to achieve Obscura pipeline.

5.3 Migration Refinement

We refine the pipeline by reducing the forward passes migrated into forward bubbles, resulting in the Obscura pipeline depicted at the bottom of Figure 9. This refinement decreases the activations footprints during the warmup phase without affecting the concealment of recomputation overhead. It is motivated by the persistence of backward bubbles in stage 0, as illustrated in the middle of Figure 9.

In a p-way pipeline, stage s can have up to $\min(m-1, 3(p-s-1))$ backward bubbles, where m denotes the total number of micro-batches. This suggests that earlier adjusted stages can theoretically conceal more recomputation overhead. However, due to data dependencies in the final backward pass of adjusted stages, the total time extension across all adjusted stages cannot recede that of the last adjusted stage, k. From this analysis, we conclude that the ability to conceal recomputation overhead is determined by the number of bubbles in stage k. This also accounts for the unused bubbles observed in earlier adjusted stages after dependency relaxation. Therefore, for adjusted stages where $s < k$, it is sufficient to align the number of backward bubbles with those in stage k.

6 Swapping-Aware Recomputation

To reduce the extra memory usage caused by the migration of forward passes, we introduce an activation swapping scheme for the Obscura pipeline, which reduces activation storage during the warmup phase. Furthermore, we analyze the trade-off between recomputation and communication overhead, formulating an optimization problem to determine the optimal recomputation strategy under a given swapping configuration.

6.1 Activation Swapping

Relying solely on increased recomputation relative to the 1F1B pipeline to eliminate extra memory consumption introduces more recomputation overhead, which conflicts with our objective of utilizing bubbles to conceal recomputation overhead. To resolve this, we incorporate swapping techniques into Obscura pipeline to alleviate recomputation pressure.

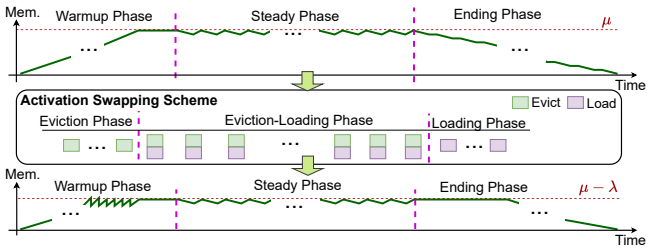

Figure 10: The activation swapping scheme.

Activation Swapping Scheme. We propose an activation swapping scheme, transferring activations to external memory at the granularity of individual micro-batches, termed "activation blocks," as shown in Figure 10. The scheme comprises three swapping phases: eviction, eviction-loading, and loading. The eviction phase occurs during the warmup phase, where memory usage rises linearly, requiring continuous eviction of activation blocks to maintain target memory levels. The eviction-loading phase operates throughout the steady phase, during which evicted activations are reloaded for backward passes. To avoid exceeding memory limits, one activation block must be evicted before reloading. Leveraging full-duplex communication, eviction and loading can be performed in parallel. The loading phase occurs in the ending phase, where activations are loaded without eviction as backward passes consume them, ensuring stable memory usage.

The various swapping implementations [10, 27] are specific instances of this scheme. By abstracting their details and focusing on the core aspects, we integrate the scheme into the Obscura pipeline's optimization, ensuring compatibility with diverse designs.

Memory Analysis. In the activation swapping scheme, memory usage is determined by two critical parameters: 1) λ, the number of activation blocks transferred in the eviction phase, and 2) β, the fraction of data transmitted per activation block. Let μ^{adj} denote the number of forward passes in the warmup phase of the adjusted stage, and a^{adj} represent the size of activations stored per micro-batch of the adjusted stage. The memory consumption of activations in adjusted stage s after swapping can be expressed as follows.

$$A_s^{adj} = (\mu_s^{adj} - \lambda_s)a^{adj} + (1-\beta)\lambda_s a^{adj} \quad (1)$$

6.2 Swapping-Aware Recomputation

Recomputation and activation swapping in Obscura create a trade-off between recomputation and communication costs. **1)** Increasing recomputation, as shown in Figure 11(a), reduces the number of activation blocks evicted during warmup to meet memory limits, and allows shorter transfer times to over-

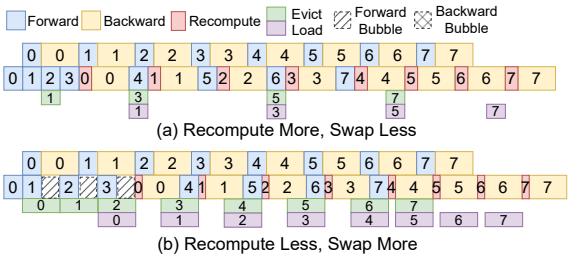

Figure 11: Trade-off Between Recomputation and Swapping.

lap with computation but incurring higher recomputation overhead. **2)** Decreasing recomputation, as in Figure 11(b), lowers recomputation overhead, which bubbles can mostly hide, but requires more swapping to satisfy memory constraints. This includes evicting more activation blocks during warmup and longer transfer times for each activation block that cannot overlap with computation, resulting in significant communication overhead. To balance recomputation and communication overhead, we model the execution time and memory usage of Obscura pipeline and construct our optimization problem.

Execution Time. We consider the p-way 1F1B pipeline with m micro-batches under even stage partition for LLMs, where the forward time f and backward time $2f$ is identical across stages. The recomputation time is denoted as r, and the last adjusted stage is denoted as stage k.

For swapping, as shown in Figure 11(b), eviction or loading operations have maximum transmission times of f, $3f+r$, and $2f+r$ in the three swapping phases, respectively. Exceeding these thresholds introduces communication overhead, with the eviction-loading phase's cost scaling with the number of micro-batches. To mitigate significant overhead, we enforce the constraint $a^{adj}\beta \leq (3f+r)\times B$, where B is the CPU-GPU communication bandwidth. Thus, the communication cost is

$$\begin{aligned} T_s^C = &\max(\lambda_s(a^{adj}\beta/B - f) - (k-s)(2f+r), 0) + \\ &\lambda_s(a^{adj}\beta/B - 2f - r) + \varepsilon \end{aligned} \tag{2}$$

Eq.2 applies when stage k has no remaining bubbles, as their presence implies that the overhead of *Full* recomputation can be fully hidden, making swapping unnecessary. The first and second terms represent the communication cost incurred in the warmup and ending phases, respectively, with the former having bubbles to mitigate the cost. ε represents the overhead not covered by the first two terms due to variations in swapping design [10, 27], with a range of $[0, 3f+r]$.

The execution time, comprising computation time and bubble time, is expressed as follows:

$$T_s = \begin{cases} 3mf + 3(p-s-1)f, & s > k \\ \max(T_{s+1} + \gamma, \gamma m + (k-s)\gamma + T_s^C), & s \leq k \end{cases} \tag{3}$$

where $\gamma = 3f+r$. T_s denotes the pipeline execution time from stage s to the final stage, primarily determined by computation, bubble delays, and communication overhead. The first term in the max function captures inter-stage data dependencies.

Memory Usage. We define a as the activation size per micro-batch without recomputation. The memory usage of stage s is $M_s = W_s + A_s$, where W_s is the size of model parameters, including optimizer states, and A_s is the memory usage of activations. For adjusted stages, $A_s = A_s^{adj}$; for non-adjusted stages, $A_s = (p-s)\times a$.

The Optimization Objective. Based on the analysis and modeling above, we formulate the optimization problem as

$$\begin{aligned} &min\ T_0 \\ &s.t.\ M_s \leq G, s \in [0, p-1] \\ &a^{adj}\beta \leq (3f+r)\times B \end{aligned} \tag{4}$$

The optimization variables include λ_s, β, a^{adj}, and r. λ_s follows a fixed relationship across stages: stage $s-1$ evicts one more activation block than stage s. Thus, λ_s can be represented as λ_k, with a range of $[2, p-k-2]$. β is a percentage in $[0,1]$. a^{adj} and r correspond the recomputation strategy, the set of operators selected for recomputation.

We quantify the recomputation strategy as follows: We define the operators of pipeline stage as $U_{op} = \{op_0, ..., op_{n-1}\}$, where n represent the total number of operators. Then we have $f \approx \sum_{op_i \in U_{op}} f_{op_i}$ and $a \approx \sum_{op_i \in U_{op}} a_{op_i}$, where f_{op_i} and a_{op_i} denote the computation time and the activation size of op_i. The recomputation strategy is represented as $R_{op}^{0-1} = [x_0, x_1, \ldots, x_{n-1}]$, a binary array where $x_i = 1$ indicates that op_i is recomputed, and $x_i = 0$ indicates it is not. Then, we have $r = \sum_{i=0}^{n-1} R_{op}^{0-1}[i] \times f_{op_i}$ and $a^{adj} = a - \sum_{i=0}^{n-1} R_{op}^{0-1}[i] \times a_{op_i}$.

By replacing a^{adj} and r in Eq.4 with the quantified definition, the optimization problem becomes an integer programming (IP) problem. We solve it by enumerating possible values of the swapping-related variables to derive the corresponding recomputation strategy, then selecting the combination of the swapping configuration and recomputation strategy that achieves the best performance. For instance, if we adopt BPipe's [10] swapping design for our activation swapping scheme, we only need to iterate over λ_k, as β is fixed at 1.

7 Partition Adjustment

To balance computation between adjusted and non-adjusted stages, we first refine the execution time and memory usage model of the Obscura pipeline, accounting for uneven stage partitioning. Based on this model, we propose a stage partition adjustment algorithm to optimize pipeline performance by identifying the optimal partitioning strategy.

7.1 Modeling in Uneven Stage Partition

Considering a pipeline with uneven stage partition, we define f_s, r_s, and a_s as the forward time, recomputation time,

and activation size per micro-batch for stage s, respectively. In pipeline parallelism, execution time is dominated by the slowest stage. We let $C_{adj} = \max_{s \le k}(3f_s + r_s)$ and $C_{non} = \max_{s>k}(3f_s)$ represent the total computation time per micro-batch for the slowest adjusted and non-adjusted stages, respectively. Thus, the execution time for stage s in Obscura pipeline with uneven stage partition can be expressed as follows.

$$\hat{T}_s \approx \begin{cases} T_s(C_{non}), & s > k \\ T_s(C_{adj}), & s \le k \end{cases} \tag{5}$$

Eq.5 is an approximation, where C_{non} and C_{adj} replace the terms $3f$ and $3f + r$ in T_s, respectively. For memory usage, we replace a and a^{adj} in M_s with a_s, as expressed below.

$$\hat{M}_s = M_s(a_s) \tag{6}$$

7.2 Partition Adjustment Algorithm

To balance computation between adjusted and non-adjusted stages, we propose a partition adjustment algorithm that transfers layers from adjusted to non-adjusted stages. For finer-grained adjustments, each transformer layer is split into an attention layer and an MLP layer, resulting in $2L+2$ layers, where L is the number of transformer layers, and the constant 2 accounts for the embedding and decoder head layers. In the even stage partition, the first and last stages contain $2L/p+1$ layers, while intermediate stages contain $2L/p$ layers.

Significant computation imbalance in the Obscura pipeline occurs only with a large number of micro-batches, where slight partition adjustments can eliminate the imbalance. For simplicity, the impact of adjustments on overhead concealment and swapping-aware recomputation is ignored.

The partition adjustment algorithm, in Algorithm 1, takes dictionaries D_{adj} and D_{non} representing adjusted and non-adjusted stages and their layer counts. The goal is to make $\hat{T}_{k+1}$ as close as possible to $\hat{T}_k - C_{adj}$, balancing computation between stages. Lines 5-8 transfer one layer from the slowest adjusted stage a to the fastest non-adjusted stage b. The algorithm outputs the updated dictionaries D_{adj} and D_{non}.

Algorithm 1: Partition Adjustment

Input: D_{non} and D_{adj}
Output: Updated D_{non} and D_{adj}.

```
1  Initialize old_D_non ← D_non, old_D_adj ← D_adj
2  Compute T̂_k, T̂_{k+1}, C_adj based on D_non, D_adj
3  while T̂_k − C_adj > T̂_{k+1} do
4      old_D_non, old_D_adj ← D_non, D_adj
5      a ← arg max_{s≤k}(3f_s + r_s)
6      b ← arg min_{s>k ∧ M̂_s ≤ G}(3f_s)
7      D_adj[a] ← D_adj[a] − 1
8      D_non[b] ← D_non[b] + 1
9      Update T̂_k, T̂_{k+1}, C_adj based on D_non and D_adj
10 D_non, D_adj ← old_D_non, old_D_adj
```

8 Design Reinforcement: Enhancing Concealability in Identifying Adjusted Stages

Problem. As discussed in §5, on one hand, the number of backward bubbles in a stage is inversely proportional to the stage ID, and the maximum concealable overhead is determined by the last adjusted stage. As a result, selecting more stages as adjusted stages reduces the Obscura pipeline's ability to conceal recomputation overhead, eventually degrading its performance to that of the 1F1B pipeline. On the other hand, identifying adjusted stages during pipeline transformation is guided by memory usage and hardware memory capacity. Under conditions of high memory usage or limited memory capacity, a larger number of stages are designated as adjusted, decreasing the performance of the Obscura pipeline.

Opportunity. Recent studies [27] reveal that cost-effective operators in transformer models, such as *RMSNorm*, *SiLU*, and *Mul* in the Llama-2 model, exhibit high space complexity but low computation complexity. Including these operators in the recomputation set (referred to as the *CMB* recomputation strategy) can reduce footprints by approximately 40%, with only a modest 2–3% increase in overhead.

Optimization. To enhance the original identification step, we introduce an alternative approach called **CMB-Identifying**. When encountering OOM issues, instead of immediately designating a stage as adjusted, the *CMB* recomputation strategy is applied first. This method reduces the number of adjusted stages, thereby improving the Obscura pipeline's ability to conceal recomputation overhead.

9 Evaluation

We evaluated Obscura on a single training node. Notably, since Obscura introduces no communication overhead between stages, it can seamlessly scale to multiple nodes.

9.1 Implementation and Experimental Setup

Implementation. We implement Obscura on DeepSpeed by designing a custom scheduler to replace the native scheduler. To enable inter-stage communication within the Obscura pipeline, we convert synchronous NCCL communication to asynchronous and introduce synchronization mechanisms to ensure seamless execution. Swapping operations are integrated into the computation schedule as execution steps, utilizing separate CUDA streams and manual memory management to enable concurrent swapping and memory reuse.

Platform. We evaluate Obscura on a data center training node equipped with 2.0 TB of DRAM, two Intel Xeon Platinum 8352S CPUs (128 threads in total), and eight NVIDIA A100-SXM-80GB GPUs. The GPUs are fully interconnected

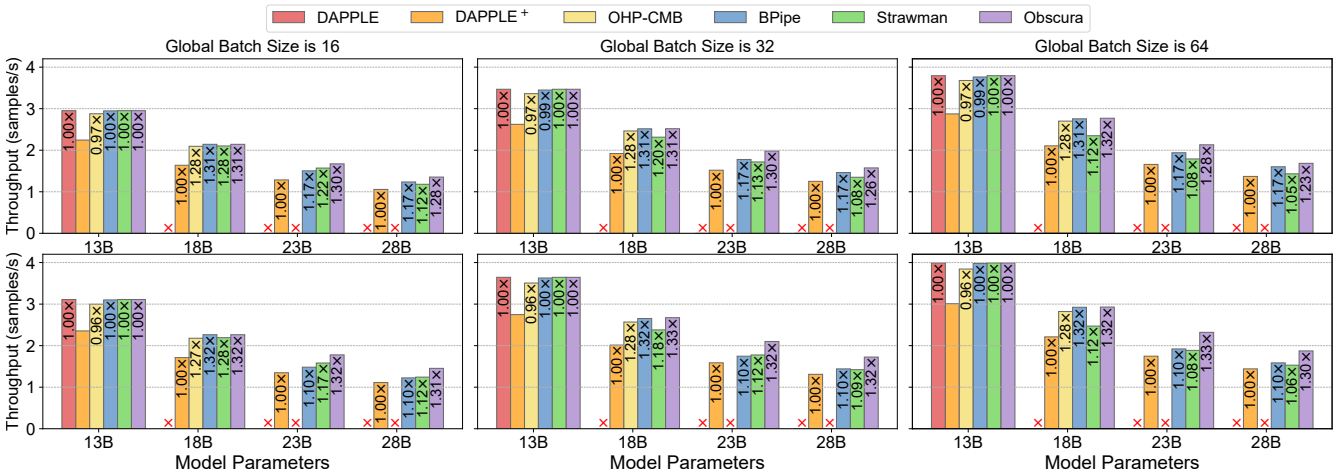

Figure 12: End-to-end performance for training various sizes of Llama-2 and GPT-3 models under different global batch sizes.

via NVLink, providing a bidirectional P2P bandwidth of 600 GB/s, and are connected to the CPUs through PCIe 4.0 x16.

Model, Datasets and Workloads. We evaluate Obscura using various model sizes based on the popular Llama-2 [23] and GPT-3 [3] models, including 13B, 18B, 23B, and 28B parameters for both base models. The GPT-3 models used in our evaluation are based on the open-source implementation from the Megatron-LM repository [11, 16, 20]. To simplify testing, we generate a random sequence before the training loop and feed it into the models. The sequence length is standardized to 4096, and the micro-batch size is set to 1, which are common configurations for multi-node training.

Baselines. We utilize the following pipeline parallelism configurations implemented on DeepSpeed with the 1F1B pipeline as baselines for comparison experiments:

- `DAPPLE` [5]: The state-of-the-art 1F1B pipeline schedule with even stage partition.
- `DAPPLE`$^+$: We evaluate `DAPPLE` using the *Full* recomputation strategy applied to all stages, which reduces memory usage and enables the training of larger models.
- `OHP-CMB`: We apply the recomputation strategy proposed in the work [27] that drops activations of specific operators, including *Norm*, *SiLU/GELU*, and *Mul*.
- `BPipe` [10]: It eliminates the memory bottleneck by transferring activations from earlier stages to later ones using an activation balancing method. As it encounters OOM issues with 23B and 28B models, we apply the *MLP* recomputation strategy for these larger models.

In addition, we measure `Strawman` with the *Full* recomputation strategy applied for the adjusted stages.

9.2 Training Performance

We evaluate the throughput of Obscura and baselines using Llama-2 13B and GPT-3 13B as base models. To analyze Obscura's performance across different scenarios, we scale the model by adding layers and extend the pipeline length by increasing the global batch size. The performance speedups of Obscura and the baselines relative to DAPPLE (for the 13B model) and DAPPLE$^+$ (for models of other sizes) is presented in each column of Figure 12. Notably, Strawman and Obscura are **NOT** applied to the 1F1B pipeline in the 13B model.

Llama-2. Figure 12 illustrates that for the 13B model, DAPPLE operates effectively and significantly outperforms DAPPLE$^+$, which incorporates recomputation. However, as the parameter size increases, DAPPLE fails to train due to excessive memory usage resulting from retaining all activations. In contrast, DAPPLE$^+$ continues training successfully by discarding most activations to reduce memory usage.

OHP-CMB leverages recomputation for cost-effective operators, achieving a computation complexity of $O(bsh)$ for the operators' recomputation and a space complexity of $O(bs^2h)$ or $O(bsh^2)$ for reducing the operators' footprints. This strategy allows OHP-CMB to efficiently train 13B and 18B models with minimal recomputation overhead. However, it cannot support larger models due to limited activation savings.

BPipe utilizes spare memory in later stages to mitigate the memory bottleneck in earlier stages, enabling the training of 13B and 18B models. Furthermore, the high-bandwidth NVLink ensures minimal communication overhead, allowing BPipe to sustain high performance. However, as all activations are retained in GPU memory, the memory usage exceeds GPU capacity for 23B and 28B models. To address this, the *MLP* recomputation strategy is applied, and BPipe achieving just 17% improvements over DAPPLE$^+$ for these larger models because of these recomputation overhead.

Strawman outperforms DAPPLE$^+$ by effectively concealing recomputation overhead. However, its performance deteriorates with increasing model sizes and global batch sizes. Larger models reduce Strawman's ability to conceal recomputation overhead due to the need for more stages to be adjusted stages, while larger global batch sizes increase recomputation demands, further intensifying the overhead.

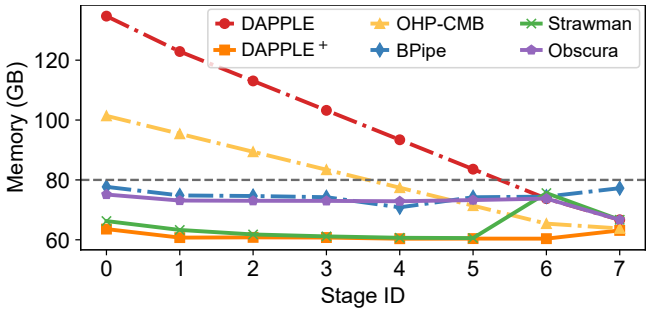

Figure 13: Memory usage in the Llama-2 28B model.

Obscura requires fewer adjusted stages than Strawman by using the **CMB-Identifying** and reduces the recomputation of non cost-effective operators through activations swapping. Therefore, Obscura more effectively conceal recomputation overhead using forward and backward bubbles, even with larger models and global batch sizes. Specifically, Obscura achieves speedups of 29–31% for the 18B and 23B models, 22–27% for the 28B model, and a 22% speedup in the extreme case of a global batch size of 64 for the 28B model.

GPT-3. Obscura and the baselines achieve comparable end-to-end performance to Llama-2. But notably, since GPT-3 uses the *GELU* activation function, which is more cost-effective than the *SiLU* function used in Llama-2 in recomputation, Obscura attains speedups of 32–33% for the 18B and 23B models, 30–32% for the 28B model, and 30% in the extreme case of a global batch size of 64 for the 28B model.

9.3 Memory Analysis

We measure peak memory usage across stages for the Llama-2 28B model with a global batch size of 32. For baselines experiencing OOM, we estimate their memory usage to ensure a fair comparison. The results are presented in Figure 13.

For DAPPLE, only stages 6 and 7 operate within the memory constraints. Memory usage across stages shows an imbalanced linear decline, with stage 0 consuming approximately 2.0× the memory of stage 7. In contrast, DAPPLE$^+$ achieves consistently low and balanced memory usage by discarding nearly all activations across all stages, leaving approximately 20 GB of unused memory in each stage. OHP-CMB reduces activation size by 40% compared to DAPPLE by recomputing only the *Norm*, *SiLU*, and *Mul* operators; however, this optimization is insufficient for training the 28B model. BPipe balances memory by retaining at most $\lceil (p+2)/2 \rceil$ micro-batches of activations across p stages. Without the *MLP* recomputation strategy, its peak memory usage reaches 106 GB during 28B model training, exceeding memory limits. With the strategy applied, memory usage stabilizes at approximately 76 GB. Since only stages 6 and 7 in DAPPLE remain within the memory constraints, Strawman selects stages 0–5 as adjusted stages, resulting in memory usage similar to DAPPLE$^+$, where available memory is not fully utilized.

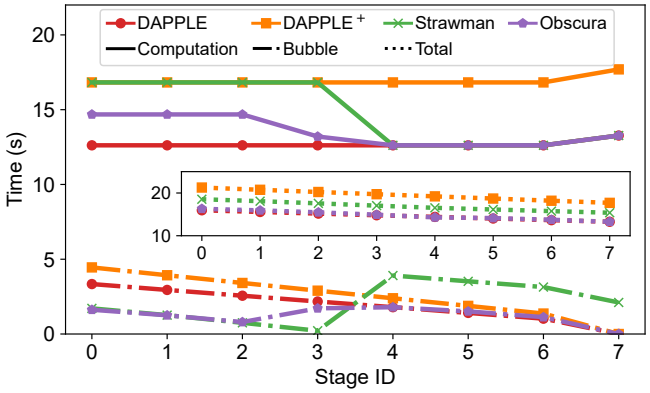

Figure 14: Computation, bubble and total execution time across all stages in the Llama-2 23B model.

In contrast, Obscura selects stages 0–4 as adjusted stages and applies the *CMB* recomputation strategy to stage 5. As a result, stage 5 shows memory usage comparable to OHP-CMB, while stages 6 and 7 align with DAPPLE. For the remaining stages, the identical recomputation strategy and objectives for activation swapping ensure memory usage that close to the constraints, achieving high memory utilization.

9.4 Computation and Bubble Analysis

To assess the effectiveness of recomputation overhead concealment in Obscura, we measure the computation and bubble times across stages for a single iteration of the Llama-2 23B model with a global batch size of 32. Computation time is defined as the cumulative forward and backward pass times for all micro-batches, while bubble time refers to the total duration of all forward and backward bubbles. The total execution time is calculated as the sum of computation and bubble times. For comparison, we estimate the performance of DAPPLE, despite its inability to run the model at this scale. The results are presented in Figure 14.

Due to the discarding and recomputation of nearly all activations, DAPPLE$^+$ incurs an 1/3 increase in computation, bubble, and execution time compared to DAPPLE. To enable training of the 23B model, Strawman designates stages 0–3 as adjusted stages, resulting in computation time for these stages matching those of DAPPLE$^+$, while stages 4–7 align with DAPPLE. By utilizing bubbles to conceal recomputation overhead, Strawman can reduces bubble time for stages 0–3 compared to DAPPLE, achieving better performance than DAPPLE$^+$. However, Strawman still exhibits longer execution time than DAPPLE, as the available bubble time is insufficient to fully conceal the recomputation overhead, evidenced by the bubble time for stage 3 dropping to zero.

Unlike Strawman, Obscura designates stages 0–2 as the adjusted stages. By utilizing swapping techniques to minimize activation footprints, Obscura employs a recomputation strategy focused solely on cost-effective operators for the

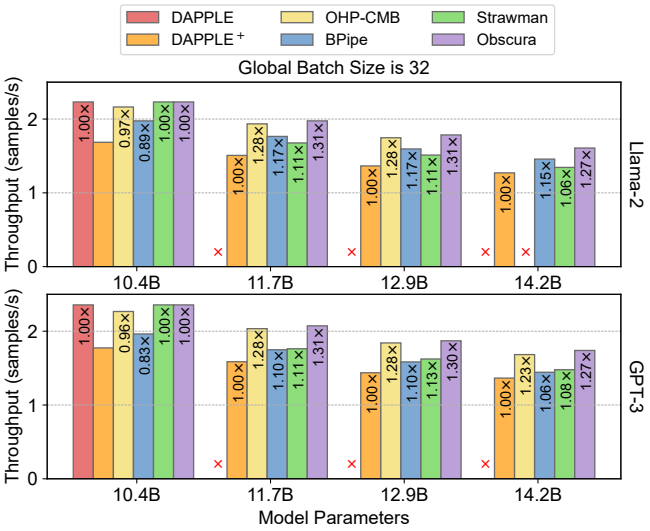

Figure 15: End-to-End performance in 4 stages pipeline.

adjusted stages, leading to only a 13% increase in computation time compared to DAPPLE. In terms of bubble time, the adjusted stages show a reduction of approximately 1.7 seconds compared to DAPPLE. Notably, stage 2 retains bubbles, demonstrating that recomputation overhead is almost entirely concealed. As a result, Obscura achieves performance closely aligned with that of DAPPLE.

9.5 Additional Performance Validation

To demonstrate that Obscura delivers robust performance across diverse training configurations and platforms, we selected another representative 4-stage pipeline configuration for validation. We re-conduct performance evaluations using various sizes of Llama-2 and GPT-3 models with a global batch size of 32. The experiments are performed on a system equipped with four NVIDIA A800 GPUs connected to CPUs via PCIe 4.0 x16, without NVLink. Due to limited P2P bandwidth between GPUs, BPipe achieves 11% and 17% lower throughput than DAPPLE on 10.4B models, mainly due to costly inter-stage activation transfers. For larger models, combining MLP recomputation reduces activation size and enables full overlap of communication and computation, but introduces recomputation overhead. In low-bandwidth settings, recomputation outperforms swapping.

In contrast, Obscura introduces no additional inter-stage communication and maintains original P2P communication between stages. As a result, it consistently achieves strong performance gains of 27–31%.

9.6 Sensitivity Analysis

To evaluate the advantages of Obscura over baseline methods, we perform a sensitivity analysis to examine the impact of dependency relaxation (DR), swapping-aware recomputation

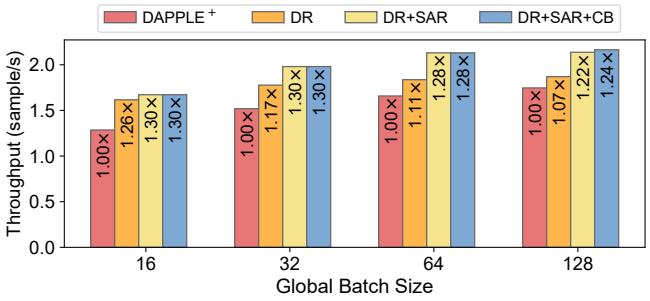

Figure 16: Sensitivity Analysis in the Llama-2 23B model.

(SAR), and computation balancing (CB). Figure 16 presents the performance of DAPPLE$^+$ and Obscura across different combinations of these core techniques, tested under global batch sizes ranging from 16 to 128 for training the Llama-2 23B model. All configurations designate stages 0–2 as adjusted stages, and the results are normalized to DAPPLE$^+$.

At a batch size of 16, bubbles can conceal most recomputation overhead, yielding significant speedups for all Obscura configurations. DR shows a slight performance drop due to recomputation overhead in the final backward pass, which cannot be concealed, and larger per-micro-batch recomputation overhead. At batch sizes of 32 and 64, DR's performance degrades significantly as recomputation overhead exceeds bubbles' capacity. In contrast, DR+SAR and DR+SAR+CB maintain higher performance by prioritizing cost-effective operators, reducing overall recomputation overhead. At a batch size of 128, DR+SAR and DR+SAR+CB experience a performance drop as bubbles cannot fully conceal recomputation overhead. However, DR+SAR+CB mitigates this by redistributing layers between adjusted and non-adjusted stages, balancing the computation load.

10 Conclusions

In this paper, we present Obscura, a computationally efficient pipeline training system, which introduces a novel pipeline transformation that utilizes existing pipeline bubbles to effectively hide recomputation costs, as well as integrates advanced techniques such as dependency relaxation, swapping-aware recomputation, and computation balancing, significantly enhancing overall performance and resource utilization.

Abstract

With the rapid innovation of GPUs, heterogeneous GPU clusters in both public clouds and on-premise data centers have become increasingly commonplace. In this paper, we demonstrate how pipeline parallelism, a technique well-studied for throughput-oriented deep learning model training, can be used effectively for serving latency-bound model inference, *e.g.,* in video analytics systems, on heterogeneous GPU clusters. Our work exploits the synergy between diversity in model layers and diversity in GPU architectures, which results in comparable inference latency for many layers when running on low-class and high-class GPUs. We explore how such overlooked capability of low-class GPUs can be exploited using pipeline parallelism and present a novel inference serving system, PPipe, that employs *pool-based pipeline parallelism* via an MILP-based control plane and a data plane that performs resource reservation-based adaptive batching. Evaluation results on diverse workloads (18 CNN models) show that PPipe achieves 41.1%–65.5% higher utilization of low-class GPUs while maintaining high utilization of high-class GPUs, leading to 32.2%–75.1% higher serving throughput compared to various baselines.

1 Introduction

While applications based on large language models (LLMs) have witnessed remarkable advancements in recent years, video analytics systems [1–4], which leverage extensive networks of cameras deployed in major cities across the U.S. and around the world [3–5], remain heavily reliant on traditional machine learning models such as convolutional neural networks (CNNs). These systems play a critical role in enabling a wide range of applications, including real-time surveillance for security purposes, efficient transportation management through traffic monitoring, enhanced public safety via crowd analysis, and improvements in healthcare through patient monitoring. The global video analytics market is estimated to grow from $3.2 billion in 2023 to $19.1 billion by 2030, at a CAGR of 29.2% [17].

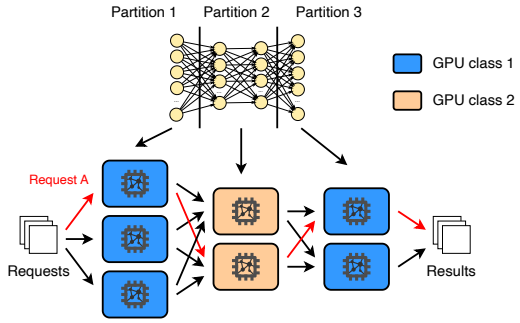

Figure 1: Pool-based pipeline parallelism on a heterogeneous GPU cluster with model partitioning. Each request (*e.g.,* request A) is processed by all partitions sequentially, and may be processed by any of the GPU servers allocated to each partition (GPU pool).

In video analytics systems, streams of video frames from cameras deployed at different locations of interest are uploaded to the cloud servers that perform analytics, *i.e.,* deep neural network (DNN) model inference. Serving such inference requests is challenging for two primary reasons. First, video analytics inference requests often have stringent service level objectives (SLOs), *e.g.,* 200 ms [26, 65]. Second, inference requests from real-world applications can be bursty [11, 34, 47, 62]. Meeting the latency SLO for all inference requests requires provisioning hardware resources for the peak load, which can be costly as the hardware resource becomes under-utilized during off-peak periods.

As with model training, model inference relies on the use of accelerators such as GPUs. With rapid innovation of GPUs [40], newer generations of GPUs are introduced to the market in short release cycles. Yet, their high cost and limited supply have dis-incentivized cloud vendors and private organizations from retiring older generations of GPUs. As a result, these organizations are increasingly operating highly heterogeneous GPU clusters [54].

This paper studies how to serve popular DNN models, *i.e.,* with high volumes of requests [8], on heterogeneous GPU

*Both authors contributed equally to the paper.

clusters. Being able to do so not only allows utilizing low-class computing resources that are otherwise unusable [43] in clusters dedicated to model serving, *e.g.,* in edge clouds or private clouds running AI-based apps [7, 18], but also, as we will show in this paper, can significantly enhance the serving throughput of high-class GPUs.

In particular, we explore the under appreciated benefits of pipeline parallelism among lower-class and higher-class GPUs in online model serving. While the benefits of pipeline parallelism have been well studied for throughput-oriented model training [14, 29, 32, 43, 56], its potential for model serving under latency (SLO)-constrained settings on heterogeneous GPU clusters has been largely unexploited. Intuitively, the benefits of partitioning a model and pipelining the partitioned inference among mixed high-class and low-class GPUs appear limited. For example, if the high-class GPU is 10× faster (*i.e.,* lower latency) than the low-class GPU for a given model, then simply running 1/10 of the model layers on the low-class GPU already leads to 1.9× longer total latency.

We instead make a key observation about the performance characteristics of DNN model inference on heterogeneous GPUs: *the two forms of diversity in model inference on a heterogeneous GPU cluster — diversity in model layers and in GPU types — can interact with each other synergistically.* First, a DNN model typically has many layers with diverse operations and tensor dimensions, leading to varying GPU utilization on a given GPU. Second, more importantly, for the same DNN model, the relative per-layer inference latency on different classes of GPUs can vary significantly across the model layers. This observation suggests that partitioning the DNN model in a GPU-aware manner and executing each partition on the GPU type that runs most effectively can improve the effectiveness of all GPU types and hence the inference throughput of the whole cluster. Effectively, lower-class GPUs offload part of the model inference from higher-class GPUs with minimum elongation of the end-to-end inference latency.

While this observation provides guidelines on efficient pipeline parallelism on heterogeneous GPU servers, partitioning a model and running the partitions along a *chain* of GPUs, as done in pipeline parallel DNN training [25, 39], is too stringent and leads to suboptimal partitions: all partition stages must have matching latencies to avoid pipeline stalls, which restricts the flexibility of model partitioning and leaves less opportunity for low-class GPUs to run layers they are efficient at.

To this end, we present PPipe, a model serving system that harnesses mixed GPU types in heterogeneous GPU clusters to maximize serving throughput. PPipe is built on three key ideas. First, to improve scheduling flexibility, it employs *pool-based pipeline parallelism* where each model partition is associated with a *pool* of GPU servers, and each request can be processed by any GPU in each partition pool along the pipeline, as shown in Figure 1. *Such pooled pipeline parallelism allows different partitions to have different numbers of GPU servers, varying inference latencies, and run with different batch sizes, as long as the inference throughput provided by each pool of GPU servers matches with each other.*

Second, to realize the scheduling flexibility exposed by pool-based pipelined model inference, PPipe generates the optimal configuration of pool-based pipelined model inference, *e.g.,* one that maximizes the model serving throughput of a given cluster while meeting inference SLOs, using Mixed Integer Linear Programming (MILP), which takes as input the per-layer inference latency on all candidate GPUs and under all candidate batch sizes from offline profiling.

Such an MILP-based optimal solution, however, effectively assumes ideal request arrivals, *i.e.,* synchronous arrival of batches in locksteps at all GPUs of the first partition pool, and flow down the pipeline partitions in sync. In practice, the inference requests arrive asynchronously and can be bursty [11, 34, 47, 62], which creates transient high load that overwhelms the throughput prescribed in the MILP solution, introducing several sources of extra delay not accounted for in the MILP solution and leading to SLO violations.

To bridge the gap between the MILP solution and runtime dynamics due to asynchronous and bursty request arrivals, PPipe treats the MILP-based formulation as the control plane which prescribes optimal DNN model partition and GPU allocation, and employs a novel data plane that performs *resource reservation-based adaptive batching* to address the unique challenges in batching pooled-based pipelines: deciding for each batch *which pooled pipeline, which path within the pipeline, and the batch size.* Our scheduler overcomes the above challenges by (1) maintaining (current and future) availability of resources (GPUs and network bandwidth) in the pooled pipelines; and (2) probing them to find the maximal batch of requests that can meet the SLOs of each request when the batch reaches the end of the pipeline path.

We evaluate PPipe using production workloads on top of 100-GPU large-scale simulations and 16-GPU testbeds on Google Cloud consisting of a variety of high- and low-class GPUs such as NVIDIA V100, L4, T4, and P4. Evaluation across 18 CNN models shows that PPipe achieves 44.1%–65.5% higher utilization of low-class GPUs while maintaining high utilization of high-class GPUs compared to various baselines, leading to 32.2%–75.1% higher serving capacity, while successfully processing 99% of the requests without dropping or SLO violations.

In summary, we make the following contributions:

- The first exploration of pipeline-parallel model serving on heterogeneous GPU clusters under latency (SLO)-constrained settings.
- The complete design of PPipe, which employs three design ideas to maximize inference throughput of heterogeneous GPU clusters: pool-based pipeline parallelism, an MILP-based control plane that prescribes optimal pool-based pipeline plans, and a data plane that performs resource reservation-based adaptive batching to handle run-

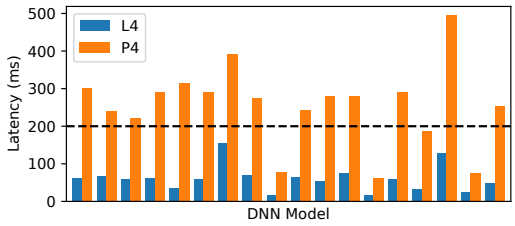

Figure 2: Inference latency of 18 popular DNN models (Table 2) under batch size 4 on different GPU classes.

time dynamics due to asynchronous and bursty request arrivals.

- Extensive evaluation of PPipe showing PPipe outperforms baseline designs by 32.2%–75.1% in inference throughput and 41.1%–65.5% higher low-class GPU utilization.

The source code of PPipe is available at https://github.com/JonnyKong/PPipe.

2 Motivation and Key Idea

We motivate how low-class GPUs can be effectively used to augment high-class GPUs in a heterogeneous cluster in model serving by exploiting pipeline parallelism.

Low-class GPUs fail to meet the inference latency SLO. On a highly heterogeneous GPU cluster, the inference time on old or low-class GPUs is usually several times longer than that on newer or high-class GPUs. For the 18 DNN models we use for evaluation (§7.1), the inference time (on the highly optimized TensorRT [10] inference framework) on the low-class NVIDIA P4 is 3.0x–7.9x longer than that on the high-class NVIDIA L4, as shown in Figure 2. Even if a model runs on the low-class GPU without violating latency SLO, it can barely perform batched inference, which could significantly improve GPU utilization and throughput [6, 12, 47]. As shown in Figure 2, only 22% of the DNN models can run on the low-class GPU (NVIDIA P4) at batch size 4 without exceeding 200 ms, a latency SLO target commonly used among video analytics pipelines [26, 65].

Key insight: Diversity in per-layer inference delay across GPUs. Given the high latency of low-class GPUs, the benefit of partitioning and running a model across low- and high-class GPUs, if done in a GPU-oblivious manner, will be limited. For example, if the high-class GPU is 10× faster (*i.e.,* lower latency) than the low-class GPU for a given model, then simply running 1/10 of the model layers on the low-class GPU already leads to 1.9× longer total latency. Our key observation is that there exist two forms of diversity in model inference on a heterogeneous GPU cluster: diversity in model layers and in GPU types, and they can interact with each other synergistically.

In particular, for many popular CNN backbone architectures, *e.g.,* EfficientNet [49] and ResNet [23], later layers have more channels compared to earlier layers, but with lower feature dimensions. Such architectural differences among layers

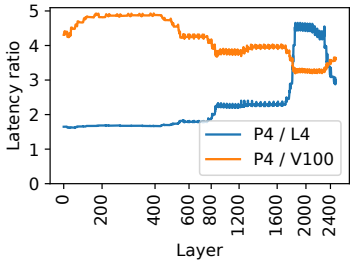

Figure 3: The ratio of inference latency on NVIDIA P4 over L4 and P4 over V100 across EfficientNet-B8 [49] layers.

within a DNN model can lead to different computational properties on GPU accelerators. To gain insight into this, we measure the *latency ratio*, *i.e.,* the ratio of the inference latency of the same layer on different GPU types for all the layers within a DNN model. Figure 3 shows that for EfficientNet-B8 on NVIDIA P4 over L4 and P4 over V100, respectively, with a moving window of 128 layers. The inference latency ratio on P4 over L4 is about 1.7 for early layers, indicating these layers have closer inference latencies on both P4 and L4. On the other hand, later layers have much higher latency ratios, and those layers will suffer significant slowdown running on P4 over L4. If we were to partition the DNN model and run it on P4 and L4, we should place earlier layers on P4 and later layers on L4, which provides higher chances to keep the inference time below the latency SLO and enables batching opportunities. All 18 DNN models we studied (Table 2) exhibit varying latency ratios across layers and we omit the rest due to page limit.

Interestingly, the latency ratios between P4 and V100 show completely different trends on EfficientNet, where earlier layers exhibit much higher latency ratios than later layers. In this case, one would run on P4 later layers instead. Such differences in the trends of latency ratios happen due to GPU design tradeoffs, architectural improvements, and their interaction with DNN layers of different characteristics. For example, GPUs with more SMs or higher ops:bytes ratio provide more benefits for layers of larger size or higher arithmetic intensity [19].

Such varying trends in per-layer latency ratios on different GPUs suggest that partitioning a DNN model in a *GPU-aware* manner is critical in exploiting pipeline parallelism so that high-class and low-class GPUs can work on model layers that they are optimized for, which improves their efficiency and hence the inference throughput of the whole cluster.

Key idea: pool-based pipeline parallelism. To apply model partitioning to exploit the diversity of per-layer inference ratio on different GPUs, a simple approach is partitioning a model and pipelining the inference of partitions along a *chain* of GPUs similarly as in pipeline parallelism in DNN training [25, 39], and feature maps generated by one GPU are transferred to the next downstream GPU. Such single-chain inference pipelines have the advantage of simple scheduling and coordination, but also come with two major drawbacks:

(1) To avoid pipeline stalls, all partitions need to have similar inference latencies. However, such a partitioning strategy is too stringent and will lead to suboptimal partitions, *e.g.,* leaving layers with high latency ratios (on high/low-class GPUs) to run on the low-class GPU or having a large feature map at the partition point. (2) Many GPUs cannot take advantage of heterogeneous inference when the cluster contains more GPUs of one class than the other.

To provide more scheduling flexibility, we instead associate each partition with *a pool of GPU servers* of the same type, and each request can be processed by any GPU allocated to the first partition, and then continue the inference on any GPU in the second partition, and so on, as shown in Figure 1. This approach mitigates the drawbacks of single-chain pipelines: different partitions can have different numbers of GPU servers (*e.g.,* N_1 servers in pool 1, N_2 servers in pool 2), have different inference latencies (*e.g.,* $t1$ and $t2$ for the 2 pools), or even run with different batch sizes (*e.g.,* $b1$ and $b2$ for the 2 pools), as long as the inference throughput provided by each pool of GPU servers matches well with each other (*e.g.,* $N_1 * b_1/t_1 = N_2 * b_2/t_2$), and the total latency is below the latency SLO. In an optimal partitioning, multiple such *pooled pipelines* may be employed at the same time, employing different ways of partitioning the DNN model running on different GPU pools.

3 Prelude to PPipe: Basic MILP Formulation

To exploit pool-based pipelined inference, one needs to figure out the optimal way to partition a DNN model, the placement of the DNN partitions onto GPU servers, and the batch size for the GPUs in each partition. It is relatively straightforward to formulate an MILP problem to figure out the optimal solution. We briefly describe the MILP formulation below and present the full mathematical formulation in Appendix §A.1.

Inputs. The MILP formulation takes as input the GPU count of each GPU type, the interconnect bandwidth of the target cluster, and the inference latency SLO. To decide the optimal model partitions, it also requires the intermediate feature map sizes and the inference latencies of individual layers within a DNN model under different batch sizes and on different GPU models, which can be obtained from the profiling output of TensorRT [10].

Encoding model partition and placement. Suppose the GPU cluster consists of 2 GPU types and we restrict a DNN model to be divided into at most 3 partitions. The placement of DNN model partitions falls into one of 14 potential pooled pipelines: if partitioned into 2 partitions, each partition can run on a pool of either GPU types (4 pipeline options); if partitioned into 3, each of the 3 partitions again has the choice to run on a pool of either GPU types (8 pipelines); the DNN model can also directly run on a pool of either GPU type without partitioning (2 pipelines). As discussed in §2, the optimal solution may contain multiple pooled pipelines.

For each partition within a pooled pipeline, we need to decide on the exact partition points, *i.e.,* the first and last layers. To this end, we construct a set of binary decision variables for each partition indicating whether each layer is the first or last layer of a partition. Apart from that, we also create decision variables to represent the batch size and the number of GPUs used by each partition.

Constraints. The total latency of each pooled pipeline, including the inference latency of each partition and the feature map transfer latency between partitions (both can be derived from the batch size), should be below the latency SLO; the total GPU count used by all partitions pertaining to a specific GPU type should not exceed the GPU count for that GPU type. Finally, the inference throughput of a pooled pipeline is bottlenecked by the partition of lowest throughput, where each partition's throughput can be calculated based on its batch size, inference latency, and the number of GPUs allocated to the partition. We observe that CNN models commonly used in video analytics pipelines are typically not memory-constrained on datacenter GPUs; hence, the MILP formulation does not account for GPU memory.

Objective. By default, we try to maximize the total inference throughput of the GPU cluster, which is the sum of the throughputs of all pooled pipelines employed by the MILP solution. The MILP formulation can also be configured for other objectives like minimum server cost [24] or provisioned power [28]. In the presence of multiple DNN models, given the ratio between the DNNs' workloads, the MILP formulation computes the normalized throughput for each DNN (throughput divided by the DNN's workload percentage), and maximizes the lowest normalized throughput among the DNNs.

Outputs. The solver of the MILP formulation outputs the pooled pipelines employed by the optimal plan, *i.e.,* those being allocated at least 1 GPU. For each pipeline, the solver outputs the DNN model partition points, the batch size used by the GPUs in each partition, and the number of GPUs allocated to each partition.

In essence, MILP holistically determines an optimal set of pooled pipelines by selecting the model partition points for each pipeline, along with the GPU type, count, and batch size for each partition in each pipeline, all of which affect the overall throughput of the GPU cluster.

4 Challenges in Developing a Working System

While the MILP formulation above provides the optimal plan in theory, turning it into a working DNN serving system faces several practical challenges, as discussed below.

C1: Extensive search space of the MILP formulation. The MILP formulation needs to decide the first and last layers of a DNN partition, whose complexity depends on the number of layers in a DNN model. For the set of representative models

in our evaluation (§7.1), the average layer count is 613.2. The partition points need to be searched for all partitions across all pipelines, making the search space combinatorial. The search space is further inflated by additional dimensions including inference batch size and GPU count used by each partition. With such a vast search space, it takes more than 7 hours (running the Gurobi [21] solver on a Google Cloud n1-standard-64 instance) to obtain the optimal solution for 80 layers, making it impractical to adapt to changing workload, *e.g.,* diurnal load [28].

C2: Asynchronous and bursty request arrival. In essence, the MILP formulation outputs a solution that assumes ideal inference request arrival. Suppose a pipeline solution consists of two partitions with 40 ms inference latency each, and the inference throughput is 1000 requests per second. The MILP solution effectively assumes that 40 requests arrive at the same time every 40 ms, which are simultaneously processed by all GPUs allocated to the first partition, and then forwarded to the second partition, and so on.

In reality, in an online inference system, inference requests arrive asynchronously and in a bursty manner, which can disrupt the MILP solution with two forms of extra delays: (1) Early arriving requests have to wait for later requests to form a batch to be dispatched to a GPU in the first partition, incurring *initial batching delay* (D1); (2) The staggered batched inference initiated on the GPUs in the first partition will cascade through the remaining partitions in the pipeline. In such staggered pipelined inference, it is possible when a GPU in partition i finishes inference on a batch, all of the GPUs in partition $i+1$ are still busy running other batches, causing *inter-partition queuing delay* (D2). Such queuing delay is further complicated when partitions use different batch sizes, requiring the split and merge of batches which creates complex dependencies between the GPUs of different partitions.

To incorporate the above extra delays at runtime, we could add a predefined margin to the latency SLO as input to the MILP formulation [44, 47] which will output adjusted (still fixed) batch sizes. But simply adding a static margin cannot handle bursty request arrival, which can still result in either too many or too few transient requests compared to the statically adjusted target batch size. Such dynamic conditions require *dynamically adjusting the batch sizes.*

C3: Network contention. We observe that heterogeneous clusters such as Google Cloud Platform (GCP) and Amazon Web Services (AWS) come with high-bandwidth networks that theoretically can finish the transfer of a feature map with a small percentage of the total inference latency. For example, GCP's P4 instances have a bandwidth of 32 Gbps, which can theoretically transfer feature maps of CenterNet (with batch size 1) which range from 3 MB to 50 MB in 0.8–13.2 ms. However, it is common for multiple GPUs to collocate on the same server, sharing the server's network bandwidth. This can lead to network contention between GPUs (D3) that disrupts pipeline schedules and causes SLO violations. The contention becomes more severe when we divide each GPU into multiple virtual GPUs (§5.3), which increases the number of "GPUs" on the same server that likely transfer feature maps at the same time. Note that this issue cannot be addressed by conservatively allocating each virtual GPU an equal share of the available bandwidth, as it results in low bandwidth for all virtual GPUs, significantly limiting the benefit of pipeline parallelism.

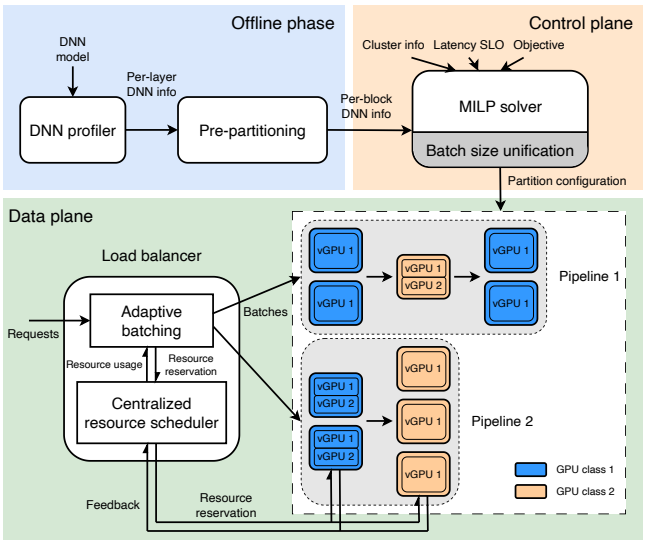

Figure 4: PPipe architecture.

5 PPipe Design

As discussed above, designing a practical pool-based pipeline parallel inference serving system faces a key challenge: the MILP formulation does not capture or handle runtime dynamics due to asynchronous and bursty request arrival or delayed feature map transfer from network contention. We tackle these challenges by splitting PPipe, our *pool-based* pipeline parallel inference serving system for heterogeneous GPU clusters, into a control plane and a data plane. First, PPipe treats the MILP-based formulation as the control plane that prescribes optimal DNN model partitions and GPU allocation for each pooled pipeline. Second, to handle delays caused by asynchronous and bursty request arrivals (D1 & D2) and network contention (D3), PPipe employs a novel data plane that performs *resource reservation-based adaptive batching* to ensure the request batches injected into the pooled pipeline meet their latency SLOs.

5.1 Architecture Overview

Figure 4 shows the architecture of PPipe, which consists of an offline phase, a control plane, and a data plane.

Offline phase. In the offline phase, the DNN model profiler profiles a model's per-layer inference latency on different GPU types. To reduce the search space of the MILP solver

(C1), we design a pre-partitioning method that groups the layers of each DNN model into blocks which are fed into the MILP solver (§5.2). With this method, the MILP solver only needs to find partition points among a few blocks instead of hundreds of layers, significantly reducing the search space. We profile each model and each block independently, and each block is profiled on every GPU type and batch size. The profiling is fast, requiring only a few hours to cover all 18 DNN models. Since the addition of models happens infrequently, and each model will be served over a long time, the one-time offline profiling cost is amortized and manageable. When solving MILP, the latency of each partition is computed as the sum of the latencies of its constituent blocks.

Control plane. The control plane, which runs the MILP solver, takes as input the profiling information of DNN blocks and the inference latency SLO for each DNN, the cluster information (GPU count for each GPU model), along with high-level objective, *e.g.,* maximum throughput, and outputs the partitioning of each DNN model and allocation of GPU resources across partitions in each pooled pipeline (detailed in §3). We observe that the synchronization among partitions (**C2**) could be much simpler if partitions within the same pooled pipeline all use the same batch size. As such, we enhance the MILP formulation with *batch size unification*.

The MILP solver runs periodically, triggered dynamically in response to workload changes, such as shifts in the load ratio when serving multiple DNNs, which typically occur once every one or a few hours [28, 68]. Note that the MILP solver runs on the CPU, and is asynchronous to the inferences running on the GPUs. Migrating to a new MILP plan involves reassigning GPUs to different partitions or pooled pipelines, and having the data plane dispatch the requests according to the updated plan. To minimize migration latency, each GPU asynchronously preloads the new model weights into memory ahead of the switch, without interrupting the ongoing inference of the existing model; this is feasible because GPU memory is generally not a bottleneck for vision models. Once all GPUs complete loading, PPipe pauses ingesting new requests to perform a pipeline flush, which takes about 1x the SLO of the currently serving DNNs (in the order of 100s of milliseconds). After the flush, all GPU switch to the new weights simultaneously and the data plane resumes request dispatching. In essence, each migration incurs a downtime of several hundred milliseconds, which is negligible compared to the interval between migrations.

Data plane. The data plane groups inference requests into batches and executes them through the pools of GPUs in each of the pipelines prescribed by MILP. To address the extra delays D1–D3, we design a novel adaptive batching scheme that selects the pooled pipeline to execute the next batch, one GPU from each pool to run the corresponding model partition (the *pipeline path*), and the actual batch size that meets the request SLOs.

5.2 DNN Pre-Partitioning

As discussed in **C1**, the sheer number of layers within a DNN model results in a huge search space for the MILP formulation and prevents the solver from finding good plans in a reasonable amount of time. To this end, we devised a simple DNN pre-partitioning approach that groups the layers in a DNN model into a few (N) blocks of approximately equal runtime on a selected GPU type; empirical results show that the choice of GPU type has minimal impact on the partitioning. Specifically, we start from the first layer and sequentially group consecutively layers together until their combined runtime is as close as possible to $1/N$ of the runtime of the entire DNN; this process is repeated until we reach the last layer. After grouping layers into blocks, we profile the blocks on different GPU types and with different batch sizes, as needed by the MILP solver. It takes only less than 10 minutes to profile a single DNN model, as each block can be profiled independently; when solving MILP, we obtain the latency of each partition by adding up the latencies of the blocks in it.

With pre-partitioning, the MILP solver only needs to find partition points among the N blocks (we tried $N = 5$ to $N = 20$ and found $N = 10$ provides a good balance between plan optimality and MILP running time), instead of 613.2 layers on average across the set of models (§7). As a result, the MILP runtime is significantly reduced to 3.5 seconds on average over different DNN model and GPU cluster setups.

5.3 Batch Size Unification

We tackle the key challenge of the data plane — bridging the gap between MILP solution and runtime dynamics (**C2** and **C3**) — in two steps. In the first step, we simplify the challenges faced by data plane scheduling with *batch size unification*.

As discussed in **C2**, mismatch of batch sizes between partitions within a pooled pipeline requires batches to be merged and split which complicates scheduling of batched inference across partitions. Things can be substantially simplified if all partitions within the same pooled pipeline use the same batch size. However, as the GPUs have different computational capacities, in the plans generated by the MILP planner, high-class GPUs tend to use larger batch sizes compared to low-class GPUs to improve GPU utilization and inference throughput. Naively forcing all partitions within the same pooled pipeline to use a uniform batch size can lead to underutilization of high-class GPUs and degrade overall system performance.

Instead of forcing all partitions of a pooled pipeline to use the same batch size, we vary the GPU size to equalize the batches per GPU. Specifically, we incorporate virtual GPUs into the MILP formulation, so that the MILP solver can take into account the throughput and inference latency differences between batches on different partitions and make

holistic decisions in choosing a unified batch size. To this end, instead of feeding a GPU as a whole to MILP, we feed four possible virtual GPU types: 1/1, 1/2, 1/3 and 1/4 of a physical GPU (this is achieved with Multi-Process Service (MPS) [38] during runtime). The use of virtual GPUs only mildly expands the search space of the MILP solver as there are only 4 virtual GPU types. Further, we profile the per-block inference latencies under not only different batch sizes and GPU types, but also different virtual GPU types.* Finally, we add additional constraints to the MILP formulation requiring all partitions within the same pooled pipeline to use the same batch size. The mathematical representation of the enhanced MILP formulation is provided in Appendix §A.2.

5.4 Resource Reservation-Based Adaptive Batching

With batch size unification, PPipe stills needs to perform adaptive batching at runtime, *i.e.,* dynamically forming and scheduling batches, in serving asynchronous and bursty inference requests.

Compared to pipelined inference over a single chain of GPUs, dynamic batching in pool-based pipelines faces unique new challenges. In a chain of GPUs, the scheduler just needs to find the largest batch size that satisfy the end-to-end SLO. In a cluster of pooled pipelines (output by the MILP solution), the batching scheduler has to make three decisions for each batch: *which pooled pipeline, which path within the pipeline, and the batch size.* The decisions are further complicated by: (1) the optimal batch size depends on which pipeline the batch is sent to; (2) the optimal pipeline path in turn depends on the batch size and resource availability in the pooled pipeline.

Resource reservation-based adaptive batching. Our resource-reservation-based adaptive batching scheduler overcomes the above challenges by (1) maintaining (current and future) availability of resources (GPUs and network) in the pooled pipelines; and (2) probing them to find the maximal batch of requests that can meet the SLOs of each request when the batch reaches the end of the pipeline path.

The scheduler works in two steps, both using a stateless probing procedure `probe()`. The procedure takes a specific pooled pipeline and a hypothetical batch size as input, and outputs the pipeline path that minimizes the end-to-end (E2E) inference time under current resource availability, with an example shown in Figure 5a. The E2E inference time includes the per-stage inference time, network transfer time, and the waiting time for required resources (GPU and NIC) along the pipeline path. The detailed algorithm of `probe()` is explained later.

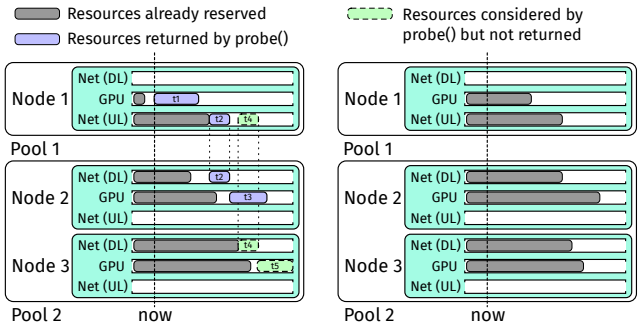
In Step 1, we identify the pooled pipeline i that can complete a batched inference at the pipeline's unified batch size bs_i (as determined by the MILP solution) with the shortest waiting time under the current resource availability. This is achieved by invoking `probe()` for each pooled pipeline with its corresponding unified batch size, and selecting the pipeline that has the lowest waiting time, where the waiting time is computed as the sum of delays waiting for each required resource along the pipeline path. Using waiting time as the metric effectively balances the load between the pipelines because it is a good indication of the load of the pipeline, *i.e.,* the lower the waiting time, the lower the load on the pipeline.

The E2E inference time of sending a batch of size bs_i down the selected pipeline i in Step 1, however, may not meet the SLO (as the batch size bs_i generated by MILP assumed synchronized request arrival). In Step 2, using the chosen pooled-pipeline i, we search for the actual largest batch size that can meet the SLOs and the corresponding pipeline path. Specifically, we iteratively invoke `probe()` with progressively smaller batch sizes, starting from bs_i (the batch size from the MILP solution), until the completion time of the pipeline path returned by `probe()` falls within the deadline of the first (oldest) pending request. Finally, one of three actions is taken depending on the chosen batch size and the number of pending requests: (1) If the deadline cannot be met even with batch size 1, the oldest request will be dropped and the adaptive batching process starts over from choosing a pooled pipeline (Step 1); (2) if the number of pending requests is smaller than the chosen batch size, the batching engine waits for more requests (till the last moment when the requests in queue can still be processed without SLO violation); (3) otherwise, the resources of the selected pipeline path returned by `probe()` are *reserved* (by calling `reserve()`), *i.e.,* their availability are updated as shown in Figure 5b, and the requests at the head of queue are grouped into a batch of the chosen batch size and dispatched to the selected pipeline path according to the resource reservation. Since the batch size is based upon the actual remaining time of the requests in the queue, the extra delay D1 (initial batching delay) is taken into account, and the requests in the batch are guaranteed to meet their SLOs.

The pseudocode for our adaptive batching algorithm is provided in Appendix §A.3.

The probing procedure. Since adaptive batching works at the batch level, the probing procedure needs to be fast to keep up with the request arrival rate. To this end, we implement `probe()` based on a greedy algorithm. In a nutshell, `probe()` works by sequentially selecting one GPU from each GPU pool along the pooled pipeline. For each GPU pool, it goes through all GPUs allocated to the pool and selects the GPU that minimize the completion time for that partition stage. During this process, `probe()` determines which resources—GPUs, uplink bandwidth, and downlink bandwidth—need to be reserved for specific future time intervals. Note that since feature map transfer require simultaneous availability of network resources on both the sending and receiving sides, `probe()` ensures the allocation of network resources that satisfy both

*We capture the interference between virtual GPUs during profiling by running the same DNN on all virtual GPUs of the same physical GPU in parallel.



(a) `probe()` takes as input a candidate pooled pipeline and batch size, and outputs the optimal pipeline path and the intervals of resources to be used (in blue).

(b) `reserve()` marks the resource intervals as reserved until the end of the intervals returned by `probe()`.

Figure 5: The resource reservation mechanism on an example pooled pipeline comprising two partitions, with 1 and 2 GPUs, respectively.

the uplink of the preceding GPU and the downlink of the current GPU.

We illustrate the workflow of `probe()` with an example in Figure 5a. Consider a pooled pipeline consisting of two pools, containing one and two GPUs respectively. For simplicity, we assume each GPU resides on a separate node, although in practice, multiple GPUs may reside on the same node and share the same network resources. In the first pool, `probe()` selects node 1 as it is the only option, which requires reserving its GPU for time duration `t1`. In the second pool, `probe()` needs to decide between nodes 2 and 3. Selecting node 2 requires the simultaneous reservation (as shown by the vertical dotted line) of node 1's uplink and node 2's downlink network during `t2`, as well as node 2's GPU during `t3`, after which the request completes; alternatively, selecting node 3 results in a completion time by the end of `t5`. Since node 2 results in an earlier completion time than node 3, `probe()` selects node 2. In the end, it returns the selected pipeline path with associated resource allocated: node 1's GPU during `t1`, node 1's uplink and node 2's downlink network during `t2`, and node 2's GPU during `t3`.

Since `probe()` is based on real-time resource availability, it directly takes into account extra delays D2 (inter-partition queuing delay) and prevents D3 (network contention delay). Furthermore, `probe()` runs in real time, and scales linearly with the number of virtual GPUs allocated to the pooled pipeline. The pseudocode for `probe()` and `reserve()` are provided in Appendix §A.3.

Feedback correction. The scheduler maintains resource reservation tables that keep track of when each resource will be used. However, this scheduler's view of resource usage might deviate from reality due to variations in inference time and network bandwidth. To this end, we let all nodes report back to the scheduler when the reserved resources were actually used immediately after every resource usage. The scheduler updates the resource usage table accordingly. The feedback correction mechanism ensures that the scheduler's view of resource usage is synchronized with reality at all times.

Extra SLO margin in the control plane. While our resource reservation-based adaptive batching algorithm ensures requests meet their SLOs, we notice that the resulting batch size may be much smaller than that in the MILP output due to extra delays D1–D3, causing large deviations from the MILP plan. To bridge the gap between control plane planning and data plane execution, we deduct an empirically determined margin from the SLO when running the control plane MILP solver, so that the adaptive scheduler picks the same batch sizes as in the MILP output most of the time.

Dispatching Complexity. In the worst case, dispatching a batch requires a number of `probe()` function calls equal to the product of the number of pipelines in the cluster and the number of candidate batch sizes. Each `probe()` function call has a time complexity linear to the number of GPUs within the corresponding pipeline. Consequently, the adaptive batching algorithm incurs low runtime overhead, as we will demonstrate in §7.2.

6 Implementation

Offline phase and control plane. We implement the offline phase and control plane in Python in 2.7 kLOC. We use Gurobi [21] as the MILP solver. We work with DNN models in their ONNX format and TensorRT format interchangeably, since the ONNX format provides flexibility, while the TensorRT format provides high inference performance.

Data plane. We implement both a discrete-event simulator for modeling large-scale GPU clusters and a prototype implementation for PPipe's data plane, in about 9.0 kLOC. The simulator is written in Java and maintains a global event queue sorted by timestamp, executing events in chronological order. Supported event types include request arrivals, batch dispatches, per-partition executions, and feature map transfers, etc. At each simulation step, the simulator dequeues the next event, invokes the corresponding event handler, which updates the system states and may produce additional events to be added to the event queue (*e.g.,* a request arrival event adds the request to the waiting queue and triggers a scheduler event).

The prototype implementation is written in a combination of Julia and C++, using TCP for control message exchanges and NVIDIA NCCL for transferring feature maps between nodes. To minimize the feature map transfer latency, we quantize float32 feature maps to float16 (only at partition boundaries), effectively reducing the transfer size by half. We find such quantization has negligible impact on task accuracy. The accuracy dropped by 0.00%, 0.01%, and 0.01% for object recognition, object detection, and instance segmentation tasks, respectively.

Table 1: Heterogeneous Cluster (HC) setups.

Setup	GPUs	Setup	Instances	GPUs	BW (Gbps)
HC1-L	25× L4, 75× P4	HC1-S	4× g2-standard-16, 2× n1-highcpu-16	4× L4, 12× P4	50
HC2-L	25× L4, 75× T4	HC2-S	1× g2-standard-48, 6× n1-highcpu-32	4× L4, 12× T4	32
HC3-L	25× V100, 75× P4	HC3-S	2× n1-highcpu-16, 12× n1-highcpu-16	4× V100, 12× P4	50

7 Evaluation

In this section, we evaluate PPipe's serving performance under a variety of DNN models from different tasks, considering various combinations of low-class and high-class GPUs. We show that PPipe can serve 32.2%–75.1% more requests compared to various baselines while meeting 99% SLO attainment, on the discrete-event simulator with 100 GPUs. Additionally, on 16-GPU clusters deployed on Google Cloud, PPipe achieves 16.7%–52.8% higher serving throughput. We also conduct sensitivity analysis to show the impact of GPU composition and SLO on PPipe's performance.

7.1 Methodology

Cluster configuration. We consider 4 heterogeneous cluster setups, labelled as HC1−HC4 in Table 1. Each setup consists of a large (L) 100-GPU variant used for the discrete-event simulator, and a small (S) 16-GPU variant deployed on Google Cloud. Note that a Google Cloud VM instance can host multiple GPUs, resulting in each HC having a varying number of VMs while maintaining a consistent number of GPUs. Accounting for the scarcity of high-class GPUs [54], our default configuration includes 25 high- and 75 low-class GPUs for each HC's large variant, and 4 and 12 for the small variant. We further evaluate PPipe's performance under different ratios of high- and low-class GPUs in §7.6. Note that for GPU-equipped VMs, Google Cloud provisions network bandwidth based on the number and type of its GPUs, leading to different interconnect bandwidths across HCs. Furthermore, the effective bandwidth for both large and small clusters is only 1/5 the claimed values in Table 1 to accommodate the observed 5× network tail latency on Google Cloud.

Workloads. Following prior works [34, 62], we use Microsoft's Azure Function (MAF) traces from 2019 [46] and 2021 [66], which were originally derived from Azure serverless function invocations, as representative inference serving workloads. When serving multiple DNNs in parallel (§7.2), functions are assigned to DNNs in a round-robin manner to determine the workload ratio among DNNs. The MAF 2019 trace only includes per-minute aggregated request counts for each serverless function, and thus we issue requests using Poisson arrival at the given target load. Conversely, the MAF 2021 trace includes per-request arrival timestamps, and thus we upscale the trace to the target load and issue requests accordingly. The Poisson-emulated 2019 trace is less bursty than the 2021 trace, and thus we refer to the two traces as "Poisson" and "Bursty", respectively.

DNN models. We select 18 popular DNN models from public DNN registries such as TorchVision [51], OpenMMLab [41], and OpenVINO model zoo [42]. The selected DNNs serve a variety of popular computer vision tasks, as shown in Table 2.

Metrics. We employ two key metrics to evaluate the inference serving capability. First, *SLO attainment* represents the percentage of requests that are successfully processed without being dropped or violating the SLO, under a specific offered load. Second, we measure the maximum load that the system can handle at 99% SLO attainment.

Baselines. The large amount of recent works on model serving on heterogeneous clusters do not incorporate pipeline parallelism, and thus we abstract them into a state-of-the-art baseline, denoted as NP below. We also compare PPipe with the only prior work that exploits pipeline parallelism across heterogeneous GPUs, DART [55], which uses a single-chain-based pipeline of GPUs. To isolate the benefit of pool-based pipeline parallelism, we enhance all baselines to use PPipe's data plane, *i.e.,* the resource reservation-based adaptive batching (§5.4) in presenting the overall results (§7.2 & §7.3). We then evaluate the benefit of PPipe's second novel design, resource-reservation-based adaptive batching, in §7.4.

- **No-Partitioning (NP)**. NP executes the entire DNN on either high-class or low-class GPUs without partitioning. This way of serving DNNs on a heterogeneous cluster is representative of various prior works [11,24,27,28,30,31,45,60]. In particular, the allocation is done by solving PPipe's MILP formulation without model partitioning. When integrated with PPipe's reservation-based adaptive batching, NP effectively dispatches the largest possible batch to the next available GPU while meeting the SLO for each request in that batch.
- **DART-r**. DART [55] is an inference framework that partitions a DNN onto heterogeneous CPU and GPU cores. However, vanilla DART constructs a pipeline by chaining all available GPUs, each serving one model partition. This restricts its use to small clusters, as long pipelines incur significant overhead due to frequent feature map transfers. To address this limitation, we introduce DART-r, a modified version that replicates DART configurations for pairs of low- and high-class GPUs (more efficient than longer pipelines from fewer feature map transfers). If one GPU class has more GPUs than the other, the leftover GPUs are allocated to individually run entire DNNs without partitioning.

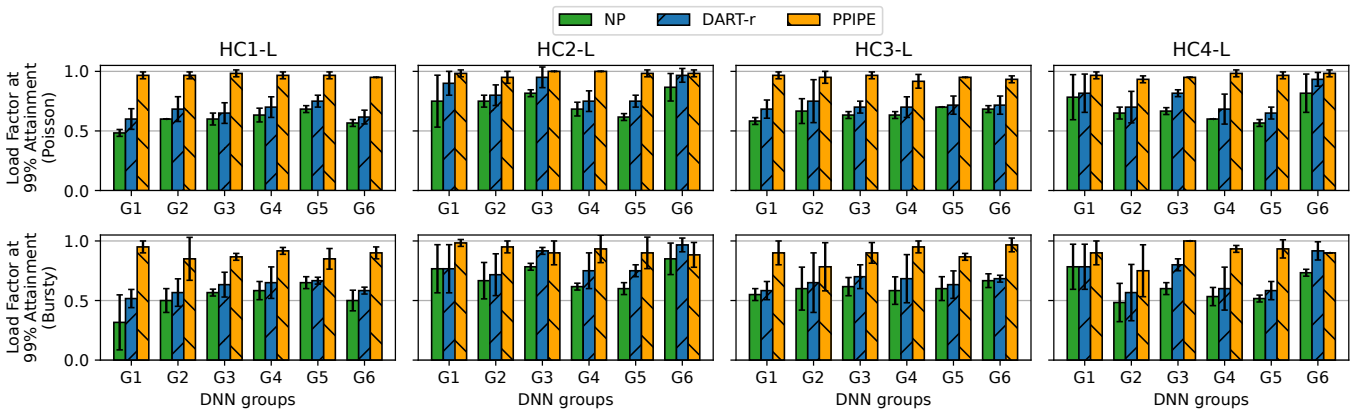

Figure 6: Maximum load factor of each framework under 99% SLO attainment on 100-GPU clusters, under "Poisson" and "Bursty" workloads.

Setup. Following prior work [34], for each DNN, we set the default SLO to be 5× its inference latency on the fastest GPU (NVIDIA L4) at batch size 1, resulting in SLOs ranging from 23.4 ms to 165.6 ms. This reflects the assumption that end users can tolerate higher latency for more complex models but are indifferent to the underlying GPU used. We further evaluate PPipe under other SLOs in §7.6, ranging from 2× to 10×. As mentioned in §5.4, to bridge the gap between control plane planning and data plane execution caused by the extra delays, a 40% margin is deducted from DART-r and PPipe's MILP formulation, and in NP in picking the maximum batch sizes that satisfy the SLOs. When comparing PPipe with the baselines, we use *load factor* 1.0 to denote the throughput in the output of PPipe's MILP. We generate requests using "Poisson" and "Bursty" traces respectively, with an average request rate (λ) ranging from 0.05 to 1.0 times the load factor, at an interval of 0.05. For each λ, the experiment lasts 30 seconds.

7.2 End-to-end Results

Overall results. In this section, we evaluate PPipe's capability of serving DNNs over 100-GPU clusters (HC1-L to HC4-L) on the discrete-event simulator. We randomly divide the 18 DNNs into 6 groups of 3 DNNs each (G1–G6), and serve DNNs within each group in parallel. During runtime, we record the maximum load ratio that each DNN can achieve under 99% attainment.

Figure 6 shows under cluster configurations HC1-L to HC4-L, the maximum load factor achieved under 99% SLO attainment, averaged over the DNNs in each group. First, we find that PPipe consistently outperforms NP. PPipe achieves on average 48.0% higher load factors than NP on the "Poisson" trace (64.9%, 34.8%, 46.7%, and 45.5% higher for HC1-L to HC4-L, respectively), and 75.1% on the "Bursty" trace (161.6%, 34.1%, 50.4%, and 54.1% higher), showing the advantage of PPipe's pipeline parallel inference scheme. Second, compared to DART-r, PPipe achieves 32.2% higher load factors on the "Poisson" trace (47.2%, 17.3%, 34.8%, and 29.3% higher on HC1-L to HC4-L, respectively), and 35.8% on the "Bursty" trace (50.4%, 18.1%, 40.2%, and 34.5% higher), showing the advantage of PPipe's pool-based pipelined inference over DART-r's chain-based pipelined inference. Finally, while all frameworks suffer reduced load factors under the "Bursty" trace (61.1%, 69.4%, and 90.3% for NP, DART-r, and PPipe respectively), compared to "Poisson" (66.8%, 74.9%, and 96.5%), the improvement of PPipe over the two baselines remain high, showing PPipe's robustness to varying request arrival patterns.

Figure 8 shows each framework's temporal utilization of high- and low-class GPUs. For brevity, we only show the utilization on the "Poisson" trace. While all frameworks achieve high utilization of high-class GPUs, NP and DART-r show zero or low utilization of low-class GPUs. On average, NP, DART-r and PPipe achieve low-class GPU utilizations of 8.1%, 29.5%, and 73.6% respectively. NP's low utilization is caused by the inference time of whole DNNs on low-class GPUs often higher than the SLO, prohibiting low-class GPUs from being used. While DART-r employs DNN partitioning, it chains only one low-end GPU with each high-end GPU, resulting in under-utilization of excess low-end GPUs when their number exceeds that of high-end GPUs.

SLO attainment under varying load factors. Figure 7 shows the SLO attainment under varying load factors. For brevity, we show only the SLO attainment for DNN group G1, which includes EfficientNet-B8, EncNet, and RtmDet, and only under the "Poisson" trace. The attainment is averaged over the 3 DNNs, *e.g.,* on HC1-L at load factor 1.0, PPipe achieve SLO attainments of 99.3%, 97.6%, and 98.4% on the 3 DNNs respectively, resulting in an averaged attainment of 98.4%, which is shown in the figure at load factor of 1.0.

We observe that PPipe outperforms both NP and DART-r, achieving the highest SLO attainment under the same load factors. Consequently, it achieves a higher load factor while ensuring 99% SLO attainment (Figure 6). For example, on HC1-L, PPipe achieves 99% SLO attainment under load factors up to 0.95, meaning it can handle at least 95% of the load calculated by the MILP solver. In contrast, NP and DART-r's

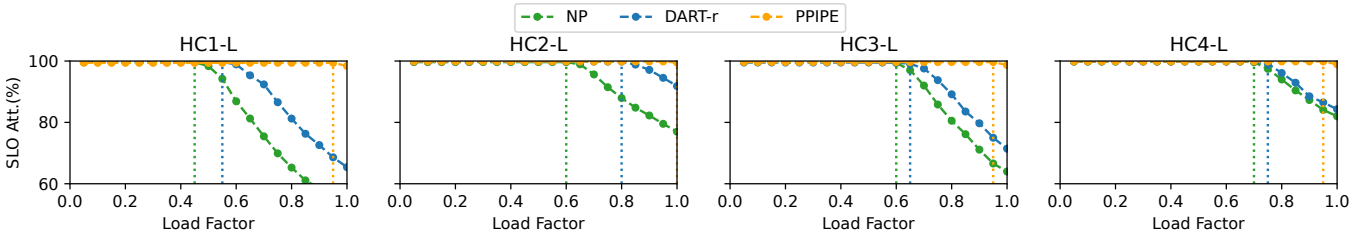

Figure 7: SLO attainment of DNN group G1 under the "Poisson" trace with varying load factors, averaged over the 3 DNNs in the group. The vertical dotted line denotes the load factor at which each system reaches 99% SLO attainment.

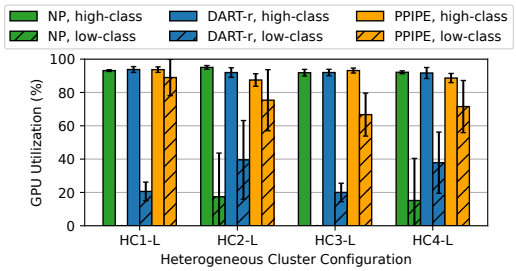

Figure 8: GPU temporal utilization under 99% SLO attainment, averaged over DNNs for each cluster configuration.

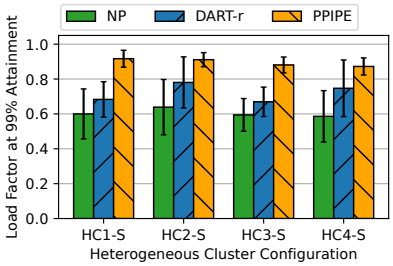

Figure 9: Maximum load factor each cluster configuration can achieve under 99% SLO attainment on the testbed, averaged over the DNNs.

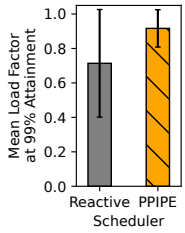

Figure 10: SLO attainment with the reactive scheduler and PPipe's data plane scheduler.

SLO attainment dips below 99% as the load factor exceeds 0.45 and 0.55, respectively. This is due to the fact that a load factor of 1.0 represents the serving capacity of PPipe, which is higher than the capacity of NP or DART-r, leading to the dropping of requests beyond their respective serving capacities. Note that although PPipe achieves higher load factors than the baselines, it may not reach the full load factor of 1.0, as seen with HC1-L, HC3-L, and HC4-L. This is due to unpredictable request arrival patterns (*e.g.,* Poisson), which cannot be fully accounted for by the MILP solver, as discussed in §4.

MILP runtime. PPipe's MILP solver takes 3.5 seconds on average, showing the effectiveness of PPipe's pre-partitioning (§5.2) in reducing the MILP complexity. This latency is negligible compared to the intervals between re-running the MILP — triggered by fluctuations in incoming load which occur relatively infrequently, *e.g.,* once every hour [28, 68].

Adaptive batching overhead. PPipe's resource-reservation-based adaptive batching mechanism is lightweight: on a 100-GPU cluster, dispatching a batch requires an average of only 3.58 `probe()` calls, incurring a total overhead of less than 9 microseconds. This overhead is negligible compared to the batch execution latency, even under bursty request patterns.

7.3 Testbed Results

We verify PPipe's DNN serving capability on real-world 16-GPU heterogeneous cluster testbeds (HC1-S to HC4-S) deployed on Google Cloud. Due to the testbed's smaller GPU counts, instead of serving DNNs in groups of three as in §7.2, we serve one DNN at a time with Poisson-arrival requests. Figure 9 shows the maximum load factor under 99% SLO attainment averaged over the 18 DNNs.

First, we observe that PPipe consistently outperforms NP, achieving 42.6%–52.8% higher load factors at 99% SLO attainment across the cluster configurations. This validates the advantage of PPipe's model-parallelism inference in a real-world setting. Secondly, compared to DART-r, PPipe achieves 16.7%–34.1% higher load factors, which shows the advantage of PPipe's pool-based pipelined inference. In summary, PPipe's significant performance gains over NP and DART-r, previously demonstrated in the discrete-event simulator, remain consistent when deployed on a real-world testbed.

7.4 Ablation Study: Benefit of Resource Reservation

As discussed in §5.4, PPipe's resource reservation-based data plane dynamically schedules requests onto GPUs to overcome the delays caused by bursty request arrival and network contention. To demonstrate its effectiveness, we compare it to a *reactive*, distributed adaptive batching scheduler. The reactive scheduler performs adaptive batching independently for each GPU pool in a pooled pipeline. For each pool, it selects the largest possible batch size that meets the pool's SLO (as determined by the MILP solver). A similar idea was used in previous model-granularity pipeline scheduling in [47].

Figure 10 shows the maximum load factor achieved by the two data plane designs under 99% SLO attainment on HC2-L, averaged over the DNNs, under the "Poisson" arrival. PPipe achieves an average load factor of 0.92, while reactive only achieves 0.71. The primary factor contributing to this performance degradation is that the reactive, distributed scheduler

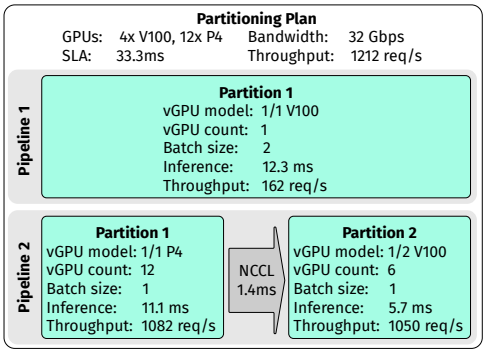

Figure 11: Partitioning plan for the FCN model on HC3-S.

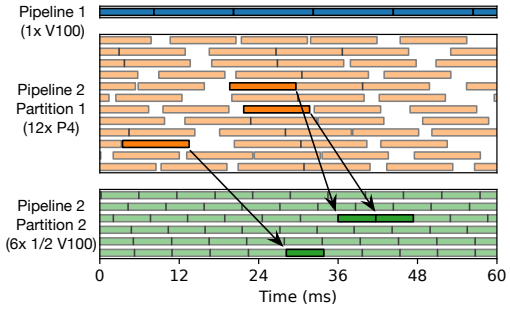

Figure 12: An example timeline serving the FCN model on HC3. Each row represents a vGPU, and each box corresponds to a batched inference. The highlighted pairs of boxes denote the same batches across the partitions within a pooled pipeline.

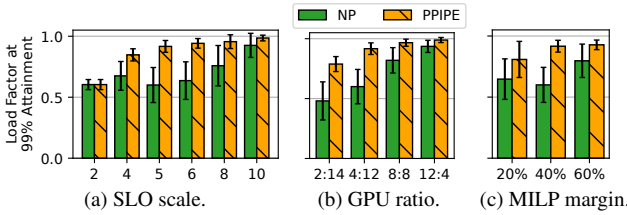
lacks resource usage tracking which leads to batches being scheduled onto servers with saturated network links, causing bloated transfer delays. For example, for EfficientNet-B8, where PPipe achieves 99% SLO attainment at 1.0 load factor, the reactive scheduler only manages a 0.35 load factor. With 10 Gbps effective bandwidth, feature map transfer between the first and second partition should take 5.1 ms, but the reactive scheduler leads to transfer times of 18.9 ms on average and 35.7 ms at the 99% percentile, resulting in excessive request drops at the second partition in order for the remaining requests to meet their SLOs.

7.5 Microscopic Analysis

In this section, we provide a microscopic analysis of PPipe, using the FCN model served on the HC3-S cluster testbed on Google Cloud as an example, where PPipe achieves a load factor of 0.95 under 99% SLO attainment.

Plan structure. Figure 11 shows the partitioning plan generated by PPipe's MILP solver for cluster HC3-S, which consists of 4× V100 and 12× P4 GPUs. The inference latency of the FCN model on the fastest GPU (NVIDIA L4) is 6.66 ms, establishing an SLO of 33.3 ms under an SLO scale of 5. The resulting plan comprises two pipelines, one with a single partition and the other with two partitions.

The first pipeline consists of a single V100 GPU, performing inference with a batch size of 2, where each batched inference takes 12.3 ms. The theoretical throughput of this pipeline is $(2 \times 1/0.0123) = 162$ requests per second. The second pipeline consists of two partitions, with 12 P4 and 3 V100 GPUs respectively, with 1.4 ms of feature map transfer time in between. Employing batch size unification (§5.3), both partitions perform batch size 1 inference. To achieve such a unified batch size, PPipe divides the three V100s in the second partition into six virtual GPUs using NVIDIA MPS. Furthermore, we observe that the two partitions yield similar throughputs of 1082 and 1050 requests per second respectively, resulting in a total throughput of 1050 (the minimum of the two). This shows PPipe's ability to balance resource allocation between partitions to achieve matched throughput.



(a) SLO scale. (b) GPU ratio. (c) MILP margin.

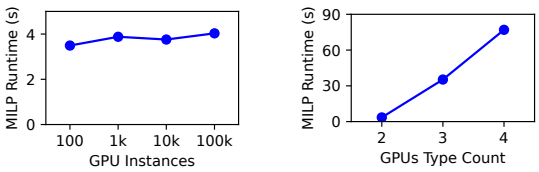
Figure 13: Sensitivity of PPipe to various factors. Results are averaged over 18 DNNs on HC1-S.

Runtime behavior. Figure 12 shows an example timeline of the DNN inference on each virtual GPU. We observe that PPipe performs inference back-to-back in pipeline 1, as well as pipeline 2 partition 2, fully using their GPUs. Note that pipeline 2 partition 1 experiences underutilization, due to the fact that it was provisioned with slightly higher serving throughput than partition 2 (Figure 11). Furthermore, the figure showcases that PPipe's pool-based pipeline allows a batch to be processed by any GPU within each partition, allowing different partitions to use different numbers of GPUs to accommodate different per-partition inference latencies.

7.6 Sensitivity Analysis

In this section, we study PPipe's sensitivity to various factors, on the cluster HC1-S testbed deployed on Google Cloud.

Varying SLO scales. Our main evaluation, which follows AlpaServe [34], uses 5x the inference latency as the SLO and shows significant performance improvement. We further evaluate PPipe considering various SLO scales ranging from 2x to 10x, as shown in Figure 13a. Although 2x and 10x SLOs are less used in practice, we include them to illustrate and validate PPipe's expected behavior relative to the baselines. With an SLO scale of 2, PPipe shows no improvement over NP, as such stringent SLOs render the utilization of low-class GPUs impractical for either NP or PPipe. Consequently, PPipe resorts to running entire DNNs on high-class GPUs, essentially falling back to NP. Conversely, as the SLO scale increases to 10, PPipe's improvement over NP becomes marginal, due to the fact that more DNNs can now meet the SLO running



(a) Varying GPU instances. (b) Varying GPU types.

Figure 14: Scalability of PPipe's MILP-based control plane.

entirely on low-class GPUs, and hence the low-class GPUs can be utilized in NP, thereby narrowing the gap between NP and PPipe.

Varying GPU ratios. In Figure 13b, we evaluate PPipe under varying ratios of high-class (NVIDIA L4) to low-class (NVIDIA P4) GPUs, which shows that PPipe attains more improvements over NP on clusters with fewer high-class GPUs. For instance, with a high-low ratio of 2:14, PPipe achieves a 64.03% higher load factor; as the percentage of high-class GPUs increases, PPipe's improvement diminishes, reaching 5.64% at a high-low ratio of 12:4.

Varying SLO margin size. As discussed in §7.1, a 40% margin was subtracted from the SLO in the MILP formulation of both PPipe and NP. The impact of the margin size is two-fold — a larger margin size reduces the ideal-case serving capacity (*i.e.,* what load factor 1.0 signifies), but increases the load factor achievable under 99% SLO attainment in practice. Figure 13c shows that under varying margin sizes, PPipe's load factor increases with larger margin sizes, but plateaus as the margin size increases beyond 40%. Furthermore, PPipe achieves the highest gain of 52.8% over NP under the margin size of 40%, but also maintains a relatively high improvement over NP at 20% and 60% margin sizes, of 24.9% and 16.4% respectively.

Varying GPU types and counts. We analyze how the runtime of PPipe's MILP-based control plane scales with the number of GPU instances and types in a cluster. First, we scale up the HC1-L cluster (Table 1) from 100 to 100k GPUs. Figure 14a shows that the MILP runtime remains nearly constant. This is because adding more GPU instances does not introduce additional MILP variables, and the problem's complexity stays unchanged. Second, as the GPU types increase to 3 and 4, Figure 14b shows the MILP runtime increases to 35.3 and 77.0 seconds, indicating the number of GPU types has a higher impact on MILP runtime. However, the increased runtime remains insignificant compared to the interval between MILP re-executions, which occurs on an hourly scale [28, 68].

8 Related Work

Pipelined partitioned DNN serving. Several works on DNN serving exploit pipeline parallelism for different scenarios and objectives. AlpaServe [34] improves serving throughput by employing pipeline parallelism to facilitate multiplexing of GPUs across multiple DNNs, but it does not take advantage of heterogeneous GPUs. Another line of works specialize in serving RNN or transformer-based models [16, 58] in a pipelined fashion. These works do not consider heterogeneous GPU clusters either. Finally, DART [55] partitions DNNs onto a chain of CPUs and GPUs. However, it does not scale to large GPU clusters, as it will generate as many partitions as the number of GPUs in the cluster, resulting in frequent transfer of feature maps which is costly.

Whole DNN serving on heterogeneous clusters. Such works typically focus on serving multiple DNNs concurrently, and study the placement of whole DNNs on servers with the goal of either minimizing the cost of cloud VMs [30, 45, 60], or maximizing the throughput of on-premise clusters [28, 31]. Furthermore, several works study serving video analytics applications that utilize multiple DNNs forming a Directed Acyclic Graph (DAG) [11, 24, 27]. None of above works exploits the diversity across the layers within a DNN.

Whole DNN serving, homogeneous clusters. Several works focus on model serving on homogeneous clusters [12, 20, 34, 47, 62]. However, these works lack resource allocation mechanisms that leverage DNN partitioning or GPU heterogeneity.

Model parallel DNN training. Various works exploit tensor or pipeline parallelism (or both) in model training [14, 25, 29, 32, 39, 43, 52, 56, 67]. Compared to inference, training has a different set of scenarios and requirements, *e.g.,* no need to meet SLOs or tackle non-deterministic request arrivals.

9 Conclusion

In this paper, we presented PPipe, a system for making effective use of mixed GPUs on heterogeneous clusters in serving video analytics applications. The key innovation of PPipe is three-fold: pool-based pipelined model inference, an MILP-based control plane that prescribes optimal pipeline plans, and a data plane that performs resource reservation-based adaptive batching to handle runtime dynamics due to asynchronous and bursty request arrivals. Evaluation results on production workloads show that PPipe achieves 32.2%–75.1% higher serving throughput compared to various baselines. In future work, we will explore extending PPipe to support transformer-based models, for instance, by partitioning them across high- and low-class GPUs. This would improve the utilization of low-class GPUs and enhance the overall serving throughput, while still meeting SLO requirements.

Appendix

A.1 Mathematical Representation of Basic MILP Formulation

As shown in Table 3, the MILP formulation takes as input the cluster configuration, the latency SLO, and profiling information of the target DNN model. For the convenience of formulating mathematical constraints, the raw inputs are further processed and transformed into different representations. Table 4 lists both output decision variables and intermediate decision variables that will only be used inside the MILP formulation. The MILP solution outputs the partition points for each pipeline, as well as the batch size and number of GPUs used by each partition. The MILP formulation maximizes the total inference throughput across all pipelines in the cluster:

$$\text{maximize} \quad \sum_l x_l \tag{1}$$

The optimization is under the constraint that inference latency of each pipeline does not exceed the latency SLO, and the total number of GPUs allocated across partitions does not exceed the cluster configuration. The constraints are formally formulated below.

Table 3: Inputs to the MILP formulation (top) and values derived from inputs (bottom).

Input	Description
N_k	GPU count of GPU class k
T	The latency SLO
L_{kbi}	The inference latency of layer i under batch size b on GPU class k
S_i	The output feature map size of layer i under batch size 1
D_l	Number of partitions in pipeline l
G_k	A list of tuples (l,d) indicating GPU class k is used for partition d of pipeline l
M	Number of layers in the DNN model
C_{ldbij}	The inference latency of DNN partition consisting of layers i to j (exclusive) with batch size b on GPU class associated with (l,d)
X_{ldbij}	The inference throughput of DNN partition consisting of layers i to j (exclusive) with batch size b on a single GPU associated with (l,d)
Y_{bj}	The transfer latency of the feature map of layer $j-1$ with batch size b

Table 4: Output (top) and intermediate (bottom) decision variables in the MILP formulation.

Variable	Description
$p_{ldbij} \in \{0,1\}$	Whether partition d in pipeline l spans from layer i to j (exclusive) and runs at batch size b
$g_{ldbij} \in \mathbb{N}$	Number of GPUs used by partition d in pipeline l
$t_{ld} \in \mathbb{R}_{\geq 0}$	Inference latency of partition d in pipeline l
$x_{ld} \in \mathbb{R}_{\geq 0}$	Inference throughput of partition d in pipeline l
$n_{ld} \in \mathbb{R}_{\geq 0}$	Transfer latency between partition d and partition $d+1$ in pipeline l
$x_l \in \mathbb{R}_{\geq 0}$	Inference throughput of pipeline l

$$\sum_{bij} p_{ldbij} = 1 \qquad \forall l,d \tag{2}$$

$$p_{ldbij} = 0 \qquad \forall l,d,b,i \geq j \tag{3}$$

$$\sum_{bi} p_{ldbij} = 1 \rightarrow \sum_{b'j'} p_{ld'b'i'j'} = 1 \qquad \forall l,d' = d+1, i' = j \tag{4}$$

$$\sum_{bj} p_{ldbij} = 1 \qquad \forall l,d = 0, i = 0 \tag{5}$$

$$\sum_{bi} p_{ldbij} = 1 \qquad \forall l,d = D_l - 1, j = M \tag{6}$$

$$p_{ldbij} = 0 \rightarrow g_{ldbij} = 0 \qquad \forall l,d,b,i,j \tag{7}$$

$$p_{ldbij} = 1 \rightarrow g_{ldbij} \geq 1 \qquad \forall l,d,b,i,j \tag{8}$$

$$\sum_{bij,(l,d)\in G_k} g_{ldbij} \leq N_k \qquad \forall k \tag{9}$$

$$t_{ld} = \sum_{bij} C_{ldbij} \cdot p_{ldbij} \qquad \forall l,d \tag{10}$$

$$x_{ld} = \sum_{bij} X_{ldbij} \cdot g_{ldbij} \qquad \forall l,d \tag{11}$$

$$n_{ld} = \sum_{bij} Y_{bj} \cdot p_{ldbij} \qquad \forall l,d \tag{12}$$

$$\sum_d t_{ld} + \sum_d n_{ld} \leq T \qquad \forall l \tag{13}$$

$$x_l = \min_d x_{ld} \qquad \forall l \tag{14}$$

Equations (2)–(6) ensure DNN partitions are well formed, *i.e.,* partitions cannot be empty, the last and first layers in adjacent partitions must also be adjacent, and the first partition within a pipeline must start with the first layer, while the opposite applies to the last partition. Equation (9) represents the constraint on the total GPU count. Equations (10)–(12) calculates for each partition the inference latency, inference throughput, and transfer latency, respectively. Finally, Equation (13) enforces the latency SLO constraint.

The formulation can be easily scaled to the case of multiple DNN models, where each DNN model has its own set of decision variables and constraints, with the additional constraint that the total number of GPUs allocated to all DNN models does not exceed the cluster configuration.

A.2 Mathematical Representation of MILP Formulation with Batch Size Unification

Table 5: Inputs to the MILP formulation (with batch size unification) (top) and values derived from inputs (bottom).

Input	Description
N_k	GPU count of GPU class k
T	The latency SLO
L_{kvbi}	The inference latency of block i under batch size b on virtual GPU of size $1/v$ and GPU class k
S_i	The output feature map size of block i under batch size 1
D_l	Number of blocks in pipeline l
G_k	A list of tuples (l,d) indicating GPU class k is used for partition d of pipeline l
M	Number of layers in the DNN model
C_{ldvbij}	The inference latency of DNN partition consisting of blocks i to j (exclusive) with batch size b on $1/v$ virtual GPU of GPU class associated with (l,d)
X_{ldvbij}	The inference throughput of DNN partition consisting of blocks i to j (exclusive) with batch size b on $1/v$ virtual GPU of GPU class associated with (l,d)
Y_{bj}	The transfer latency of the feature map of block $j-1$ with batch size b

Table 6: Output (top) and intermediate (bottom) decision variables in the MILP formulation with batch size unification.

Variable	Description
$p_{ldvbij} \in \{0,1\}$	Whether partition d in pipeline l spans from block i to j (exclusive) and runs at batch size b on $1/v$ virtual GPU
$g_{ldvbij} \in \mathbb{N}$	Number of virtual GPUs used by partition d in pipeline l
$t_{ld} \in \mathbb{R} \geq 0$	Inference latency of partition d in pipeline l
$x_{ld} \in \mathbb{R}_{\geq 0}$	Inference throughput of partition d in pipeline l
$n_{ld} \in \mathbb{R}_{\geq 0}$	Transfer latency between partition d and partition $d+1$ in pipeline l
$x_l \in \mathbb{R}_{\geq 0}$	Inference throughput of pipeline l

The inputs and decision variables to the MILP formulation with batch size unification (Table 5 and Table 6) are similar to that of the basic MILP formulation (§A.1), with the exception that both the model profiling inputs and decision variables now include an additional dimension representing virtual GPUs, and that the profiling inputs are for blocks instead of layers, and the same applies to the last two dimensions of the output decision variables. The MILP formulation optimizes for the same throughput objective:

$$\text{maximize} \quad \sum_l x_l \tag{15}$$

The optimization is under a similar set of constraints as shown below.

$$\sum_{vbij} p_{ldvbij} = 1 \qquad \forall l,d \tag{16}$$

$$p_{ldvbij} = 0 \qquad \forall l,d,v,b,i \geq j \tag{17}$$

$$\sum_{vi} p_{ldvbij} = 1 \rightarrow \sum_{v'j'} p_{ld'v'bi'j'} = 1 \quad \forall l,b,\ d' = d+1,\ i' = j \tag{18}$$

$$\sum_{vbj} p_{ldvbij} = 1 \qquad \forall l,d=0,i=0 \tag{19}$$

$$\sum_{vbi} p_{ldvbij} = 1 \quad \forall l,d = D_l - 1, j = M \tag{20}$$

$$p_{ldvbij} = 0 \rightarrow g_{ldvbij} = 0 \qquad \forall l,d,v,b,i,j \tag{21}$$

$$p_{ldvbij} = 1 \rightarrow g_{ldvbij} \geq 1 \qquad \forall l,d,v,b,i,j \tag{22}$$

$$\sum_{vbij,(l,d)\in G_k} g_{ldvbij}/v \leq N_k \qquad \forall k \tag{23}$$

$$t_{ld} = \sum_{vbij} C_{ldvbij} \cdot p_{ldvbij} \qquad \forall l,d \tag{24}$$

$$x_{ld} = \sum_{vbij} X_{ldvbij} \cdot g_{ldvbij} \qquad \forall l,d \tag{25}$$

$$n_{ld} = \sum_{vbij} Y_{bj} \cdot p_{ldvbij} \qquad \forall l,d \tag{26}$$

$$\sum_d t_{ld} + \sum_d n_{ld} \leq T \qquad \forall l \tag{27}$$

$$x_l = \min_d x_{ld} \qquad \forall l \tag{28}$$

The major differences lie in Equations (18) and (23). In Equations (18), the dimension b is not summed over, which enforces that the same batch size used by the first partition will also need to be used by the next partition. In Equations (23), the decision variable g represents the count of *virtual* GPUs, thus, dividing it by v gives us the number of *physical* GPUs that the partition uses (note that v is not a decision variable and such divisions are allowed in MILP).

A.3 The Resource Reservation-Based Adaptive Batching Algorithm

Algorithm 1 shows the pseudocode for the resource reservation-based adaptive batching algorithm, which was explained in §5.4. To recap, the algorithm first identifies a pooled pipeline that can complete a batched inference at the pipeline's unified batch size bs_i with the shortest waiting time (lines 4–8). It then searches for the largest batch size that can satisfy the SLO (lines 9–14).

The two supporting functions used by §5.4, `probe()` and `reserve()`, is shown in Algorithm 2. The helper function `earliestSlot(res, t, l)` returns the earliest time (no earlier than t) when a list of resources `res` are free for duration l. First, since feature map transfer requires the network resources on both sending and receiving sides to be available at the same time, we use `earliestSlot(res, t, l)` to find the earlist available transfer slot that works for both the last GPU's uplink and current GPU's downlink (lines 12–14). After reserving the two links for feature map transfer, we update current time t and then find and reserve the earliest available inference time slot for the current GPU (lines 15–16).

Algorithm 1: Resource reservation-based adaptive batching.

```
1  Inputs: q (pending requests sorted by arrival);
2          pooled_pipelines (pooled pipelines in the cluster);
3  while true do
       // choose the pooled pipeline
4      p* = nil, t* = ∞;
5      for p in pooled_pipelines do
6          r = probe(p, p.bs);
7          if waitTime(r) < t* then
8              t* = waitTime(r), p* = p;
       // choose the pipeline path and batch size
9      bs* = nil, path* = nil, resv* = nil;
10     for bs = p*.bs down to 0 do
11         path, resv = probe(p*, bs);
12         if finishTime(resv) ≤ q[0].deadline then
13             bs* = bs, path* = path, resv* = resv;
14             break;
       // perform request drop, wait, or dispatch
15     if bs == 0 then
16         drop q[0];
17     else if q.length < bs then
18         wait for more requests till requests in q are about to
             miss deadline;
19     else
20         reserve(r);
21         dispatch first bs requests in q according to r;
```

Algorithm 2: Resource reservation functions.

```
1  function probe(pooled_pipeline, bs)
2      Inputs: The assumed selected pooled pipeline and the
         batch size;
3      Outputs: The optimal pipeline path and the resources
         that need to be reserved;
4      t_g = now(), path = [], resv = [];
5      for partition in pooled_pipeline do
6          l_n = calcNetLat(partition, bs);
7          l_i = calcInferenceLat(partition, bs);
8          t* = ∞, r* = [];
9          for gpu in partition do
10             t = t_g, r = [];
               // est. time to transfer feature map
11             if not first partition then
12                 u = lastGpu.netUL, d = gpu.netDL;
13                 t = earliestSlot([u, d], t, l_n);
14                 r += [{u, t, l_n}, {d, t, l_n}], t += l_n;
               // est. time to finish inference
15             t = earliestSlot([gpu], t, l_i);
16             r += [{gpu, t, l_i}], t += l_i;
17             if t < t* then
18                 t* = t, r* = r, gpu* = gpu;
19         t_g = t*, lastGpu = gpu*;
20         path += gpu*, resv += r*;
21     return (path, resv); // resource usage
22 function reserve(resv)
23     for {res, start, dur} in resv do
24         markReserved(res, start, dur);
```

Voltrix: Sparse Matrix-Matrix Multiplication on Tensor Cores with Asynchronous and Balanced Kernel Optimization

Abstract

Sparse Matrix-Matrix Multiplication (SpMM) is crucial in scientific computing and machine learning. Despite advancements in GPU architectures, efficiently leveraging Tensor Cores for SpMM remains challenging. The core issue is the mismatch between the inherently sparse nature of the matrices and the dense computational patterns. Existing methods struggle with substantial overheads in loading data to computation units and cannot adequately manage data imbalance across computations, thereby limiting the high computational throughput potential of Tensor Cores.

In this paper, we introduce Voltrix-SpMM, a revolutionary GPU kernel design that overcomes these challenges. First, we implement an asynchronous data loading pipeline that employs a bit-wise compressed format for sparse matrices and bulk memory copy instructions for dense matrices. This innovative design enables efficient data access and incorporates a warp-specialized producer-consumer model to seamlessly overlap data loading with computation. Second, we develop a persistent and I/O co-balanced kernel mechanism that features a two-stage partition strategy to achieve balance between input and output. Implemented with CUDA 12.6, Voltrix-SpMM substantially improves performance, delivering an average speedups of 36.5x and 1.8x over Tensor Core-based TC-GNN and DTC-SpMM respectively, and an average 1.7x speedup over the CUDA Core-based RoDe, fully unleashing the power of Tensor Cores for SpMM.

1 Introduction

Sparse Matrix-Matrix Multiplication (SpMM), which refers to the multiplication of a sparse matrix with a dense matrix, plays a pivotal role in a wide range of scientific computing applications [1,3,13,20,22,40,45–47,52], from simulations and linear algebra to advanced machine learning. Recent studies have identified SpMM as a significant performance bottleneck in these applications, particularly in the training of Graph Neural Networks (GNNs), where SpMM accounts for over 80% of the total computational cost during training [43].

GPUs have become the primary processing units for modern high-performance computing and have been widely adopted to accelerate SpMM computations. Recent studies have utilized CUDA cores, the fundamental processing units within NVIDIA's GPU architecture, to speed up the multiplication process [12,16,17,24,32]. With advancements in GPU power, NVIDIA introduced a specialized unit known as the Tensor Core, beginning with the Volta architecture [29]. Tensor Cores offer significantly higher computational throughput than traditional CUDA cores and are specifically optimized for dense matrix multiplication and accumulation operations using fixed-precision arithmetic. However, the inherent sparsity of matrices in SpMM presents challenges. Tensor Cores struggle with the irregular memory access and data sparsity typical of these operations, making them less effective for SpMM without specialized optimizations.

One of the prominent attempts to apply Tensor Core acceleration to SpMM is TC-GNN [43], which introduces sparse graph translation to convert sparse matrices into compressed dense blocks, called TCU blocks. Although this method overcomes the traditional barriers between sparse SpMM workloads and dense computation patterns, the inefficient process of loading data into Tensor Core units severely limits their full potential. Our experiments have shown that data loading consumes over 80% of kernel execution time, significantly constraining the effective use of Tensor Cores. Recently, DTC-SpMM introduces an asynchronous loading technique that overlaps computation with data loading through a pipeline [10]. However, the benefits of this approach are limited by several factors: firstly, DTC-SpMM's asynchronous loading instruction can only process 16-byte chunk at a time, which is insufficient for the high-dimensional data typical in applications like GNN training, where matrix sizes often exceed 256 [37]. This limitation necessitates numerous loading instructions, diminishing the pipeline's potential benefits. Secondly, the single-layer pipeline of DTC-SpMM results in

*Contributed equally to this work.
†Co-corresponding authors.

minimal overlap between computation and data loading, and the required synchronization at the warp level introduces additional overhead, further impairing the expected performance gains.

In addition to inefficient data loading, the irregular data distribution in SpMM further exacerbates performance bottlenecks during kernel execution on GPUs. A critical challenge lies in efficiently partitioning unevenly distributed data across different Streaming Multiprocessors (SMs) to achieve hardware load balancing. Current methods typically focus either on input balance or output balance. TC-GNN attempts to address output balance by controlling how each Cooperative Thread Array (CTA) processes rows of TCU blocks. However, this approach results in significant variations in the data processed per CTA, leading to underutilization of some SMs and overloading of others. Conversely, DTC-SpMM prioritizes input balance by assigning each CTA a fixed number of TCU blocks, aiming for a more uniform workload distribution. While this strategy reduces discrepancies, it fails to address imbalances during the write-back phase. Moreover, the atomic operations required to ensure accurate results during write-back introduce substantial overhead, thereby undermining the potential performance benefits of the optimization.

We introduce Voltrix-SpMM, a revolutionary GPU kernel design that addresses the outlined challenges and fully leverages the capabilities of Tensor Cores for accelerated SpMM computations. Voltrix-SpMM features two key innovations: First, a novel asynchronous data loading pipeline that establishes seamless overlap between computation and data loading. Unlike current SpMM kernels that manage these processes within the same warp, our model uses a warp-specialized workflow control to distinctly separate these tasks. This approach allows for fine-grained, multi-tiered overlap, significantly reducing the overhead associated with data loading. Second, a persistent and I/O co-balanced kernel mechanism that ensures even partitioning of irregular workloads across the underlying SM units. By integrating coarse-grained input partitioning with fine-grained output partitioning, we achieve an optimal balance between input and output, while eliminating the overhead linked to atomic operations.

The first innovation, the warp-level asynchronous pipeline, significantly reduces data loading overhead while achieving seamless overlap with computation. Specifically, we design a bit-wise compressed format for sparse matrices that is both vectorization-friendly and conflict-free, accelerating access and transformation. For dense matrices, we utilize the bulk asynchronous loading instruction TMA [30], which reduces the number of instructions while enabling the asynchronous loading of large data blocks. Leveraging our warp-specialized producer-consumer model, we decouple data access from computation at the warp level. This separation allows for finer granularity and higher overlap between data loading and computation through a multi-tiered pipeline.

In the second innovation, a persistent and I/O co-balanced kernel mechanism, we align each CTA task with SMs and ensure persistent execution, thus achieving a seamless software-to-hardware balance. Through a greedy and heuristic search algorithm, we determine the optimal partition points for each CTA task, ensuring co-balance between input and output. Additionally, by performing coarse-grained partitioning at the input stage and fine-grained partitioning at the output stage, we resolve the issue of data crossing row boundaries, avoiding the additional overhead of atomic operations.

In summary, our key contributions are as follows:

1. Through in-depth analysis, we identify the primary challenge in current Tensor Core-accelerated SpMM methods: a significant gap between high-throughput computation units and inefficient, heavy data loading processes.

2. We design a bit-wise sparse matrix compression format to enable efficient data access via vectorized loading, and a bulk asynchronous loading instruction to load dense matrices with reduced number of instructions.

3. We propose a warp-specialized producer-consumer model to efficiently pipeline data access and computation, along with a multi-tiered pipeline to effectively conceal the overhead associated with data loading.

4. We develop a persistent and I/O balanced kernel mechanism, ensuring uniform kernel execution across hardware that balances both input and output processing.

Voltrix-SpMM, implemented with CUDA 12.6, has been integrated into PyTorch 2.5 [33]. On the SuiteSparse dataset [7] and 12 real-world graph datasets, it achieves average speedups of 36.5x and 1.8x over the Tensor Core-based TC-GNN and DTC-SpMM respectively, and 1.7x over the CUDA Core-based RoDe [32]. Additionally, it delivers 2.0x speedup over the popular GNN training framework DGL [2] in end-to-end training. Notably, Voltrix-SpMM is the first to fully unleash the power of Tensor Cores, achieving speedups that surpass those of traditional CUDA Core-based methods.

2 Background and Motivation

2.1 Matrix-Matrix Multiplication on Hopper

General Matrix-Matrix Multiplication (GEMM) is a core operation in deep learning [39, 50]. On NVIDIA Hopper [30], GEMM performance is enhanced through warp-specialized and persistent kernel designs [31]. Warps are split into producers, which use Tensor Memory Accelerator (TMA) to load tiles into shared memory, and consumers, which perform Warp-Group Matrix Multiply-Accumulate (WGMMA) operations. This producer-consumer model enables overlap of data load and computation, maximizing Tensor Core utilization.

Hopper's persistent kernel strategy assigns a fixed number of Cooperative Thread Arrays (CTAs), typically equal to the

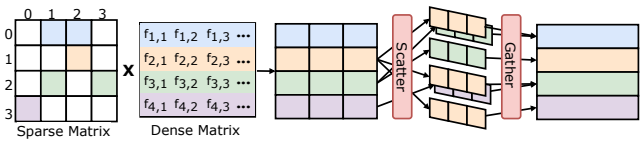

Figure 1: Illustration of SpMM workflow.

number of Streaming Multiprocessors (SMs), allowing them to remain resident and avoid relaunch overhead. This design also overlaps epilogue storage with the next stage's prologue and compute loop, enhancing pipeline efficiency.

Sparse Matrix-Matrix Multiplication (SpMM) multiplies a sparse matrix with a dense one, using only the non-zero elements [7]. Unlike GEMM, SpMM identifies non-zero indices to guide a `scatter` from the dense matrix and a `gather` for accumulation, as shown in Figure 1. However, due to sparsity and irregularity, SpMM cannot directly adopt GEMM's warp-specialized and persistent kernel designs: 1. TMA and WGMMA require dense data blocks, wasting resources on zeros. 2. Irregular non-zero patterns cause workload imbalance, making persistent kernels inefficient.

This paper introduces a BMat encoding for fast non-zero identification, a multi-tiered async loading scheme to maximize bandwidth, and a balanced partitioning strategy that enables an effective sparse-aware persistent kernel.

2.2 SpMM on Tensor Cores

NVIDIA Tensor Cores are specialized units that accelerate matrix operations essential for deep learning. They efficiently perform dense mixed-precision matrix multiplications, such as TF32 inputs with FP32 accumulation, computing

$$C = A \times B + C$$

where A and B have dimensions $m \times k$ and $k \times n$. Matrices are distributed across thread registers (fragments) within a warp, arranged in layouts like row- or column-major [29]. Applying Tensor Cores to SpMM is challenging because, unlike dense models (e.g., Transformers [19, 38] and CNNs [14, 21]) with regular memory access, SpMM exhibits irregular access and sparse computation patterns that conflict with the fixed-size fragment requirements of Tensor Cores.

TC-GNN [43] represents the first significant effort to bridge the gap between SpMM and Tensor Core capabilities by introducing a novel sparse graph translation technique. As illustrated in the top part of Figure 2, this approach compresses a sparse matrix into multiple condensed sparse blocks, referred to as TCU blocks. Each block is carefully sized to align with the computational dimensions of Tensor Cores. This transformation allows TC-GNN to effectively map irregular computation workloads onto the regular computational framework of Tensor Cores, thereby enabling these specialized units to handle sparse computation tasks efficiently.

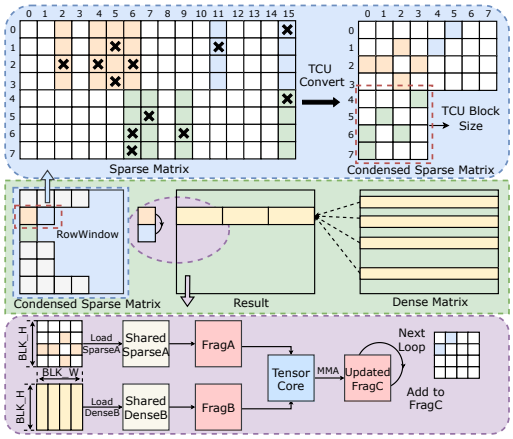

Figure 2: Illustration of the typical Tensor core-based SpMM implementation, TC-GNN's workflow.

In TC-GNN, the TCU block data for each row (a RowWindow) is processed iteratively. The workflow of TC-GNN operates as follows: First, the compressed TCU block is expanded into a BLK_W × BLK_H matrix, named SparseA, where BLK_W and BLK_H are specifically set to 8 and 16, respectively, to fit the dimensions of the Tensor Core MMA operations. Then, based on the column index of the TCU block, the corresponding row data from the dense matrix is identified and transformed into a BLK_W × BLK_H matrix, DenseB. Both matrices are first loaded into shared memory and then into registers for MMA operations, as depicted in the bottom part of Figure 2. The results are stored and subsequently used to update the output matrix C, which is accumulated with the next SparseA in the RowWindow in the subsequent loop iteration, ensuring the correctness of the results.

2.2.1 Tensor Core's Hunger: Starved by Data Loading

Utilizing Tensor Cores significantly enhances computational throughput for sparse operations, providing potential performance gains over traditional CUDA Cores. For instance, in optimized conditions, Tensor Cores can achieve up to 495 TFLOPS for TF32 datatype matrix multiplications, in contrast to the 67 TFLOPS for FP32 typically delivered by CUDA Cores in similar scenarios [30]. However, despite these impressive advancements, the overall efficiency of kernel execution is often bottlenecked by the data loading process. Our experiments across multiple datasets, as illustrated in Figure 3, reveal that data loading accounts for over 80% of the execution time. This significant overhead, due to loading matrices SparseA and DenseB into shared memory, severely restricts the overall computational efficiency, thereby diminishing the full potential of Tensor Core acceleration.

To address the data-loading bottleneck in Tensor Core-accelerated SpMM computation, DTC-SpMM [10] introduces a pivotal innovation: a pipeline arrangement that effectively

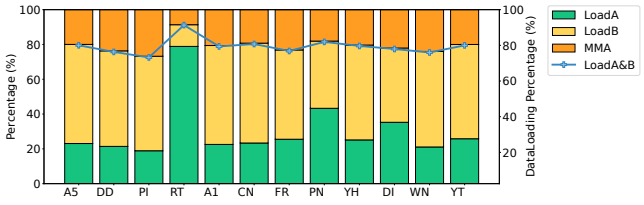

Figure 3: Breakdown of TC-GNN.

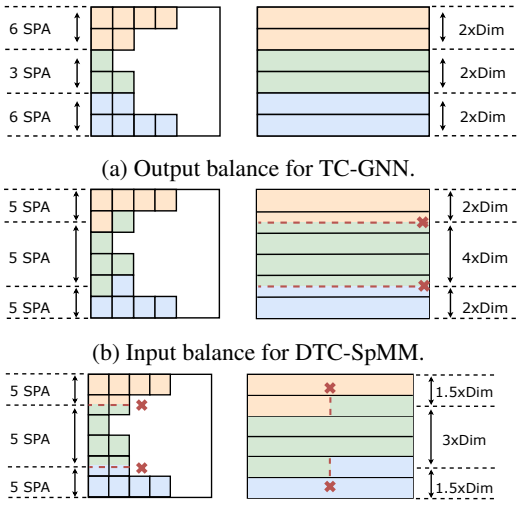
overlaps the loading of SparseA with Tensor Core computations, mitigating loading time. However, the typically large dimensions of the dense matrix in GNNs, often exceeding 256, mean one SparseA corresponds to multiple tiled DenseB matrices, creating a data copy overhead that significantly exceeds that of SparseA. Our experimental results, as shown in Figure 3 , reveal that in most cases, loading the dense matrix (DenseB) accounts for over 60% of the total execution time. Thus, despite the full overlap of SparseA loading, the primary challenge persists: the prolonged stalls caused by loading DenseB continue to dominate kernel execution time.

Furthermore, the pipelining strategy in DTC-SpMM struggles to effectively parallelize the loading of DenseB with MMA computations for several reasons: (1) DTC-SpMM leverages the `LDGSTS` SASS instruction [28] for asynchronous loading, which initiates data transfers without stalling computation. However, this instruction is limited to loading only 16 bytes of data per operation. When applied to the DenseB matrix, the substantial number of `LDGSTS` instructions required increases dramatically, leading to a high instruction count that undermines the benefits of pipelining. (2) The single-layer and intra-warp pipeline used by DTC-SpMM results in minimal overlap and frequent synchronization within warps, thereby reducing overall efficiency. (3) DTC-SpMM loads DenseB data directly into the registers, bypassing shared memory. This access pattern does not support asynchronous prefetching, further limiting the effectiveness of the pipeline.

Summary. Given these issues, there is an urgent need for a novel pipelining design that can effectively bridge the gap between lengthy data loading times and efficient Tensor Core computations. Such a design should enable enhanced overlap of memory copying with computation, ultimately addressing the persistent data-loading challenge.

2.2.2 Unbalanced Workload: Failure to Balance I/O

NVIDIA GPUs use a Streaming Multiprocessor (SM) architecture, where multiple CTAs are executed concurrently on each SM. In CUDA programming, CTAs are mapped to SMs and execute in parallel. This model is highly efficient when workloads are evenly distributed among CTAs. However, the irregular nature of sparse data often leads to significant imbalances in workload distribution. For example, each row of



(a) Output balance for TC-GNN.

(b) Input balance for DTC-SpMM.

(c) Our input and output co-balance.

Figure 4: Workload partitioning strategies at the CTA level.

the sparse matrix has a different number and arrangement of non-zero entries, leading to a varying number of TCU blocks per RowWindow, as shown in Figure 4. Furthermore, results from multiple TCU blocks within the same RowWindow must be accumulated, adding complexity. This uneven distribution of TCU blocks across RowWindows poses a substantial challenge in maintaining balanced workload distribution across each SM. To address this, current methods employ various workload partitioning strategies at the CTA level, which we categorize into two main types.

Output Balancing. The approach, employed by TC-GNN as illustrated in Figure 4a, assigns each CTA the task of processing all TCU blocks corresponding to a single row within a RowWindow. This strategy ensures that the output from each CTA is confined to the results of one specific RowWindow. While this design standardizes output workloads across CTAs, it leads to a significant input imbalance due to the large variations in the number of TCU blocks per row. Since the input directly influences the volume of data loading and computation, this discrepancy causes some CTAs to complete their tasks quickly while others lag, resulting in inefficient utilization of SM resources and diminished overall performance.

Input Balancing. Conversely, DTC-SpMM adopts the input balancing approach, as demonstrated in Figure 4b. This strategy ensures that each CTA processes an equal number of TCU blocks, distributing the input workload evenly across CTAs. While this method equalizes the amount of data each CTA handles, it complicates the management of output results. Specifically, when one RowWindow contains a large number of TCU blocks, multiple CTAs might need to contribute to the same row. To address this, DTC-SpMM employs atomic operations to accumulate results from different CTAs. Although these atomic operations maintain result accuracy,

they significantly increase computational overhead. On the other hand, when a RowWindow includes only a few TCU blocks, a single CTA may need to write results across multiple rows, which exacerbates the disparities in output overhead among CTAs. Consequently, DTC-SpMM still incurs considerable overhead and does not fully resolve the imbalance issue, thereby impacting its overall efficiency.

Summary. Due to the irregular nature of sparse data in SpMM, attempting to balance the workload solely from either the input or output perspective often leads to an imbalance on the other side. Furthermore, partitioning data across RowWindows requires atomic operations to ensure the correctness of results. Given these challenges, an ideal partitioning scheme should not only achieve input-output co-balance but also maintain coarse granularity for sparse data to prevent crossing RowWindow boundaries, as illustrated in Figure 4c.

3 Voltrix-SpMM Design

Voltrix-SpMM significantly improves sparse matrix-matrix multiplication through three key innovations. First, it utilizes a bitwise-level format to compress sparse matrices, which enables coalesced memory accesses and bank conflict-free decoding. Second, a warp-level asynchronous pipelining model effectively decouples data loading from computation, leading to greater overlap and improved throughput. Third, its persistent and balanced kernel design ensures co-balanced input and output workloads, ultimately boosting overall efficiency.

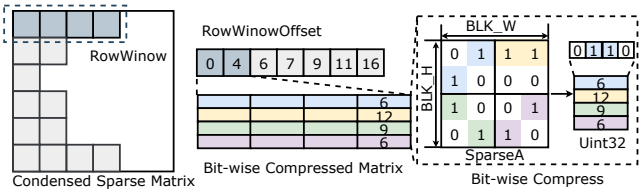
3.1 Warp-level Asynchronous Pipelining

In this subsection, we first introduce the BMat data format for accelerating sparse matrix loading. Then, we present the warp-specialized producer-consumer model that enables multi-tiered data access and asynchronous computation, effectively hiding dense data loading overhead.

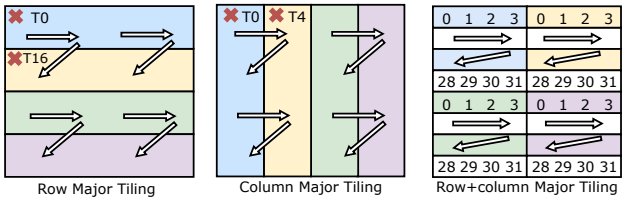
3.1.1 Bit-wise Compressed Data Format

In the design of Tensor Core-based SpMM kernels, SparseA used in MMA calculations is typically represented as a 16x8 dense matrix. However, to accommodate the high proportion of zero elements, which can exceed 90% as reported in DTC-SpMM [10], SparseA is stored in a sparse format during non-computational phases. For instance, TC-GNN uses the CSR matrix format, while DTC-SpMM employs the ME-TCF format. Directly storing SparseA in a dense format would place undue pressure on memory resources and incur substantial data copy overhead during kernel execution.

Therefore, the processing of SparseA involves two steps when transitioning from global memory to fragment: 1. loading SparseA in its sparse format, and 2. converting SparseA from a sparse to a dense format. In the data loading stage, the goal is to minimize both the data volume and the number of



(a) Bit-wise compressed matrix.



(b) Various tiling methods. Different colors represent 128-byte contiguous segments in shared memory, corresponding to one group of 32 banks. The arrows indicate the layout distribution of registers held by threads in a warp during MMA execution.

Figure 5: Loading and decoding of BMat.

loading instructions. In the conversion stage, the goal is to avoid bank conflicts during shared memory access.

While TC-GNN and DTC-SpMM have focused primarily on optimizing one of these aspects, Voltrix-SpMM aims to comprehensively address all these factors. We propose a novel data format that is both vectorization-friendly and conflict-free, termed the bit-wise compressed matrix, or BMat.

How to load? As illustrated in Figure 5a, we use `RowWindowOffset` to record the offset of each RowWindow in the condensed sparse matrix, with each offset corresponding to a SparseA. Each 0 and 1 element of SparseA is represented by just 1 bit, allowing us to compress a 16x8 matrix into a 128-bit BMat. Specifically, a BMat is stored using four Uint32 values, enabling us to access the entire BMat with a single vectorized load instruction `LDGSTS.128`.

How to decode? We address the challenge of tiling SparseA to compress it into four Uint32 values, as different tiling strategies significantly impact conversion efficiency. As illustrated in Figure 5b, one could employ row-major tiling—as adopted by the BitTCF format of ACC-SpMM [51]—resulting in four 4×8 sub-blocks, or column-major tiling, which splits it into four 16x4 sub-blocks. However, we adopt a hybrid row + column-major tiling approach, segmenting SparseA into four 8x4 sub-blocks. This method offers two key benefits:

1. Efficient decoding by each thread in a Warp using thread ID-based shifting, where each Uint32 facilitates streamlined data access. 2. The alignment of each Uint32's BMat decoding with its corresponding submatrix in the MMA computation prevents bank conflicts, enhancing computational efficiency. This contrasts with other tiling methods that often lead to cross-bank accesses, marked by red crosses in Figure 5b.

By optimizing both the loading and conversion phases, our

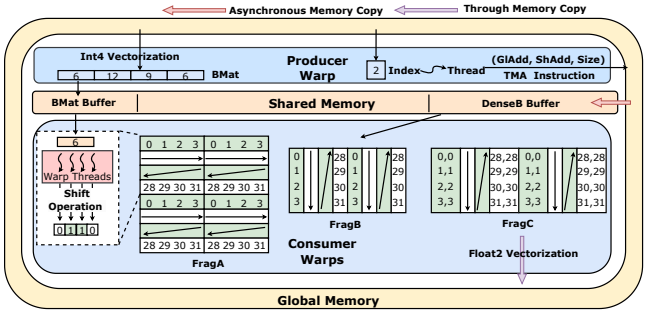


Figure 6: The warp-specialized producer-consumer model.

BMat approach enables more efficient handling of SparseA. Moreover, the decoded content is directly loaded into registers for immediate computation. In contrast to previous methods that required a 16x8-sized Int32 shared memory space, our strategy only uses four Uint32 values to store the BMat, reducing the demand on shared memory resources.

Non-binary cases. To support non-binary SparseA with floating-point values, our BMat format only requires an additional value vector to store the non-zero floating-point values. Within a warp, the i-th thread (thread T_i) constructs a 32-bit position mask M_i. The first $i+1$ bits of this mask are set to 1, while the remaining 31-i bits are set to 0. This mask is then bitwise-and with the BMat to obtain P_i. Subsequently, each thread calculates the bitwise-sum of its P_i using the `__popc()` intrinsic. This bitwise-sum determines the offset of its corresponding non-zero element within the value vector.

For instance, consider an 8x4 sparse matrix SparseA containing floating-point values at indices 3, 7, and 20. The BMat representation for this matrix is B = `0x00100088`. For thread $i = 7$, the binary mask is M_7 = `0x0000000f`. The bitwise-and operation yields P_7 = `0x00100088` & `0x0000000f` = `0x00000008`. The bitwise-sum of P_7, calculated as bitwise-sum(0x00000008), is 1, indicating that the non-zero element associated with this thread is located at the second position in the value vector (using zero-based indexing).

Unlike DTC-SpMM, which requires an explicit offset to track non-zero counts, BMat encodes this information directly. By performing a bitwise-sum on BMat, we can obtain the non-zero count without extra metadata. In our method, we only need to allocate a register within the kernel to accumulate the total count of non-zero elements. This accumulated count directly provides the starting offset for accessing the value vector in the current iteration. This design contributes to more efficient compression and memory access when using BMat.

3.1.2 Warp-Specialized Producer-Consumer Model

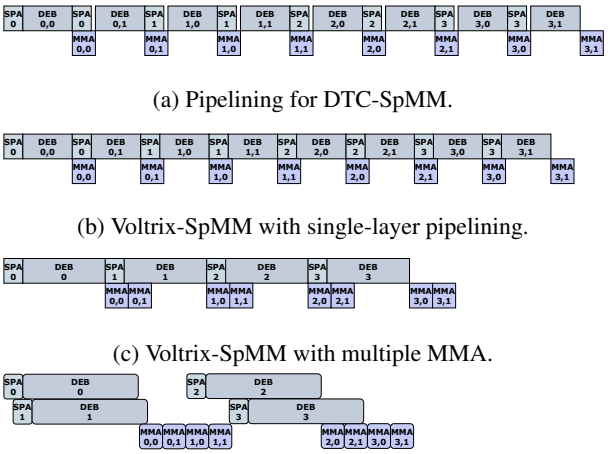
To mitigate the significant data access overhead, particularly the stalls caused by loading SparseA and DenseB, we implement an inter-warp pipelining strategy. In our kernel design, specific warps within a CTA are assigned to load data from global memory into shared memory, while other warps concurrently fetch preloaded data from shared memory to perform Tensor Core computations. This warp-specialized task allocation establishes a producer-consumer model within each CTA, where shared memory serves as a shared buffer to facilitate the overlap of computation and data access.

How to fetch data? As depicted in Figure 6, the Producer is tasked with loading data and issuing instructions, managing the transfer of SparseA and DenseB from global memory to shared memory. For SparseA, as detailed in Section 3.1.1, we employ vectorization techniques to copy the BMat to shared memory using a single INT4 instruction. For DenseB, each SparseA corresponds to a number of DenseB elements equal to BLK_W × D, where D represents the dimension of the dense data. The Producer utilizes its index to locate these elements in global memory and subsequently transfers them to shared memory. This transfer leverages asynchronous TMA instructions for efficiency: 1) TMA requires only a single instruction to access dense data, reducing the overhead associated with multiple `LDGSTS` instructions; 2) TMA allows just one thread to issue the instruction, enabling all the dense data corresponding to a SparseA in a CTA to be loaded using only 8 threads. As a result, a single Warp acts as the Producer to issue the instructions, minimizing the resource wastage caused by excessive producer warps.

The Consumer retrieves data from shared memory and loads it into registers for MMA computation using Tensor Cores, configured to an MMA size of `m16n8k8`. For SparseA, each consumer performs shift operations for decoding. For DenseB, pending operations are performed to prevent bank conflicts in shared memory. After completing all SparseA in a RowWindow, each thread retains two float32 results per MMA. Consequently, we utilize FLOAT2 write-through instructions to directly transfer data from registers to global memory, effectively bypassing shared memory.

How to pipeline? In Voltrix-SpMM design, shared memory buffers are managed using a memory barrier (`MBarrier`) signaling mechanism to efficiently coordinate producer and consumer operations. All barriers are classified as either 'ready' or 'filled'. Initially, 'ready' barriers use the `SYNCS.ARRIVE` instruction to signal the producer to load data, while 'filled' barriers use the `SYNCS.TRYWAIT` instruction to block the consumer. Once the producer finishes loading, it releases the 'filled' barrier with `SYNCS.ARRIVE`, notifying the consumer to transfer the preloaded data for computation. Subsequently, the 'ready' barrier suspends the producer with `SYNCS.TRYWAIT` for the next batch. Conversely, the consumer coordinates with the producer to wait and refill the buffer.

This creates a ping-pong scheduling mechanism, where data loading and computation alternate seamlessly across buffers. As illustrated in Figures 7a and 7b, unlike DTC-SpMM which only overlaps the loading of SparseA with MMA computation, our producer-consumer model facilitates pipelining of MMA with both SparseA and DenseB, allowing



(a) Pipelining for DTC-SpMM.

(b) Voltrix-SpMM with single-layer pipelining.

(c) Voltrix-SpMM with multiple MMA.

(d) Voltrix-SpMM with multi-tiered pipelining.

Figure 7: Different pipelining strategies.

for enhanced potential to conceal data loading overhead.

3.1.3 Fine-Grained Multi-Tiered Pipelining

Although a single-layer pipeline can mitigate some data loading overhead, it often results in low overlap and suboptimal resource utilization. In contrast, our producer-consumer model enables a higher-level extension of the traditional pipeline, maximizing hardware resource usage and facilitating seamless parallelism between computation and data access. By deploying a warp to manage multiple MMAs and buffers within the pipeline, this approach significantly minimizes idle cycles and enhances overall system throughput.

Multiple MMA. Given that the data access phase incurs higher stalls than the computation phase—due to the producer's loading speed lagging significantly behind the consumer's consumption speed—a practical solution is to increase the computation workload for each consumer without altering the producer's throughput. A single CTA can manage a maximum of 512-dimensional dense data, allocated across 32 warps, with each warp handling up to 16 dimensions of dense data. Consequently, any data exceeding 512 dimensions necessitates a reloading of SparseA. As depicted in Figure 7a, a DenseB data chunk is divided into two loading phases, with the MMA computations also split accordingly. We enable each consumer to load multiple tiled DenseB data simultaneously and conduct multiple MMA operations to enhance processing efficiency, as shown in Figure 7c. This strategy not only reduces the instruction issuing overhead associated with loading but also promotes a higher degree of overlap between computational tasks.

Multiple buffer. To maximize bandwidth utilization and enable seamless pipelining, we introduce multiple buffers, as shown in Figure 7d, to accommodate concurrent MMA operations. Each buffer operates independently, allowing the producer to issue data copy instructions for multiple buffers simultaneously. Once a buffer's barrier is set to 'filled', the consumer begins to read the data from that buffer for computation. Upon completing the computation, the consumer immediately accesses data from another buffer, while the previously used buffer is reloaded with new data. This multi-tiered fine-grained pipeline, compared to traditional single-layer pipeline, significantly enhances hardware data copy bandwidth utilization. It bridges the gap between data loading and computation and facilitates more seamless overlap of these processes, ultimately improving overall system performance.

Trade off. While incorporating more MMAs and buffers enhances pipelining potential, this approach does not guarantee improved performance due to two primary factors:

1. Shared memory is a limited resource. Since it shares the same hardware storage with the L1 cache, increasing the number of buffers can reduce cache hit rates for other data, potentially impacting overall performance.

2. Effective pipelining depends on the ability to simultaneously load corresponding DenseB data for different SparseA matrices within the same RowWindow. If a RowWindow contains only a few SparseA matrices, extensive pipelining might lead to underutilization of resources.

Consequently, striking a balance between maximizing overlap and minimizing resource wastage is crucial. In Voltrix-SpMM, we observe that the optimal configuration depends solely on the dimensions of the dense matrix. By pretesting various configurations for dense data of differing dimensions, we can identify the most efficient setup for each scenario.

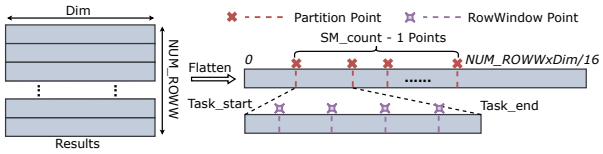
3.2 Persistent and Balanced Kernel

In this subsection, we'll first present our persistent kernel design, which eliminates atomic operations while simultaneously achieving co-balanced input and output. Following this, we'll introduce a greedy and heuristic partitioning strategy developed to identify workload-balanced partition points.

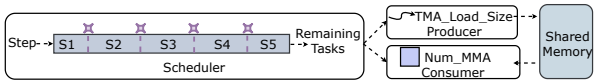
3.2.1 SM-Aligned and Atomic-Free Partitioning

Software-hardware balance. In Section 2.2.2, we discussed the challenges of achieving balance in Tensor Core-accelerated SpMM kernels. A well-balanced GPU kernel evenly distributes tasks across hardware units. However, in CUDA, software-level balance among CTAs doesn't always ensure hardware-level balance across SMs, since the number of CTAs may not match the number of SMs, causing idle SMs during later scheduling stages.

For example, TC-GNN sets CTAs based on RowWindow rows, while DTC-SpMM assigns a fixed number of SparseA elements per CTA. Both adjust CTAs dynamically based on sparse matrix structure. Given millions of SparseA elements, CTAs often far outnumber SMs, increasing overhead associated with CTAs scheduling and prologue/epilogue execution.



(a) Illustration of task partitioning.



(b) Task coordination by the scheduler.

Figure 8: SM-aligned and atomic-free partitioning.

To address this, we adopt an SM-aligned kernel design by fixing the number of CTAs to match the number of SMs. This persistent approach offers two key benefits:

1. It ensures that the software-level distribution of tasks (CTAs) corresponds directly with the hardware-level distribution (SMs). This alignment results in a balanced execution with no idle units.

2. It accommodates the high number of SparseA elements relative to the available SMs, allowing the kernel to run persistently until all tasks are completed. This continuous operation mode reduces the frequent launching and termination of kernel CTAs, which typically incur significant prologue and epilogue execution overhead.

Input-output co-balance. As detailed in Section 2.2.2, TC-GNN suffers from output imbalance, causing uneven data loading and computation across CTAs. DTC-SpMM's input balancing mitigates SparseA distribution issues but introduces atomic addition overhead and output imbalance.

To address these challenges, we propose an atomic-free partition method that balances both input and output while eliminating atomic operations. This dual-perspective approach simplifies partitioning and improves computational efficiency.

On the input side, SparseA is partitioned at the RowWindow level to keep data contiguous and complete within each partition, eliminating the need for atomic operations. On the output side, the dense matrix is partitioned by its dimensions to ensure balanced output distribution. This fine-grained, flexible partitioning fits naturally with our SM-aligned design, allowing the kernel to persist until all tasks finish. As a result, the kernel must continuously track its progress within each RowWindow and monitor remaining tasks, which introduces complexity in boundary detection.

To manage this, we integrate a scheduler within our producer-consumer model tailored to the balanced partitioning method. Task partitioning is based on result allocation, as shown in Figure 8a, by flattening the result matrix into a 1D vector. The total task count equals the number of RowWindow rows times the result matrix's dimension. We divide these tasks evenly across $\mathcal{M}$ SMs by selecting $\mathcal{M}-1$ split points, using a single warp MMA operation (i.e., 16) as the partition unit for finer granularity.

By tracking each task's start and end points, the scheduler effectively defines task and RowWindow boundaries. At runtime (as shown in Figure 8b), tasks are divided into stages aligned with RowWindow boundaries. The scheduler computes remaining tasks in the current stage and instructs the producer how much data to load via TMA. It also dynamically adjusts the number of MMA operations per warp in the consumer accordingly.

While this segmentation removes the need for atomic additions in output, it may require reloading SparseA at boundary stages with incomplete tasks (i.e., tasks that do not fully form a RowWindow). However, since RowWindows typically contain many more rows than SMs and SparseA is efficiently loaded via the BMat format, the overhead of this secondary loading is effectively negligible.

Algorithm 1: Greedy and heuristic-based partition point search algorithm

input : Total cost: $\mathcal{C}_{all}$, SM counts: $\mathcal{M}$
output : Partitioned points $\mathcal{S} = \{0, S_1 \ldots, S_{\mathcal{M}}, \mathcal{C}_{all}\}$

Calculate the average cost $\mathcal{C}_{avg} = \mathcal{C}_{all}/\mathcal{M}$.
for $S_i \in \mathcal{S}, j \leftarrow 1$ **to** $\mathcal{M}$ **do**
  Move the S_i points forward until the accumulated cost between S_{i-1} and S_i exceeds $\mathcal{C}_{avg}$.
  Calculate column position of the end point $Col = S_i \% \mathcal{D}$
  if $Col < \mathcal{D}/8$ **then**
    $S_i = S_i - Col$
  end
  else if $Col > \mathcal{D} * 7/8$ **then**
    $S_i = Si + \mathcal{D} - Col$
  end
end

3.2.2 Input-Output Co-Balance Searching

With our SM-aligned and atomic-free partitioning, the kernel balancing problem is simplified by dividing all tasks evenly among the SMs to ensure balanced workloads. To evaluate different splitting methods, we propose a cost model for the entire SpMM operation:

$$\mathcal{C}_{all} = \sum_{i=0}^{R_W} Num_SPA(i) \cdot cf_1 \cdot \mathcal{D} + R_W \cdot cf_2 \cdot \mathcal{D} + cf_3 \qquad (1)$$

The first term captures input costs across all RowWindows, including overhead from SparseA loading and computation, scaled by $\mathcal{D}$, the dense matrix dimension. The second term represents output costs from write-back operations, with R_W as the number of RowWindows. Coefficients cf_1, cf_2, and cf_3 quantify the costs of input, output, and fixed kernel overheads, respectively, and are tuned to reflect hardware characteristics.

In the experimental section 4.7, we will measure these three coefficients to validate the accuracy of our cost model. From this model, we derive the optimization objective, which is formulated as follows:

$$\mathcal{S}^* = \arg\min_{\mathcal{S}} \left(\max \left\{ \frac{C_i(\mathcal{S})}{\sum_j C_j(\mathcal{S})} \middle| i \right\} + P(\mathcal{S}) \right) \quad (2)$$

Here, $\mathcal{S}$ denotes a partitioning scheme, and $P(\mathcal{S})$ is the penalty from crossing RowWindow boundaries. To find the optimal scheme $\mathcal{S}^*$, we design a greedy, heuristic-based search algorithm, detailed in Algorithm 1.

The algorithm starts by computing the ideal per-SM cost from the total task cost (Line 1). For each SM, it incrementally extends the partition endpoint until the accumulated cost exceeds this average (Lines 3–4). To reduce boundary-crossing overhead, partition points near RowWindow boundaries are adjusted to align with them (Lines 5–10). Finally, a genetic algorithm [8, 15] refines these points for a globally optimal solution, requiring only one iteration in practice.

Utilizing the greedy and heuristic-based partition point search algorithm, we aim to balance the tasks across each SM as evenly as possible while minimizing the additional overhead incurred by crossing RowWindow boundaries.

4 Evaluation

Voltrix-SpMM is a pure CUDA-based [28] library with around 5k lines of code and no third-party dependencies. It extensively utilizes the C++ template metaprogramming paradigm to adapt to our multi-tiered pipelining design, making the code highly configurable and minimizing kernel runtime overhead. We employ inline PTX instructions to leverage specific hardware features of the Hopper GPU [30], including `MMA`, `TMA`, and `MBarrier`, to maximize efficiency.

Voltrix-SpMM is integrated into the popular machine learning framework PyTorch 2.5 [33] and can be easily invoked from both Python and C++ backends using common sparse matrix formats like CSR and COO. Voltrix-SpMM has been open-sourced at `github.com/YaqiXia/Voltrix-SpMM`, encouraging community use and contributions.

4.1 Experimental Setup

Platform. Our experiments are conducted on a Hopper H100 PCIe GPU [30], equipped with 456 Tensor Core units, 14,592 CUDA cores, and 80 GB of graphics memory.

Dataset. As detailed in Table 1, we employ 12 real-world graph datasets, categorized into two types: Type I datasets, with a smaller average row length (less than 20), and Type II datasets, with an average row length close to 500. This distinction in row length influences the data volume in each RowWindow's TCU blocks, impacting efficiency. To evaluate the adaptability of different methods, our selection includes datasets with varied average row lengths. We also incorporate the SuiteSparse dataset [7], a comprehensive collection of sparse matrix benchmarks, for extended validation.

Methodology. We benchmark SpMM against state-of-the-art CUDA Core-based and Tensor Core-based methods. The CUDA Core baselines include Sputnik [12], GE-SpMM [17], RoDe [32], and cuSPARSE [24], while the Tensor Core baselines include TC-GNN [43] and DTC-SpMM [10]. For GNN testing, comparisons are made with GNNAdvisor [42], TC-GNN, and the widely-used DGL framework [2]. Our GNN model features two GCN [20] convolutional layers, each with a hidden dimension of 256.

4.2 SpMM Performance

First, we evaluate the performance of Voltrix-SpMM against other SpMM kernels using real-world graph datasets and the SuiteSparse collection to provide the sparse matrices on the left-hand side. The dimensions of the dense matrices on the right-hand side are set to 256, 512, and 1024, respectively.

Graph datasets. As illustrated in Figure 9, Voltrix-SpMM achieves superior performance across nearly all graph datasets. It outperforms cuSPARSE with an average speedup of 2.7x and surpasses the state-of-the-art CUDA Core-based method, RoDe, by the 1.9x speedup. Against the Tensor Core-based method, DTC-SpMM, Voltrix-SpMM delivers an average speedup of 1.8x, demonstrating its high efficiency.

Voltrix-SpMM particularly excels as the dimension of the dense matrix increases, achieving speedups of 2.4x, 2.8x, and 3.0x over cuSPARSE for dimensions of 256, 512, and 1024, respectively. This improvement is attributed to our multiple MMA and buffer design, which can load more data per operation at higher dimensions, thereby reducing instruction overhead and making more effective use of bandwidth.

Furthermore, while DTC-SpMM and TC-GNN also utilize Tensor Cores for acceleration, their performance lags behind the CUDA Core-based RoDe by 2% and 69%, respectively. This highlights that despite the high computational throughput of Tensor Cores, significant data loading overhead can restrict their performance, leading to underutilized and 'starved' Tensor Cores. In contrast, Voltrix-SpMM overcomes these limitations with its warp-level asynchronous pipelining and balanced workload design, effectively unlocking the full

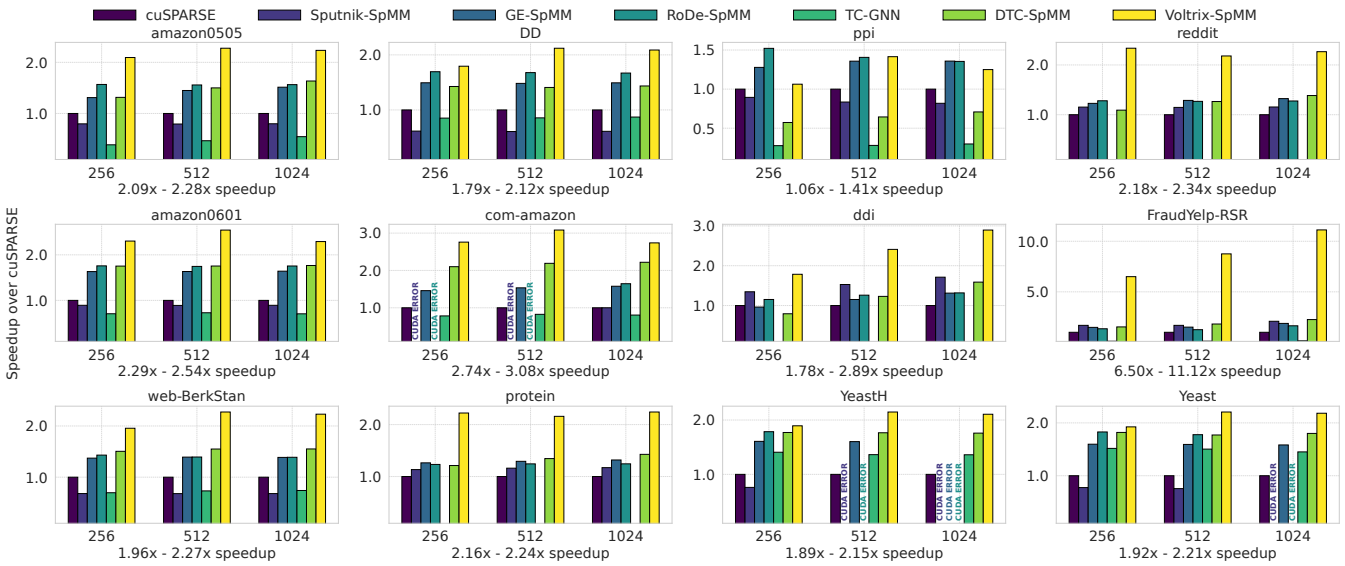

Figure 9: Performance comparison on graph datasets, with each subplot showing Voltrix-SpMM's speedup over cuSPARSE.

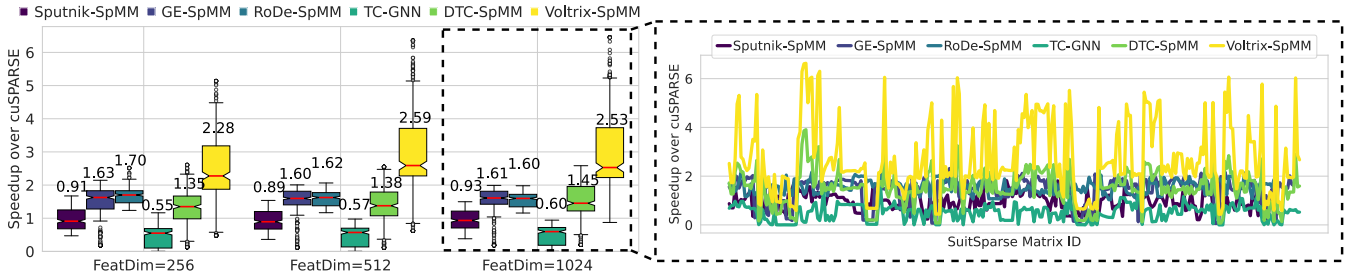

Figure 10: Speedup comparison on SuiteSparse: Box plot shows the overall distribution, while line chart shows detailed speedup.

potential of Tensor Cores for SpMM. While some CUDA Core-based methods, such as Sputnik and RoDe, encounter CUDA errors under specific conditions due to shared memory limitations, Voltrix-SpMM consistently adapts to all scenarios, thanks to its robust persistent kernel design.

SuiteSparse datasets. As shown in Figure 10, Voltrix-SpMM achieves average speedups of 2.5x compared to cuSPARSE. These results not only outperform all other methods but also demonstrate that the effectiveness of our design increases with the matrix dimensions, consistent with results observed on graph datasets. In the SuiteSparse tests, DTC-SpMM and TC-GNN still fall short of the performance achieved by the state-of-the-art CUDA Core-based method, RoDe, lagging by 11% and 70%, respectively. In contrast, Voltrix-SpMM achieves a 1.6x speedup over RoDe. This underscores that existing Tensor Core-based designs typically do not outperform CUDA Core-based methods. Our work is the first to fully leverage the capabilities of Tensor Cores, achieving speedups that surpass those achievable with traditional CUDA Core-based methods.

Mirco-level analysis. To provide a more granular understanding of the performance characteristics of various SpMM implementations, we augment our evaluation with micro-level hardware analysis. Using NVIDIA Nsight Compute, we collected key metrics such as register allocation, DRAM reads (GB), bank conflicts, and Tensor Core Unit (TCU) pipe utilization, as shown in Figure 12. These measurements are based on experiments using the Reddit dataset.

Results show Voltrix-SpMM consistently outperforms DTC-SpMM and RoDe-SpMM across multiple hardware metrics. It uses fewer registers and consumes less memory bandwidth, reflecting the efficiency of our bit-wise compressed data format, BMat.

Furthermore, Voltrix-SpMM exhibits a competitive L2 cache hit rate and significantly fewer bank conflicts, demonstrating effective memory access management, especially during the BMat decoding phase. It also demonstrates a competitive L2 hit rate and significantly fewer bank conflicts, highlighting its effective memory access management, particularly in optimizing BMat decoding phase.

Additionally, Voltrix-SpMM achieves the highest TCU pipe utilization, demonstrating superior pipeline efficiency and

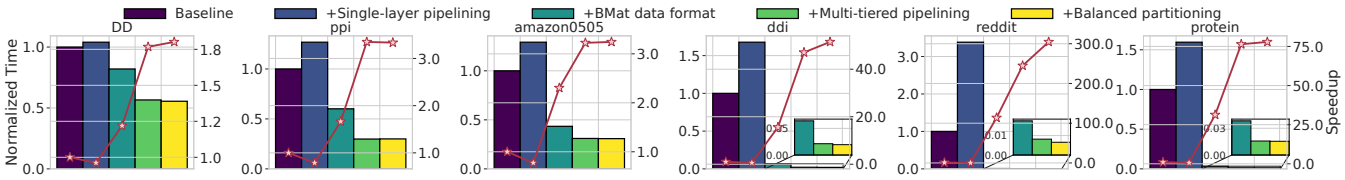

Figure 11: Performance Breakdown: The left axis shows normalized time, and the right axis shows speedup.

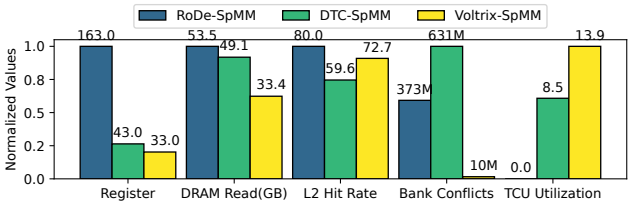

Figure 12: Micro-level performance comparison.

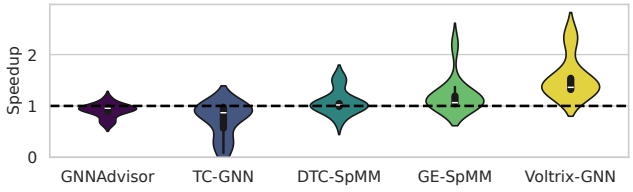

Figure 13: End-to-end GNN testing on different graph datasets: The vertical axis represents the speedup over DGL.

more effective use of GPU tensor cores. In contrast, RoDe-SpMM, limited to CUDA cores, shows zero TCU activity.

In summary, Voltrix-SpMM outperforms the other implementations in terms of memory efficiency and hardware utilization, making it the most optimized choice for SpMM tasks.

4.3 SpMM Performance Breakdown

We assess the performance contributions of Voltrix-SpMM's core components. Experiments are conducted on the graph datasets with dense matrix dimensions set to 256, using TC-GNN as the baseline. We incrementally integrate Voltrix-SpMM's components to gauge the performance improvements, which are illustrated in Figure 11.

Initially, we integrate the bulk asynchronous data transfer instruction, TMA, to establish a single layer of pipelining. However, in most datasets, this addition results in a performance degradation, with an average decrease of 32.6%. This occurs because, while the TMA instruction can transfer a large volume of data per operation, its latency is relatively high. Therefore, with the data dimension set to 256, each operation is limited to transferring only 256 float32 elements, restricting the potential for bulk data transfer. Additionally, the single-layer pipelining provides minimal overlap, further reducing the overall benefits of pipelining.

Adding our bit-wise compressed data format (BMat), we observe over a 77x average speedup, with results on Reddit reaching up to 384x. This significant improvement is due to datasets like Reddit, Protein, and ddi having larger average row lengths, which results in more SparseA blocks per RowWindow after TCU compression. In comparison, TC-GNN struggles with inefficient loading and transformation of SparseA, causing substantial delays. Voltrix-SpMM, with its bit-wise compressed data format, leverages vectorized loading and a conflict-free transformation design, dramatically reducing the processing time for SparseA.

Next, incorporating our multi-tiered pipelining yields an average 2.1x speedup. Although bulk asynchronous transfers introduce some overhead, Voltrix-SpMM counteracts this through multiple MMA operations and buffers, which amortize the instruction overhead while optimizing bandwidth utilization. Our warp-specialized producer-consumer model further facilitates fine-grained, multi-tiered pipelining, achieving higher levels of overlap and yielding significant benefits.

Lastly, integrating our persistent kernel design results in up to a 1.3x speedup. On datasets like Reddit, which feature more uneven data distributions, we observe even greater improvements, showcasing our balance search algorithm's efficacy in addressing challenges associated with uneven data distribution on input-output balance.

Overall, through the strategic design of these four components, Voltrix-SpMM achieves speedups ranging from 2.0x to 304x, underscoring the effectiveness of each module in enhancing SpMM performance.

4.4 GNN End-to-end Training

We evaluate the performance of Voltrix-SpMM in end-to-end GNN training, which we refer to as Voltrix-GNN, exploring its potential in machine learning tasks. We use GCN [20], one of the most widely used GNN models, which comprises multiple graph convolutional layers. Each layer's computation primarily involves a SpMM operation and a GEMM operation, indicating that any computational gaps in SpMM may be balanced by other operations during training.

The experimental results in Figure 13 use DGL [2], which leverages cuSPARSE library for SpMM acceleration, as the baseline. Voltrix-GNN consistently outperforms all baselines

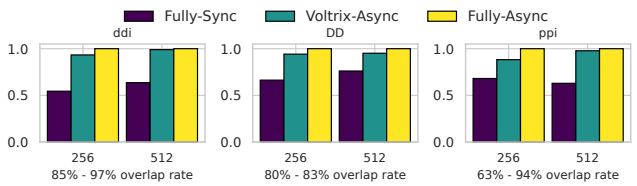

Figure 14: Overlap rate testing: The horizontal axis shows dimensions, and the vertical axis shows normalized speedup.

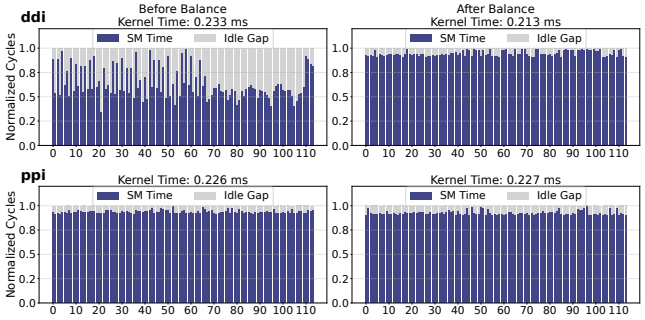

Figure 15: SM-Level active cycle distribution comparison.

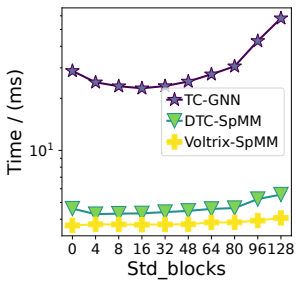

Figure 16: Sensitivity.

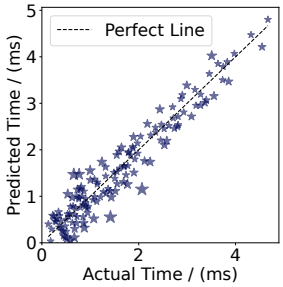

Figure 17: Time alignment.

across diverse graph datasets, with average speedups of 1.55×, 1.77×, 4.01×, 1.45×, and 1.29× over DGL, GNNAdvisor, TC-GNN, DTC-SpMM, and GE-SpMM, respectively. These findings underscore the applicability and outstanding performance of Voltrix-SpMM in GNN training tasks.

4.5 Overlap Rate of Pipelining

We investigate the overlap rate of Voltrix-SpMM's pipelining strategy. Profiling the kernel's time trace is challenging, so we adopt an approximation method to determine the kernel's overlap rate: First, we implement a configuration using a single buffer, termed `Fully-Sync`, where the consumer begins computation only after production has completed, forcing the kernel to operate serially without any pipelining. Next, we configure the kernel to run completely asynchronously by removing all `MBarrier` instructions, which we refer to as `Fully-Async`. This scenario represents the upper bound of our kernel's performance. We define the overlap rate, R_o, as:

$$R_o = \frac{T(Fully_Sync) - T(Voltrix_Async)}{T(Fully_Sync) - T(Fully_Async)} \times 100\% \quad (3)$$

Here, `Voltrix-Async` refers to our method. As depicted in Figure 14, Voltrix-SpMM achieves peak overlap rates of 85% and 97% at 256 and 512 dimensions, respectively. These results demonstrate the effectiveness of our warp-specialized asynchronous data loading pipelining. With near-seamless overlap, Voltrix-SpMM significantly reduces the data loading overhead, showcasing its high efficiency.

4.6 Workload Balance Analysis

Active SM cycles analysis. To evaluate the effectiveness of our workload balancing design, we analyze the distribution of active SM cycles using runtime data from both non-balanced and balanced kernel executions, as shown in Figure 15. The impact of our approach varies across datasets. On imbalanced workloads like ddi, our method significantly improves SM utilization and reduces kernel time by 8.6%. In contrast, for already balanced datasets like ppi, the benefit is marginal, with only a 0.4% increase in kernel time.

While the balancing introduces minor overhead, it is largely hidden by the persistent kernel design, which overlaps epilogue execution with ongoing computation. As a result,our method delivers clear gains on imbalanced workloads while preserving original performance on balanced ones.

Sensitivity analysis. We investigate the balance of different methods to irregular distributed data. By configuring the number of SparseA elements in each RowWindow, we generate sparse datasets with varying levels of uniformity. Using a Gamma distribution [25], we create datasets with a mean of 256 and variances ranging from 0 to 192, and evaluate their performance.

As shown in Fiure 16, under different variance distributions, our method outperforms both DTC-SpMM and TC-GNN in terms of speed. Moreover, as the distribution of SparseA becomes increasingly uneven,our method remains stable with only a 4% performance drop, while TC-GNN experiences a significant 47% degradation. These results demonstrate the superiority of Voltrix-SpMM in balancing I/O while avoiding the high overhead of atomic operations.

4.7 Validation of Cost Model

We evaluate the effectiveness of the cost model outlined in Equation 1, utilizing kernel execution time as the cost measure. To understand the relationship between time and the two variables, Num_SPA and R_W, we generate datasets with varying values for these parameters. Given the linear relationship postulated in our model between the cost and these variables, we employ linear regression for fitting, as demonstrated as:

$$T = \alpha_1 \cdot Num_SPA + \alpha_2 \cdot R_W + \alpha_3 \quad (4)$$

Here, α_1, α_2, and α_3 represent the coefficients of the linear regression model, correlating positively with cf_1, cf_2, and cf_3, respectively. We divide the data into a training set (80%) and a testing set (20%). Using this model, we predict values on the testing set and compare these predictions to the actual values. This comparison is visually represented in Figure 17, where the predicted values are plotted against the actual values on the x and y axes, respectively. The discrepancy between them is indicated by the size of the scatter markers, with smaller sizes denoting a closer fit to the perfect prediction line.

As depicted in Figure 17, nearly all points closely align with the ideal prediction line. Moreover, we calculate the coefficient of determination, $R^2 = 0.92$, indicating a strong linear relationship. An R^2 value exceeding 0.9 reaffirms the high accuracy of our model's fit to the data.

5 Related Work

CUDA Core-accerateled SpMM. Recently, numerous studies have focused on optimizing SpMM computation on GPUs, primarily utilizing CUDA Cores [12, 16–18, 26, 32, 34]. NVIDIA's official sparse matrix library, cuSPARSE [24], offers highly optimized GPU-accelerated routines for SpMM. Merge-SpMM [48] accelerates SpMM using the CSR format, emphasizing instruction-level parallelism. Sputnik [12] introduces a 1D tiling scheme that enhances operand reuse and employs subwarp tiling and reverse-offset memory alignment to optimize vector memory access for misaligned addresses. GE-SpMM [17] integrates a coalesced row caching method for efficient memory access and a coarse-grained warp mapping method to reduce threading overheads. GNNAvisor [42] proposes an adaptive runtime system with a novel 2D workload management strategy to improve GPU utilization. DA-SpMM [6] employs a data-aware heuristic GPU kernel, while HP-SpMM [9] uses dynamic task partitioning and hierarchical vectorized memory access. Lastly, RoDe [32] introduces a row decomposition-based method that enables efficient computation, load balancing, and fine-grained pipelining, setting a new performance benchmarks for SpMM.

Collectively, these methods optimize SpMM across various dimensions but often overlook the potential of Tensor Cores for accelerating computations. This oversight limits their ability to leverage the high throughput of modern GPUs.

Tensor Core-accerateled SpMM. With the advancement of Tensor Core computational throughput, an increasing number of studies have focused on leveraging Tensor Cores to accelerate SpMM [1, 5, 23, 41, 44]. However, most of these efforts target structured SpMM, which assumes a predefined pattern for the non-zero element distribution in sparse matrices, thereby limiting their applicability in real-world scenarios.

In contrast, TC-GNN addresses the more challenging application of unstructured SpMM on Tensor Cores. By introducing a sparse graph translation method that compresses sparse matrices into Tensor Core-sized TCU blocks, TC-GNN enables the efficient mapping of SpMM workloads to Tensor Core units. This approach has been further integrated into SparseTIR [49]. Despite its advances, however, TC-GNN's performance is compromised by inefficient data loading, which leaves the Tensor Cores underutilized. DTC-SpMM [10] attempts to enhance efficiency through several optimization methods, such as bypassing shared memory to accelerate dense data loading and implementing a pipeline arrangement to overlap sparse data loading and computation. However, the intra-warp asynchronous pipeline of DTC-SpMM struggles with the overhead caused by a large number of instructions and the costs of intra-warp synchronization.

While ACC-SpMM [51], FlashSparse [36], Groot [4], and SpInfer [11] make valuable contributions and optimizations beyond DTC-SpMM, they all operate within the same asynchronous design paradigm. To address these limitations, Voltrix-SpMM employs a multi-tiered inter-warp pipeline for enhanced computational overlap through warp specialization and utilizes bulk asynchronous data loading via TMA to efficiently handle high-dimensional data.

Libraries like cuBLAS [27], CUTLASS [31], and FlashAttention-3 [35] optimize GEMM operation using warp specialization and persistent kernel design, but the unique challenges posed by the sparse and irregular workload of SpMM make these approaches inapplicable.

6 Conclusion

In this paper, we introduced Voltrix-SpMM, a novel GPU kernel design that enhances SpMM on Tensor Cores. Voltrix-SpMM maximizes the computational potential of Tensor Cores for unstructured SpMM tasks. Its innovations include a new compression format for sparse matrices, bulk asynchronous data loading and a warp-specialized producer-consumer model, which streamline data handling and computation. Additionally, its SM-aligned, atomic-free partitioning mechanism ensures balanced workload distribution across SMs. The impact of Voltrix-SpMM is significant, achieving an average 1.8x improvement over DTC-SpMM, 1.7x over RoDe, and a 2.0x increase in end-to-end GNN training speeds, proving its effectiveness in real-world applications.

Abstract

Incremental policies and anomaly logs require operators to update network configuration during network operations. However, existing configuration methods lack the capability for intent understanding, traffic analysis optimization, and network dynamic adaptability, complicating overall configuration management.

We propose *NetKeeper*, an autonomous network configuration update framework. *NetKeeper* updates network configurations based on multimodal network intent comprising natural language input and anomaly logs, enabling adaptability to network dynamics and enhancing resilience through analyzing traffic patterns and anomalies. We implement northbound and southbound interfaces to translate network intents from operators and network management platforms respectively, bridging the gap between network intents and network behaviors. A multi-agent reinforcement learning model is designed for network configuration updates based on traffic patterns in dynamic networks. This model divides agents based on configuration parameter types, achieving both network resilience optimization and forwarding policy satisfaction.

Experiments in dynamic network show that *NetKeeper* updates network configurations with 99.6% average policy consistency, improves network performance by 5.3%, and reduces traffic shift by 8.7% on average.

1 Introduction

Network operators today face a wide range of management challenges from numerous network events [37], including service changes, topology changes, facility anomalies, and network congestion [15]. They must analyze network and events to formulate and implement low-level policies across devices throughout the network [17], thereby updating configurations to maintain forwarding policies and ensure service assurance. However, as enterprise networks grow increasingly complex, this manual process becomes more time-consuming and error-prone [17]. Moreover, a study reveals that over half of networks experience at least ten change events monthly [1]. The combination of network complexity and frequent changes necessitates substantial human effort from operators to learn and update networks in response to various events.

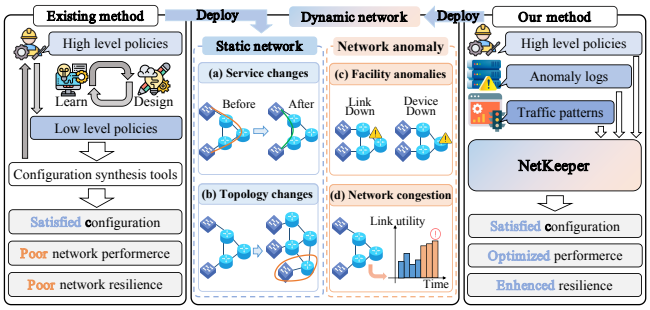

Figure 1: Illustration of intent-driven network configuration update. Comparison of existing methods with ours includes applicable scenarios, intent forms, processes, and functions.

Recently, several configuration update tools [1, 5, 9, 10, 15, 31, 46] are proposed to assist network operators. These tools input network intents in various forms and produce network configuration as output. However, when facing configuration update in dynamic networks, significant challenges still remain in aligning network intents and automating operational processes.

Firstly, different tools [1, 9, 15, 31] design various network modeling approaches. As shown in Fig. 1, before using these tools, operators need to learn specific modeling languages for networks and policies to express intents [43], which not only demands a high level of expertise but also makes policy writing and maintenance challenging. Moreover, anomaly logs related to network failures (e.g., device or link malfunctions) and network congestion from network management platforms [18] are crucial for network update, serving as update guidance and requiring operators to maintain assure services and performance [39]. Existing tools [17, 46] cannot automatically update network configurations based on these logs, necessitating manual analysis and solution development by

*Corresponding author: Jingyu Wang (wangjingyu@bupt.edu.cn) and Haifeng Sun (hfsun@bupt.edu.cn).

operators.

Secondly, these tools are unable to update configuration that effectively perform load balancing or reduce traffic shifts based on analyzing traffic patterns [34], resulting in network updates with poor resilience. This situation requires operators to manually simulate and address complex network performance issues, which is extremely difficult for them. Furthermore, as networks constantly evolve in architecture, services, and traffic patterns [5], existing work [1, 9, 15, 24] that updates configurations based on static networks fails to adapt to these changes, limiting their ability to maintain efficient service in dynamic network environments.

The concept of autonomous networks (AN) [12] represents a paradigm in network management, envisioning networks that can interpret high-level intents, autonomously explore solutions, and continuously optimize their performance. Based on this vision, we propose a framework that takes multimodal network intent as input and updates network configurations based on analysis of traffic patterns and anomalies. However, three challenges remain to be addressed.

How to implement intent translation interfaces for both operators and networks? Network operators utilize natural language for configuration intent description, offering high readability but vague information. Conversely, network anomaly logs, generated as formatted text, lack readability but contain specific information. While works in [1, 9, 15] employ domain-specific languages (DSL) [27] for intent input and works in [17, 46] accept natural language intent for network updates, none of these can effectively handle multimodal intents. Bridging gap between diverse intent representations and effectively mapping them to low-level policies leads to more comprehensive configuration update.

How to achieve traffic-based network configuration update while also enhancing network resilience? Configuration update solely focusing on forwarding policies often fall short in ensuring network performance. Traffic patterns, reflecting service demands, significantly impact the effectiveness of network configurations. Ignoring traffic information during updates can lead to suboptimal settings, causing unexpected performance issues even when policies are met. Existing approaches such as NetRen [15] and AED [1] have limitations in traffic awareness or overlooking configuration impacts on traffic distribution. To achieve effective and resilient network configurations, it's crucial to incorporate traffic-aware mechanisms into the update process, optimizing for both policy compliance and real-world network conditions.

How to realize configuration update for dynamic networks? As networks are dynamic with changing policies and traffic patterns [6], configuration update based on static network snapshots without considering actual network conditions cannot be a one-time, permanent solution, especially when facing network dynamics. Existing approaches to network configuration update, such as those using supervised learning [7, 15] or logical expression construction [9, 10, 24], require manual intervention before update. Whether modifying input network templates or crafting logical expressions, these methods limit automation and adaptability to dynamic networks, as they cannot actively gather network information or respond to changes without manual intervention.

To address aforementioned challenges, we propose *NetKeeper*, an autonomous network configuration update framework. It provides interfaces for both operators and network management systems, updating configurations based on multimodal intents, and enhancing network resilience through analyzing traffic patterns and anomalies. In summary, our contributions are as follows:

- A bidirectional interface of intent translation is proposed, featuring northbound interfaces for operators to manage network policies and southbound interfaces for network management platforms to handle anomalies.
- A goal-oriented traffic-based configuration update model is proposed that can autonomous updates configuration in dynamic network, while enhancing network resilience through analyzing traffic patterns and anomalies and satisfying forwarding policies.
- An autonomous network configuration update framework is proposed, which enables service assurance and self-managing under anomalies, or interacts with operators to update network configuration.

The rest of the article is organized as follows: §2 briefly introduces the related work. §3 outlines the systematic workflow of *NetKeeper*. §4 presents the design of intent translation. §5 details the network configuration update model. §6 discusses and analyses the result of evaluation. §7 discusses the limitations. §8 concludes the paper.

2 Related Work

2.1 Intent-based Networking

Existing works express network intents using various approaches, including domain-specific languages [3, 7, 10, 15, 30], logical expressions [1, 10], and high-level languages for policy expression, as seen in Propane [4], Genesis [40], and Frenetic [36]. For non-natural language intents, operators need to write policies in specific formats before performing updating network. Although Lumi [17] and CONFPILOT [46] can handle intents expressed in natural language, they can not handle anomalies without operators' effort. These tools fail to bridge the gap between non-natural and natural language intents, map intents of different formats to low-level policies, and provide no interfaces to handle various anomalies generated by management platforms, which are crucial for network self-managing.

2.2 Configuration Update

Configuration update aims at synthesizing a set of values that meet policies based on parameters and options involved in

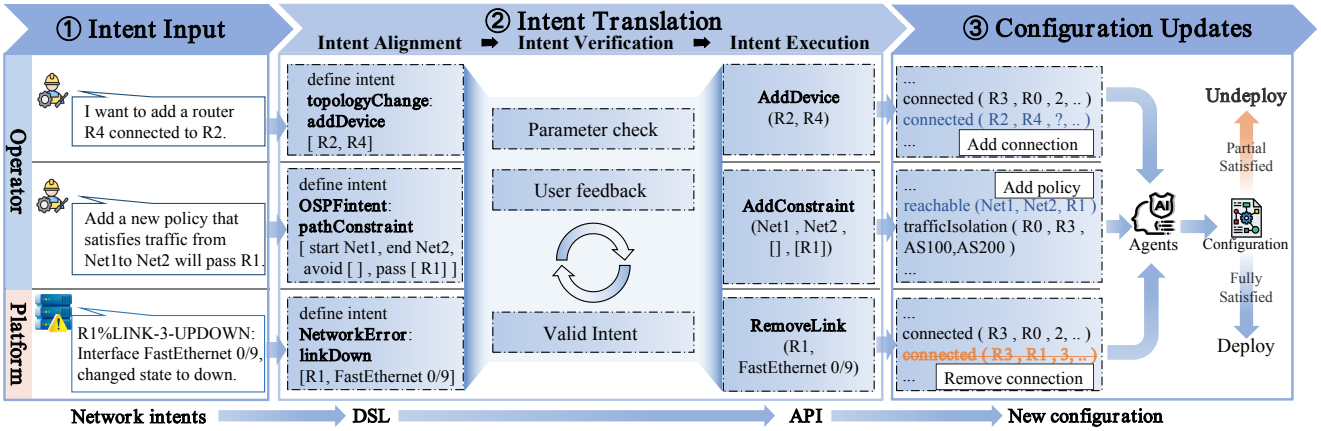

Figure 2: Overview of autonomous network configuration update framework *NetKeeper*. ① Get intent from operator or platform. ② The LLM translates different types of intent into DSL, validates them through a parameter check and feedback, and calls the appropriate APIs based on the DSL. ③ Modify network sketch and update network configuration through agents if configuration is fully satisfied. Three examples are illustrated in the figure (from left to right respectively).

	Initial	Sketch$_1$	...	Sketch$_n$	Final
Policy Consistency	0.75	0.96	...	0.88	1.00
Load Measurement	0.41	0.47	...	0.59	0.28
Traffic Shift	0.02	0.1	...	0.03	0.01

Figure 3: Illustration of configuration update progress.

protocols[35]. Based on different implementation methods, existing approaches can be divided into two categories, including supervised learning [7, 15, 24, 46] and satisfiability modulo theories (SMT) [1, 9, 10]. Original network configuration reflects how traffic forwards, while traffic format can guide optimization. However, both supervised learning and SMT approaches disregard existing configuration parameters and lack the ability to perceive network traffic. More importantly, these methods produce static configurations that cannot adapt to long-term dynamic network, as they lack the ability to interact with and respond to changing dynamic network.

3 NetKeeper in a Nutshell

We begin with a runtime workflow shown in Fig. 2 and demonstrate how *NetKeeper* processes multimodal intents to update network configurations and optimize performance.

First, for the Intent Translation module (§4), *NetKeeper* integrates northbound and southbound interfaces to process natural language intents from operators and anomaly logs from the operation and maintenance platform. These intents are translated into DSL, ensuring their alignment and unification. User feedback and parameter validation further refine the intents through the intent verification, enhancing their accuracy and ensuring the reliability of the LLM used for translation.

The LLM then utilizes the DSL to trigger appropriate APIs, enabling a variety of network updates such as basic configuration changes, topology adjustments, policy modifications, and congestion mitigation. Predefined APIs operate on network configuration files or network sketches [15], where direct edits—e.g., changing IP addresses, link weights, or OSPF metrics—are tailored for predefined operator plans, facilitating quick responses to specific intents.

For global configuration changes, such as network-wide topology revisions or policy optimization, the system first updates the network sketch before applying changes to global configurations. These complex updates employ a multi-agent deep reinforcement learning (MADRL) model [45] described in §5, which optimizes configuration changes based on categorized parameters.

As illustrated in Fig. 3, we design three specialized agents, each responsible for specific parameter categories. These agents interact with the network environment, iteratively generating new configurations. The system evaluates key metrics—policy consistency, load measurement, and traffic shifts—based on real-time traffic matrices and network states. Feedback in the form of rewards guides agents to produce configurations with improved alignment to policies, enhance load measurement, and minimal traffic shift. This iterative process ensures configurations are optimized for both operational goals and network polices.

Table 1: Examples of network intent.

#	Natural language intent
1	Configure IP address 127.39.236.169 and subnet mask 255.255.255.248 for the Ethernet34 port of R55.
2	Set the OSPF Hello packet interval on R5 to 20 ms.
3	Configure access control for R45's own traffic, performing a deny operation on traffic from R19.
4	Remove R6 from the global network.
5	Adjust port weights to form a route from R2 to R8, avoiding R6 and R1 while including the routing nodes R5 and R3.
#	Network anomaly log
6	R1%LINK-3-UPDOWN: Interface Fe 0/9 change state to down.
7	HOST_X%Node down: ping timeout (0 / 5).
8	R1%LINK-3-CONGESTION: Interface Gi1/0/1 output queue full, packets dropped: 1532.

4 Intent Translation

Intent translation is the critical process of transforming high-level network intents into actionable configurations. This involves three key stages: semantic alignment, validation through DSL abstraction and execution with APIs. This workflow ensures that diverse inputs converge into a unified representation, are rigorously validated for correctness and completeness, and are reliably converted into operational network updates.

4.1 Intent Alignment

In enterprise network environments, understanding and managing network intents is essential for maintaining operational efficiency. These intents can originate from two primary sources : user-driven natural language inputs and system-generated anomaly logs. Natural language intents reflect high-level objectives, such as "`optimize traffic for critical applications`," while anomaly logs highlight internal system issues, such as "`link congestion on Router B, Interface C.`" Both forms of intent are critical yet inherently different: natural language provides proactive, surface-level goals, whereas logs deliver reactive, diagnostic insights. Addressing complex and dynamic network scenarios requires a consistent approach that integrates these two types of intent into a unified model.

To achieve this, we propose a structured and formalized intent description as a unified method to represent the semantic domain of network intents. This model serves several purposes: it aligns diverse intent representations, bridges the gap between high-level goals and low-level configurations, and provides clear semantic boundaries for translating intents. Furthermore, it establishes a theoretical foundation for the subsequent design of DSL in §4.2, enabling precise and verifiable intent-to-configuration translation.

We formalize this intent description as $IT = \{ND, NP, PO, NR, AT, FP\}$. The components of IT are defined as follows: ND represents network devices such as routers and switches. NP denotes network protocols like Open Shortest Path First Protocol (OSPF) [29] and Border Gateway Protocol (BGP) [32]. PO stands for protocol options, for instance, the OSPF Hello interval. NR refers to network rules, including Access Control Lists (ACL) [33]. AT signifies attributes such as interface IP addresses. Finally, FP represents forwarding policies, which include path selection policies. It's important to note that a specific intent may not necessarily include all elements of this description. For example, intents 1 and 6 in Table 1 can be represented as $IT = \{ND : R55, AT : \{interface : Ethernet34, ip_address : 127.39.236.169, subnet_mask : 255.255.255.248\}\}$ and $IT = \{ND : R1, AT : \{interface : FastEthernet0/9, state : down\}\}$ respectively.

Table 1 presents a series of network intents, encompassing both natural language intents and network anomaly logs, all of which fall within the scope of IT. For operators with varying levels of network expertise, from novices to experts, they can input intents ranging from high-level goals to precise configuration parameters, which include: (1) Port IP allocation or modification. (2) Specific parameter specifications for routing protocols including OSPF and BGP. (3) Addition, removal, or modification of ACL entries. (4) Changes to physical topology including device or link alterations. (5) Specific routing polices. Meanwhile, we process various types of network anomaly logs, including device malfunction and network congestion logs, collected from network management systems [18] to guarantee business continuity and maintain network performance, including: (6) Link failures. (7) Device node failures. (8) Link congestion or underutilization.

4.2 Intent Verification

While IT provides a structured and unified model to describe network intents, it focuses on static representations and lacks the mechanisms for direct validation or feedback. We design a DSL as an abstraction layer between network intents and low-level network configurations, building on the semantic framework provided by IT.

The DSL adopts a syntax inspired by interpretive languages, enabling it to support both the definition and execution of network intents. As shown in Fig. 2②, each DSL intent starts with a context declaration, followed by a sequence of operations and parameters. The DSL operationalizes IT by transform-

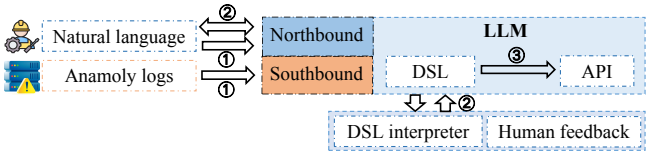

Figure 4: The process of intent translation.

ing elements like *ND*, *NR*, and *FP* into actionable operations. These operations cover a wide range of network tasks, including device configuration, ACL rules, OSPF and BGP settings, topology adjustments, link load optimization, and forwarding policies, part of them are shown in Table 2.

LLM excels at understanding the semantic nuances of natural language inputs, making them a powerful tool for converting high-level operator intentions into structured DSL representations while preserving the intent's original meaning. To facilitate the mapping of unstructured intents into operations in DSL, we utilize LLM fine-tuned with P-tuning [26], a parameter-efficient approach for adapting pre-trained models to downstream tasks. However, LLM suffer from the hallucination problem and cannot guarantee the accuracy of the translation. To further validate and ensure the correctness of generated DSL intents, we introduce a dedicated DSL interpreter. The interpreter checks the syntax correctness, verifies the completeness of parameters, and identifies any logical inconsistencies in the DSL representation.

In addition, LLM plays a key role in incorporating feedback during the translation process. Errors from the compiler are described in natural language and fed back to the user through the LLM, so that the user can further provide feedback to correct missing or incorrect parameters. For example, when a network intent involves an invalid device, such as: `"I want to add a router A1 connected to R2"`, the DSL interpreter would provide feedback: `"A1 is not a valid device in the network. Please provide a device from [R1, R2, ...]."` The system then passes this feedback to the user via LLM, allowing for adjustments to the intent. This bidirectional feedback loop ensures an accurate and iterative translation process between high-level intent and DSL. By combining the reasoning flexibility of the LLM with the robustness of DSL's static validation models, this hybrid approach guarantees both the expressiveness and reliability required for intent translation.

4.3 Intent Execution

While LLM excels in nature language processing tasks, they lack both the specialized knowledge [43] and robust reasoning capabilities required for network updating. Network configuration updates require protocol expertise, device-specific knowledge, and system-wide impact analysis. By utilizing pre-defined APIs, we compensate for these limitations, allowing us to combine the flexibility of LLM in understanding intent with the reliability of well-tested, domain-specific APIs.

We deploy the fine-tuned LLM within the LangChain [41] framework, with a series of APIs established for the LLM to call, enabling it to execute configuration updates. The APIs accept parameters in DSL as input to perform configuration update. Internally, they update configuration either by directly modifying device configurations or by utilizing the configuration update model described in §5.

Table 3: Parameters of OSPF, link attributes and BGP.

Description	Parameter	Description	Parameter
OSPF weight	α	Local preference (LP)	γ_1
Bandwidth	β_1	AS path length (AS)	γ_2
Capacity	β_2	Multi-exit discriminator (MED)	γ_3
Queue length	β_3		

The Fig. 4 illustrates a complete intent translation process: ① The LLM receives the operator's natural language intent through northbound interface or the platform's anomaly logs via southbound interface. ② The LLM translates this input into DSL and refines it through feedback from humans and logs generated by the DSL interpreter. ③ Once the DSL is validated, the LLM invokes the corresponding API to update the network configuration. Otherwise, if the DSL fails validation, no action is performed.

5 Configuration Update

As the final step of *NetKeeper*, the internal operation of these APIs determines how effectively the network adapts to dynamic conditions. To enhance adaptability, we leverage Deep Reinforcement Learning (DRL) [2] within the API execution layer, enabling configuration updates that dynamically optimize network performance while maintaining alignment with network intents.

5.1 Task Description and Goals

Traditional network configuration updates are mainly based on the adjustment of static network protocol parameters to meet forwarding policies, which leads to limited consideration of configuration parameters, a lack of adaptation to dynamic network traffic patterns, and low flexibility. Meanwhile, the configuration update process often ignores the original network state, including policy satisfaction, network performance, etc., fails to effectively utilize existing configuration information for synthesizing and optimizing new configurations, and does not fully consider changes in forwarding behaviors and traffic patterns before and after the update, which can easily result in network instability after the update.

To address these limitations, we need to consider three new factors: (1) link attributes, such as bandwidth, which impact network performance. (2) traffic patterns, including traffic matrix, enabling more targeted configuration optimization. (3) changes in the forwarding plane before and after updates. By leveraging these additional factors, we aim to achieve two main objectives: (1) Optimize network performance and comply with policies by adjusting parameters of BGP, OSPF and link attributes listed in Table 3. (2) Dynamically adjust net-

work configuration based on network environment, enhancing network resilience.

To address these requirements, we seek a solution that can incorporate diverse network attributes, capture dynamic traffic patterns, and adjust to evolving network conditions. DRL [2] naturally fits this need: it is able to learn from real-time environment feedback [25] and optimize decisions toward explicit objectives [28]. With DRL, we can automatically synthesize new configurations adaptive to both the current network state and traffic changes, thus improving performance and stability. Consequently, DRL is well-suited for our task.

We define a series of goals to leverage these capabilities for configuration update:

1. Policy Consistency π: Considering efficient service delivery, secure data transmission, and reliable business continuity, we adopt three kinds of policies (A, B and C can be router, autonomous system or sub-network) : (1) `forward(A, B, C)`: Traffic from A to B must be forwarded to its neighbor C. (2) `reachable(A, B, C)`: Traffic from A to B must pass by C. (3) `isolation(A, B, C, D)`: One of `forward(A, B, C)` or `forward(A, B, D)` must be true at the same time.

Policy consistency defined in Eq. 1 characterizes the degree of satisfaction of forwarding policies. Here, P represents the set of forwarding policies, where p_i denotes an individual policy in P. $Satisfy(p_i)$ is a function that returns 1 if policy p_i is satisfied, and 0 otherwise.

$$\pi = \frac{\sum_{p_i \in P} Satisfy(p_i)}{|P|}. \tag{1}$$

2. Load Measurement ρ: Changes in traffic patterns or routing decisions can disrupt load distribution, causing congestion and degraded service quality. Link utilization is a key metric to measure global load, and minimizing the maximum link utilization helps balance traffic, prevent bottlenecks, and improve overall network performance.

For calculation of ρ, we extend the network performance metrics designed in [38], including bandwidth, capacity, link utilization, queue length and lose rate. We use various network information as input, including the network topology $G = (N, M_{Arc})$, where N is the set of nodes and M_{Arc} is an adjacency matrix describing the network topology, as well as the link weight matrix M_W, traffic matrix M_T, bandwidth matrix M_B, capacity matrix M_C, queue length matrix M_Q, lose rate matrix M_{Lose}, and queue packet size q_s.

We first initialize the link loads ld and maximum link utilization U_{max}. For each traffic class with destination dst, we follow these steps:

1) Calculate the shortest distance d_u^{dst} from each node $u \in N$ to dst.
2) Identify shortest-path node pairs (u,v) to dst where $M_{Arc(u,v)}^{dst} = 1$ indicates traffic from u reaches dst via v:

$$M_{Arc}^{dst} = \{(u,v) \in M_{Arc} : d_u^{dst} - d_v^{dst} = M_{W(u,v)}\}. \tag{2}$$

3) Calculate δ_u^{dst}, the number of next-hop nodes on shortest paths from u to dst, to determine the Equal-Cost Multi-Path (ECMP) [16] options for each node:

$$\delta_u^{dst} = |v \in N : (u,v) \in M_{Arc}^{dst}|. \tag{3}$$

4) Calculate the actual traffic load $ld_{(v,w)}^{dst}$ on link (v,w) towards destination dst, where link capacity, bandwidth, and queue length impose upper limits, while also considering upstream traffic accumulation, ECMP load balancing, and packet loss:

$$ld_{(v,w)}^{dst} = \min(M_{B(v,w)}, M_{C(v,w)}, M_{Q(v,w)} \cdot q_s, \sum_{(u,v) \in M_{Arc}^{dst}} \frac{1}{\delta_u^{dst}} \cdot (d_v^{dst} + (1 - M_{Lose(u,w)}) \cdot ld_{(u,w)}^{dst})). \tag{4}$$

After processing all traffic classes, we aggregate these values to determine the total load on each link $(v,w) \in M_{Arc}$:

$$ld_{(v,w)} = \sum_{dst \in N} ld_{(v,w)}^{dst}. \tag{5}$$

Finally, we compute the utilization for each link $(v,w) \in M_{Arc}$ and update the maximum utilization:

$$M_{U(v,w)} = ld_{(v,w)} / M_{C(v,w)}, \tag{6}$$

$$U_{max} = \max(M_{U(v,w)}, U_{max}). \tag{7}$$

3. Traffic Shift τ: Changes in protocol configuration parameters can affect the forwarding plane of the entire network, causing changes in device routing tables, which bring traffic shifts. Traffic shift can lead to increased latency, load imbalance, and inconsistent performance, thereby impacting network quality [23]. We consider the degree of traffic shift introduced by the new configuration, which we define as Eq. 8.

$$\tau = \frac{1}{|ND| \cdot |PF|} \sum_{nd \in ND} \sum_{pf \in PF} \begin{cases} 1, & \text{if } nh_{t-1}(nd, pf) \neq nh_t(nd, pf), \\ 0, & \text{otherwise.} \end{cases} \tag{8}$$

Here, ND and PF represent all network devices and reachable network prefixes, respectively. $|ND| \cdot |PF|$ is the total routing table entries. The function $nh_t(nd, pf)$ denotes the next hop from device nd to prefix pf at timestep t. The traffic shift cost increments by 1 for each entry where $nh_{t-1}(nd, pf) \neq nh_t(nd, pf)$, indicating a change in routing. Higher traffic shift causes more severe mismatches between network resources and traffic demands, leading to overload in some areas and underutilization in others.

5.2 Agents Setup

In §5.1, we define the configuration update task, which requires updating three types of parameters from Table 3. This categorization is based on their distinct roles and functions in the network: BGP parameters manage inter-domain routing policies and path selection, OSPF parameters handle intra-domain routing and path calculation, while link attributes reflect physical characteristics and determine traffic-carrying capacity. We set parameter ranges to reflect generalized resource constraints inherent in real-world networks, capturing the limitations typically encountered during configuration updates.

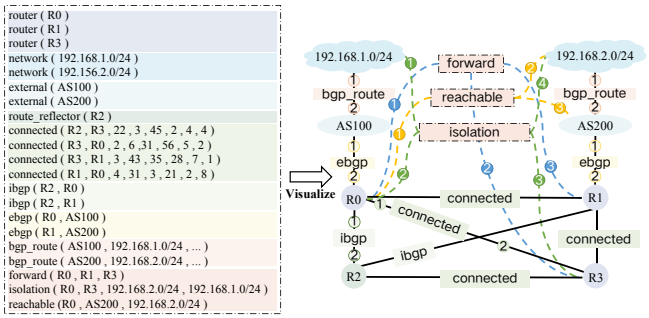

Figure 5: An example of network sketch.

For single-agent approach, configuration update task presents significant challenges due to its vast solution space, complex parameter interactions, and the need for specialized knowledge across different network domains (BGP, OSPF, and link attributes). To address these challenges, we employ a multi-agent for configuration update. This approach divides the complex task among multiple agents, each specializing in a specific parameter type, thereby reducing solution space complexity, enabling domain-specific optimization, and promoting inter-agent collaboration.

Hence, we employ three agents for configuration update: (1) A_{OSPF}: responsible for OSPF configuration update. (2) A_{BGP}: responsible for BGP configuration update. (3) A_{perf}: responsible for link attributes update. We define the set of agents as I, which contains three types of agent.

5.3 Environment Model

1. State Space S: We define the state $s \in S$ as the network sketch introduced in [15]. Fig. 5 illustrates a network sketch abstracting network information and forwarding policies as nodes with attributes. The sketch is visualized using different colors to represent various node types and connections between nodes.

Based on the network sketch, we encode the node features and connection relationships to obtain the state $s = (V, E)$, representing the network configuration. Here, $V = \{v_1, ..., v_n\}$ is the set of nodes, such as router, ibgp and isolation, where each $v_i = [f_{i,0}, \ldots, f_{i,19}]$ represents a node with its features. The edge information $E = (E_{adj}, E_{type}, E_{pos})$ consists of three components. $E_{adj} \in \mathbb{R}^{2\times m}$ is the adjacency matrix with m edges, where each column $[src_i, dst_i]$ represents an edge. $E_{type} = \{E_{type,1}, ..., E_{type,m}\}$ denotes edge types. $E_{pos} = \{E_{pos,1}, ..., E_{pos,m}\}$ indicates edge ordering information. For example, the *ibgp* node in Fig. 5 is represented as $ibgp(R2, R1)$ in the sketch. It connects to both $R1$ and $R2$ nodes, thus establishing two links numbered 1 and 2.

2. Action Space A: We define the action as $a_{i,k} = [f_{0,k}, \ldots, f_{n,k}]^T$, where k represents parameters in Table 3, n represents node number and i represents agent. Based on the agent setup in Section 5.1, different agents generate specific actions: A_{OSPF} produces $a_{OSPF,\alpha}$, A_{BGP} generates a_{BGP,γ_1}, a_{BGP,γ_2}, and a_{BGP,γ_3}, while A_{perf} creates a_{perf,β_1}, a_{perf,β_2}, and a_{perf,β_3}. These actions are combined into a joint action a. Subsequently, Alg. 1 is employed to update the current state s using this joint action, generating a new state s' by replacing the corresponding parameter k in s (lines 3 to 5).

3. Reward Function R: To output a configuration that satisfies policies and enhances network resilience, we need to guide the agents towards higher π with lower ρ and τ by designing reward functions R_s for policy consistency (Eq. 9) and network resilience R_d (Eq. 12), where τ and ρ jointly affect the latter. Agents receive larger rewards as π increases, while ρ and τ decrease. In addition, policy satisfaction is treated as the highest-priority objective, as it directly impacts the correctness of network operation, whereas load measurement and traffic shift are secondary goals to be optimized as much as possible. To enforce this prioritization, we introduce dynamic rewards (Eq. 10 and Eq. 11) in the design.

$$R(s,a)_{pol} = K \cdot \pi + R_s + R_d, \tag{9}$$

$$R_s = \begin{cases} 0, & \text{if } t = 0 \text{ or } a_t \neq a_{t-1}, \\ R_s - 1, & \text{if } a_t = a_{t-1}, \end{cases} \tag{10}$$

$$R_d = \begin{cases} 0, & \text{if } t = 0, \\ \sum_{p_i \in P}(Satisfy(p_i)_t - Satisfy(p_i)_{t-1}), & \text{if } t > 0. \end{cases} \tag{11}$$

$$R(s,a)_{res} = K \cdot ((1-\rho) + (1-\tau)). \tag{12}$$

Eq. 9 combines rewards for policy consistency with stationary and dynamic rewards to enhance the model's perception of action impacts on the state. The stationary reward R_s (Eq. 10) penalizes consecutive repetitions of the same action to prevent the agent from getting stuck in local optima. At timestep t, R_s resets to 0 when $t = 0$ or $a_t \neq a_{t-1}$; otherwise, decreasing by a fixed amount. The dynamic reward R_d (Eq. 11) encourages exploration of new configurations to meet previously unmet policies while preserving currently satisfied ones. Negative rewards are applied when previously satisfied policies become unsatisfied, balancing exploration and policy adherence. Given that R_S and R_d are integers while π, ρ, and τ are decimals not exceeding 1, a postive constant K is set to align the reward magnitudes.

Different agents use varied reward function combinations based on their specific tasks:

$$R(s,a)_{A_{OSPF}} = R(s,a)_{pol} + R(s,a)_{perf}, \tag{13}$$

$$R(s,a)_{A_{BGP}} = R(s,a)_{pol}, \tag{14}$$

$$R(s,a)_{A_{perf}} = R(s,a)_{perf}. \tag{15}$$

In Eq. 13, because OSPF weight impacts on traffic forwarding, affects both policy consistency and network performance, we combine two reward types. Due to the parameters generated by A_{BGP} and A_{OSPF} affect policy consistency and network performance respectively, their reward function values each include one component.

To enable agents to perceive traffic patterns and optimize network configuration, we provide a traffic matrix M_T, where

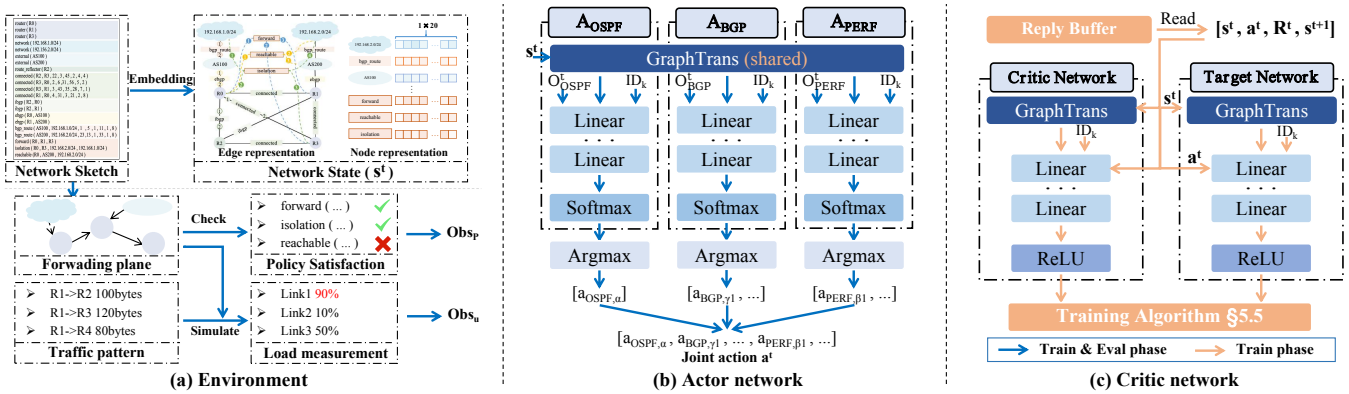

Figure 6: Architecture of configuration update model.

Algorithm 1: State Update Process

Input: Current state $s = (V, E)$, Joint action a
Output: New state s'

Initialize s' as a copy of s;
for *each action* $a_{i,k} \in a$ **do**
  $i_k \leftarrow$ index corresponding to parameter type k;
  for *each node* j *in* V' **do**
    $V'_j[i_k] \leftarrow a_{i,k[j]}$;
  end
end
return $s' = (V', E)$;

$M_{T(i,j)}$ records the traffic from $node_i$ to $node_j$. Agents can obtain observation information through the environment shown in Fig.6 (a), including policy satisfaction status and the utilization of links. Policy satisfaction is defined as a vector $Obs_p = [Satisfy(p_1), \ldots, Satisfy(p_i), \ldots, Satisfy(p_n)]$, where n is the number of polices. p_i is validated by computing its forwarding plane from the network configuration, which reveals how traffic is routed and whether the policies are correctly enforced. Link utilization is defined as a vector $Obs_u = [u_1, \ldots, u_m]$, where m is the number of links, and u_i reflects the utilization of the i-th link, indicating the congestion level of links. Each u_i is computed through Eq.2 - Eq.7.

5.4 Model Architecture

In our network, multiple agents update different parameters based on network information. Their collective decisions affect configurations, complicating individual contribution assessment. We employ an Actor-Critic (AC) [22] network with a centralized critic and decentralized actors. This balances efficient local decision-making by actors with global performance optimization by the critic. The overall architecture of the configuration update model is shown in Fig. 6, comprising actor networks corresponding to the agents, critic network and network environment.

The actor network generates actions based on the current state, implementing the agent's policy. It is designed as encoder-decoder architecture, where all agents share a common network sketch encoder $ENC_{network}$ in the lower layer to acquire the same network information, implemented using Graph Transformer (GraphTrans) [44]. The decision network $DEC_{LIN,i}$ of each agent i consists of L_{DEC} linear layers. Due to varied tasks, agents receive different observations, resulting in different input dimensions for their decision networks. Specifically, $O_{OSPF} = [Obs_p, Obs_u]$, $O_{BGP} = [Obs_p]$, and $O_{perf} = [Obs_u]$, where O_i represents the observation list for agent $i \in I$.

$$x_i = ENC_{network}(s^t), \tag{16}$$

$$x'_{i,k} = [x_i \| O_i \| ID_k], \tag{17}$$

$$h_{i,k} = \text{softmax}(DEC_{LIN,i}(x'_{i,k})), \tag{18}$$

$$a^t_{i,k} = \arg\max(h_{i,k}). \tag{19}$$

To obtain $a^t_{k,i}$, the action for parameter k generated by agent i at timestep t, as described in Eq. 16, we first embed the state s^t at timestep t using $ENC_{network}$. Then, the embedding x_i, along with the environment's observation O_i and the index of parameter ID_k, are merged through Eq. 17. ID_k represents the parameter generation ID where $k \in \{\alpha, \beta_1, \beta_2, \beta_3, \gamma_1, \gamma_2, \gamma_3\}$. The action probability distribution of k, denoted as $h_{i,k}$, is predicted through $DEC_{LIN,i}$ and softmax using Eq. 18. Finally, the action $a^t_{i,k}$ is obtained via arg max through Eq. 19.

$$y_i = ENC_{network}(s^t), \tag{20}$$

$$y'_{i,k} = [y_i \| a^{t-1}_{i,k} \| a^t_{i,k} \| ID_i], \tag{21}$$

$$Q(s^t, a^t_{i,k}) = \text{ReLU}(DEC_{LIN}(y'_{i,k})). \tag{22}$$

Critic network is used to evaluate the quality of the actor's decisions. The critic network has a similar architecture to the actor network. It ultimately needs to output a Q-value; we replace softmax and argmax with $ReLU$. The critic is only used during the training phase. To obtain $Q(s^t, a^t_{i,k})$, representing the estimated value of agent i taking action $a^t_{i,k}$ for parameter k in state s^t at timestep t, similarly to Eq. 16, state s^t is encoded using Eq. 20. We merge the encoding y_i with the agent ID ID_i, the current timestep's action $a^t_{i,k}$, and the previous timestep's action $a^{t-1}_{i,k}$ in Eq. 21 as input to predict $Q(s^t, a^t_{i,k})$ through Eq. 22.

5.5 Training Algorithm

The relationship between actions and rewards is often obscure, and the combination of actions influences the final outcome, necessitating careful consideration of each action's contribution. This makes training multiple agents particularly challenging, especially in credit assignment and decision-making under partial observability. We choose the counterfactual multi-agent (COMA) algorithm [11], which adopts the same architecture in §5.4. This approach allows for more accurate evaluation of each agent's contribution and informed decision-making with limited local information.

The training algorithm takes a network sketch s with n nodes and traffic matrix M_T as inputs. We initialize the actor network θ^{μ}, critic network θ^{Q}, target network $\theta^{Q'}$ (the latter two for improving training stability [14]), replay buffer B, agent mask M_k, and other parameters. We set EP training episodes, each ending when π reaches 1 or after TM timesteps.

In each episode, we initialize the environment and obtain state s^0. For each timestep t, We use the actor network θ^{μ} to select actions a^t for all agents, employing a decaying ε-greedy strategy. This strategy balances exploration (random strategy) and exploitation (learned policy) over time. We then execute these actions through Alg. 1 to obtain the new state s^{t+1}. We calculate the reward value R^t using Eq. 9 and Eq. 12 , and store the historical experience (s^t, a^t, R^t, s^{t+1}) in B.

We begin the training process when the data in B exceeds one entry. First, we use the target network $\theta^{Q'}$ to calculate the target Q-values $Q(s^t, a^t_{i,k})$ through Eq. 20 to Eq. 22. Subsequently, we compute the baseline $baseline_{i,k}$ and advantage $Advantage_{i,k}$. $baseline_{i,k}$ represents the average expected value of all possible actions for a given agent i and parameter k, calculated as the dot product of the action probability distribution $h_{i,k}$ and $Q(s^t, a^t_{i,k})$ in Eq.23. $Advantage_{i,k}$ measures how much better the chosen action is compared to $baseline$, computed by subtracting the $baseline_{i,k}$ from the Q-value of the selected action in Eq. 25. For nodes that do not include the parameter k, we set the advantage value to 0 through M_k.

$$baseline_{i,k} = h_{i,k} \cdot Q(s^t, a^t_{i,k}), \tag{23}$$

$$Q'(s^t, a^t_{i,k}) = \{Q(s^t, a^t_{i,k})_{j,\arg\max z} \mid j \in \{1, \ldots, n\}, z \in h_{i,k}\}, \tag{24}$$

$$Advantage_{i,k} = (Q'(s^t, a^t_{i,k}) - baseline_{i,k}) \odot M_k. \tag{25}$$

Finally, we calculate the actor network's loss, followed by backpropagation. Eq. 26 selects the most probable actions $h'_{i,k}$ from the original distribution $h_{i,k}$. Eq. 27 then computes the loss by averaging the product of advantage and log probability of these selected actions. This process aims to increase the likelihood of advantageous actions.

$$h'_{i,k} = \{z_{j,\arg\max z} \mid j \in \{1, \ldots, n\}, z \in h_{i,k}\}, \tag{26}$$

$$Loss_{Actor} = -\frac{1}{n} \sum_{j=1}^{n} Advantage_{i,k} \cdot \log(h'_{i,k}). \tag{27}$$

The critic network is updated to estimate Q-values, representing expected future rewards. This process begins with constructing inputs for each timestep using Eq. 20 to Eq. 22. Subsequently, Q-values $Q'(S^{t'}, a^{t'}_i)$ are calculated using the evaluation critic network θ^{μ}. These Q-values, along with corresponding rewards, are then selected based on action probabilities h_j using Eq. 28 and Eq. 29. Finally, masks are applied to the selected Q-values through Eq. 30.

$$Q'(s^{t'}, a^{t'}_{i,k}) = \left\{Q(s^{t'}, a^{t'}_{i,k})_{j,\arg\max z} \mid z \in h_{i,k}, j \in \{1, \ldots, n\}\right\}, \tag{28}$$

$$R^{t'} = \left\{R^{t'}_{j,\arg\max z} \mid z \in h_{i,k}, j \in \{1, \ldots, n\}\right\}, \tag{29}$$

$$Q'_M(s^{t'}, a^{t'}_{i,k}) = Q'(s^{t'}, a^{t'}_{i,k}) \odot M_k. \tag{30}$$

We use the $TD(\lambda)$ algorithm for learning updates, as shown in Eq. 31, which calculates the target value $r^{t'}$ for the critic network. If the episode ends, $r^{t'}$ equals the immediate reward $R^{t'}$. Otherwise, it combines the current Q-value with a correction term. This term includes the immediate reward $R^{t'+1}$, discounted future Q-value $\gamma \cdot Q'(s^{t'+1}, a^{t'}_{i,k})$, and current Q-value $Q'(s^{t'}, a^{t'}_{i,k})$. The equation uses lr_c and discount rate γ to balance current and future rewards.

$$r^{t'} = \begin{cases} R^{t'}, & \text{if } done, \\ Q'_M(s^{t'}, a^{t'}_{i,k}) + lr_c \cdot (R^{t'+1} & \\ \quad + \gamma \cdot Q'_M(s^{t'+1}, a^{t'}_{i,k}) - Q'_M(s^{t'}, a^{t'}_{i,k})), & \text{otherwise.} \end{cases} \tag{31}$$

We calculate $Loss_{Critic}$ using MSE between predicted $Q'_M(s^{t'}, a^{t'}_i)$ and target rt' values in Eq. 32, then backpropagate to update θ^{Q}.

$$Loss_{Critic} = \frac{1}{n} \sum_{j=1}^{n} \left(Q'_M(s^{t'}, a^{t'}_{i,k})_j - r^{t'}_j\right)^2. \tag{32}$$

We update the target critic network $\theta^{Q'}$ with the parameters of the evaluation critic network θ^{Q} at fixed intervals.

6 Evaluation

6.1 Setup

Dataset. We build two datasets: A network intent dataset and a network sketch dataset. The network intent dataset includes natural language intents, both manually written and template-generated, as well as anomaly logs collected from network maintenance platform and template-generated. Both contain mappings from network intents to DSL to API calls. The dataset size is 11,000, with a 7:4 ratio of intents to anomalies, and a 10:1 ratio of training to test data. The network sketch dataset is based on Topology Zoo [21] and comprises 258 real-world network topologies. These topologies are categorized into three groups: *small (S)* with 18–30 nodes, *medium (M)* with 30–56 nodes, and *large (L)* with 56–170 nodes, with 8 representative topologies sampled from each group. To further characterize task complexity, we generate three subsets based on the number of forwarding policies: 3×2, 3×8, and 3×16 with a total number of 1,024.

Environment for DRL. We use a Python-based network simulation environment for both online training of the agent and evaluation of *NetKeeper*. The environment incorporates

Table 4: Parameters in COMA algorithm.

Parameter	Value
Episodes (EP)	10
Timestep (TM)	200
Replay Buffer Size	100
Batch Size	16
Discount Factor (γ)	0.85
Initial Exploration Rate	1.0 (decaying)
Final Exploration Rate	0.01
Exploration Decay Rate	0.99 per timestep
Soft Target Update Interval	16 timestep
K in reward function	10
Disobey reward in reward function	-1

Table 5: Parameters of network.

Parameter	Value	Parameter	Value
OSPF weight (α)	[1, 64]	Local preference (γ_1)	[1, 64]

variations in topology size, routing protocol configurations (OSPF/BGP), forwarding policies, and traffic patterns, enabling the agent to adapt to diverse network scenarios. For testing, the agent is evaluated on fixed subsets of the network sketch dataset, ensuring consistent performance evaluation across varying topology sizes and policy complexities.

Testing Platform and Experiment Parameter. All experiments are performed on a machine equipped with an NVIDIA GeForce RTX 3090 GPU with 24GB VRAM, 64GB RAM, and a 13th Gen Intel Core i9-13900K processor. To ensure the fairness of our experiments, all experiments are conducted using the same seed. We fine-tuned the ChatGLM3-6B[13] through P-tuning using Adam [19] optimizer with a learning rate of 0.02 for 400 steps and deployed it within the LangChain. Other hyperparameters remained unchanged from the default settings. The Actor-Critic network is trained using COMA algorithm. The actor and critic networks share identical structures: an encoder $ENC_{GraphTrans}$ with 8 graph convolutional network (GCN) [20] and 8 transformer [42] layers, and a decoder DEC_{LIN} with 4 linear layers. All layers have a hidden dimension of 128. We use Adam optimizer with learning rates of 0.0001 and 0.0002 for actor and critic networks respectively. Other hyperparameters are listed in Table 4 and network parameter settings are listed in Table 5.

Metrics and Comparisons. We evaluate *NetKeeper* based on intent translation accuracy, configuration quality, load measurement, traffic shift, and adaptability to dynamic networks. Intent translation accuracy refers to the correct invocation of APIs based on natural language intents or anomaly logs. Configuration quality depends on the policy consistency (Eq.1). Load measurement is quantified by maximum link utility, using a routing simulation program described in §5.1. Traffic shift (Eq.8) evaluates the degree of traffic redistribution after configuration update. We also assess network resilience improvements through simulations of dynamic changes and anomalies. For comparison, we use three categories of baselines: SMT-based [8] methods like NetComplete [10], neural network-based methods like GAT [7], and SMT+supervised learning hybrids like NetRen [15], which integrates SMT solvers with neural network predictions, falling back on neural network's outputs when the solver fails (overtime).

Table 6: Intent translation under three different tasks with different conditions.

Task	Feedback	DSL	Precision	Recall	F1
NL2API	✗	✗	83%	79%	0.81
NL2API	✓	✗	88%	83%	0.85
NL2API	✗	✓	92%	90%	0.91
NL2API	✓	✓	94%	93%	0.93
AL2API	✗	✗	90%	88%	0.89
AL2API	✓	✗	95%	94%	0.95
AL2API	✗	✓	97%	96%	0.96
AL2API	✓	✓	100%	100%	1.00
IT2API	✓	✓	**96%**	**94%**	**0.95**

6.2 Intent Translation Accuracy

To evaluate intent translation accuracy for natural language intents (NL) and anomaly logs (AL), we measure precision, recall, and F1 scores across three tasks: `NL2API`, `AL2API`, and `IT2API` (a combined task integrating both NL and AL scenarios), under different conditions, including the presence or absence of feedback and the use of DSL as an intermediary.

Table 6 demonstrates that the introduction of DSL and feedback significantly enhances performance, achieving a precision of 96%, recall of 94%, and an F1 score of 0.95 for `IT2API`. Additionally, 58 participants were involved in the manual feedback process, with each feedback iteration averaging 2s in duration, and erroneous translations were typically resolved with only one round of feedback. Compared to the baseline (without DSL or feedback), `NL2API` exhibits notable improvements: precision increases by 11%, recall by 14%, and the F1 score by 0.12. Similarly, `AL2API` achieves a 10% boost in precision, a 12% increase in recall, and a 0.11 gain in the F1 score. These results demonstrate the critical role of DSL and feedback in enhancing both the accuracy and reliability of intent translation, improving API invocation precision, reducing errors, and supporting diverse intent types in combined tasks.

6.3 Configuration Quality

To evaluate the ability of updating network configuration, we evaluate the policy consistency and time consuming across tasks with varying complexity, including different topology scales, policy categories and policy quantities. We replicate Netcomplele (SMT), GAT and NetRen as benchmarks, following the experimental settings in work [15], and present the average policy consistency. Because SMT solving can be time-consuming on complex tasks, we set a time limit of

Table 7: Comparison of average policy consistency under tasks of varying complexity.

Task	Topology Scale	Forward				Reachable				Isolation				Overall

	L	1500+	20.71	**3.16**	4.07

1500 seconds for all methods and methods that fail to generate a valid configuration within this time are considered failures. Additionally, since *NetKeeper* uses DRL for configuration update, enhancing configuration quality through multiple timesteps and environmental interaction, We evaluate the capability by measuring average policy consistency within a limited timesteps.

Fig. 7 shows the average policy consistency achieved by *NetKeeper* within 5, 20, and 100 timesteps, with 96.2%, 98.7%, and 99.6% respectively, demonstrating a continuous improvement in consistency as timestep (average 0.4s) increases. Moreover, Table 7 demonstrates that *NetKeeper* achieves a policy consistency of 99.6%, outperforming SMT, GAT and NetRen with improvement of 1.3%, 10.4% and 1.2% respectively. Additionally, Table 8 shows that in the most complex network synthesis scenarios, NetRen achieves an average running time of 3.16 seconds with a policy consistency of 98% and a 2% configuration synthesis timeout rate. In comparison, *NetKeeper* achieves a slightly higher average running time of 4.07 seconds, but with a higher policy consistency of 99.6%, a much lower timeout rate of only 0.04%, and superior results in terms of network performance and traffic shift. Notably, *NetKeeper* can exceed NetRen's policy satisfaction rate (98%) within no more than 8 iterations (approximately 3.2 seconds), while maintaining a comparable average running time. These results suggests that *NetKeeper* exhibits superior adaptability across various network scenarios in configuration update compared to both SMT, GAT and NetRen.

6.4 Load Measurement

To test the network performance optimization capability, we evaluate load measurement by computing maximum link utility under different network scenarios with random traffic.

We set three types of network scenarios: `Ideal`: This scenario disregards negative factors, including packet loss and latency, and queue length limitations; `Normal`: This scenario considers all link attributions; `High-load`: This scenario increases the load to three times that of the normal test scenario. The design of these scenarios reflects real-world network conditions: `Ideal` represents an optimized network with minimal interference; `Normal` captures typical operational environments with realistic link attributions; `High-load` emulates peak traffic or network stress conditions. Although the traffic in this study is synthetically generated, it reflects patterns commonly observed in real-world networks.

In addition, under these scenarios, we establish 4 traffic generation ranges reflcting different traffic patterns, including 1∼2, 2∼4, 4∼8, and 8∼16. In high-load scenarios, the maximum range for a single traffic flow reaches 24 to 64. To make the model more focused on network performance optimization, we set only 3×2 network policies for all network topologies in this case. We establish three parameter modes for comparison: (1) Random, (2) OSPF default mode, and (3) NetRen. Due to the occurrence of excessively high utilization, we set maximum link utilization exceeding 1.1 as ≥ 1.1.

Comparing our method with Random, OSPF default mode, and NetRen, Table 9 shows that *NetKeeper* outperforms these three in most network performance optimization tasks. Random and OSPF default mode exceed our critical utilization threshold in most cases. Compared to NetRen, *NetKeeper* achieves average congestion mitigation of 6.3%, 3.9%, and

Table 9: Comparison of maximum link utility under three scenarios and four traffic patterns.

Topology Scale	Traffic Range (bytes)	Ideal				Normal				High-load			
		Random	OSPF	NetRen	Ours	Random	OSPF	NetRen	Ours	Random	OSPF	NetRen	Ours

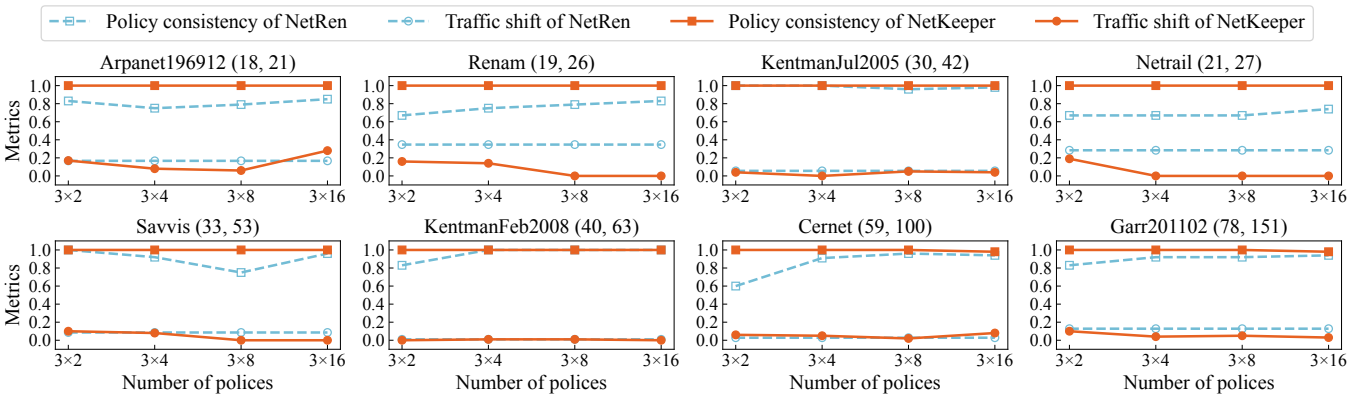

Figure 8: Traffic shift during configuration updates and policy consistency with policy count increases. Each subplot is titled with the topology name, its corresponding number of node and edge.

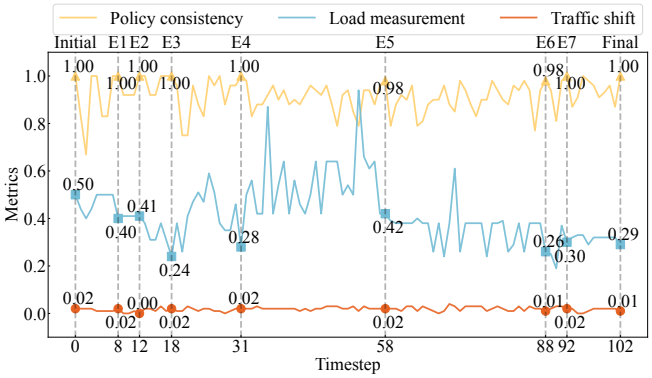

Figure 9: *NetKeeper*'s performance in dynamic network: Policy consistency, Load measurement and Traffic shift.

5.8% in the three test scenarios respectively, with maximum mitigation reaching 18.0%, 15.0%, and 26.0%, resulting in an overall network performance improvement of 5.3%. This indicates that *NetKeeper* is capable of analyzing traffic patterns and performing better network performance optimization based on the current network conditions.

6.5 Traffic Shift

To evaluate traffic shifts during the configuration update process, we sample four groups of networks with cumulatively increasing numbers of policies: 3×2, 3×4, 3×8, and 3×16. Each configuration builds upon the constraints of the previous one, generating topologies with cumulative policies. We select NetRen as the baseline.

Fig. 8 depicts traffic shift and policy consistency after configuration update. *NetKeeper* outperforms NetRen with lower average traffic shift of 5.9% versus 13.9% and higher policy consistency of 99.9% versus 85.8%. Compared to NetRen, *NetKeeper* can reduce traffic shift by an average of 8.7% and a maximum of 34.7%. *NetKeeper* significantly outperforms NetRen in network update, demonstrating superior efficiency through reduced traffic shift and higher policy consistency.

6.6 Adaptability To Dynamic Network

To evaluate *NetKeeper*'s adaptability to dynamic network, we simulate dynamic environments with three types of events reflecting challenges commonly encountered in real-world scenarios: `Physical`: Including device failures, link failures, etc; `Forwarding`: Addition or reduction of forwarding policies, thereby limiting traffic forwarding paths; `Network traffic`: Link congestion or underutilization requiring load balancing.

This experiment is conducted on the Pern network, a real-world topology with 125 nodes, 129 edges, and 3×2 policies. We simulate seven sequential events (E1-E7), with *NetKeeper* updating configurations after each. These events include policy expansions (E1-E4), link load fluctuations (E2 and E5), and component removals (E6 and E7). The changes progressively increase complexity, reduce performance, and weaken

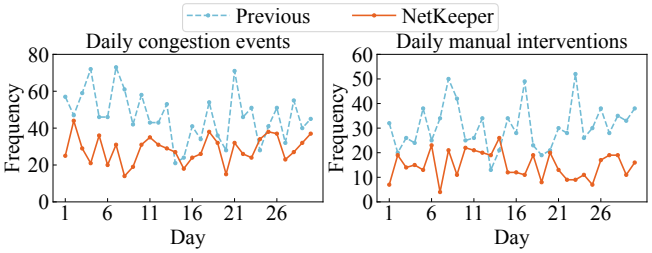

Figure 11: *NetKeeper*'s performance in production network.

connectivity. Each event concludes when consistency reaches 100% or exceeds 30 timesteps (A timestep ranges from 0.5s to 1s).

Fig. 9 shows how *NetKeeper* updates network configurations in response to different events. We observe that *NetKeeper* generally achieves full policy satisfaction alongside network optimization. However, under certain exceptional conditions, this may not hold. In E4, policy conflicts—stemming from natural language inputs that may contain inconsistencies—limit satisfaction to a maximum of 98%. In contrast, in E5, despite link load fluctuations, *NetKeeper* maintains full policy satisfaction while optimizing load distribution. In E6, device failures render associated policies inherently unsatisfiable; these are excluded from reconfiguration, and all remaining conflict-free policies are fully satisfied. This multi-faceted capability showcases *NetKeeper*'s flexibility in dynamic network. Furthermore, *NetKeeper* improves network performance while maintaining stability, demonstrating its practical value in dynamic network management.

6.7 Deployment in Production Network

To evaluate *NetKeeper*'s performance in real world, we deployed it in a large-scale enterprise network with hundreds of routers and switches. The network handles high daily traffic and supports critical applications like video conferencing and cloud services. *NetKeeper* was integrated into the existing network management system. As shown in Fig. 10, part of the deployment logs highlights the optimization of network metrics when facing network congestion.

During deployment, *NetKeeper* achieved 94.8% correct reconfigurations, with 2.1% false negatives and 3.1% false alarms, while safeguards effectively prevented cascading failures during anomaly responses. Fig. 11 illustrates a 39.4% improvement in network resilience (congestion event reduction) and a 51.5% decrease in manual interventions due to the natural language interface and automation. These enhancements enabled operators to focus on strategic tasks like network design and policy optimization, demonstrating significant improvements in network performance and operational efficiency through *NetKeeper*.

7 Limitations

NetKeeper still has limitations, which we will further address as future work.

Limited Autonomy in Policy Generation. *NetKeeper* enables network configuration updates based on operators' intent, yet still requires human involvement in strategic planning and decision-making when handling business requirement changes or network environment shifts. Specifically, network operators must provide granular policies under such dynamic conditions. Currently, the system cannot autonomously generate policy-level configurations directly from business objectives — automated policy generation adapted to specific business-network contexts remains a critical objective for our future work.

Limited Traffic Awareness for Resilience. *NetKeeper* considers traffic patterns when updating configurations to improve resilience, but its current traffic modeling is coarse-grained. It lacks fine-grained analysis of bursty flows or application-specific behaviors, limiting its adaptability to complex or rapidly changing traffic. Enhancing traffic profiling remains an important direction for future improvement.

8 Conclusion

To address the challenges of aligning network intent, optimizing networks based on traffic patterns, and adapting to dynamic network, we propose an autonomous network configuration update framework. Our framework incorporates a bidirectional north-south interface that aligns intents from user inputs and network anomalies. We design a dynamic network configuration update model based on MADRL, enhancing network resilience based on analyzing traffic patterns. *NetKeeper* effectively translates multimodal intents, enabling configuration updates through natural language interactions and facilitating network self-management and update based on anomaly logs. Furthermore, *NetKeeper* achieves a higher degree of automated configuration update, reduces manual intervention and potential human errors.

Abstract

Fail-slows, or stragglers, are common problems in large-scale hybrid-parallel training that runs on a large fleet of GPU servers for an extended period of time. Yet, these problems are not well studied. In this paper, we first present a characterization study on a shared production cluster with over 10,000 GPUs. We find that fail-slows manifest as *transient stragglers* caused by slow computations or communications due to contention, device degradation, or network congestion, lasting from sub-minutes to nearly ten hours, and delaying large training jobs by 1.34× on average. The current practice is to manually detect fail-slows and treat them as fail-stops by means of checkpoint-and-restart failover, which is time-consuming. In this paper, we propose GREYHOUND, a system that rapidly identifies slow GPUs and/or communication links, and effectively tackles them with a novel multi-level mitigation mechanism, all without human intervention. GREYHOUND correctly detects fail-slows in a production cluster with over 99% accuracy. Testbed experiment on 256 H800 GPUs further shows it effectively handles (manually injected) stragglers, improving end-to-end throughput by 1.58×.

1 Introduction

Large deep learning models have taken the industry by storm [1, 40, 42, 51, 52, 55, 62]. These large models boast unprecedented sizes, containing billions to trillions of parameters, and are trained over massive datasets in a large cluster. A typical training job often runs on tens of thousands of GPUs for weeks or even several months [1, 12, 62]. At this scale, failures become a norm rather than an exception. Therefore, developing runtime mechanisms that rapidly detect failures and efficiently tackle them is crucial to achieving high reliability in large model training.

Many of these mechanisms are developed to handle *fail-stop failures* that result in a complete halt of training [20, 26, 28, 33, 56], e.g., GPU hangs and runtime crashes. However, fail-stop alone does not cover the full spectrum of failure issues encountered in hyperscale training. Many system components, including CPUs, GPUs, and communication links, may still function but experience occasional performance degradation due to resource contention, thermal throttling, power supply, and network congestion. These failures, known as *fail-slows* or *stragglers*, do not cause a crash stoppage but significantly slow down the training progress [12, 22], as state-of-the-art large model training requires synchronization at each iteration boundary to achieve optimal model quality [50]. Despite their prevalence, fail-slow failures are hard to detect and have not been well studied. Although briefly mentioned in recent reports [12, 22], the overall characteristics of fail-slow failures in hyperscale training remain not well understood.

To shed light on this, in this paper, we first conduct a comprehensive characterization study (§3) in a *shared* production cluster comprising over 10,000 GPUs on 4,000 nodes interconnected through a RoCE network with up to 400 Gbps bandwidth. Our study reveals that fail-slows manifest as *transient failures* in both computation and communication. Specifically, *computation fail-slows* primarily result from CPU contention and GPU performance degradation due to thermal throttling or other issues (§3.2). These fail-slows occur occasionally ($< 2\%$) on individual nodes, with a short mean duration of 10 minutes. In comparison, *communication fail-slows* caused by network congestion on a communication link occur more frequently (40%) and last longer time, with a mean duration of 24 minutes. When it comes to at-scale distributed training, computation and communication fail-slows become even more prevalent, collectively causing more damage than that on small-scale training. We manually inspected large training jobs submitted in July 2024, each requiring at least 512 GPUs. Among all 27 large jobs, 16 experienced fail-slow failures, with a mean straggler duration of 72 minutes. These fail-slows delay the job completion time by an average of 1.34×.

Compared to fail-stops, fail-slows are more elusive to detect and locate [12, 22], especially when advanced *hybrid parallelism* techniques are utilized [35, 50], which combine tensor, data, pipeline, and possibly other parallelism to expedite training [13, 27]. Simply collecting hardware metrics like GPU SM utilization and RNIC's CNP (congestion notification packet) responses through telemetry offers little clue in this regard: given the synchronous nature of training, the presence of a straggler results in *simultaneous* utilization drops of *all* GPUs; likewise, a link could be shared by multiple jobs, and an RNIC's CNP response may not necessarily indicate a job-level performance issue for all. Although ad-

*Corresponding author.

vanced benchmarking tools are available [58, 65], using them to locate fail-slows requires stopping the entire training job and benchmarking all the involved GPUs and links, which is prohibitively expensive.

In this paper, we propose GREYHOUND, a system that rapidly identifies computation and communication fail-slows and reacts with effective mitigation mechanisms. GREYHOUND achieves this through two subsystems. The first subsystem, GREYHOUND-DETECT, employs a non-intrusive, framework-agnostic mechanism for fail-slow detection. It transparently tracks the training iteration time on each worker by hooking to NCCL [38] function calls and identifies prolonged iterations using the Bayesian Online Change-point Detection (BOCD) algorithm [2]. It then initiates lightweight profiling on each worker to obtain a fine-grained execution profile for each parallelization group, without interrupting the ongoing training job. By analyzing these execution profiles, it narrows the search space to a few *suspicious worker groups* where fail-slows may reside. To pinpoint their exact locations, GREYHOUND-DETECT briefly hangs the training job and runs benchmarking tests within suspicious groups to validate the GPU computation and link communication performance. Slow GPUs and links are then identified as straggling components. Notably, our detection system uniquely introduces online anomaly detection and micro-benchmarking to localize fail-slows at runtime, without disrupting training or relying on intrusive, full-job validation. This approach enables accurate, framework-agnostic diagnosis of both computation and communication stragglers at scale.

Once fail-slows are identified, GREYHOUND-MITIGATE takes over with an efficient mitigation mechanism. As fail-slows are usually transient, simply handling them as fail-stops using checkpoint-and-restart is an *overkill*. We explore the design space and identify four strategies to tackle fail-slows: (S1) ignoring them in the hope that they will soon be alleviated, (S2) resharding data parallelism to alleviate the load on slow GPUs, (S3) adjusting the parallelization topology to move congested links to light-traffic groups, and (S4) checkpoint-and-restart. As we move from S1 to S4, the mitigations become more effective, while the cost of action taking also increases. Therefore, the choice of optimal strategy depends on the duration (and severity) of the ongoing fail-slows, which cannot be known *a priori*. This problem resembles the classical *ski-rental problem* [23]. Drawing inspirations from its solution, we propose an effective online heuristic that starts with a low-cost strategy (S1) and progressively switches to a more effective, yet costly one if fail-slow persists and the current strategy proves ineffective. The mechanism falls back to job restart as a last resort. By explicitly modeling it as an online decision process and applying ski-rental theory, our system provides a principled solution for straggler mitigation. This approach systematically balances effectiveness and cost, which is not considered in previous solutions.

We have implemented GREYHOUND-DETECT as a framework-independent detection system and GREYHOUND-MITIGATE as a plugin for Megatron-LM [50]. We use GREYHOUND-DETECT as the primary tool in our characterization study to identify computation and communication fail-slows for 499 probing jobs submitted to the production cluster. Cross validation with human inspection shows that GREYHOUND-DETECT correctly diagnoses 498 jobs (99.8% accuracy), with less than 1% performance overhead. We further evaluate GREYHOUND-MITIGATE with manually injected fail-slows. It reduces the slowdown from computation fail-slows by up to 1.59× and from communication fail-slows by up to 1.23×. Experiments involving a training job on 256 H800 GPUs demonstrate that GREYHOUND accurately identifies the injected fail-slows and improves end-to-end throughput by 1.58×.

Our contributions are summarized as follows:

1. We present the first comprehensive characterization study in a production cluster to understand the overall characteristics and performance impacts of fail-slow failures in hyperscale large model training.
2. We propose GREYHOUND-DETECT, a non-intrusive, framework-agnostic detection system that identifies computation and communication fail-slows at runtime.
3. We propose GREYHOUND-MITIGATE, a system that effectively addresses fail-slow failures through a novel multi-level straggler mitigation mechanism.

2 Background

Parallelism for distributed training. Hyperscale training can require thousands of petaFLOP/s of compute power, necessitating the use of high-performance computing (HPC) clusters [12, 22, 35, 44]. These HPC clusters typically consist of tens of thousands of GPUs interconnected through high-speed fabrics such as InfiniBand [43] and RoCE [24]. To efficiently train large models on HPC clusters, various parallelism strategies have been developed to partition and distribute models across GPUs and nodes.

1) Tensor Parallelism (TP) is a technique that partitions the computation of specific operators, such as MatMul or Attention, along non-batch axes [25, 50, 63]. It enables parallel computation of each partition across multiple devices. TP often incurs significant communication costs due to the need for synchronization of each operator, and is often confined to a single node to minimize latency [22, 35].

2) Data Parallelism (DP) involves creating multiple model replicas and distributing them across multiple GPUs [35, 46, 50]. In each iteration, the global data batch is split into mini-batches, allowing each model replica to handle a portion of the data concurrently. After each iteration, the gradients from all replicas are synchronized. DP communication involves a *moderate* data transfer volume, which can occur either within a single node or across multiple nodes.

3) Pipeline parallelism (PP) partitions the model by placing different groups of layers, called *stages*, on separate

GPUs [19,35,63]. It further divides the mini-batch into micro-batches, allowing for pipelined forward and backward passes across different nodes. PP incurs the smallest communication overhead among all three strategies.

4) Hybrid parallelism. To maximize training efficiency, different parallelism strategies can be combined, allowing the model to be partitioned in multiple dimensions [12, 22, 35]. This technique, known as hybrid parallelism, have demonstrated the ability to train models with over a trillion parameters across thousands of GPUs [12, 22, 35].

Reliability issues. Given the complex nature of distributed training and the sheer scale of resources involved, large model training presents significant reliability challenges, manifested as crash stoppage (***fail-stop***) and still-functioning but slow stragglers (***fail-slow***). Both types of failures stem from software or hardware problems, and their impacts are magnified in large-scale setup: a single component experiencing fail-stop or fail-slow can crash or slow down the entire training process due to the frequent synchronization required in distributed training. Compared to fail-stops, fail-slow problems are hard to detect [12], necessitating sophisticated performance analysis tools [22, 58]. Despite brief reports from recent studies [12,22,58], the overall characteristics of fail-slows remains largely unknown, which motivates our study.

3 Characterization Study

In this section, we intend to answer the question, *how do fail-slows manifest in large model training*? We present a characterization study in a shared production cluster.

3.1 Cluster Setup and Methodology

Cluster setup. Our production cluster consists of over 4,000 nodes and more than 10,000 heterogeneous GPUs, including approximately 1,800 NVIDIA H800 GPUs and 2,600 A100 GPUs. These nodes are connected through a high-performance network employing the popular spine-leaf architecture [44]. The network offers up to $4 \times 200/400$ Gbps RoCE bandwidth for A100/H800 nodes. Within a node, GPUs are interconnected with NVLink/NVSwitch [36]. The cluster is a *shared, multi-tenant system* that runs diverse workloads, including: (1) large-scale model training jobs utilizing over 1,000 GPUs, (2) inference jobs encompassing both online inference and offline batch inference, (3) jobs for recommendation models, such as training embedding tables, and (4) short-running spot jobs for model debugging. Unless a job requests 8×GPUs per node, it may *colocate* with other jobs on the same node, e.g., embedding training collocated with inference. No GPU sharing [57] is allowed.

Methodology. As we are not allowed to instrument production workloads, we use two approaches to characterize fail-slows. (1) *Online probing with repeated sampling.* We repeatedly submitted identical small training jobs as *spot* workloads, which were *randomly scheduled* on available nodes across the cluster, often colocated with other production jobs. These

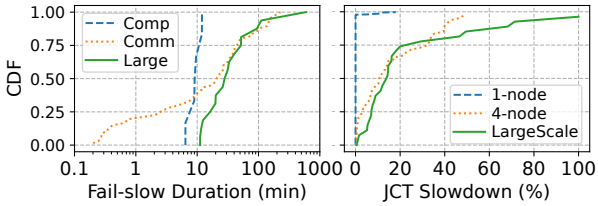

Figure 1: **Left**: CDF of fail-slow duration. **Right**: CDF of fail-slows' impact on job completion time (JCT).

Category	Online Probing		Offline Inspection
	1-Node	4-Node	At Scale ($\geq$ 512 GPUs)
No fail-slow	386	64	11
CPU Contention	4	1	0
GPU Degradation	2	0	0
Network Congestion	0	42	13
Multiple Issues	0	0	3
Total # Jobs	392	107	27
Avg. JCT Slowdown	11.79%	15.45%	34.59%

Table 1: Root causes and JCT slowdown of fail-slow issues in our characterization study.

training jobs are specially designed to act as *probes*, collecting key performance metrics to identify computation and communication fail-slows at runtime using techniques developed in §4. By submitting many of these probing jobs, we can cover a large number of nodes and links, effectively *sampling* a large portion of the cluster to characterize fail-slows at microscale (e.g., individual nodes and links). (2) *Offline inspection with collected traces.* To characterize fail-slows at macroscale, we collected a one-month trace containing numerous large training jobs, each utilizing at least 512 GPUs. We manually inspected the trace to identify fail-slows.[1]

3.2 How Do Comput. Fail-Slows Manifest?

Probing jobs. We start to characterize computation fail-slows occurred on individual nodes. We submitted 400 single-node training jobs to the cluster, of which 392 completed successfully without fail-stop errors. Each job trains a GPT2-11B model on one node using 4×H800 GPUs with a hybrid parallelism strategy of (2TP, 1DP, 2PP) to fully utilize GPU memory. The training framework used is Megatron-LM. Each job runs 10,000 iterations, taking 70 to 90 minutes. These probing jobs were scheduled to run on approximately 500 out of 1,800 H800 GPUs in our cluster (28% coverage).

Frequency and impacts. As summarized in Table 1, among 392 completed probing jobs, six experienced computation fail-slows, of which four are due to CPU contention and two are resulted from GPU performance degradation. Figure 1 (left) further shows the distribution of fail-slow duration. All computation fail-slows (blue curve) are short-lived, with an average duration of 10 minutes, extending the job completion time (JCT) by 11.79%. We next provide two case studies to better understand the root causes of these issues.

[1]We are working on open releasing the trace for public access.

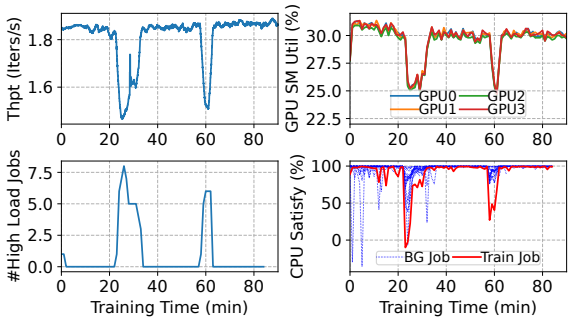

Figure 2: A case of a fail-slow job due to CPU contention. **Upper-left**: Training throughput. **Upper-right**: GPU SM utilization of the four GPUs used by this job. **Bottom-left**: The number of high-CPU jobs running on the same node. **Bottom-right**: CPU satisfaction rate of the training job (red) and other colocated background jobs (blue).

Case-1: CPU contention. As shown in Figure 2 (upper-left), the job under study experienced two fail-slows at 22 and 55 minutes, resulting in a maximum performance drop of 21.6%. Correspondingly, the job measured simultaneous declines in SM utilization across all four GPUs during fail-slow periods (upper-right), suggesting GPU slowdown. To validate this, we paused the job and conducted a matrix computation to assess GPU performance upon fail-slow detection, but found no performance degradation. Further investigation revealed a surge in the number of high-CPU jobs coinciding with the fail-slow occurrence (bottom-left), leading to a decreased CPU satisfaction rate (bottom-right), increased CPU time, and ultimately, a reduction in throughput.

Case-2: GPU performance degradation. Computation fail-slows can also be attributed to GPU performance degradation, often linked to thermal throttling. Figure 3 illustrates a case where the job under study experienced slowdown in the first 10 minutes (upper-left), during which *all four GPUs* measured low SM utilization (upper-right). Further investigation indicated that *only GPU0* was 20% slower than others (bottom-left) because of thermal throttling (bottom-right). Notably, rising temperatures do not always lead to performance issues; this may indicate a hardware problem, with an occurrence rate of about 0.5%, consistent with ByteDance's report [22].

Requirements for mitigation strategies. Given that compute fail-slows are typically transient—often resolving within tens of minutes—the overall impact on training performance is moderate. Thus, mitigation strategies must be lightweight and impose minimal overhead. Costly interventions are unsuitable, as their adjustment costs can exceed the potential performance gains, thereby negating the benefits of mitigation.

3.3 How Do Commun. Fail-Slows Manifest?

Probing jobs. To explore communication fail-slows, we submitted 120 multi-node probing jobs, of which 107 successfully completed without fail-stop. Each job utilizes 8×A100 GPUs across four nodes to train a GPT2-7B model with (2TP, 4DP, 1PP), where TP communications are over NVLink and DP communications are cross-node through a 400 Gbps RoCE link. Each job runs 10,000 iterations, taking approximately five hours. These probing jobs were distributed among 690 out of 2,600 A100 GPUs in our cluster (26.5% coverage).

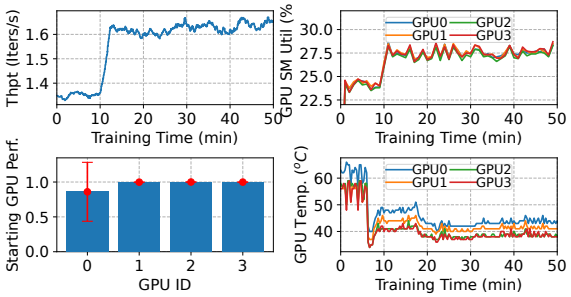

Figure 3: A case of a fail-slow job due to GPU performance degradation. **Upper-left**: Training throughput. **Upper-right**: GPU SM utilization of the four GPUs used by this job. **Bottom-left**: Normalized GPU performance during fail-slow. **Bottom-right**: NVML [39] reported GPU temperature.

Frequency and impacts. As summarized in Table 1, 43 out of 107 jobs experienced fail-slows. Among them, only one job was slowed due to CPU contention, while the other 42 encountered communication fail-slows caused by network congestion. We observed no hardware-induced fail-slows, such as issues with RNICs. Compared to computation slowdowns, communication fail-slows exhibit a wider range of duration, from sub-minutes to over 100 minutes(Figure 1, left). On average, communication fail-slow persists for about 24 minutes, delaying the average JCT by 15.45%.

Network congestion. Compared to computation slowdowns, network congestion emerges as a more significant factor contributing to performance degradation in multi-node training [12,45], with a notably higher frequency. Figure 4 presents a case study on a probing job that experienced two communication fail-slows at t=90 and t=265 minutes. The initial fail-slow resulted in throughput drop from 0.57 to 0.41 iterations/s; shortly thereafter, at t=265, the second slowdown further reduced throughput to merely 0.31 iterations/s (Figure 4, left). The two throughput drops align with the surges of congestion notification packets (CNPs) reported by the RNICs (center), indicating severe network congestion. Upon the onset of communication fail-slows, the SM utilization across *all eight GPUs* reduced simultaneously (right), despite healthy GPUs. We further investigated the spike in CNPs and discovered that other jobs were sharing the same link as our probing job, leading to throttled communication bandwidth.

Although this behavior is expected for network congestion control, such congestion is typically *unavoidable* and *unpredictable* in multi-tenant clusters, leading to reduced training performance [4, 45]. This is primarily due to the spine-leaf topology in modern clusters, where multiple jobs must share spine switches. As a result, isolating network traffic between

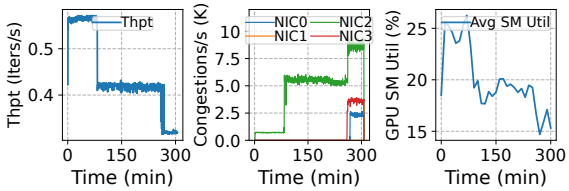

Figure 4: A case of fail-slow jobs caused by network congestion. **Left**: Training throughput. **Center**: The number of congestion notification packets (×1000) sent by RNICs. **Right**: Average GPU SM utilization of the 8 GPUs used by this job.

jobs remains difficult, even with advanced scheduling policies [4, 45] and network-level optimizations [44]—though improved isolation can help reduce the frequency of congestion events. Given its inevitability and impact, we classify such congestion-induced slowdowns as a type of fail-slow.

Requirements for mitigation strategies. Due to their long duration and substantial impact, communication fail-slows can cause severe performance degradation if left unaddressed or mitigated ineffectively. This justifies and motivates the use of more effective, aggressive—and potentially higher-overhead— strategies, as the benefits can ultimately outweigh the associated costs.

3.4 How Do Fail-Slows Manifest at Scale?

Limited by the small scale of each probing job, previous studies can only characterize fail-slows at microscale, i.e., on individual nodes or links. To characterize fail-slows at a larger scale, we collected and manually examined a one-month trace containing 27 large-scale training jobs that ran on our cluster in July 2024, each utilizing 512 to 1024 GPUs.

Frequency and impacts. Among 27 jobs, 16 encountered fail-slows, delaying the average JCT by 34.59%. In particular, 20% of these jobs were delayed more than 50% (green curve in Figure 1, right). The mean fail-slow duration is 72 minutes, significantly longer than that measured in the small sampling jobs (Figure 1, left). Table 1 summarizes the causes of the encountered fail-slows, where 13 slow jobs were due to network congestion, while the remaining were attributed to both network and GPU degradation. We observed no CPU contention for these jobs as they require 8×GPU per node and hence do not collocate with other workloads.

Deep dive. Figure 5 illustrates the throughput of two 1024-GPU jobs, one for LLM training and the other for MoE model training. Both jobs experienced severe network congestion, leading to considerable throughput fluctuations, one at the initial stage (left) and the other throughout training (right). Worse still, at this scale, a job may experience multiple fail-slows at certain times, causing more damage to training. Figure 6 illustrates a real case. Throughout the training process, the observed throughput closely aligns with the GPU SM utilization. The first severe network congestion occurred at t=62 minutes, slashing the training throughput by 80%. This degradation

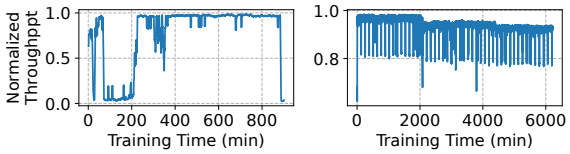

Figure 5: Two 1024-GPU jobs that failed slow due to network congestion. **Left**: An LLM training job. **Right**: An MoE training job with high variance and ladder-shaped fail-slow.

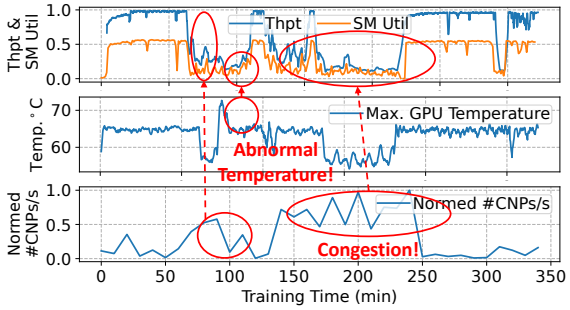

Figure 6: A 1024-GPU training job experiencing multiple performance issues, where fail-slow is caused by a compound of high GPU temperature and congested network. Y-axis of the top and bottom sub-figures are normalized.

was further exacerbated by a GPU thermal throttling event occurred at around t=80 while the network congestion remains unabated, further reducing the throughput to only 10% of the normal performance. Subsequently, from t=120 onward, another severe network congestion persisted for about two hours, cutting the throughput by 85% again. This case highlights the *compounding effects* of multiple performance issues in large-scale training, significantly undermining training efficiency.

Requirements for mitigation strategies. At large scale, training jobs are likely to be affected compound of compute and communication fail-slows. Therefore, mitigation strategies must be adaptive and flexible, able to dynamically handle these complex and compounded performance issues to maintain training efficiency.

3.5 Takeaways and Other Evidences

Our characterization study brings three takeaways:

Takeaway #1. Fail-slows are usually *transient*, primarily caused by degradation in computation and communication; the former typically stem from slow GPUs or CPU contention, while the latter are mainly due to network congestion.

Takeaway #2. Computation fail-slows tend to be short-lived and less frequent, leading to relatively minor performance degradation. In contrast, communication fail-slows due to network congestion are more common and tend to last longer, resulting in more significant training slowdowns.

Takeaway #3. As training scales up, the likelihood of simultaneously encountering multiple performance issues increases. The compounding effects of these issues can lead to significant training slowdowns, potentially exceeding 90%.

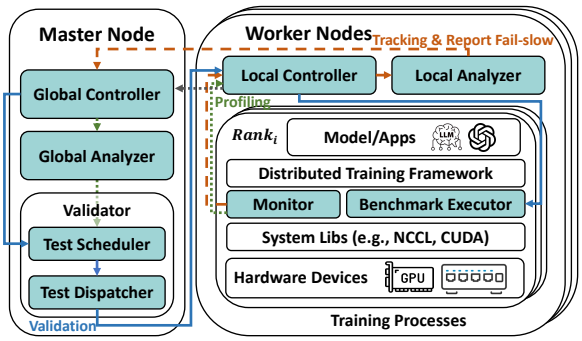

Figure 7: Architecture overview of GREYHOUND-DETECT.

Evidence from other companies. In addition to our study, ByteDance has reported computation fail-slows in its training platform [22]. Also, Meta's Llama team and Alibaba Cloud have reported communication fail-slows in LLM training [4, 12]. Our contacts with other companies bring attention to the similar fail-slow problems in large model training even on a *single-tenant* cluster of a hyperscale. While fail-slow issues are generally aware to practitioners, the general consensus, as noted in [12, 22], is that they are *hard to detect at scale*.

4 GREYHOUND-DETECT

Simply performing telemetry at cluster or node level, such as collecting GPU SM utilization and RNIC's CNP responses using standard tools like `nvidia-smi` or NVML [39], is insufficient to locate fail-slows. As discussed in §3, given the synchronous nature of training, any degraded component results in *simultaneous utilization drops* of *all* GPUs. Also, in a multi-tenant cluster, a network link is commonly shared by multiple jobs, and an increase in CNPs does not mean that all jobs are experiencing communication fail-slows, especially for those transferring light traffics over the link.

In this section, we design GREYHOUND-DETECT, a distributed monitoring system for large-scale training that accurately identifies performance issues in computation and communication at runtime. We have four design requirements.

R1: Non-intrusive and framework-independent. The detection system should not be bound to a specific training framework or require any modifications to the framework.

R2: Rapid and accurate. The system should rapidly identify the onset and resolution of fail-slow degradation while accurately locating the slow GPUs or communication links.

R3: Automated. The detection should be fully automated.

R4: Lightweight. The system should introduce minimal inspection overhead to training, without costly full-job validations that typically require checkpoints and restarts.

4.1 System Overview

GREYHOUND-DETECT is a distributed performance monitoring system deployed together with a large model training framework, such as DeepSpeed [46–48] or Megatron-LM [50]. Figure 7 provides an architecture overview, where components introduced by GREYHOUND-DETECT are highlighted in cyan. GREYHOUND-DETECT employs a master-worker architecture. On each worker node, multiple worker agents are co-deployed with the framework processes to monitor the training performance and report potential degradation to the master for further analysis and handling. Specifically, GREYHOUND-DETECT identifies fail-slows through a three-phase workflow: *tracking*, *profiling*, and *validation*.

1) Tracking. In this phase, each worker keeps track of the training iteration time for all training processes, called *ranks*, and detects slow iterations that indicate the onset of fail-slows. The worker reports these issues to the `GlobalController`, which transitions the system to the profiling phase.[2]

2) Profiling. During this phase, the `GlobalController` instructs each worker to collect the detailed execution profiles of the ongoing training job. These log profiles are sent to the `GlobalAnalyzer`, which identifies *suspicious* worker groups that may contain fail-slows. The `GlobalController` then transitions the system to the validation phase.

3) Validation. In this final phase, the system initiates fail-slow validations within the suspicious worker groups to precisely locate slow GPUs or congested network links.

We next describe the detailed designs in the three phases.

4.2 Tracking

GREYHOUND-DETECT enters the tracking phase upon the execution of a training job, continuously monitoring its performance on each worker node. Note that the monitoring is performed *per-job* on a multi-tenant cluster. To maintain transparency to the training framework (**R1**), GREYHOUND-DETECT inserts a *shim monitoring and benchmarking layer* between the framework and the underlying system libraries, such as NCCL and CUDA (Figure 7). In this shim layer, a `Monitor` intercepts communication operations (e.g., NCCL function calls) from the training framework and logs their *types* and *timestamps*. This is done by hooking to NCCL functions using Linux's `LD_PRELOAD` mechanism. Our system only intercepts top-level communication interfaces that are *uniform* in all communication libraries, such as `AllReduce` or `AllGather`, regardless of the underlying library implementation. Consequently, GREYHOUND-DETECT can seamlessly integrate with other communication libraries like ACCL [10], MSCCL [8], or customized NCCL as long as their top-level interfaces are consistent. The node's `LocalAnalyzer` then retrieves the communication call logs, maintained in shared memory, to infer the iteration time and detect slow iterations using two *time series analysis* techniques as follows.

Iteration time analysis. Throughout iterations, various collective communication functions, such as `ReduceScatter` (RS), `AllGather` (AG), and `AllReduce` (AR), are invoked periodically. Figure 8 illustrates an example, where a training

[2] If a transient fail-slow resolves during subsequent profiling or validation phase, our system identifies no anomaly and resumes normal training.

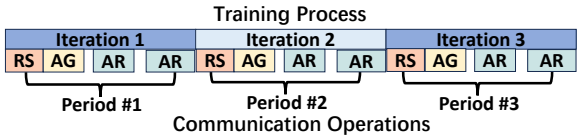

Figure 8: In iterative training, communication operations exhibit a clear periodic pattern, leading to recurring periods.

process exhibits a recurring period containing four communication calls. In practice, the number of communication calls involved in a recurring period and their patterns *vary* depending on the framework and the training model, which cannot be known due to the framework-agnostic requirement (**R1**).

To identify the recurring period from a call sequence, we employ a time series analysis approach based on autocorrelation function (ACF) [5]. Formally, given a call sequence $X = \{x_1, x_2, \ldots\}$, let X_t be a subsequence of X containing L elements starting from x_t. Let k be the *lag*, ranging from 1 to a predefined maximum. We evaluate the likelihood of k being the recurring period of X by calculating the corresponding ACF defined as follows:

$$ACF(X)_k = \frac{Cov(X_t, X_{t+k})}{Var(X_t)} = \frac{\sum_{t=1}^{L-k}(X_t-\mu)(X_{t+k}-\mu)}{\sum_{t=1}^{L}(X_t-\mu)^2},$$

where μ is the mean of X. A higher value of $ACF(X)_k$ indicates a greater likelihood that k is a recurring period. Thus, we can determine the recurring period of X by identifying the first k for which $ACF(X)_k$ exceeds a certain threshold M (set to 0.95 in our experiments), i.e.,

$$\text{Period} = \arg\min_k (ACF(X)_k \geq M).$$

Once the recurring period is identified, the iteration time derives as the time difference between a communication operation and its occurrence in the previous period.

Slow iteration detection. Training performance inherently fluctuates due to factors like periodic Python garbage collection, PyTorch CUDA memory allocator cache misses, and uneven sequence lengths in the dataset [59]. Thus, a robust statistical method is required to reliably identify true performance degradations while filtering out normal fluctuations (**R2**). To achieve this at runtime, we propose to use the Bayesian online change-point detection (BOCD) algorithm [2] followed by a verification checking to differentiate between real fail-slow issues and normal performance jitters.

1) The BOCD algorithm is an efficient time series algorithm that finds *change-points* online in a dynamic sequence in *linear* time. Feeding the algorithm the iteration time sequence, the identified change points usually correspond to the iterations with its duration change of over 10% due to the onset or relief of fail-slows. Specifically, the algorithm defines a run-length r_t for each timestamp t, which equals to $r_{t-1}+1$ if t is not a change point, otherwise it is reset to 0. It then applies Bayesian inference to calculate the likelihood of $r_t = 0$ for each timestamp. If the likelihood exceeds a certain threshold (0.9 in our experiments), it reports t as a change-point.

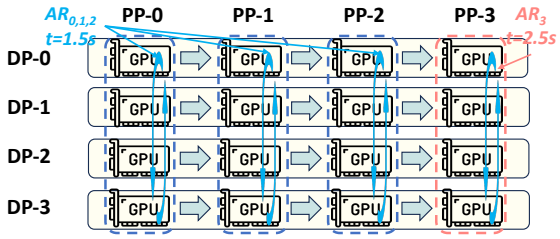

Figure 9: An example of *cross-group comparison*, $AR_{0,1,2,3}$ form a *comparable cluster* and AR_3 is a degraded group.

2) Change-point verification. While the BOCD algorithm identifies potential change-points, applying it directly to fail-slow detection results in numerous false positives, as it misclassifies normal performance jitters as fail-slow incidents. To improve the detection accuracy (**R2**), we propose an additional verification step that compares the average iteration time before and after each identified change-point, treating it as a jitter if the difference is less than 10%.

The ACF-based iteration time analysis, combined with BOCD plus change-point verification, detects slow iterations reliably and in linear time, thereby meeting requirement **R2**. Once slow iterations are detected, the `LocalAnalyzer` reports to the master for further analysis and handling.

4.3 Profiling and Validation

Profiling. The detection of a slow iteration is a clear indicator of stragglers, which must be located rapidly. To avoid benchmarking all GPUs and links (**R4**), which is costly, GREYHOUND-DETECT narrows the search to a few suspicious worker groups. This is achieved through lightweight profiling. On each worker node, the GPU `Monitor` injects CUDA events into intercepted NCCL calls to measure the execution time of each communication group. The measurement results are then collected by the master's `GlobalAnalyzer` to identify the degraded groups via *cross-group comparison*. The basic idea is to categorize communication profiles into *comparable clusters*, where each communication group (e.g., `NCCLGroup`) within a cluster handles an identical data transfer volume. Ideally, communication times within the same comparable cluster should be consistent. However, stragglers manifest as groups with prolonged execution times due to performance degradation. For instance, as illustrated in Figure 9, the four DP all-reduce groups $AR_{0,1,2,3}$ have identical communication volumes under uniform PP stage division, forming a 4-group comparable cluster. Nevertheless, AR_3 measures a markedly longer execution time compared to the other groups, indicating the presence of a straggler within it. In practice, we identify a group as degraded if its execution time exceeds the median by over 10%.

Validation. Once a suspicious group is identified, further validation is needed to locate the degraded components in it. As this requires running benchmark tests, the training job must be temporarily suspended. To avoid expensive checkpoint-

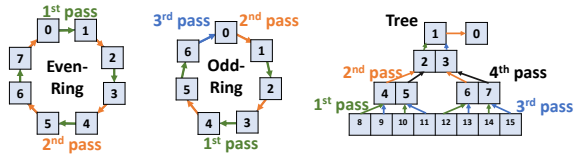

Figure 10: $O(1)$ validation of Ring and Tree communicators. Each cell is a rank, and the lines represent network links.

and-restart, we devise a lightweight training suspension mechanism (**R4**). Since GPU `Monitor` hooks NCCL calls, it can *hang* the training by simultaneously "trapping" those calls into a wait loop and give control back to the hanged training process once validation is done, *without* costly restarting the process or re-initialization.

While the training is being hanged, computation and communication benchmark tests are dispatched automatically to the identified suspicious worker groups to precisely locate the degraded components (**R2** and **R3**).

1) Computation validation. To benchmark computation performance within a group, the master's `TestDispatcher` dispatches standard GEMM [37] tests to all worker GPUs in parallel to identify slow stragglers, if any. We use GEMM as it is a building block training operation and is commonly used as a standard test in advanced benchmarking tools like SuperBench [58]. Customized tests are also supported.

2) Communication validation. Exhaustive evaluation of all possible links within a communication group is time-consuming ($O(N^2)$, where N is the group size). As collective communications can be performed with *ring* or *tree* topologies, we propose to divide the collective topology into non-overlapping peer-to-peer (P2P) operations and evaluate only the links used in training. These operations can be executed efficiently in $O(1)$ time, regardless of the group size (**R2**), as illustrated in Figure 10. Specifically, for a *ring* topology, the algorithm differentiates between even- and odd-rank rings. It divides even-rank rings into P2P send-receive operations that can be covered in *two* passes. In the first pass, data is transferred from even to adjacent odd ranks *simultaneously* (i.e., $0 \rightarrow 1, 2 \rightarrow 3, \ldots$); the second pass sends data from odd ranks to adjacent even ranks simultaneously (i.e., $1 \rightarrow 2, 3 \rightarrow 4, \ldots$, as shown in Figure 10, left). For odd-rank rings, an additional pass is needed to accommodate the remaining link (Figure 10, center). For *tree* topology, the validation requires *four* passes (Figure 10, right). The first pass simultaneously sends from left-child ranks at even levels to their parents, followed by the second pass which sends from right-child ranks at even levels, also simultaneously. The third and fourth passes reverse the roles of the senders, starting from odd levels. Since the transmission sizes are identical, slows link measures longer communication times and can be easily identified. In our implementation, both ring- and tree-topology validation are needed in a worker group as NCCL determines the actual collective communication topology dynamically.

Limitation. Our current design cannot detect fail-slows that occur only when computation and communication kernels co-execute in specific patterns [58]. However, these instances are typically linked to defects in particular hardware batches and are extremely rare in production environments.

5 GREYHOUND-MITIGATE

Unlike fail-slow detection, which is non-intrusive, fail-slow mitigation requires supports from the training framework. Therefore, it cannot be entirely non-intrusive to the training job. In this section, we present GREYHOUND-MITIGATE, a system that effectively addresses fail-slows with a novel adaptive multi-level mitigation mechanism.

5.1 Adaptive Multi-Level Mitigation

Solution space. Simply treating transient fail-slows as fail-stops by means of checkpoint-and-restart can do more harm than good, as dumping and restoring checkpoints for large models is time-consuming. In fact, dumping a GPT2-100B model takes nearly 100 minutes [56], even longer than the mean fail-slow duration in our cluster (§3). We explore the solution space and identify four strategies.

(S1) Do nothing. This approach simply ignores fail-slow problems in the hope that the straggler components will soon be self-recovered. Many existing systems choose to do so due to the lack of an effective detection tool.

(S2) Adjust micro-batch distribution. This strategy is efficient in addressing computation fail-slows, which result in *uneven processing speed* among model replicas (i.e., DP groups). The strategy reacts by redistributing micro-batches across DP groups based on their processing speed, alleviating the load on slow GPUs and rebalancing the computation (§5.2).

(S3) Adjust parallelism topology. This strategy effectively mitigates *both computation and communication stragglers* by: 1) reassigning heavy-traffic communications to less congested links, thereby mitigating network congestion; and 2) consolidating multiple stragglers into the minimal number of PP stages, thus reducing their overall impact (§5.2).

(S4) Checkpoint-and-restart. As a last resort, the system performs checkpointing and restarts training on healthy nodes. While this approach effectively eliminates all fail-slows by replacing slow components, it incurs the highest overhead and may require significant human intervention.

We compare the four strategies in Table 2.[3] As we move from S1 to S4, the mitigation effectiveness improves, but the action overhead also increases. Therefore, the optimal strategy *varies* depending on the severity and the duration of fail-slows. While the severity can be measured, fail-slow duration exhibits a large dynamic range, from tens of seconds to several hours (Figure 1, left), and cannot be predicted accurately.

Ski-rental-like multi-level straggler mitigation. We find that the mitigation planning problem resembles the classical

[3] Adapting TP is ineffective for mitigating fail-slow, as TP operates within a single node, which is not susceptible to communication fail-slow.

Strategy	Effectiveness		Action Overhead
	Slow Comp.	Slow Comm.	
S1: Ignore	No Effect	No Effect	None
S2: Adjust Microbatch	Mitigate	No Effect	Low
S3: Adjust Topology	Mitigate	Mitigate	Medium
S4: Ckpt-N-Restart	Eliminate	Eliminate	High

Table 2: Comparison of mitigation strategies in terms of effectiveness and overhead.

ski-rental problem [23], which involves balancing recurring ski-rental costs (akin to experiencing fail-slows) against a one-off ski-buying investment to avoid those costs (akin to taking mitigation action), all without prior knowledge of duration. Inspired by the classical ski-rental algorithm, we design an *adaptive multi-level* fail-slow mitigation mechanism. It begins with a low-cost strategy (**S1**) and progressively switches to more effective—and hence more costly—strategies (**S2** to **S4**) if fail-slow persists and the current approach proves ineffective. To determine when to switch strategy, the algorithm tracks the number of iterations affected by fail-slow and the resulting slowdowns to calculate an *accumulated performance impact*. It switches to the next strategy when the cumulative slowdown *equals* the action overhead of that strategy; that is, the algorithm is better off taking that more aggressive strategy upon the detection of fail-slow should it have known its performance impact (i.e., buy a ski when the cumulative rental cost *equals* the one-off buy cost). Algorithm 1 formally describes this mechanism.

5.2 Micro-batch and Parallelism Adjustment

We now describe the detailed design of the four strategies employed in the multi-level mitigation scheme. Since **S1** and **S4** are straightforward, we focus specifically on the two parallelism adjustment strategies **S2** and **S3**.

S2: Adjust micro-batch distribution. This strategy dynamically adjusts the number of micro-batches allocated to DP groups according to their computation performance, effectively mitigating *computation* fail-slows at a low cost. Specifically, DP shards a large global batch into multiple micro-batches and distributes them evenly among all groups (i.e., model replicas) at initial. When a certain group experiences computation fail-slow, we rebalance the workload by accordingly reducing the number of micro-batches allocated to it.

Formally, let D be the number of DP groups and M be the number of micro-batches in a global batch, where group DP_i is allocated m_i micro-batches. The processing time for a micro-batch in DP_i is denoted as t_i, which is profiled by GREYHOUND-DETECT (§4.3). Our goal is to minimize the processing time of the slowest DP group, which can be formulated as a quadratic programming problem that minimizes the variance in processing times across all DP groups:[4]

$$\min \max_{i=1,\ldots,D} m_i t_i \Leftrightarrow \min \sum_{i=1}^{D} (m_i t_i - \frac{\sum_{i=1}^{D} m_i t_i}{D})^2, \quad \text{Subject to} \quad m_i \in \mathbb{N}^+ \text{ and } \sum_{i=1}^{D} m_i = M. \tag{1}$$

Although the micro-batches are not evenly distributed after this adjustment, the training loss can remain consistent using a weighted gradient aggregation method [6]. This leads to the same training result and hence ensures the correctness. Moreover, this adjustment only modifies the number of micro-batches (m_i) assigned to each DP group, both the global batch size and micro-batch sizes remain unchanged. Given the peak GPU memory usage in memory-efficient pipelines such as 1F1B [34] is independent of m_i, this strategy does not increase memory footprint during training.

Implementation and overhead. Our implementation uses `cvxpy` [9] to solve Equation (1), which typically takes only a few seconds (detailed in Table 5). Before each iteration, each DP group retrieves its assigned m_i from the global controller, allowing the new distribution to take effect immediately in the subsequent iteration, without requiring a job restart.

S3: Adjust parallelism topology. We design this strategy as a *reactive* method to handle communication stragglers. It adjusts the parallelism topology to reduce congestion and minimize PP stages affected by stragglers, more effectively mitigating communication fail-slows with moderate overheads.

Reassign congested links to light-traffic groups. One key characteristic in hybrid-parallel training is that PP communication involves significantly less data transfer than DP [35,50]. Specifically, per-GPU PP traffic is $O(m_i \times \text{activation_size})$, typically in tens to hundreds of MBs per iteration, while DP gradient synchronization can exceed tens of GBs. Therefore, DP groups are much more susceptible to network congestion. To mitigate fail-slow events caused by congestion, we can reassign congested links from heavy-traffic DP groups to light-traffic PP groups, reducing the overall performance impact. For example, as shown in Figure 11, suppose the link between nodes 3 and 4 is congested and originally used for DP communication. By exchanging the DP and PP roles for nodes 2 and 3, we can redirect the traffic from node 3 to node 4 into light-traffic PP communication, effectively alleviating

[4] For a 1F1B pipeline, we add another constraint: $m_i \equiv 0 \bmod PP$.

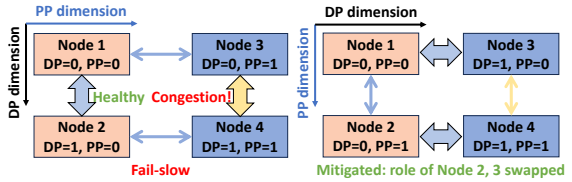

Figure 11: Topology adjustment to mitigate network congestion. After swapping Nodes 2 and 3, the congested link shifts from a heavy-traffic DP group to a lighter-traffic PP group.

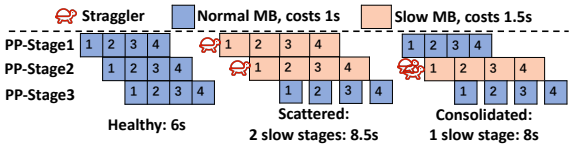

Figure 12: The number of straggling PP stages determines iteration time. With two stragglers are scattered across two stages, the execution time is prolonged to 8.5s, while it can be mitigated to 8s by consolidating two stragglers in one stage.

the impact of network congestion.

Straggler consolidation. When multiple stragglers are present, consolidating them into one PP stage mitigates slowdown. Since workers within the same PP stage operates synchronously, the performance is determined by the slowest straggler, irrespective of the number of stragglers within this stage. In contrast, as shown in Figure 12, having stragglers scatter across multiple PP stages is sub-optimal. Therefore, in case of multiple stragglers, our topology adjustment aims to consolidate them into the minimal PP stages. To achieve this, we calculate the minimal number of PP stages needed to contain stragglers by $\lceil$#Stragglers/# GPUs per PP stage$\rceil$ and consolidate the stragglers accordingly. We also prefer to shift them to interior stages, as the first and last stages typically endure a higher load due to the pre- and post-processing modules (e.g., embedding layers) allocated to them.

Implementation and overhead. Topology adjustment can be implemented in four steps: 1) pausing the ongoing training, 2) temporally dumping parameters to swap into main memory, 3) swapping parameters via peer-to-peer RDMA, and 4) restarting the training process. This adjustment incurs moderate overhead, only determined by the number of parameters per GPU, irrespective of the training scale given that each GPU operates independently. This adjustment is typically done in about one minute (detailed in Figure 19).

6 Implementation

We have implemented GREYHOUND-DETECT in approximately 5.5k lines of code (LOC) of C++ and Python. The worker's GPU `Monitor` hooks NCCL functions using Linux's `LD_PRELOAD` mechanism. Intra-node and inter-node communications between modules are achieved through shared memory and Redis [49], respectively. During validation, the `BenchmarkExecutor` reuses the same CUDA context and NCCL communicators from training, eliminating initialization overhead. For compute benchmarking, we use GEMM kernels with various data types, as GEMM is the primary building block in training and a common benchmarking standard. Specifically, `BenchmarkExecutor` sequentially run FP8, FP16, and FP32 GEMM kernels, with each kernel execution monopolizing all SMs to accurately assess the performance. For communication benchmarking, we perform concurrent NCCL send/receive operations shown in Figure 10, using message sizes of 16, 32, and 64 MB. Each computation and communication test is repeated three times, with the mean execution time used as the final metric. The benchmarking component is designed in a modular fashion, which facilitates the easy integration of additional benchmarks in the future.

GREYHOUND-MITIGATE is implemented in 1.5k LOC of Python. The planner receives straggler IDs from Redis and generates adjustment strategies, which are then executed a lightweight plugin of Megatron-LM [50].

7 Evaluation

In this section, we evaluate GREYHOUND-DETECT and GREYHOUND-MITIGATE to answer the following questions:

1. How accurately does GREYHOUND-DETECT estimate iteration time and identify fail-slow incidents across various models and parallelism configurations? (§7.2)
2. Is GREYHOUND-MITIGATE effective in alleviating various fail-slow failures with different root causes and parallelism configurations? (§7.3)
3. What is the overhead associated with GREYHOUND-DETECT and the various mitigation strategies implemented in GREYHOUND-MITIGATE? (§7.4)
4. How effective is GREYHOUND in enhancing training efficiency and mitigating the impact of fail-slow incidents in large-scale real-world training scenarios? (§7.5)

7.1 Experiment Setup

Testbed configuration. We conduct our evaluation on a high-performance cluster comprising 55 nodes, each equipped with 8 NVIDIA H800 GPUs connected via NVSwitch. The nodes are interconnected through a 400Gbps InfiniBand network in a spine-leaf topology, ensuring symmetric inter-node bandwidth. Our tests utilize Megatron-LM [50], a large-scale distributed training framework built on PyTorch [3], to train a set of GPT-2 models in various sizes and parallel strategies. The testbed runs CUDA version 12.2 and NCCL version 2.18.1.

Fail-slow injection. We evaluate the effectiveness of our mitigation system using deterministic manually injected fail-slows. To simulate computational fail-slows, we employ `nvidia-smi` to lock the GPU SM frequency. To inject communication fail-slows, we initiate side-channel communication jobs that create network bandwidth contention, thereby reducing the available bandwidths on specific network links.

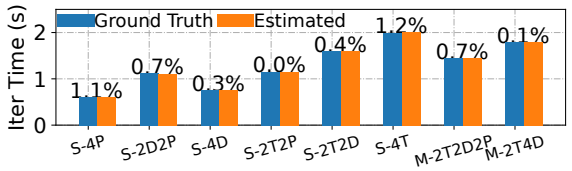

Figure 13: Accuracy of iteration time estimation in single-node (*S*) and multi-node (*M*) settings. The notation *xTyDzP* specifies the TP size *x*, DP size *y*, and PP size *z*.

Algorithm	Accuracy↑ (%)	FPR↓ (%)	FNR↓ (%)
SlideWindow	99.5(390/392)	**0.0(0/386)**	25.0(2/8)
BOCD	77.8(305/392)	18.39(87/473)	**0.0(0/6)**
BOCD+V	**100.0(392/392)**	**0.0(0/386)**	**0.0(0/6)**

Table 3: Detection evaluation for computation fail-slows.

7.2 How Accurate Is Detection?

Iteration time estimation. We first evaluate the accuracy of the ACF-based iteration time estimation across various hybrid-parallel strategies as it is the foundation of fail-slow detection. We deploy GPT2-7B training jobs using different parallelism strategies on 1, 2, and 4 nodes. As illustrated in Figure 13, in single-node experiments with 4 GPUs, the relative error remains below 1.2% compared to the ground truth iteration time, regardless of the parallel strategies employed. In a 2-node experiment with a (2TP, 2DP, 2PP) configuration, the error is 0.7%, while in a 4-node test with a (2TP, 4DP) setup, it remains highly accurate at just 0.1% relative error.

Fail-slow detection. We then assess the effectiveness of our BOCD and verification algorithm (BOCD+V) in detecting computation and communication fail-slows. The baseline methods are sliding window and classical BOCD; the former reports a fail-slow if there's a >10% performance change in the sliding window from the current median, while the latter performs no verification. Using traces from §3, we assess their accuracy against human-labeled ground truth. As shown in Table 3, BOCD+V achieves perfect 100% accuracy with 0% False-Positive Rate (FPR) and 0% False-Negative Rate (FNR) in detecting computation fail-slow. In case of communication fail-slow (as illustrated in Table 4), BOCD+V attains 99.1% accuracy, 0% FPR, and only 2.3% FNR. The FNR primarily results from a rare case containing consecutive <10% degradations. The original BOCD has a lower FNR by reporting all suspicious change-points but suffers from a high FPR. Similarly, the sliding window method is less accurate, missing many fail-slow cases with a higher FNR.

7.3 How Effective Is Mitigation?

In this section, we assess the effectiveness of the mitigation strategies introduced in § 5.2. Since GREYHOUND does not have prior knowledge of stragglers, they must be detected online during training. As a result, these experiments also serve as an implicit end-to-end test of GREYHOUND-DETECT, which achieves 100% accuracy in all cases reported below.

Algorithm	Accuracy↑ (%)	FPR↓ (%)	FNR↓ (%)
SlidingWindow	93.5(100/107)	1.5(1/65)	12.2(6/49)
BOCD	69.2(74/107)	34.0(33/97)	***0.00(0/43)***
BOCD+V	***99.1(106/107)***	***0.00(0/64)***	2.3(1/44)

Table 4: Detection evaluation for communication fail-slows.

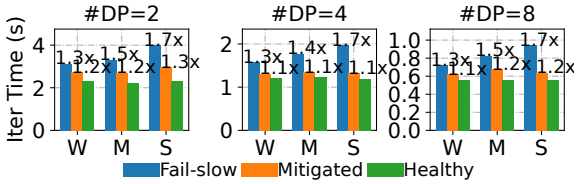

Figure 14: Effectiveness of micro-batch adjustment strategy of mitigating various fail-slow severities and DP settings.

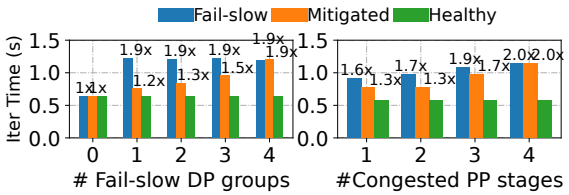

Figure 15: **Left**: Effectiveness of micro-batch adjustment (**S2**) on various number of slow DP groups. **Right**: Effectiveness of straggler consolidation (**S3**) on various slow PP stages.

Micro-batch distribution adjustment (S2). To evaluate the effectiveness of strategy **S2** in mitigating computation fail-slows, we deploy a single-node training with 8 GPUs. We inject weak (W), medium (M), and severe (S) computation fail-slows to training jobs with 2, 4, and 8 DP groups, as illustrated in Figure 14. Our approach reduces the average iteration time from 1.7× the baseline to 1.3/1.1/1.2×, yielding up to 1.52× optimization. This strategy proves effective across various setups and fail-slow severity since it consistently ensures a dynamic load balance across all DP groups.

As shown in Figure 15 (left), we also evaluate **S2** when multiple DP groups experience fail-slow. In a 4-DP training job, we inject medium slow computation into 0 to 4 DP groups. **S2** achieves its best performance with only one slow group, reducing iteration time from 1.31s to 0.83s, yielding 1.59× improvement. While multiple slow DP groups do not further increase iteration time, the room for mitigation decreases as the number of degraded DP groups rises. This is because with multiple DP groups degraded, total computational power decreases, limiting adjustment flexibility, and there is no room for adjustment if all groups are slow.

Topology adjustment (S3). We evaluate strategy **S3** in a 2-node experiment with 16 GPUs. As shown in Figure 16, we inject communication fail-slows into training jobs with 4 or 8 PP stages. The results reveal a reduction in the average iteration time by up to 1.23× for PP=4, and 1.14× for PP=8, both under severe congestion. The strategy is more effective with 4-stage PP due to the increased bubble rate and longer idle times associated with the longer pipeline in the 8-stage

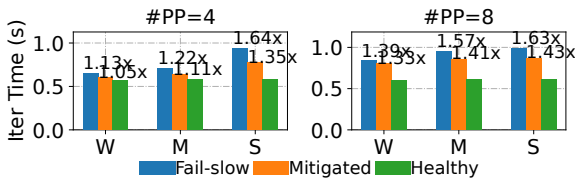

Figure 16: Effectiveness of topology adjustment strategy of mitigating various fail-slow severity and PP settings.

setup, which ultimately understates the effectiveness.

To evaluate the effectiveness of straggler consolidation in topology adjustment, we conduct an experiment with 16 GPUs using (4DP, 4PP) setup. As shown in Figure 15 right, congestion in one or two links raises iteration time to 1.6/1.7×, which can be both mitigated to 1.3× through consolidating them into only one PP stage. With three congested links affecting 6 GPUs, mitigation reduces iteration time from 1.9× to 1.7×, since one stage contains only four GPUs and six stragglers must occur across two PP stages. If all links are slow, there is no room for adjustment.

7.4 How Large Is the Overhead?

Overhead of GREYHOUND-DETECT. As discussed in §4, GREYHOUND-DETECT comprises a three-phase workflow: *tracking, profiling, and validation*, with corresponding overhead evaluated as follows.

Tracking. We conducted training under the same settings as in §7.2. As shown in Figure 18, the average overhead is only 0.39%, with a maximum of 1.1% compared to training without the detector. In some cases, enabling the detector results in an even slightly faster iteration (indicated by 0.0% in green), highlighting that such overhead is caused by inherent fluctuations instead of detector itself. These results prove that the overhead of GREYHOUND-DETECT is negligible. Upon fail-slow events, the BOCD algorithm can detect it in the next 2-3 iterations, costing typically <5 seconds for reaction.

Profiling. Since this phase only collects profiles for offline analysis, it does not introduce any additional overhead.

Validation. The validation phase runs the compute and communication benchmarks described in §6. As shown in Figure 17, compute validation completes within 0.59/0.51/0.24s on NVIDIA A10, A100, and H800 GPUs under normal conditions, and within 1.94/1.23/0.87s under fail-slow scenarios (GPU clock rate locked at 300 MHz). For communication validation, we assess NVLink, PCIe, and RDMA, where RDMA is most susceptible to congestion, but all benchmarks (3 repetitions) still finish within 3.04 seconds. Overall, the total benchmarking overhead remains about 5 seconds even under severe fail-slow scenarios or on lower-end GPUs.

Overhead of GREYHOUND-MITIGATE. We then evaluate the overhead of the strategies in GREYHOUND-MITIGATE.

*Micro-batch adjustment (**S2**).* We evaluate the overhead for adjusting the micro-batch distribution, which primarily arises from solving Equation (1). As shown in Table 5, although

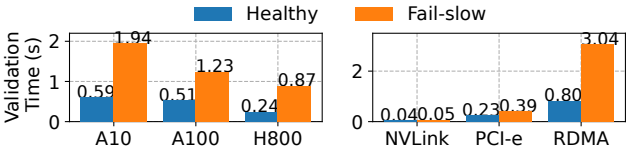

Figure 17: **Left**: overhead of executing compute benchmarks. **Right**: overhead of executing communication benchmarks.

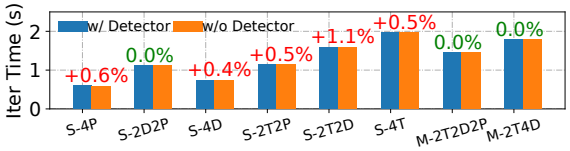

Figure 18: Overhead introduced by GREYHOUND-DETECT across various parallel strategies.

this overhead increases exponentially with the number of DP groups, it remains around 30 seconds even with 512 DP groups, showing its efficiency for hyperscale training.

*Topology adjustment (**S3**).* We evaluate the topology adjustment overhead under various parameter settings. We set the per GPU memory footprint to dump to 10, 22, 38, and 76GB, and conduct training on a single node with 8 GPUs. The adjustment time will no more increase as training scales up, since each node operates independently. As shown in Figure 19, our approach reduces pause time by up to 6.72× compared to the disk-based C/R, primarily by eliminating checkpoint dumping and loading times. The performance gains are more pronounced with more parameters, as the disk operation times increase significantly for large I/O sizes.

7.5 How Does GREYHOUND Perform at Scale?

To evaluate GREYHOUND 's effectiveness at scale, we conduct a GPT2-40B training experiment on 256 NVIDIA H800 GPUs with (8TP, 16DP, 2PP). We manually inject 12 fail-slow events, including two communication congestion events and ten compute slowdowns, each with varying severity levels, as detailed in Table 6. We also simulate compound cases where compute and communication fail-slows occur simultaneously, mirroring the scenarios presented in our characterization (§3.4). The training job is executed twice under identical straggler injection schedule: once with GREYHOUND and once without for A/B testing. Note that the straggler schedule is unknown to GREYHOUND—all fail-slows must be detected first and then mitigated, yielding an end-to-end evaluation.

Detection. First, we evaluate GREYHOUND-DETECT 's detection accuracy and reaction time. As presented in Table 6, it accurately identifies all 12 fail-slow events, achieving a 100% detection rate. For each fail-slow event, we measure the time difference between when GREYHOUND-DETECT

# DPs	16	32	64	128	256	512
Time(s)	0.01	0.01	0.01	0.11	6.78	35.93

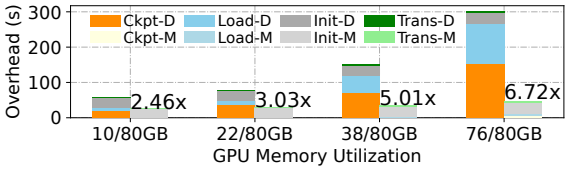

Figure 19: Overhead breakdown of **S3**. *M*: memory-based dump and load (our method), *D*: disk-based C/R.

Comm. Slow	Comp. Slow	Detect Acc.	Avg. Reaction
Medium: 2	*Weak*: 3 *Medium*: 5 *Severe*: 2	100%	*BOCD*: 3.7s *Prof.&Val.*: 6.86s *Total*: 10.56s

Table 6: Detection accuracy and average reaction time of GREYHOUND-DETECT in the 256 H800 GPU experiment.

reports it and the actual injection timestamp, representing the reaction time. The average reaction time is 10.56 seconds in this 256-GPU experiment, indicating low detection overhead at scale. This reaction time consists of two phases: the BOCD algorithm signals a change point, occurring approximately 4 seconds post straggler injection. Subsequently, GREYHOUND-DETECT enters profiling and validation mode, requiring an additional 6 to 10 seconds to identify the root cause.

Mitigation. Accurate and timely detection enables effective mitigation strategies. As shown at the top of Figure 20, without GREYHOUND, computation stragglers cause significant throughput declines. In contrast, with GREYHOUND, throughput quickly recovers to near-optimal levels, demonstrating the effectiveness of micro-batch adjustment (**S2**). During communication congestion periods, GREYHOUND initiates brief pause for topology adjustments (**S3**) at t=850 and t=2100, each lasting under one minute. These adjustments are faster than traditional C/R methods which takes tens of minutes. Once congestion ends, the topology is promptly reverted (at t=1150 and t=2350). Notably, compound fail-slows can reduce training throughput by about 55%, but it can be mitigated to only 25% degradation with GREYHOUND.

End-to-end performance. Combining accurate detection and effective mitigation, GREYHOUND significantly reduces the impact of stragglers. Without GREYHOUND, end-to-end throughput decreases from 37.4 to 18.9 iterations per minute due to injected fail-slow events. In contrast, with GREYHOUND, throughput recovers to 29.8 iterations per minute (including the detection and validation overhead), achieving 1.58× improvement in end-to-end throughput.

8 Related Work

Reliability issues in training. Several studies address the fail-stop issue using checkpoints [28, 33, 56], re-computation [53], and elastic frameworks [11, 20, 53, 56, 64]. For example, Oobleck [20] pre-computes *static* parallelism adjustments for predictable resource changes (e.g., node removal). In contrast, while fail-slow have been acknowledged in various reports [12, 22], only a concurrent work, Holmes [59], addresses

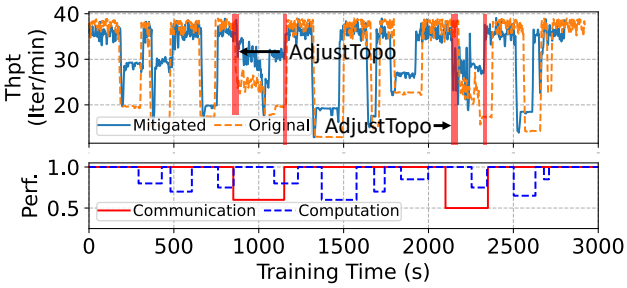

Figure 20: Evaluation of GREYHOUND for a 256 H800 GPU training with computation and communication fail-slows.

this issue but lacks mitigation. However, fail-slow mitigation is orthogonal to fail-stop recovery and more challenging as it requires *dynamic* reactions according to the detected stragglers without altering the number of available resources.

Fail-slow in other fields. Fail-slow also exists in cloud services [7, 14, 15, 17, 18, 29], operating systems [61], and storage [16, 30], but presents unique challenges in large-scale training. In these domains, the main issue is identifying the source of *gradually* propagating [14, 15] or independent [30] fail-slows. In contrast, large-scale training is synchronous, one slow component can *immediately* propagate to the entire cluster. Additionally, replacing degraded components in these fields often does not impact the entire system.

Heterogeneous DL training. Several researches focus on efficient parallel training on heterogeneous hardware with various performance [6, 21, 31, 32, 41, 54, 60, 63]. However, mitigating fail-slow presents distinct challenges. Heterogeneous training is *static*, where performance does not fluctuate over time, thus allowing for higher-cost parallel strategy searches at initial [54, 63]. In contrast, fail-slow handling must be *dynamic*, precluding those high-cost searches.

9 Conclusion

In this paper, we presented the first comprehensive characterization study in a production cluster to understand the overall characteristics and performance impacts of fail-slow failures in large-scale LM training. We proposed GREYHOUND, a framework that swiftly identifies fail-slowed compute or communication components and effectively mitigates them using a novel multi-level mechanism, all without human intervention. GREYHOUND achieves over 99% accuracy in detecting fail-slows and improves the end-to-end performance by 1.58× in large-scale training.

Crash Consistency in Block-Level Caching Systems: An Open CAS Case Study

Shaohua Duan
Washington State University

Youmin Chen
Shanghai Jiao Tong University

Abstract

Byte-addressable non-volatile memory (NVM) proposes a new opportunity to enable file systems with better performance and durability by adding a new persistent caching layer. However, crash consistency of caching layers and compatibility with diverse reliability features of file systems remains unknown. This paper conducts a crash consistency case study of Open CAS, a popular block-level caching system. Through careful and thorough crash consistency experiments, we show that Open CAS cannot always maintain crash consistency in the persistent caching layer. We also demonstrate some reliability features of file systems are not compatible with Open CAS. Our analysis reveals the importance of a systematic crash consistency test to caching systems and reliability feature co-design with file systems in the construction of a reliable end-to-end file system.

1 Introduction

Byte-addressable non-volatile memory (NVM) opens a new opportunity in designing high-performance block-level caching systems for file systems. NVM provides byte addressability and low-access latency like DRAM and offers data persistence like HDD. Like page cache in traditional file systems, similar hybrid storage is adopted in persistent caching systems, where a fast persistent device is used for a caching layer and a slow but large storage capacity is used for a backend file system to achieve high I/O performance while reducing monetary costs. For example, Open CAS [11], an advanced caching solution recently developed by Intel, allows NVM, SSD, and other high-performance storage devices to be used as a caching layer for improving the I/O performance of Linux file systems.

While the primary goal for introducing non-volatile memory into block-level caching systems is to improve the performance of file systems that are typically installed at the HDDs, i.e., backend devices, it also improves the data durability of file systems. Unlike traditional block-level caching systems (e.g., in-DRAM page cache), block-level caching systems on non-volatile memory guarantee better data durability and enable system designers to leverage new tiered persistent storage devices (e.g., Intel Optane persistent memory [37]) to recover the cached data from system crashes. For example, Open CAS [11] and other persistent caching systems such as bcache [5] and flashcache [28] guarantee the data durability once returning an acknowledgment to users.

Although the advent of fast storage and interconnect technologies present new opportunities to achieve better performance and durability, they also cast new questions on system reliability: How robust are persistent block-level caching systems to system crashes? How compatible are caching systems with diverse reliability features of file systems which were typically designed with in-DRAM page cache? To maximize the performance of block-level caching systems, more and more complicated software architectures, cache strategies and modes, and storage hierarchies are applied which make block-level caching systems tend to be less reliable. Although some block-level caching systems promise data durability and crash consistency in certain crash scenarios by using multiple robustness features, the effectiveness of these reliability designs and the complete crash behavior of the caching systems remain unknown due to a lack of third-party systematical crash consistency tools. For example, Open CAS developers noticed the risk of data durability loss in case of system crashes in certain cache modes, i.e., write-only and write-back modes due to unknown reasons [9]. By contrast, there are multiple third-party domain-specific test libraries and tools [38, 46] focus on crash-consistency tests to file systems, and the crash behaviors of state-of-the-art file systems are well studied. Furthermore, state-of-the-art reliability features of file systems are designed, implemented, and tested with in-DRAM page cache which is modeled as all data in the caching layer are not available after a crash. It is unclear whether these file system reliability features still work well with the new persistent storage hierarchy without suffering compatibility issues. To answer these questions, we analyze Open CAS, a representative block-level caching system, by performing careful and

thorough crash consistency experiments. To the best of our knowledge, this is the first work that specifically focuses on the crash consistency of block-level caching systems.

In this paper, we use Open CAS as an example of block-level caching systems and perform a thorough crash consistency study on persistent block-level caching layers. Our study unveils important, previously undetected crash inconsistency and incompatibility in Open CAS. In our analysis, we find that Open CAS fails to maintain crash consistency and returns bad data to the user due to system crashes. We further find that some reliability features of state-of-the-art file systems are not compatible with Open CAS[1]. Besides Open CAS, we also analyzed a simpler caching system, NVCache [15], and observed similar experiment results. In summary, we make the following contributions:

- The first study (to the best of our knowledge) to empirically analyze the crash consistency behavior of Open CAS, a state-of-the-art block-level caching system.
- A novel workload-oriented test framework (WLOT) to analyze crash consistency behavior of caching systems by leveraging implicit information.
- Results and observations that demonstrate the importance of systematical crash-consistency tests to caching systems and compatibility tests with diverse reliability features of file systems.

The rest of this paper is organized as follows. In Section 2, we motivate our work and discuss the challenges for crash-consistency tests to block-level caching systems. Section 3 provides some background on Open CAS. Section 4 presents the principle of crash-consistency tests to caching systems and our code inspections to Open CAS. In Section 5 and Section 6, we present our analysis of crash consistency experiments on Open CAS. In Section 7, we present the initial results of the crash consistency analysis in NVCache. Section 8 discusses related work and Section 9 concludes our work.

2 Block-Level Caching Systems

Caching systems have long been the most popular design for improving the performance of storage systems [6, 20, 40]. In caching systems, consider a system with two storage layers: a (fast, expensive, small) performance layer and a (slow, cheap, large) capacity layer. With caching, all data resides in the capacity layer, and copies of hot data items are placed, via cache replacement algorithms [7, 34], in the performance layer. With a high-enough fraction of requests going to the fast layer, the overall performance approaches the peak performance of the fast layer. In the context of block-level caching systems, e.g., Open CAS [11], OrthusCAS [50], First Responder [42], Assise [1], and NVCache [15], they are generally implemented as a kernel module in operating systems, and provide caching service for block devices which typically are file systems.

[1]We have reported the issues exposed in our study to the developers and have received acknowledgment.

The advent of fast storage and interconnect technologies, such as persistent memory (PMem) [37], Non-Volatile Memory Express (NVMe) [30], and Compute Express Link (CXL) [13], present new opportunities in boosting the performance of memory hierarchy and caching systems. With new storage technologies like 3D XPoint [43], NVMe SSDs (over the PCIe bus) achieve much higher bandwidth (e.g., 8 GB/s) and lower latency (e.g., 3μs) [58]. Further, byte-addressable persistent memory has also been commercially available [37] and offers an order of magnitude higher capacity than DRAM and within an order of magnitude performance of DRAM [52].

2.1 Why Crash Consistency Does Matter

Although the main goal for introducing nonvolatile memory to caching systems is for performance boosting [12, 19, 24, 25, 49, 51, 57], this technique also poses opportunities and challenges to the reliability of end-to-end file systems, including caching layers and backend file systems. During the past decades, there have been many related works to improve the reliability of file systems [14, 23, 29, 35, 36, 55], and they typically modeled the behavior of in-memory cache, i.e., page cache, as all information in the caching layer is lost upon a crash. However, when nonvolatile memory is introduced into block-level caching systems, this stale crash model doesn't hold, and it provides a new opportunity for caching systems to reuse the cached data for fast system recovery. For example, Open CAS provides a configuration option for the system managers to perform a fast recovery and reuse the cached data from an unplanned system shutdown.

Although a persistent caching layer automatically provides data durability due to the natural behavior of nonvolatile memory, i.e., it retains data even when power is removed, adding a new tiered persistent caching layer also poses critical challenges to the system reliability. First, a persistent caching system is much more complex than traditional in-memory page cache. To meet the various use scenarios and user requirements, a persistent caching system normally provides multiple cache modes to cope with. For example, compared with a single cache mode in page cache, Open CAS provides six cache modes for the different use scenarios. Similarly, First Responder offers seven cache modes for users. Furthermore, to maximally deliver the performance of nonvolatile memory, caching systems normally design complicated caching algorithms and asynchronous data movement mechanisms to fit in nonvolatile memory characteristics. For example, in OrthusCAS [50] the cache eviction strategy not only considers the characteristics of workloads but also is decided by the performance model of caching devices. In general, the more complicated software design and implementation means the systems are less reliable.

Second, testing persistent caching systems poses unique requirements and challenges. In caching systems, the code

logic usually requires a heavy workload to change the caching system status and/or trigger the specific cache operation. For example, cache eviction and cache cleaning operations generally require a heavy workload to be implicitly triggered by cache replacement policies [7,34]. The requirement for heavy workloads makes traditional system testing tools, such as fuzzing [4,17,23,53] and black-box testing [29] less effective which tend to generate lightweight test cases by applying syntax and semantic mutations [22,54]. Furthermore, implicitly triggering through heavy workloads also means there are enormous potential crash points in the heavy-workload test case for a test framework to explore. Therefore, crash-consistency tests to caching systems specifically require a test framework that can generate heavy workloads while precisely identifying crash points for implicit cache operations.

Third, it still remains unknown whether the added persistent caching layer is compatible with the diverse reliability features of file systems. For file systems, the reliability features such as logging [18,39], journaling [48], write-back [47,48], and copy-on-write [21], are designed on a simple crash model that file systems on the persistent device, e.g., HDD, are the only survived data source upon system crashes [3]. When introducing a new persistent caching layer in end-to-end file systems, this stale crash model doesn't hold anymore, and the reliability design based on this model may not be compatible with the newly added persistent caching layer. Actually, in case of a system crash, data movement between the persistent caching layer and the backend file system immediately terminates, which is the same as in-memory page cache. However, during the post-recovery process, the survived data in caching layers and file systems can be inconsistent. If the reliability design between caching layers and file systems is not well coordinated, the end-to-end file system may suffer from durability loss or data inconsistency issues.

In this work, we focus on the crash consistency of block-level caching systems. We specifically take Open CAS as an example and try to answer the system reliability questions in two aspects: does the persistent caching layer maintain crash consistency in case of system crashes? Are state-of-the-art reliability features of file systems compatible with the newly added persistent caching layer?

3 Introduction to Open CAS

Open Cache Acceleration Software, short for Open CAS [11], is a block-level caching solution that is primarily designed to improve the performance of HDDs (backend devices) by caching data on nonvolatile memory (cache devices). Open CAS is widely used and studied in both industrial solutions [31,33] and research projects [16,50]. Open CAS Linux is a kernel module that works under Linux in-kernel file systems. It handles I/O requests from upper-layer file systems through a virtual block device and submits I/O requests to underlying storage devices according to cache modes and policies. In the official document, Open CAS guarantees that data integrity is maintained on the persistent cache device once returning an acknowledgment to users for all cache modes [10]. To achieve this guarantee, Open CAS developers utilize multiple reliability techniques. Besides, a set of built-in test cases is provided to ensure the correct implementation of functionalities and reliability features.

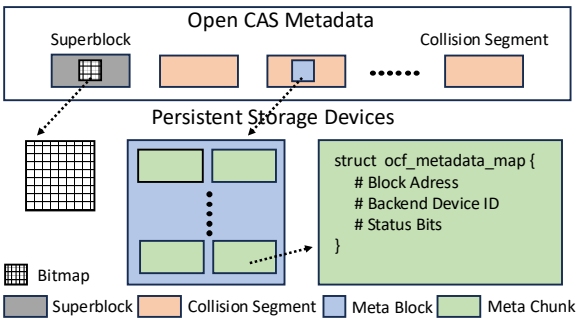

Figure 1: **Metadata Structures in Open CAS**

For the rest of this section, we first introduce the key data structures in Open CAS. We then introduce cache modes and basic cache operations including their reliability features for maintaining crash consistency. After that, We analyze the challenges of performing crash-consistency tests to implicit cache operation. Finally, we describe the post-recovery process of Open CAS.

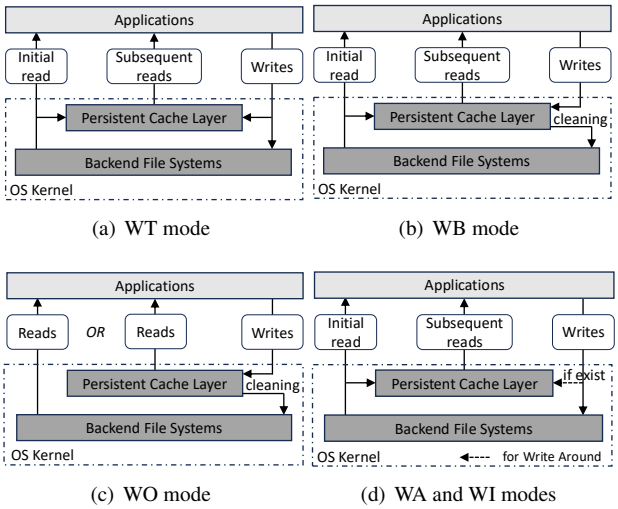
3.1 Data Structures

A `cache line` is the smallest data unit that Open CAS can manage. Every occupied `cache line` is associated with a `core line` on the backend file system and the `cache line` will be eventually written back to its associated `core line`. Open CAS supports different `cache line` sizes ranging from 4KB to 64KB. For each `cache line`, Open CAS maintains a small portion of metadata, which contains the information including core id, core line number, and valid and dirty bits for every sector. The core id determines on which core is the `core line` corresponding to the given `cache line` located, whereas the core line number determines the precise `core line` location on the backend file systems. Valid and dirty bits define the current `cache line` state. When a `cache line` is valid, it means that it's mapped to a `core line` determined by a core id and a core line number. Otherwise, all the other cache line metadata information is invalid and should be ignored. When a `cache line` is in an invalid state, it may be used to map `core line` accessed by I/O requests, and then it becomes valid. The dirty bit determines if the user data stored in the caching layer is in sync with the corresponding data on the backend file systems. If a `cache line` is dirty, then only data on the caching layer is up to date, and it needs to be flushed at some point in the future and be marked as clean by zeroing the dirty bit.

More specifically, as shown in Figure 1, Open CAS has different types of metadata information stored in multiple

Cache modes	Read cache hit	Write cache hit	Read/Write cache miss	Cache eviction	Cache cleaning	Cache flushing
Write-Through (WT)	-	Update	Mapping, Insertion	Eviction, Invalidation	-	-
Write-Back (WB)	-	Update	Mapping, Insertion	Eviction, Invalidation	Cleaning, Invalidation	Flushing, Invalidation
Write-Around (WA)	Invalidation	-	Mapping, Insertion	Eviction, Invalidation	-	-
Write-Invalidation (WI)	-	Update	Mapping, Insertion	Eviction, Invalidation	-	-
Write-Only (WO)	-	Update	Mapping, Insertion	Eviction, Invalidation	Cleaning, Invalidation	Flushing, Invalidation
Pass-Through (PT)	-	-	-	-	-	-

Table 1: **The involved cache operations in different cache modes.** Blank cells mean that none of the cache operations is applicable.



(a) WT mode (b) WB mode

(c) WO mode (d) WA and WI modes

Figure 2: **Cache modes of Open CAS.** Cache eviction and flushing are not shown in all figures.

segments, among which the "collision" segment is the key data structure for storing Open CAS `cache line` metadata. The collision section includes a set of 4KB metadata blocks in DRAM, each of which consists of multiple 12-byte chunks (12, 18, and 42 bytes for `cache line` sizes = 4KB, 16KB, and 64KB respectively) storing the mapping between a `cache line` and a `core line` and status bits (valid and dirty). In addition, the superblock segment includes the available `cache line` bitmap block and the recovery block which stores the option of post-recovery process.

3.2 Cache Modes

Open CAS accelerates Linux file systems by caching active (hot) data to caching layers, i.e., performance devices, thus reducing storage latency. Open CAS provides six cache modes, and based on performance improvements to read and/or write I/O requests, we generally classify them into two categories. In the read cache, initial read data is retrieved from backend file systems and copied to the caching layer. Subsequent reads are returned the copied data from the caching layer at the speed of performance devices. In the write cache, all data is written to the caching layer and eventually flushed to the backend file systems through the cache eviction and cleaning operations. For all cache modes, when the caching layer is full, newly identified active data evicts stale data from the caching layer by utilizing the cache eviction operation.

Write-Through mode: as shown in Figure 2(a), Open CAS writes data to the caching layer and simultaneously writes the same data "through" to the backend file systems. Write-through ensures the data written to the caching layer is always in sync with data on the backend file system. This mode only accelerates read requests, as writes need to be performed on both the backend file system and caching layer.

Write-Back mode: as shown in Figure 2(b), Open CAS writes the data first to the caching layer and acknowledges to the application that the write request is completed before the data is actually written to the backend file systems. Based on the cleaning policy, Open CAS writes back those data to the backend file system opportunistically. Write-back mode improves both write-intensive and read-intensive requests.

Write-Only mode: as shown in Figure 2(c), Open CAS writes user data exactly like in Write-Back mode so the data is written to the caching layer without writing it to backend file systems immediately. Read requests do not promote data to the caching layer.

Write-Around mode: as shown in Figure 2(d), Open CAS writes data to the caching layer if and only if that cache line is already mapped into the caching layer that it can be mapped during read requests. Simultaneously, Open CAS writes the same data "through" to the backend file systems. This cache mode only accelerates read-intensive requests.

Write-Invalidate mode: as shown in Figure 2(d), Open CAS handles write requests by writing data directly to backend file systems, and if the written cache line is already mapped into the cache, then it becomes invalid. Write-invalidate mode only improves read-intensive requests. It also reduces the number of eviction operations for workloads where written data is not often subsequently read.

Pass-Through mode: Open CAS bypasses the caching layer for all I/O requests. This mode is used for dynamically enabling/disabling caching layers without requiring to manually alter the I/O path in the application.

3.3 Cache Operations

There are seven cache operations upon which cache modes are constructed. To guarantee crash consistency of cache operations, Open CAS utilizes multiple techniques like atomic metadata update, I/O request ordering, and flapped sections. Getting familiar with them is essential to understanding how the test procedure is designed to cover all possible crash sce-

narios. It also helps us to explain our crash consistency experiment results.

Mapping is a cache operation of linking up a `core line` with a `cache line` in the `cache line` metadata. During mapping, a single `cache line` is assigned to the `core line`, and during cache operations, this area can be used for storing `core line` data, until the `cache line` is evicted.

In Open CAS, `cache line` metadata is stored in a small and constant block, i.e., 4K. Cache operations such as `insertion`, `invalidation`, etc. can atomically update `cache line` metadata to the caching layer by requiring a single I/O request and guarantees `cache line` metadata transactional consistency during performing I/O operations.

In addition, to ensure atomic update of the `cache line` bitmap, the flapped sections are designed. Specifically, the flapped sections in Open CAS maintain two copies of the `cache line` bitmap and information about which copy is valid. On the bitmap update, the bitmap flush is performed to an invalid copy, and then only after this operation succeeds the updated copy is marked as valid in the superblock, which is flushed afterward.

Insertion is a cache operation of writing `core line` data to a `cache line`. During insertion, the data of the I/O request is written to the `cache line` corresponding to `core line` being accessed. The valid and dirty bits of the cache line in the metadata are being updated accordingly during this operation.

To guarantee `cache line` data integrity, `insertion` operation is designed by ordering the I/O requests of `cache line` data and its metadata. Specifically, `insertion` first flushes the user data to `cache line`. When it is done, it then changes the corresponding validation bit from invalid to valid and updates the corresponding `cache line` metadata in the caching layer. Due to the initial invalid state of `cache line`, the corrupted data, which are caused by a system crash during flushing them to the caching layer, aren't accessed by users or flushed to the backend file system.

Update is a cache operation of overwriting `cache line` data in the caching layer. It's performed when the `core line` accessed during a write request is mapped into the caching layer and the accessed sectors are marked as valid.

Invalidation is a cache operation of marking one or more `cache line` sectors as invalid. It can be done during the handling of discard requests, during purge operations, or as a result of some internal cache operations.

Flushing is a cache operation of flushing all dirty data to the backend file system. `flushing` is a cache management operation and has to be triggered by users or Open CAS Udev rule. It is typically done for safely detaching the backend file system from the caching system or recovering the backend file system without risking data loss.

Eviction is a cache operation of removing `cache line` mappings. It's performed when there is not sufficient space in the caching layer for mapping data of incoming I/O requests, i.e., when cache occupancy is close to 100%. The `cache lines` to be evicted are selected by an eviction policy algorithm. Open CAS supports multiple eviction policies including the Least Recently Used (LRU) which selects `cache lines` that have not been accessed for the longest period of time.

Cleaning is a cache operation of synchronizing data in the caching layer and the backend file system. It involves reading sectors marked as dirty from the caching layer, writing them to the backend file systems, and setting dirty bits in `cache line` metadata to zero. It's performed by the cache automatically as a background task. The process of cleaning is controlled by a cleaning policy. Open CAS supports multiple cleaning policies including Approximately Least Recently Used (ALRU), Aggressive Cleaning Policy (ACP), and No Operation (NOP).

Finally, it is important to note that Open CAS doesn't record an operation log and persist it in the caching layer for the debug or failure recovery due to maximizing the caching performance. Table 1 summarizes the involved cache operations in different cache modes.

3.3.1 Implicit Cache Operation

Block-level caching systems like Open CAS are typically integrated into Linux operating system as a kernel module. The advantage of the integration is that the cache solution is transparent to the user applications and existing storage infrastructures, and no storage migration or application changes are required. However, due to restrictions by the existing Linux user interfaces, i.e., the POSIX standard [32], some cache operations cannot be explicitly invoked by the user interfaces. It also means that it is hard for a test framework to test these operations by explicitly invoking while performing system crashes. Furthermore, as a portion of Linux operation system, kernel modules are unexpected to change for software testing, e.g., adding the stub code. Actually, these cache operations are only invoked by internal cache policies, e.g., Least Recently Used (LRU) [7, 34, 50], which are typically decided by a heavy workload. We call these cache operations an implicit cache operation. For example, in Open CAS, `eviction` and `cleaning` are implicit cache operations. In summary, due to the implicit invocation and heavy workload requirement, an implicit cache operation is hard to test, and we will introduce our solution, workload-oriented test framework (WLOT) in Section 5.

3.4 Post-Recovery Process

Open CAS post-recovery process provides two options to recover a caching layer from a crash. The first option is to deal with a caching layer as page cache in volatile memory (e.g., DRAM). Specifically, Open CAS reinitializes the caching layer with new metadata, which clears the cache device, resulting in the loss of all cache data that is currently residing in the cache device.

The second option, a more sophisticated one, is to restart a caching layer and utilize the previous cache data, including metadata, in the cache device for a fast recovery. Specifically, Open CAS first performs CRC checksums for all metadata sections in the cache device and then compares them with ones stored in the recovery section to guarantee the metadata data integrity. To guarantee the data integrity of the recovery section, the recovery size is kept under 4K, which makes Open CAS update the recovery section atomically with a single 4K I/O. Then, Open CAS mounts the core devices, i.e., backend file systems, and the corresponding file system recovery process is activated according to the file system's reliability configuration. If the cache device and core device are successfully recovered, the recovered data in the caching layer can be accessed and reused by the backend file system and the applications. Open CAS recovery process is performed automatically in accordance with dynamic device management `Udev` [26]. Open CAS administrator can set the post-recovery process option and enable the caching layer to automatically flush the dirty data to the recovered file systems by configuring the in-built `Udev` rules in `60-persistent-storage-cas.rules`. Note that although Open CAS developers also mention the potential risk of data durability loss under this recovery option [9], there is no clear description or guidance to help users to evaluate the tradeoff between performance benefit and reliability risk for choosing the suitable recovery options. Therefore, we believe a thorough study is much needed.

4 Crash-Consistency Tests to Caching Systems

In this section, we first investigate the general principles for crash-consistency tests to a block-level caching system. Then, we take the in-build test suite in Open CAS as an example and specifically inspect its crash-consistency tests. Our aim is to find whether Open CAS in-build crash-consistency tests can guarantee data consistency in case of system crashes.

4.1 Principle of Reliability Test

Principle 1: *Crash-consistency tests should explore the crash behaviors of a caching system for crashes at any time.* Although crash consistency and data durability may not be guaranteed in any crash scenario, a system crash, such as a power outlet and system corruption, can happen at any time. It's necessary to understand complete crash behavior rather than solely crash scenarios where crash consistency is promised by caching system developers. By contrast, the crash consistency behaviors of file systems under any time system crashes were well studied [36]. More importantly, it helps system administrators to identify the root cause of crash inconsistency issues in the end-to-end file system. For end-to-end file systems, it can include multiple persistent caching layers, local file systems, and remote storage components. Each persistent layer and component may exhibit various crash consistency characteristics. Finding the root cause of crash inconsistency issues to such systems can be a daunt task. Understanding the complete crash consistency characteristics of individual storage layers eases system administrators to identify the root cause of crash inconsistency issues.

Principle 2: *Crash-consistency tests should cover all crash-vulnerable cache operations.* Like crash-consistency tests to other storage systems, it's necessary for test cases to cover all crash-vulnerable operations that potentially cause crash inconsistency. For example, many file system test tools [23, 29] more focus on testing the write-related operations since they change the internal state and the persistent user data. For caching systems, if a cache operation updates user data and/or caching system metadata in the caching layer, it will change the caching system state and be potentially vulnerable to system crashes. This cache operation can be seen as a crash-vulnerable cache operation. For example, in Open CAS, all cache operations can be seen as crash-vulnerable cache operations. By contrast, the cache operation for responding to a read cache hit request is not a crash-vulnerable cache operation since it doesn't change user data or caching system metadata.

Principle 3: *Crash-consistency tests should include diverse reliability features of file systems to guarantee compatibility with them.* The state-of-the-art reliability features of file systems, such as data journaling, copy-on-write, etc., are designed under the assumption that cached data is not available after crashes. During the post-recovery process, reusing the cached data in the persistent caching layer for a fast recovery may cause compatibility issues such as durability loss and crash inconsistency.

4.2 Crash-Consistency Tests in Open CAS

Open CAS provides a set of test cases, including unit tests and integration tests to guarantee correct implementation. Regarding system reliability, Open CAS offers crash-consistency tests in the integration test suite. We find that the test cases provided by Open CAS aren't enough to guarantee crash consistency and compatibility.

Code Observation 1: *Open CAS didn't provide crash-consistency tests to implicit cache operations.* Open CAS provides the test cases to all cache operations for functionality testing under normal cache scenarios. However, in crash-consistency tests, the test cases didn't include implicit cache operations. One possible reason for crash-consistency tests without including implicit cache operations is that it is difficult for a test framework to identify the running state of such cache operations for precisely injecting synthetic crashes.

Code Observation 2: *Open CAS didn't explore crash behaviors when crashes happen during cache operations on the fly.* In Open CAS, the in-built crash-consistency tests only cover the crash scenarios in which system crashes happen right after an acknowledgment of user APIs, which are the guarantees

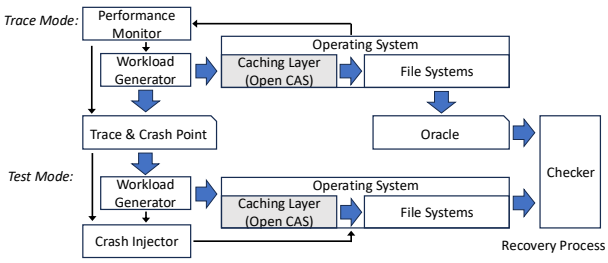


Figure 3: **Overview of crash-consistency test framework.**

of data durability and consistency.

Code Observation 3: *There are no test cases testing the compatibility with diverse reliability features of file systems.* In Open CAS, crash-consistency tests only perform synthetic crashes to the caching layer and takes one specific file system, i.e., ext-4, with the default configuration as the backend file system. The back logic of such test cases is based on the following assumption. If the newly added caching layer itself can keep crash consistency successfully, it should naturally work well with other file systems that include diverse reliability features.

In summary, crash consistency of Open CAS remains unknown in some crash scenarios. Also, extra test cases are required to guarantee the compatibility with diverse reliability features of file systems. We will present our analysis, including test methodology and results in later sections.

5 Crash-Consistency Tests to Caching Layer

Our crash-consistency tests to Open CAS includes two parts. One is crash-consistency tests to caching layers. The other is compatibility tests with backend file systems. In this section, we mainly focus on crash consistency of caching layers and perform system crashes solely on caching layers and try to answer the following research question: Can Open CAS keep the internal metadata and cached data crash consistency under all cache operations, cache modes, and crash scenarios? We will present compatibility tests to file systems in section 6, in which we explore Open CAS compatibility with diverse reliability features of state-of-the-art file systems.

This section is organized as follows. We first introduce our test framework, procedure, and workload for crash-consistency tests. We then discuss the results of our crash-consistency tests.

5.1 Test Framework

In this section, we first show the overview of our test framework. We then specifically present the workload-oriented test (WLOT) for testing implicit cache operations.

5.1.1 Overview of Test Framework

Our test framework is specifically performed on an HPE ProLiant DL380 Gen10 Plus server with 1 × Intel Xeon Silver 4314 processor, 1 × 4GB Optane Pmem as a cache device, and 1 × 256GB Samsung SATA SSD PM9A3 as a backend storage device. Above the hardware, we install Red Hat enterprise server 7.9 with 5.4.0-144-generic Linux kernel. We install Open CAS (version 22.03.2) as a caching system and ext-4 [47] as a backend file system. In addition, we set ext-4 with the default configuration and enabled direct I/O (–direct=1) to bypass page cache. WLOT has two modes of operation: trace mode and test mode. Figure 3 shows the main components and workflow in these two modes.

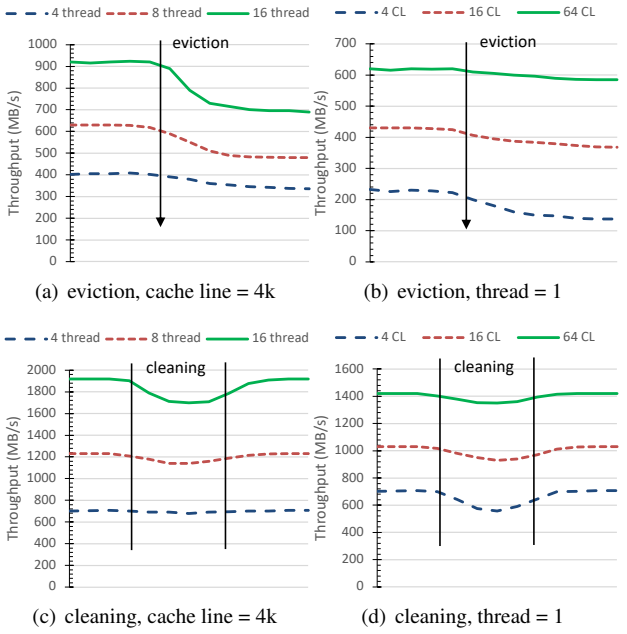
In trace mode, the framework first generates a specific workload and tracks write and/or read requests. While generating I/O requests to the caching layer, the framework utilizes the Open CAS command `casctl static` to monitor the I/O performance of the caching layer and sets crashing points which is based on the performance degradation caused by implicit cache operations. Right after setting crashing points, the framework stops the I/O requests and performs a flush operation to flush all cached data to a file to generate the test oracle. Except for the performance monitoring, we do similar steps for the trace generation and crash point setting to other cache operations.

In test mode, the framework first feeds the workload trace and injects a preset synthetic crash to the caching layer, and then triggers the post-recovery process of the caching systems. Finally, the checker checks the correctness by comparing the reads from the recovered caching system with the oracle. Two modes of operation are specifically important for testing implicit cache operations because the framework cannot identify the crash "window" for implicit cache operations without running the workload to the caching layer.

5.1.2 Workload-Oriented Test

The key challenge for performing crash-consistency tests to caching layers is to precisely inject a synthetic crash while executing an implicit cache operation, i.e., eviction and cleaning operation. As we discussed in section 3, an implicit cache operation can only be activated by cache policies rather than being explicitly invoked by user APIs. To address this challenge, we utilize the concept of implicit information [2, 41] in the operating system design and present the workload-oriented test (WLOT), a generic crash-consistency test framework for caching systems. Implicit information is a powerful tool to understand the running state of a gray box system, such as the operating system kernel, which knows the internal mechanism and external behavior but is ineligible to change the internal design including the interfaces. In crash-consistency tests to caching systems, WLOT detects the performance degradation of a caching system and leverages the performance degradation as implicit information to identify cache operation running states for a crash injection.

To better understand the performance degradation caused by implicit cache operations, we demonstrate an experiment for cache `eviction` and `cleaning` operations. We apply 4GB



(a) eviction, cache line = 4k (b) eviction, thread = 1

(c) cleaning, cache line = 4k (d) cleaning, thread = 1

Figure 4: **Performance Degradation by eviction and cleaning operations.** We measure the throughput degradation of Open CAS while performing eviction and cleaning operations under different cache line sizes and the number of threads.

Optane Pmem and 256GB PM9A3 as a cache device and a backend storage device separately. For the `eviction` operation, we continuously write data to the cache device, until it is full, to force the cache eviction policy to trigger the `eviction` operation. For the `cleaning` operation, we initialize the cache device with a 2GB cached data and repeatedly write a small subset of cached data (2MB) to the cache device, and wait for the cache cleaning policy to trigger the `cleaning` operation. To understand impacts of various factors, we test different `cache line` sizes = 4KB, 16KB, and 64KB, and various intention of workloads (# threads = 2, 4, 8, and 16). Figure 4 shows the I/O throughput degradation when performing `eviction` and `cleaning` operations. The results indicate that throughput degradation becomes significant when applying an intensive workload and a small size `cache line` size. Based on the above observations, we apply the following settings for our test procedure to help the test framework to identify the running state of `eviction` and `cleaning` operations more precisely. We use FIO (version 3.34-13) in 16 threads as the workload setting and 4K `cache line` size as the caching layer setting.

To confirm the accuracy of WLOT further, we specifically implement user APIs `casctl cleaning` and `casctl eviction` as testing drivers on Open CAS (version 22.03.2) for cache implicit operations `cleaning` and `eviction` separately. We then applied the same workloads above and explicitly invoked `cleaning` and `eviction` operations, and saw the same performance degradation pattern shown in Figure 4. We believe WOLT provides high accuracy for testing implicit cache operation with better generality and less human effort involved.

5.2 Test Procedure and Workloads

Since we specifically focus on the crash consistency of caching layers, we only perform synthetic crashes on the caching layer and leave the backend file system alive throughout our crash-consistency tests. Specifically, we use `unmount` and Open CAS's command `casctl stop` to perform a synthetic crash on the caching layer. By doing so, all in-DRAM user data and metadata that are related to the caching system are not available after a synthetic crash. We utilize `mount` and Open CAS's command `casctl start` to only activate the caching layer post-recovery process. We perform synthetic crashes during performing a cache operation and right after receiving an API return. Also, for each cache mode, we perform crashes for each cache operation multiple times to cover all possible crash scenarios.

The workloads are carefully crafted to cover all cache modes and cache operations including implicit cache operations. We set the capacity of the cache device as 4GB while utilizing FIO to write and read an oversized file with 6GB size to the Linux virtual block device. We specifically list workloads for each cache mode and cache operation below.

Write-Through mode: We apply sequential write (SW) and sequential read (SR) workloads, in which we sequentially write/read data into/from an oversize file, to test cache operations `mapping`, `insertion`, and `eviction` in the read cache miss, write cache miss, and cache eviction states separately. To test cache operation `update` in the write cache hit, we also apply repeat write (RW) workload, in which we repeatably write a small portion of the cached data to the caching layer.

Write-Back mode: We apply sequential write (SW) and sequential read (SR) workloads to test cache operations `mapping`, `insertion`, and `eviction` in the read cache miss, write cache miss, and cache eviction states separately. To test cache operations `update`, `cleaning`, and `flushing` in the write cache hit, cache cleaning, and cache flushing, we also apply repeat write (RW) workload.

Write-Around mode: We apply sequential read (SR) workload to test cache operations `mapping`, `insertion`, and `eviction` in read cache miss and cache eviction states separately. We also apply an update-after-read (UR) workload, in which we sequentially read and then write the same user data from an oversized file to test cache operation `update` in the write cache hit.

Write-Invalidate mode: We apply sequential read (SR) workload to test cache operations `mapping`, `insertion`, and `eviction` in read cache miss and cache eviction states separately. In addition, we apply repeat write (RW) workload to test cache operation `invalidate` in a write cache hit.

Write-Only mode: We apply sequential write (SW) workload to test cache operations `mapping`, `insertion`, and `eviction`

Cache mode	Workload	Crash point	Result-1	Result-2
Write-Through	sequential write	write cache miss	R	C
		cache eviction	R	C
	sequential read	read cache miss	R	C
		cache eviction	R	C
	repeat write	write cache hit	R	B
Write-Back	sequential write	write cache miss	R	C
		cache eviction	R	C
	sequential read	read cache miss	R	C
		cache eviction	R	C
	repeat write	cache cleaning	-	C
		cache flushing	R	C
		write cache hit	R	B
Write-Around	sequential read	read cache miss	R	C
		cache eviction	R	C
	update after read	read cache miss	R	C
		cache eviction	R	C
		read cache hit	R	B
Write-Invalidate	sequential read	read cache miss	R	C
		cache eviction	R	C
	repeat write	write cache hit	R	B
Write-Only	sequential write	write cache miss	R	C
		cache eviction	R	C
	repeat write	cache cleaning	-	C
		cache flushing	R	C
		write cache hit	R	B

Table 2: **Crash-consistency test results of caching layers.** The table shows the results of crash-consistency experiments on caching layers. Result 1 and result 2 represent crashes that happen right after acknowledgments and during performing cache operations separately. Each cell indicates whether Open CAS was able to recover data from a crash (R), whether Open CAS maintains crash consistency but did not successfully persist user data (C), and whether Open CAS returned bad data to the user (B). Blank cells mean that the result was not applicable.

in the write cache miss and cache eviction states separately. In addition, we apply repeat write (RW) workload to test cache operations `update`, `cleaning`, and `flushing` in a write cache hit, cache cleaning, and cache flushing. Table 2 summarizes the test workloads with the inserted crash points for all cache operations and modes.

For the check criteria, we check Open CAS log files and API returns for error messages and states. We also compare the cached data with the oracle, which is recorded during generating I/O workload, to ensure user data correctly persists in the caching layer when an acknowledgment returns to applications.

5.3 Results and Observations

The results of our crash-consistency tests are shown in Table 2. We now explain the results in detail in terms of the observations we made from our crash-consistency tests.

Observation 1: *Open CAS gracefully maintains crash consistency and data durability to caching layers in all cache operations and modes once it returns an acknowledgment to users.* This behavior is shown by the results (R) in the result-1 column of Table 2. Just like what Open CAS designers guarantee, we found that Open CAS gracefully recovers from a crash and maintains data consistency and durability, including internal metadata, after returning acknowledgment to users. There are no asynchronous I/O operations to flush data from DRAM to the persistent caching layer. Before returning an acknowledgment, all data and metadata have safely persisted in the caching layer.

Observation 2: *Open CAS maintains crash consistency to caching layers if a crash happens during cache miss and cache eviction.* This behavior is shown by the results (C) in the result-2 column of Table 2. Write/Read cache miss is activated by an initial write/read request and involves cache operations `mapping` and `insertion` which include three key steps:

1. Mapping `cache line` to `core line` and initialize valid bit of `cache line` to be invalid (atomic operation).
2. Write new user data to the cache device.
3. Write new metadata to the cache device (atomic operation).

Since the initial valid bit of `cache line` for caching the new data is invalid. Any corrupted data due to a crash in step 2 will not be returned to users or flushed to backend file systems. The corresponding `cache line` will be reused for caching other data in the future. Similarly, cache eviction involves cache operations `cleaning` and `invalidate` which include five key steps:

1. Read old data from the cache device to DRAM.
2. Write old data to the backend storage device.
3. Update status bits to be invalid and write it to the cache device (atomic operation).
4. Write new user data to the cache device.
5. Write new metadata to the cache device (atomic operation).

Notice again, since the valid bit of the evicted `cache line` for the new user data is updated to invalidate, any corrupted data later in that `cache line` will not be returned to the user or flushed to backend file systems.

Observation 3: *Except for write-around mode, Open CAS returns bad data to users if a crash happens during a write cache hit.* This behavior is shown by the results (B) in the result-2 column of Table 2. Unlike a write cache miss, in the write cache hit, there is no step 1 that initializes the corresponding `cache line` metadata as invalid when updating user data. The corrupted user data due to a crash can be cached to the caching layer and finally flushed to the backend file system and returned to users.

Observation 2 and Observation 3 also lead to an interesting conclusion that cold data is likely to tolerate more serious crashes than hot data which frequently update or access.

Observation 4: *Open CAS returns bad data to users if a crash happens during a write request to the cached data in write-around mode.* This behavior is shown by the results (B) in the result-2 column of Table 2. In write-around mode, processing a write request is mainly processed by the cache operation `invalidate` and involves two key steps:

1. Write the updated data to the backend file system.

2. Update status bits of metadata to invalid and flush it to cache device (atomic operation).

If Open CAS successfully writes the new data to the backend file system but fails to flush the corresponding metadata to the caching layer, the stale user data in the caching layer can return to users. Notice again, since the read cache hit doesn't involve cache operations in other cache modes, we only inject synthetic crashes during a read cache hit in write-around mode.

In summary, for all cache operations and modes, Open CAS successfully maintains crash consistency and persists the cached data once returns an acknowledgment to users. Meanwhile, when a system crash happens during cache operations on the fly, some cache operations cannot maintain crash consistency or data durability. The corrupted data may return to users and flush to the backend file system.

6 Compatibility Tests with File Systems

In Section 5, we showed crash-consistency tests to the caching layer. In this section, we try to explore how compatible Open CAS is with diverse reliability features of state-of-the-art file systems, i.e., whether post-recovery processes of file systems can coordinately work well with persistent caching layers. Our compatibility tests with file systems indicates that some reliability features of file systems are not compatible with Open CAS: incompatibility issues are various from minor issues, e.g., performance degradation to serious ones, e.g., durability loss.

This section is organized as follows. First, we discuss our test framework, procedure, and workloads we used to conduct compatibility tests. Then, we present the results and our observations.

6.1 Test Framework

Our test framework for compatibility tests is similar to crash-consistency tests to caching layers. The difference is the backend file system setting. We choose five state-of-the-art file systems with diverse reliability features as backend file systems. The target file systems roughly fall into three categories: 1) file systems with no or simple reliability features, i.e., ext-2 [8]; 2) file systems with journaling approaches, i.e., ext-3 [48] and ext-4 [47] in writeback, ordered, journal, and nodealloc configurations, and xfs [45]; 3) copy-on-write file systems, i.e., btrfs [27]. Table 3 lists backend file systems and their reliability features, i.e., configuration settings, we choose for our compatibility tests.

6.2 Test Procedure and Workloads

We study the compatibility of Open CAS under the more realistic crash-recovery procedures. During the crash procedure, we perform a crash as a clean power fault. Specifically, at the time of crashes, all I/O operations between the caching layer and the backend file system terminate immediately, and the caching layer cannot receive I/O errors from the backend device. In addition, all in-DRAM data and metadata that are related to the caching system and backend file system are not available after a crash. For the recovery procedure, we perform the post-recovery process on both the caching layer and the backend file system. Also, we reuse the cached data and metadata in the caching layer for a fast recovery. The specifics of our crash-recovery procedure in our test framework are as follows: we use `unmount` and Open CAS's command `casctl stop` to perform synthetic crashes on the both caching layer and backend file system. We utilize `mount` and Open CAS's command `casctl start` to perform the caching layer post-recovery process. After that, we utilize `mount` to automatically invoke the post-recovery process of the backend file system.

Since we are only interested in the post-recovery process of caching layers and backend file systems, we apply with the simpler workload and cache mode settings than Section 5. We only choose the repeat write workload and two write cache modes, i.e., write-back mode and write-only mode for compatibility tests. The reason for choosing WB and WO modes is that these cache modes can cache the latest user data, i.e., dirty data, in the caching layer and leave the stale user data in the backend file system, which enables us to expose more interesting results such as crash inconsistency or durability loss during the post-recovery process. Specifically, We first restore a file on the backend file system and then apply repeat write (RW) workload in the write-back mode and write-around mode separately, in which we repeatably write a small portion of the cached data to the caching layer.

For the crash point setting, we simultaneously inject synthetic crashes on both the caching layer and the backend file system. In addition, since we attempt to activate the post-recovery process of backend file systems, we always inject synthetic crashes during the backend file system performing I/O operation. We utilize the cache operations `cleaning` to raise I/O requests to the backend file system.

For the check criteria, we flush the cached data to the backend file system and compare the recovered file system image with oracle, which is generated by performing the same workload without a crash. We also check log files and API returns in both Open CAS and the backend file system for error messages.

6.3 Results and Observations

The results of our compatibility tests are shown in Table 3. The table reports the results of compatibility tests with state-of-the-art reliability features of file systems. We now explain the results in detail in terms of the observations we made from our compatibility tests.

Observation 1: *For ext-2 with all configurations and ext-3 with the default configuration, performing the file system post-recovery process and flushing dirty data to the file systems keep crash consistency and durability.* In Table 3, this behavior is shown by the results (SR). Since the recovered caching

File system	Configuration	Cache mode	Result
ext-2	-	Write-Back	SR
		Write-Only	SR
	sync	Write-Back	SR
		Write-Only	SR
ext-3	-	Write-Back	SR
		Write-Only	SR
	writeback	Write-Back	FE
		Write-Only	FE
	orderd	Write-Back	FE
		Write-Only	FE
	journal	Write-Back	FE, LE
		Write-Only	FE, LE
ext-4	nodelalloc	Write-Back	FE
		Write-Only	FE
	writeback	Write-Back	FE
		Write-Only	FE
	orderd	Write-Back	FE
		Write-Only	FE
	journal	Write-Back	FE, LE
		Write-Only	FE, LE
btrfs	-	Write-Back	FE, LS
		Write-Only	FE, LS
xfs	-	Write-Back	FE, LS
		Write-Only	FE, LS
	wsync	Write-Back	FE, LS
		Write-Only	FE, LS

Table 3: **Compatibility test results of caching layers.** The table shows the results of caching layer compatibility experiments with state-of-the-art file systems and their reliability configurations. SR represents end-to-end file systems fully recovered with a slow post-recovery process; FE represents flushing dirty data to file systems incurred an I/O error; LE indicates end-to-end file systems suffered from durability loss with an I/O error; LS indicates end-to-end file system suffered from durability loss silently. Blank cells mean the default configuration settings.

layer maintains the complete and up-to-date user data, including the related metadata, flushing dirty data to the recovered file systems can help file systems to keep up-to-date and maintain crash consistency. One minor issue is that during the file system post-recovery process, the time-consuming checking task, i.e. fsck, is performed and incur a slow recovery process. It finally makes Open CAS "fast" recovery guarantee impossible.

It seems the solution for this incompatibility issue is simple which just requires file systems to degrade their reliability features and omit to check entire file systems. However, there is a dilemma to do so. Actuarily, not all cache modes cache the complete and up-to-date user data so flushing dirty data to backend file systems are not always helpful for keeping file system crash consistency. For example, in write-around mode and write-invalidate mode, the caching system may or may not cache the up-to-date user data in the caching layer, which depends on workload and data access pattern. For these cache modes, degrading the reliability features and omitting internal data consistency checking can potentially cause the file system crash inconsistency.

Observation 2: *For ext-3 and ext-4 in journaling-related configurations, xfs, and btrfs, performing the post-recovery process and flushing the dirty data to the file systems incur I/O error.* In Table 3, this behavior is shown by the results (FE). For the file systems with journaling-related configurations, if a crash causes an incomplete journal transaction, the file systems will automatically switch to read-only mode in post-recovery process. As a result, flushing the dirty data to the recovered file systems incurs I/O error. Naively forcing the file systems to the read-write mode incurs a similar dilemma situation which we discussed in Observation 1.

Observation 3: *For ext-3 and ext-4 in journal configuration and xfs, performing the post-recovery process and flushing the dirty data to the file systems incur durability loss with an error.* Similar to Observation 2, ext-3 and ext-4 in journal configuration and xfs automatically switched into read-only mode when they were remounted to the caching system due to the incomplete journal transaction. However, forcing these file systems to read-write mode still cannot solve all compatibility issues. Different from Observation 2, ext-3 and ext-4 in the journal configuration and xfs write both data block and the related metadata, which are normally larger than 4K `caching line` size, to the journal. During the post-recovery process, if the journal transaction is complete, the data block and metadata in the journal are checkpointed to its final in-place block location. Otherwise, the incomplete transaction is discarded. On the other hand, Open CAS only guarantees data transaction at the grain of `caching line` size. By setting the dirty bits for each `cache line` , Open CAS can identify whether a `cache line` is successfully synchronized to the backend file system or not. Furthermore, during the post-recovery process Open CAS doesn't redo the last failed cache operation, i.e., `cleaning` in our case. Since the flushed dirty `cache line` didn't include the complete journal transaction, the file systems discarded the flushed data and raised an I/O error. Although Open CAS persisted the complete journal transaction data in the caching layer, part of them had been marked as a clean state i.e., setting the dirty bit to zero, and cannot be flushed to the backend file system again but be evicted by `eviction` cache operation which finally cause durability loss.

Observation 4: *For btrfs, performing the post-recovery process and flushing the dirty data to the file system incur durability loss without an error.* Btrfs is a copy-on-write file system that writes to the same block only once except for the superblock which contains root-node information. Specifically, btrfs first writes to a log tree to record changes and then writes the data block and any related metadata to new locations and updates the roots in its superblock. In case of a crash, btrfs effectively reverts the contents of the data block and metadata back to its old state. Similar to Observation 3, btrfs simply discards the incomplete user data and metadata during the post-recovery process. Flushing the rest data blocks and metadata cannot help btrfs to maintain crash consistency and keep user data up-to-date. However, unlike Observation 3, flushing the dirty data to btrfs does not return an error which finally causes a silent durability loss.

In summary, Open CAS fails to be compatible with the

diverse reliability features of state-of-the-art file systems. The incompatibility issues are various from minor issues, e.g., performance degradation to serious ones, e.g., durability loss. The results also indicate the more rigid reliability features may suffer from the more serious incompatibility issues.

7 Beyond Open CAS

In addition to Open CAS, we have applied the same test framework used in Section 5 to a simpler caching system, NVCache [15]. NVCache is an approach that leverages a non-volatile main memory (NVMM) as a write cache to improve the write performance of legacy applications. Similar to Open CAS, NVCache intercepts and redirects in user-space I/O function calls to achieve this transparency. Also, NVCache guarantees data durability once returning an acknowledgment to users. Unlike Open CAS, NVCache uses log structures for persisting `cache line` and its metadata. In each write request, NVCache appends the new user data at the end of `cache line` area and directly embeds a commit flag within each `cache line`. The commit flag indicates whether `cache line` data is successfully committed to the caching layer or not. In order to handle non-committed writes left in the caching layer after a crash, NVCache firstly saves user data to `cache line` and then updates the corresponding commit flag from non-committed to committed.

Our initial results indicate that NVCache is also vulnerable to system crashes. As shown in table 4, NVCache gracefully recovers data from system crashes for the write cache after returning an acknowledgment. Moreover, thanks to the log structure to `cache line`, NVCache maintains crash consistency to the caching layer if a crash happens during cache miss and hit which is better than Open CAS. However, similar to Open CAS, NVCache returns bad data to users if a crash happens during the cache operation `cleaning`, the only implicit cache operation in NVCache. In addition, we see the significant throughput collapses when performing the cache operation `cleaning` which indicates the generalization of the workload-oriented test for identifying the running state of implicit cache operations.

In summary, so far we have studied two examples: Open CAS, a complex block-level caching system with techniques to maintain crash consistency, and NVCache, a simpler block-level caching system with few mechanisms to provide extra reliability. Both are vulnerable to system crashes. In addition, since OrthusCAS [50] was integrated with Open CAS with minor modifications for performance optimization, we believe most of our observations of Open CAS should also apply to OrthusCAS. It seems that regardless of the complexity of the caching system and the amount of machinery used for crash consistency, implicit cache operations are still a bottleneck for crash consistency, and systematical crash-consistency tests are necessary for various caching systems. In addition, reliability feature co-design on caching layers and backend file system is necessary for keeping crash consistency.

Cache mode	Workload	Crash point	Result 1	Result 2
Write-Cache	sequential write	cache miss	R	C
		cache cleaning	-	B
	repeat write	cache hit	R	C

Table 4: **Crash-consistency test result to NVCache.** Each cell indicates whether NVCache was able to recover data from a crash (R), whether NVCache maintains crash consistency but did not successfully persist user data (C), and whether NVCache returned bad data to the user (B). Blank cells mean that the result was not applicable.

8 Related Work

There is a lack of related work on crash-consistency tests to block-level caching systems. In addition, previous work on the crash-consistency tests to end-to-end file systems simply models the crash behavior of caching layers as an in-DRAM page cache in which all cached data is lost in case of a crash. We compare our work with ones on file systems and databases. Crash-consistency test frameworks and fault injection techniques have been widely used to analyze the robustness and find bugs in file systems and databases [23, 29, 36, 44, 55, 56] For example, Crashmonkey [29] exhaustively performs file system crash-consistency tests within a bounded space, a heuristic pruning rule based on the bug study of real file systems. Hydra [23] mutates both file systems image and operation sequences when performing feedback-oriented fuzzing to identify crash consistency bugs. Block Order Breaker (BOB) [36] creates crash states from recorded I/O to show that different file systems persist file-system operations in significantly different ways. The Application-Level Intelligent Crash Explorer (ALICE), explores application-level crash vulnerabilities in databases, key-value stores, etc. The logging and replay framework from Zheng et al. [56] is focused on verifying ACID guarantees of databases, works on iSCSI disks, and uses four dedicated manual workloads.

However, our work on Open CAS is the first comprehensive crash consistency analysis of the block-level caching system that covers carefully controlled crash-consistency tests to caching layers and compatibility tests with backend file systems.

9 Conclusion and Discussion

In this paper, we analyzed a representative block-level caching system, Open CAS, to study the reliability of the persistent caching layer in case of system crashes. We introduce a novel approach the workload-oriented test to systematically perform crash consistency experiments to the caching layer and selectively perform integration test to the diverse reliability features of file systems. We presented our observations about Open CAS crash consistency and compatibility with the diverse reliability features of file systems.

Although these are always the tradeoffs one has to make for crash consistency, as one tier of the end-to-end file system, the block-level caching layer should provide strong crash consistency against crashes. We conclude by discussing some techniques that caching systems can use to increase system

reliability and compatibility.

Checksums in cache lines: Caching systems could protect the user data in the `cache line` by using checksums. For example, Open CAS could use a checksum inside `cache line` in the caching layer, update it on caching operation `update`, and verify the checksum on read-related caching operations or during the post-recovery process (Observation 3 in Section 5.3). However, this does incur an overhead in computation as well as some complexity in implementation.

Data synchronization during post-recovery process: To deal with the stale user data in the caching layer due to system crashes (Observation 4 in Section 5.3), a caching system could synchronize user data with backend file systems during post-recovery process.

Reliability-feature-aware post-recovery process: A caching system could be aware of the reliability features of the backed file system, and take a well-co-designed post-recovery process with them (Observation 1 - 4 in Section 6.3).

Acknowledgments

We thank the anonymous reviewers and our shepherd, Mai Zheng, for their insightful comments and feedback. We thank Kan Wu for the invaluable discussions. Abstract

Failure detection is one of the most fundamental primitives on which distributed fault tolerant services and applications rely to achieve liveness. Typical crash failure detectors resort to using timeouts that have to take into account the unpredictability in interaction times among remote processes, caused by resource contention in the network and in endhost processors. While modern (gray) failure detectors have improved in detecting a wide range of failures, the problem of prohibitively large and unreliable timeouts for crash failures still persists, hampering performance of both the failure detector themselves and modern µs-scale services sitting on top.

We propose a novel fully reliable failure-detector (FiDe) that can report the crash of a remote process in a datacenter within less than 30µs (7.2× faster than the current state of the art) with *extremely high reliability*, thanks to a ground-up design which provides stable end-to-end process interactions. By reliably lowering worst-case crash detection time, FiDe enables a class of algorithms that can be used to boost coordination services even in the absence of failures. We devise two novel, FiDe-based, highly efficient consensus protocols and integrate them into a key-value store and a synchronization service, improving throughput by up to 2.23× and reducing latency down to 0.46×.

1 Introduction

An increasing number of user-facing services are being developed as distributed applications, many running 24/7 in cloud datacenters leveraging cheap hardware parallelism.

Failure detection in datacenters. Alas failures are a common issue in all distributed systems, especially in cloud datacenters. Chiefly, processes can fail due to a variety of reasons, including hardware faults. Process failure detectors (FDs) are thus a common building block in fault-tolerant distributed systems, which include highly available core services underlying user-facing applications. FDs allow the cross-cutting concern of detecting and notifying process failures to be factored out into one module, encapsulating timeouts and more, used by various components and systems. Timeouts are at the center of the prominent *heartbeat* crash FD design which has distributed processes periodically send "I am alive" messages to each other, interpreting the absence thereof beyond a certain time limit as indication of failure.

Limits of current timeout-based detectors. FDs are fundamentally limited by the systems they are built on. Distributed systems, including datacenters, are commonly viewed as being completely asynchronous, which makes it in theory impossible to achieve reliable failure detection, i.e., failure detection without any false suspicions. In practice, any FD must eventually make some synchrony assumptions and resort to heartbeats/timeouts to detect the unresponsiveness of monitored processes. Timeouts can be easily set too short, leading to premature false suspicion of processes. Inversely, setting timeouts too large can hamper system performance by delaying reactions to actual failures which is unaffordable for the growing µs-scale application market [2, 46]. With several processes failing in short time without their timely removal or replacement, common systems relying on majority quorum voting can block as the number of correct processes drops below the necessary quorum size. Tradeoffs between safety and liveness can not be navigated reliably by applications using an FD built on top of standard communication and OS abstractions. A common mitigation strategy is to resort to error-prone manual deployment and resource reservation [35, 38, 83].

Multi-level and gray failure detection. Previous fast, reliable FDs described in literature [7, 24, 44] build on the concept, spearheaded by Falcon [45], of closely monitoring multiple layers of a system (e.g., application process, OS, VM) through a network of probes. Increasingly popular gray failure detectors [27, 49, 58] use similar techniques to very effectively detect subtle failures (e.g. deadlocks) which harm availability without processes crashing. While these approaches excel at addressing a large variety of failure scenarios, they increase

software and system complexity. In the context of crash failures this leads to additional observation overhead, a conundrum of having to "monitor the monitor", besides requiring the programmer to implement failure detection logic. These design side-effects can decrease reliability by increasing performance non-determinism in applications, often compensated for by actively killing monitored application/host to back up a false failure suspicion [20, 45].

FiDe. This paper proposes a different novel approach specialized for crash failure detection, based on the observation that existing crash FDs are limited by being realized as modules, not as components, and do not fully exploit precision and programmability of modern OSes and networking hardware. More precisely, our approach is *system-driven*: leveraging custom lean system support from the ground-up, our approach, dubbed FiDe[1], achieves ultra-low and ultra-stable latency process interactions (communication and reaction) in a subset of the system custom built for failure detection enabling reliable heartbeats, as opposed to prior approaches which are at best adapted to a given system (*system-tailored*). In short, this is achieved by a combination of techniques including highly stable OS-supported send/receive pipelines and traffic engineering (TE) to reserve communication resources on switches via a centralized controller upon pre-registration by applications. FiDe also caters for network failures, making the probability of a false positive (i.e., a late or missed heartbeat with no process crash) to be once in years of uptime. To be clear, the correctness and efficiency of FiDe/FiDe-based protocols depend on assuming synchrony. While all-encompassing synchrony is unfeasible, the probability of synchrony violations in FiDe's controlled environment is negligible for practical purposes thanks to its reliable system substrate enforcing the assumption. Moreover, our approach is *externally observed*: application processes are monitored by dedicated, uninterrupted FD processes which leverage insights already provided by the OS as opposed to burdening programmers to modify applications to make them *internally observed* and in the process making them perform non-deterministically.

The extremely high reliability and promptness of FiDe serve two main purposes: (1) provide a foundation for developing novel, more efficient and simpler distributed coordination primitives and (2) improve crash detection accuracy and performance of core services with high availability requirements as standalone or combined with a more comprehensive (e.g. gray) failure detector. In summary, this paper presents:

- the design of FiDe which is system-driven and externally observed, allowing it to be very reliable and timely, while remaining non-invasive.
- FiDe's implementation using a high-performance system substrate based on custom process and network isolation, traffic engineering, and network processing pipelines.
- the design and implementation of novel FiDe-based broadcast and consensus primitives for simple fast replication.
- the empirical evaluation of our prototype in a production datacenter of SAP. FiDe consistently detects failure within less than 30µs outperforming the fastest state of the art crash failure detector by 7.2×.
- the integration of FiDe-based algorithms into the Redis key-value store [62] and Zookeeper synchronization service [29] to increase throughput by 1.7× and 2.23× and reduce latency down to 0.46× and 0.57× respectively, in failure-free execution.

The paper is structured as follows. § 2 presents model and assumptions, and § 3 FiDe's design. § 4 outlines FiDe-based algorithms. § 5 presents implementation details. § 6 evaluates FiDe by comparison to prior art. § 7 contrasts FiDe with related work. § 8 concludes with final remarks. App. A details FiDe-based algorithms, and App. B the TE algorithm. in detail. App. C provides details on network failure probability.

2 Model and Scope

2.1 System and failure model

FiDe is designed primarily to detect *crash-stop process failures* in networked distributed systems, and for use in applications dealing with such failures. When not specified further, a "failure" refers to when a process drops from the process table of the underlying OS.

Gray failures [49], fail-slow [52], and partial software/process failures [50] are not directly targeted by FiDe. However, one of FiDe's intended use-cases is to be used in combination with more comprehensive failure detectors aiming to improve their remote failure detection.

Due to the need for communication in failure detection, and the possibility of communication failures being falsely interpreted as process failures, FiDe has to cater for *network failures*, manifesting by packet drops (i.e. generalization of switch and link faults). We address this by exploiting 2-fold physical redundancy in the network configuration and introducing a network failure recovery mechanism (see § 3.3). FiDe tolerates multiple network failures unless they occur in very quick succession within the recovery time (we denote such set of failures as *critical compound failure*). We do not consider Byzantine failures but design FiDe to serve as a high-performance component of FDs providing broader coverage, i.e., gray/Byzantine failure detectors. We assume that software bugs, which are omitted even by several works on Byzantine fault tolerance (BFT) as corresponding bugs would be triggered across replicas, are handled by formally verifying FiDe-based algorithms (cf. [12]).

[1] ("Fee-deh") Latin for "with trust", a declination of *fides* = "trust", "faith".

2.2 Properties

We revisited the FD primitive and designed FiDe from the ground up aiming for three salient properties:

Reliability: FiDe's primary goal is to approximate (*in practice*) the strong completeness and strong accuracy properties of Chandra&Toueg's failure detector classification [14]. In short, if a process fails all interested correct processes are notified (completeness), and only then (accuracy).

Timeliness: FiDe explicitly aims for µs range failure detection, going beyond simple "eventual" notification of actual failures to correct processes.

Non-intrusiveness: Unlike existing failure detectors [2, 24, 45, 76] that require application-specific code injection even for crash failures to guarantee prompt detection, FiDe embraces the separation of concerns principle. Applications should be able use it immediately out-of-the-box through a lean API.

FiDe ensures reliability and timeliness by establishing *stable*, *end-to-end timely interaction* among its processes. The key to achieving this is minimizing interference at both process and network level: FiDe reduces maximum jitter to a point where it becomes consistently so small relative to the latency, that, in practice, it can be assumed to be bounded. We acknowledge that, in general, all-encompassing synchrony is unfeasible and that there is a probability that a series of failures (i.e. critical compound failure) and delays could break FiDe's model assumptions and reliability property. FiDe is explicitly designed and system-driven to make such probability negligible for a "slice" of the datacenter (FiDe domain). We show an estimate of this probability to be once in years of uptime, orders of magnitude less likely than failures in commonly-believed reliable services such as TCP.

2.3 Targeted services

We target core services with high availability requirements, like replicated storage or databases and increasingly relevant µs-scale services [2, 10, 24, 38]. FiDe's primary goal is to boost common fault-tolerant coordination protocols, e.g., consensus, underlying such services, through reliable and fast crash failure detection (§ 4). While we could use the reliable system substrate provided by our design to support more complex services, we choose to specifically support only failure detection in order to preserve modularity, allowing FiDe to be tailored to custom coordination protocols and failover mechanisms. Our solution requires a minimal setup time, which is negligible compared to its uptime, and acceptable for such services. We assume that a number of resources can be dedicated to FiDe, which is the case for modern over-provisioned datacenters and is commonly enforced *manually* in current practice when deploying critical services [19, 83]. Our primarily targeted services are in practice limited in scale, with replication clusters typically around 3 to 5 nodes (e.g. Zookeeper advises 5 nodes for exceptional maintenance [83]), almost never above 9 as shown in previous work [2, 6, 24, 34, 39]. While FiDe's design does not prevent it from larger scale deployment as in blockchains, this paper does not explore that angle.

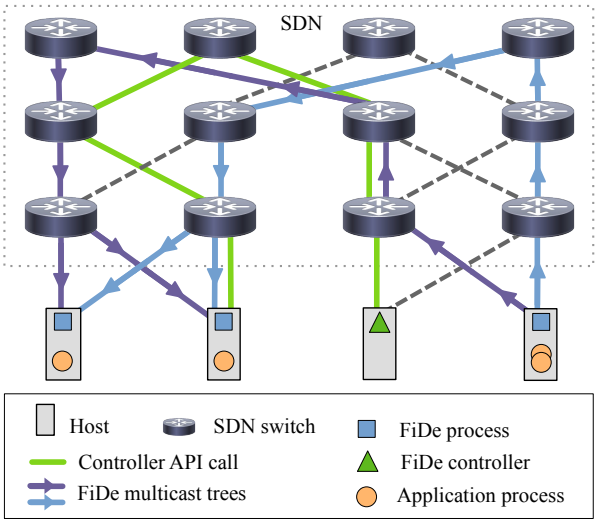

Figure 1: Simplified datacenter fat-tree topology showing FiDe's architecture and process interactions.

3 System Design

3.1 Architecture

Components. Fig. 1 illustrates the architecture of a typical FiDe deployment. It consists of a set of client processes (simply called *FiDe processes*), deployed alongside a distributed application, and a *FiDe controller* which dynamically configures the switches of a software-defined network (SDN) using our custom traffic engineering (TE) techniques (§ 3.3). FiDe processes are at most one per host, where they monitor one or more local *application processes* (§ 3.4). At the same time, each FiDe process can monitor and/or be monitored by other FiDe processes. Monitoring in a FiDe *cluster* need not be symmetrical, allowing for more flexibility and efficiency, covering application use cases where not all hosts play the same role (e.g. clients monitoring servers but not vice-versa).

Communication. FiDe processes communicate via a set of redundant directed multicast trees (cf. blue and purple lines in Fig. 1). The FiDe controller adjusts trees dynamically with cluster join request by allocating resources to each FiDe process according to the network topology, capacity, and number of monitoring processes (cf. § 3.3). The controller provisions and monitors such resources with TE techniques that cap jitter

```
struct resources {
  int pbsize;    // max piggyback size
  int timeout;   // min wrt request
}
// Downcalls from app to FiDe
↓ resources monitor(int appid, resources r);
↓ void unmonitor(int appid);
↓ bool join(appid);
↓ void quit();
↓ bool piggyback(char[] message);
// Upcalls from FiDe to monitoring apps
↑ void on_failure(int appid);
↑ void on_piggyback_recv(char[] message);
↑ void on_timeout_changed(int timeout);
// Upcalls from FiDe to monitored apps
↑ void on_monitor_req(int appid, int pbsize);
↑ void on_pbsize_changed(int pbsize);
```

Listing 1: Summary of FiDe's C API exposed to applications.

introduced by concurrent traffic. We use standard Ethernet links while prioritizing FiDe traffic and exploiting a custom TE-driven periodic IP-level multicast protocol, thus enabling reliable communication (see § 3.3).

Monitoring, allocation and piggybacking. Applications interact with FiDe through the API shown in List. 1. At a high level, applications can `join`, `quit` and `monitor` another application supplying a desired timeout value and a minimum piggyback message size. The FiDe controller the proceeds with the TE-driven allocation (§ 3.3), possibly relinquishing resources for processes already in the cluster (through callbacks `on_timeout_changed` and `on_pbsize_changed`) in case the current network capacity is not sufficient. After registration, a FiDe process uses the `on_failure` upcall to notify of a failure, which might be followed by a re-allocation find a more optimal resource assignment for remaining applications. Monitored applications can `piggyback` a limited amount of messages on FiDe's monitoring payload. The size of the piggyback payload (`pbsize`) is determined by the TE-driven allocation process to a maximum of 1418B. FiDe declines `piggyback` calls that try to exceed `pbsize` as it would break the guarantees provided by TE. Piggybacking enables seamless integration with gray/multi-level failure detectors, improving the propagation time of custom failures as we exemplify later. When applications and FiDe processes use distinct network paths, it could occur that the communication between applications is interrupted while respective FiDe processes monitoring such applications can still communicate, hence resulting in a "false negative". Piggybacking can prevent such scenarios since it ensures that the traffic of both application and FiDe processes goes through the same network path. Moreover, piggybacking exposes FiDe's reliability property to the monitored processes, bridging the gap between modularity (i.e., using FiDe as a general-purpose reliable crash FD module) and protocol-specific optimizations. We exploit piggybacking to define an efficient consensus primitive in § 4.

3.2 Reactive, uninterrupted processing

Task preemption is managed by the OS kernel scheduler which, generally, distributes running processes in a fair manner across all CPU cores. This is detrimental for time-sensitive tasks, in which preemption overhead is often the predominant cause of high processing tail-latency, as shown in previous work [21, 37, 53]. FiDe minimizes jitter through selective isolation and custom reactive network processing pipelines. We pin a FiDe process to a *dedicated CPU core*, set it to the highest active power state and isolate it from OS interrupts to provide uninterrupted execution. FiDe's Linux kernel module (LKM) exploits kernel space privileges to provide prompt monitoring of application processes (§ 3.4). It also uses an uninterrupted dedicated loop for ultra-stable periodic sending of heartbeat packets, bypassing the jitter-prone network stack. On the receiving side, we optimize packet delivery latency by reserving one specific queue in the network interface controller (NIC) to FiDe's traffic and throwing an interrupt request (IRQ) to FiDe's core at packet reception. This allows the separation of FiDe traffic and regular traffic both for reception and processing, allowing to maintain timeliness and low jitter even under heavy load. Finally, FiDe uses eXpress Data Path (XDP) [78] to intercept its packets as early as possible in the network stack and quickly deliver them, reducing network stack overhead on the receiving side as well. We experimentally found that using XDP and core isolation techniques account for the great majority (> 90%) of the jitter reduction, while other techniques are used to mitigate low, sporadic latency spikes. We fine tune low-jitter processing optimizations based on existing interaction latency breakdown studies [51, 82] and leave in-depth analysis contributions of each optimization for future work.

3.3 Fast-track, redundant networking

Fast-track multicast trees. FiDe minimizes network interference by establishing "fast-track" communication between FiDe processes, using TE techniques to manage and assign resources of links and switches within the limits of availability in order to avoid congestion upfront. This is made possible through an software-defined network (SDN)-assisted *periodic multicast protocol*. The FiDe controller enables the use of the protocol without making any explicit bandwidth reservations in the network, relying instead on reserving highest-priority queues and rate limiting at endhosts. The latter is a part of a contract between a sending FiDe process p_i^*, a set of receiving FiDe processes $\{p_j^*\}_{j \in J}$, and the network, where we use p_i^* instead of p_i to denote that p_i^* is a FiDe process and not an application process. Concretely, if p_i^* sends multicast

messages of maximum size $\sigma_{\max}(i,J)$ to the receiving processes with the minimum period $\pi_{\min}(i,J)$, then for every $j \in J$ the messages experience minimum latency $\lambda_{\min}(i,j)$ with maximum jitter $\delta_{\max}(i,j)$ when delivered to p_j^*. The prioritization ensures that the guarantees hold under arbitrarily heavy network load. TE techniques (see App. B) are used to compute and assign such parameters to a set of directed (single-source) *multicast trees*, each tree representing one-to-many network connections from a single sending process to a set of receiving processes. The trees in the set are vertex-disjoint (in internal nodes) providing redundancy. The TE algorithm takes as input i, J, $\sigma_{\max}(i,J)$, and the lower bound on $\pi_{\min}(i,J)$, and then constructs the new multicast tree set in such a way as to minimize the sum of maximum latencies among all trees, taking into account and possibly changing protocol parameters of already existing trees. The algorithm makes a crucial use of regularity of datacenter networks in tackling the challenge of vertex-disjoint tree set construction. We use the periodic multicast properties given by TE to determine the timeouts. FiDe exploits this within a simple heartbeat mechanism, where the heartbeat interval HB_i of every monitored FiDe process p_i^* is larger than or equal to the period $\pi_{\min}(i,J)$ assigned by TE to the corresponding set of multicast trees. Given a monitored *application* process p_i, an application process p_j monitoring p_i can set a timeout $TO(i,j)$ to $TO(i,j) = HB_{i'} + \lambda_{\min}(i',j') + 2 \cdot \delta_{\max}(i',j')$, where $p_{i'}^*$ is a FiDe process at p_i's host, and $p_{j'}^*$ is a FiDe process at p_j's host. Note, this ensures that all heartbeats sent by p_i are delivered to p_j before p_j's timeout expires. Our TE can be configured to use at most a given fraction of network bandwidth and queue capacity, or to restrict FiDe interaction to a desired subset of network links.

Redundancy and tree recovery. Network failures may cause a monitoring process to miss a heartbeat message, leading to a false positive. FiDe uses twofold physical redundancy with a tree recovery mechanism to increase robustness to such failures. First, the FiDe controller builds a pair of redundant trees for every cluster. A monitoring process detects a network failure (including slowdowns or suboptimal trees) when it receives a single heartbeat. It then informs the FiDe controller which computes an alternative tree to substitute the faulty one, contacts relevant switches to reserve priority queues and change routing tables. FiDe can be configured for the case when no alternative tree is available. One option is to simply notify the application and carry on, which might lead to compromising FiDe's properties (cf. §2.2) upon (additional) network failures. FiDe can be configured to also terminate gracefully without compromising reliability guarantees, by discontuing operation, which can for instance further involve the option of terminating protocols relying on FiDe before FiDe processes. This mechanism prevents any number of network failures from affecting reliability unless two or more affect both trees within the recovery time, i.e., in case of a critical compound failure. We give an estimated probability bound on such event occurring in §6.5.

Deployment notes. The simplest and most efficient deployment option is having all FiDe processes *as close as possible* while still maintaining redundancy (e.g. nodes linked to 2 ToR switches via redundant multicast trees of depth 1). This allows for minimal latency, network utilization/reservation as well as maximal network fault tolerance since the number of links and devices that can fail is minimal. FiDe can however be deployed over a larger topology if desirable, e.g., to follow application constraints, differentiate power supply or resources. In such deployments, FiDe continues to rely on the tree recovery mechanism to mitigate the probability of additional network failures. We evaluate the impact of deployments over larger networks in §6.5. Moreover, since the number of priority queues at the switches is limited, it can be desirable to share them with other services. FiDe TE can also account for these services and adjust periodic multicast properties accordingly, making use of the fact that high-priority queues often correspond to near real-time or control traffic, both of which are likely rate-limited already.

3.4 Failure detection

Domains. Distributed applications relying on a failure detector (e.g., replicated key-value stores or relational databases) are typically deployed as ordinary processes and therefore use system resources in the usual best-effort manner. We make no changes to this behavior and only focus on shielding FiDe from jitter sources. The resulting system, illustrated in Fig. 2, is split into two domains. We call "*best-effort domain*" the application environment where network and endhost resources are shared with other processes and "*FiDe domain*" FiDe's privileged system substrate. This system-driven design allows FiDe to achieve unprecedented timing consistency and differentiates it from previous performance-enhancing approaches (e.g. systems based on data plane development kit (DPDK), remote direct memory access (RDMA) and kernel-bypass [2, 17, 24, 80]).

Workflow. Fig. 2 shows the flow of events following different types of failures in our model. In *passive* failure detection (used to detect all failures that render the system unusable), a host fails causing both the FiDe process and the application process p_1 to fail as well ①. The periodic sending of heartbeat messages containing monotonically increasing values is therefore interrupted ②. Remote FiDe processes poll an extended Berkeley packet filter (eBPF) map containing the heartbeat value of each monitored process at every `timeout` interval and triggers a failure notification upcall ③ when they read the same value twice. Note that the scenario, where a FiDe process fails but its monitored application process does not, is prevented by the fact that FiDe runs in the kernel and is

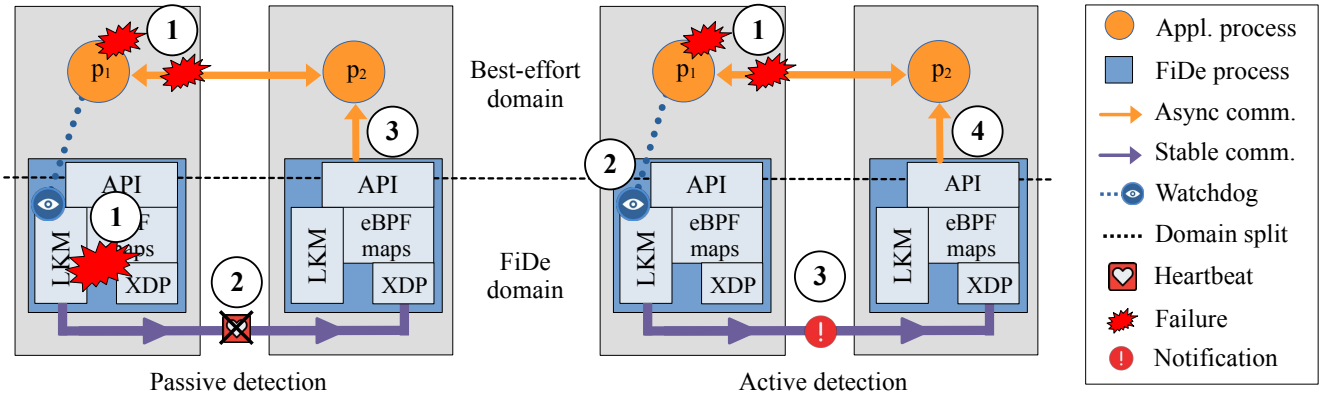

Figure 2: Failure detection flow in different scenarios. FiDe uses passive detection (left) when a FiDe process (i.e. the whole host) fails and active detection (right) when only an application process fails.

designed to not be subject to partial OS failures. In *active* failure detection (right scenario), an application process p_1 fails ① and becomes unresponsive to other applications. FiDe's LKM detects this promptly ② using a *watchdog* and immediately sends a failure notification ③ to all monitoring FiDe processes. Remote XDP hooks trigger the failure notification upcall ④ to the application.

Prompt detection with OS watchdog. FiDe uses an OS watchdog to monitor applications. The watchdog is implemented inside the LKM and uses a `kprobe` [47] registered on Linux's `do_exit` function. Every time the process id of the failed (i.e. exiting) process matches one of the application process ids monitored by FiDe, the OS watchdog logic in the `kprobe` pre-handler is executed just *before* the process actually fails. This design grants accurate detection, as the OS watchdog only reports a failure when it is officially "registered" by the system, prompt detection (technically negative latency) and solely relies on a single external observer.

External vs internal observation. Reliability and timeliness of a failure detector are often associated with its fine granularity: monitoring of as many as possible system components at multiple levels, from network nodes to application threads. This has been a common design principle in several systems [4, 50, 55], among which we find Falcon [45] of particular relevance, as it constitutes the base of several other systems [24, 27, 43, 44, 58, 76]. Such multi-level, system-tailored failure detectors are implemented by placing several probes (also called hooks or spies) in the software stack, a technique that we refer to as *internal observation*. This approach provides higher specificity: programmers can tailor detection probes to detect custom failures - including gray and partial failures - inside the application. However, this comes at the cost of increased complexity and intrusiveness for crash failures. system-tailored FDs have to take into account the failure of the probes themselves through a network of probes-monitoring-probes, introducing observation overhead which is often compensated for by selective killing and/or unreliable timeouts. Additionally, internal observation requires hundreds of lines of application-specific code for every monitoring probe [27, 43, 45, 49]. Thanks to its *external observation* approach which uses a single, external, timely observer (§3.4) on top of stable interactions, FiDe instead achieves reliable and non-intrusive detection of crash failures, trading off coverage for improved performance in order to boost services running on top (including gray FDs).

4 FiDe-based Novel Fast Services

4.1 Boosting consensus

A core contribution of this work is exploiting the extremely high reliability and speed of FiDe to improve the efficiency and simplicity of distributed services in *failure-free* executions. We use FiDe as a practical approximation of Chandra and Toueg's perfect failure detector $\mathcal{P}$ [14] to devise three novel algorithms: one reliable broadcast and two uniform consensus primitives which achieve consistent replication more efficiently than classical, quorum-based alternatives (Tab. 1). We give a concise overview of the algorithms below, please refer to App. A for in-depth specification and description. The algorithms were specified with TLA+ [74] and their correctness verified with TLC [79]. Algorithm TLA specifications and Redis implementation will be submitted to artifact evaluation can be found at: `https://github.com/swystems/fide-fd`.

Optimistic stabilizing reliable broadcast (OSRB). We start by introducing OSRB: a novel broadcast primitive which we later use in HSUC. OSRB optimistically implements BROADCAST using a multi-send, DELIVERS and buffers received messages, which it may need to retransmit later upon detecting a process failure. Classical lazy reliable broadcast

primitives require messages to be buffered infinitely because they might need to be re-transmitted eventually [13]. Since buffering in long-running applications can result in a prohibitively large memory footprint and possibly buffer overflow, OSRB introduces a novel performance improvement via an additional downcall called STABILIZE, which takes a message *id* as an argument. STABILIZE gives the possibility to apply a stabilization criterion to limit the messages buffered for lazy message relay upon failure. Ensuring that the stabilization criterion is satisfied is responsibility of a OSRB user, i.e., the protocol/application using OSRB must call STABILIZE only when every correct process has RECEIVEd a message (cf. App. A); otherwise, the *agreement* property of RB can be violated.

Hierarchical stabilizing uniform consensus. The first algorithm, hierarchical stabilizing uniform consensus (HSUC), solves uniform consensus (see [13] for specification) using a hierarchy among the processes and FiDe as a reliable failure detector. Processes that participate in consensus (e.g., key-value store replicas) are given an *id* to establish a hierarchy, in which the process with the highest ID corresponds to the first leader. During normal execution, a client sends a write request to the leader which starts the consensus instance, adopts the request as its proposal and multi-sends it to all other processes. Processes which receive the proposal from the leader adopt it as theirs and send an acknowledgment (ACK) to the leader. Once the leader collects ACKs from all processes, it disseminates its decision using OSRB and DELIVERs itself. Replicas also DELIVER once they receive the leader's decision. OSRB guarantees *Termination*, i.e., that the decision is delivered by all processes. Upon leader failure, FiDe notifies every process so that the next leader in the hierarchy can proceed with the algorithm. FiDe's accuracy enables an important algorithmic optimization: unlike quorum-based asynchronous algorithms which tolerate only a minority of crash process failures, HSUC can tolerate N-1 failures with same message complexity (cf. Tab. 1). The reception of the next round's decision defines the stabilization criterion of OSRB. Once this phase of the algorithm is reached, HSUC can safely call STABILIZE so that the message from the previous consensus will not be retransmitted by OSRB upon future failure detections, limiting the number of messages to be relayed to 2.

Fail-consistent uniform reliable broadcast We abstract FiDe's piggyback feature, i.e., the mechanism that allows applications to add a message into FiDe's heartbeats, into a primitive called fail-consistent uniform reliable broadcast (FCURB). FiDe's heartbeats have two important properties. First, every correct process either receives a heartbeat from a given process or no process does since multicast, redundancy and tree recovery guarantee uniformity (unless an extremely rare critical compound failure occurs, cf. §3.3, §6.5). Second, for any two FiDe processes p_i, p_j in a cluster, all heartbeats sent by p_i are delivered to p_j before p_j detects the failure of p_i. This is due to FiDe's upper-bounded interaction latency and the choice of large-enough timeouts (see $TO(i, j)$ in §3.3). Note that this order applies for both (1) passive failure detection since a crashed FiDe process is unable to send further heartbeats and (2) active failure detection since a FiDe process stops sending heartbeats after detecting a failed application (note that messages are not piggybacked into active notifications). Hence, applications using FCURB are guaranteed that all processes deliver a message before failure notifications. We call this property *fail-consistency* (refer to App. A for a formal specification).

Table 1: Complexity of FiDe-based algorithms in comparison with Raft and Zab in the failure-free (best) case. Note that Raft and Zab also tolerate process slowdowns.

	Message delays	Message complexity	Tolerated process failures
Raft	2	$O(N)$	$\lfloor \frac{N-1}{2} \rfloor$ (crash/slow)
Zab	3	$O(N)$	$\lfloor \frac{N-1}{2} \rfloor$ (crash/slow)
HSUC	3	$O(N)$	$N-1$ (crash only)
HUC	2	$O(N)$	$N-1$ (crash only)

Heartbeat uniform consensus. The second algorithm, heartbeat uniform consensus (HUC), is shown in Alg. 1. Here, all processes send proposal to a designated leader (line 5-7). The leader waits to collect proposals from all correct processes, i.e., all processes which are not signaled by FiDe, DETerministically chooses one of the proposals (line 12) and then broadcasts the decision using FCURB (line 11). Failures are detected by FiDe (line 15) causing HUC to update the *correct* set (line 16) and possibly triggering a new leader election in case the failed process is a leader (lines 18-21). FiDe's accuracy (cf. §2.2) guarantees that all processes consistently detect the failure of a leader, i.e., no two processes can have different leaders at one time. Unlike HSUC, HUC does not need an explicit ACK-ing round before calling DECIDE as the moment a proposal is sent to a new leader (line 21 or 7) it is already known that no decision from an earlier leader will ever be delivered. This is due to FCURB. To send a proposal to a newly elected leader, a process must first receive crash notifications from all previous leaders without receiving any decisions. Hence due to uniformity (all processes receive a message or no process does) and fail-consistency (messages are delivered before failure notifications) of FCURB, no other process will ever receive a decision from a previous leader. The lack of the ACK-ing round gives HUC an advantage over HSUC, Raft and other asynchronous consensus algorithms, as we will discuss shortly. Note that the throughput is limited by FiDe's periodic multicast protocol and the limit in message size imposed by the piggyback buffer, but as we show shortly, these limits are ample in practice.

Algorithm 1: Heartbeat uniform consensus (HUC). Uses fail-consistent uniform reliable broadcast (FCURB). Executed by every process p_i

```
1  correct ← {1,2...N}
2  leader ← MIN(correct)
3  proposals ← [⊥]^N
4  acks ← ∅
5  to PROPOSE(val)
6      proposals[i] ← val
7      SEND(val) to p_leader
8  upon RECEIVE(val) from p_j
9      proposals[j] ← val
10     acks ← acks ∪ {j}
11 upon acks ⊇ correct
12     val ←DET(proposals)
13     acks ← ∅
14     BROADCAST(val)
15 upon CRASH(j) from FiDe
16     correct ← correct \ {j}
17     proposals[j] ← ⊥
18     if j = leader then
19         leader ←MIN(correct)
20         if proposals[i] ≠ ⊥ then
21             SEND(proposals[i]) to p_leader
22 upon DELIVER(val)
23     DECIDE(val)
```

4.2 Advantages over traditional approaches

Simple and efficient crash-tolerant services. The advantages of using FiDe as a building block for fault-tolerant services are both improved performance and improved simplicity, a byproduct of FiDe's reliability and timeliness (§2.2). Tab. 1 compares complexity of the FiDe-based algorithms with Raft in the failure free case. Our algorithms can tolerate more crash failures with less resources and have same or comparable performance to Raft and Zab (Zookeeper Atomic Broadcast) [36], as we showcase in the evaluation shortly (§6). Traditional consensus algorithms are often so complex that they are hard to implement and verify (e.g. Raft was conceived as a simpler version of Paxos [41]). Such complexity often comes at the cost of safety which can be harmed by incorrect implementations and optimizations. FiDe provides a way of building and reasoning about simpler algorithms without compromising safety and performance.

Consensus and slow processes. By default, asynchronous consensus algorithms like Raft and Zab treat process slowdowns and crashes interchangeably. For instance, followers might time out on a leader process whether it is crashed or is simply delayed in computation, elect a new one, and carry on with the consensus execution given a majority of active processes. In comparison, HSUC and HUC do not cater for slowdowns and require participation of every non-crashed process, meaning that consensus execution will stall until a process recovers or crashes (and is detected by FiDe). The integration of FiDe with gray failure detectors (cf. §6.6) is an effective strategy to improve HSUC and HUC reactiveness to slow processes in such scenarios, while maintaining their performance and simplicity improvements. It is important to note that, while Raft and Zab-like algorithms tolerate slowdowns, they do not actively evict or replace faulty processes (whether slow or crashed) since they assume that process interactions can be arbitrarily delayed. This can degrade performance as the number of undetected faulty processes increases, resulting in a stall when a majority fails. Therefore, employing a gray failure detector is essential for improving the availability of both traditional and FiDe-based consensus algorithms. In addition, the use of formal verification is a good practice to effectively prevent software bugs such as deadlocks when developing critical consensus-based services.

5 Implementation Details

FiDe was implemented in 4032 lines of C code, split into LKM, XDP (eBPF) hooks and userspace API. We use the `libbpf` library (v0.5.0) and Linux kernel eBPF support as of v5.9.8 for XDP (Mellanox NIC `mlx4` driver). HSUC and HUC are implemented as Redis modules using the API version 1 in 910 and 810 lines of code respectively. Zookeeper variants were tested modifying configuration parameters according to the algorithmic complexity, without requiring internal modification. Both algorithms use a batch optimization to send multiple messages for a single consensus instance.

Fine-tuning is crucial to ensure stable communication; below we list some of the most relevant measures and settings. We isolate FiDe's core by assigning it to `isolcpus` kernel boot parameter and shielding the core from standard IRQ by setting their `smp_affinity` on other cores only, and from inter-processor interrupt IRQs by using `local_irq_save()` [51]. We maximize the power state of FiDe cores to avoid costly sleeping periods by setting them to the maximum C-state (C0). During testing, we found paging to be another source of jitter, which we addressed by using hugepages for our buffers. We also disable detrimental read-copy-update (RCU) stall detector warnings from kernel boot options to prevent the OS from interfering with the FiDe core which loop with interrupts disabled [51]. FiDe uses custom network processing pipelines to accelerate and stabilize packet transmission and delivery. The LKM manages its own socket kernel buffers (SKBs) [68] and uses an active pacemaker loop bound to FiDe's uninterrupted core to send heartbeat messages (and active notifications) at as precise time as possible. On the receiving side,

FiDe uses XDP hooks to bypass the network stack. These use eBPF maps of type `BPF_MAP_TYPE_ARRAY` for device `mmap`ing, allowing for efficient communication between kernel and user space. XDP was chosen over other kernel bypass methods for its superior stability in tests. We measure time using POSIX's `clock_gettime()`, with `CLOCK_MONOTONIC` parameter.

6 Evaluation

We evaluate FiDe by comparison with state-of-the-art services and applications, addressing four research questions:

RQ1: How stable is FiDe's underlying remote process interaction (cf. Reliability)?

RQ2: How quickly can FiDe detect failures (cf. Timeliness)?

RQ3: How well does FiDe scale in a real-world application (cf. Reliability, Timeliness)?

RQ4: By how much can FiDe accelerate replication (cf. Timeliness)?

RQ5: How do network faults and deployment impact FiDe (cf. Reliability, Timeliness)?

Finally, we discuss the impact of FiDe on the underlying system in terms of integration cost (cf. Non-intrusiveness), and overheads of processing and network.

6.1 Benchmark setup

Datacenter. We ran all our evaluation on 6 servers of a *production datacenter* of SAP hosting Arista 7280CR-48 [8] switches and servers with Intel Xeon E5-2680 v4 at 2.40GHz (28 cores, 56 threads), 1 TB RAM, Mellanox ConnectX-4 4x10 GbE [54] and Intel XL710 4x10 GbE [32] as commodity NIC, Ethernet interconnects. All the servers are connected via two redundant physical paths organized in a mini fat-tree topology. Every node runs our own customized version of Ubuntu 20.04 [75]. Our tests compare against a service/application that uses RDMA due to the relevance of the technology in modern systems and literature. For such applications we use RDMA over converged Ethernet (RoCE) [65]. While RDMA performs better on Infiniband networks we compare against RoCE as the majority of existing datacenters still relies on Ethernet. For multi-switch evaluation we use an additional cluster of 2 Cloudlab's [18] xl170 server, connecting its ConnectX-5 NICs to a number of Dell-s4048 type switches.

Comparison. We compare against three services chosen for their relevance in research and practice, and diversity:

Falcon [45], the seminal multi-level reliable FD (cf. §3.4);

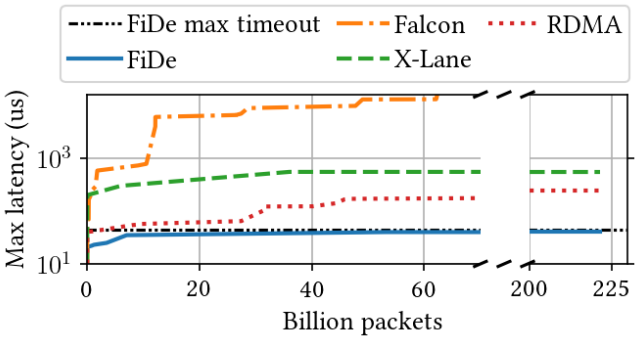

Figure 3: Maximum peer-to-peer latency evolution of the compared approached over 2.3 trillion packets

X-Lane [35], a state-of-the-art system designed to achieve ultra-latency and ultra-low relative jitter in datacenter interaction, used to build a passive FD;

uKharon [24], a state-of-the-art group membership protocol using RDMA and a Falcon-like multi-level FD. We compare against its FD only, referred to as uKharon-FD.

uKharon-FD can be seen as a re-implementation of Falcon on RDMA; to our knowledge, it reports the fastest failure detection in literature, as "*within few tens of microseconds*" [24] (without exact quantification). We compare FiDe primarily against uKharon-FD and X-Lane for performance, and use a re-implemented version of Falcon on commodity hardware as baseline. Note that, since Falcon can be customized to detect more complex types of (gray) failures whose detection is inherently slower, we compare only against Falcon's crash detection mechanism. We compare integrations of FiDe into Redis and Zookeeper against the originals. For Redis, we also compare against RedisRaft [64], an official module developed by RedisLabs using Raft for state machine replication (SMR).

6.2 Interaction stability (RQ1)

Our first experiments evaluate the possibility of achieving stable, bounded interaction latency (§3.2) in practice.

Methodology. We test FiDe's heartbeat mechanism by running a simple ping-pong protocol *over several weeks* with concurrent real-life traffic and logging the peer-to-peer latency for every packet. The dataset size amounts to 2.3 trillion consecutive packets which is 10× the amount used in previous work evaluating stable interactions [35] and over 1000× the amount used in works focusing on performance (vs. stability), e.g. [30, 60]. We found 20µs to be the lowest possible interval that provides stability with maximal throughput. All other works were tested with $>$ 100µs sending interval, favoring them over FiDe in terms of expected jitter. We use `stress-ng` [70] and `iPerf` [33] to generate periodic spikes of maximum CPU and network utilization. Priority queues are

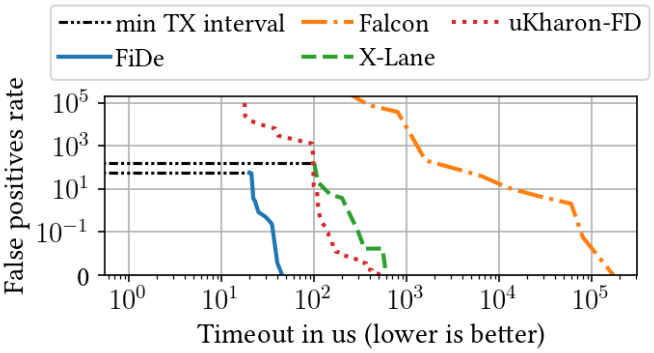

Figure 4: Failure detection accuracy for application crashes: false positives per minute (lower is better) at increasing timeout values. Timeout is meant as maximum time to wait before declaring a remote process unresponsive: a suitable value should yield no false positives (i.e., strong accuracy)

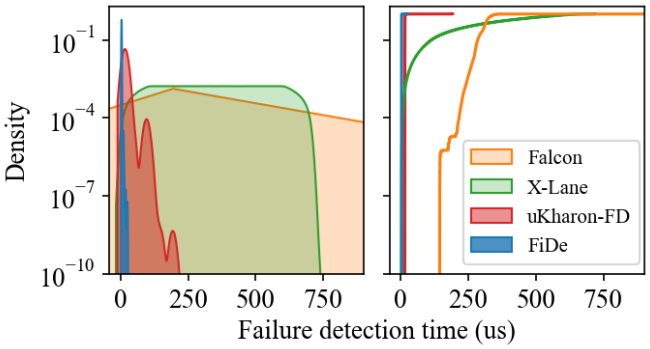

Figure 5: Failure detection empirical density distributions. The left plot shows the PDF (thinner is better) while the right plot shows the CDF. Each approach uses 10^7 datapoints taken from the respective empirical distributions.

reserved for FiDe. In this benchmark, we tested Falcon's communication between its client library and the spies in isolation (i.e., without failure detection logic). The same was done for uKharon-FD, that we refer to as "RDMA" since we consider only the communication and the packet processing layer.

Results. Fig. 3 shows that FiDe achieves upper-bounded interaction latency at $<$ 45µs (black dotted line), outperforming other approaches by over 5.4×. RDMA's latency is the closest to FiDe in terms of magnitude quickly reaching $\approx$ 50µs but peaking at 243µs after 70 billion packets. Regular "jumps" in latency including this last one suggest that despite having excellent average performance, RDMA by itself is not sufficient for stable interactions. We attribute the cause of this instability to network and process interference which FiDe actively aims to minimize. X-Lane shows better stability with latency ranging from 100µs to 550µs which is above the values reported [35], most likely because it was tested at much higher throughputs. Lastly, Falcon shows the most unstable latency, showcasing the importance of reactive processing (§ 3.2) which Falcon does not optimize. In fact, jumps in latency often correspond to an increase in the CPU load of the involved nodes. The graph line was cropped for readability.

6.3 Application failure detection (RQ2)

We define failure detection latency as the time between (1) an application process crash and (2) a failure notification delivery on a remote monitoring node. As (1) are (2) occur on different nodes, we divide latency into segments which are relative to each node to account for clock mismatch.

Methodology. We use optimal sending intervals and same settings as § 6.2. Since multi-level FDs such as Falcon and uKharon-FD have different detection "modes", we compare against the fastest of each.

Failure detection timeouts. Fig. 4 shows the failure detection accuracy in terms of number of false positives per minute. Every FD monitors an application and is set to send regular heartbeats at the smallest interval possible. False positives are obtained by counting how many times a local FD instance incorrectly signals a remote application process failure (i.e., no heartbeat) at a given timeout which is strictly larger than the heartbeat interval. Results show that FiDe can use timeouts larger than 48µs which is ca. 16× faster than uKharon-FD and X-Lane which reach perfect accuracy only at around 800µs.

Average and maximum failure detection times. The second requirement set for our design is low failure detection time (§ 2.2) which is required for fast process recovery in critical scenarios in production systems. Since we do not have access to a global clock in our system, we measure crash failure detection time based on the empirical joint distribution of the latency of the 3 steps involved in a successful failure notification delivery: (1) time from the manually injected crash to when it is picked up by the local FD instance; (2) communication latency from the local FD instance to the remote node; (3) latency for "delivery" from message reception at the remote FD instance to the remote monitoring application. We measure the *inspector-enforcer* crash detection latency for Falcon which consists in the time between the detection of an application crash and its communication to the local monitoring process trough inter-process communication (IPC).

Fig. 5 shows the empirical density distributions. The CDF in the right plot shows two almost vertical lines which flatten at the very top for FiDe and uKharon-FD, indicating that the vast majority of failures will be detected close to the average latency, with increases only around the 99.999th percentile. The PDF plot on the left of the figure provides a smoothed view of the same data which further highlights the differences between the two approaches. FiDe's failure detection is more deterministic and reliable, showing a low number of modest outliers contained in the narrow base of the curve. Tab. 2

Table 2: Summary of evaluated + state-of-the-art failure detectors, considering crash failures of A = application, OS = operating system, C = catastrophic (worst-case timeout). All values are in µs. *Slanted* numbers are taken from respective publications and blank values were not addressed.

Approach	A_{avg}	A_{max}	OS	$C_{timeout}$
FiDe	4.58	26.54	45.00	45.00
uKharon	17.39	193.56	*30.00*	*1000.00*
X-Lane	354.75	718.54	600.00	600.00
Falcon	496.29	169000.00	*204000.00*	3.00×10^8
Zookeeper	*3000.00*	*12000.00*		
Panorama	*2000.00*	*8000.00*		

summarizes average and maximum failure detection latencies of the compared approaches. FiDe achieves µs-range average failure detection outperforming the state-of-the-art uKharon-FD by 3.8× on average and by 7.2× at maximum (worst-case) latency, and X-Lane by 77× and 27× respectively. The table reports timeouts used to detect OS and catastrophic failures which uKharon-FD and Falcon address using specific probes. FiDe can use a general, worst-case timeout as low as 45µs, orders of magnitude below other approaches apart from uKharon-FD's OS timeout, reported as 30µs [24]. We believe that a much higher timeout would be needed in our (non-Infiniband) setup as suggested by previous measurements. Tab. 2 includes statistics from Panorama [27], a state-of-the-art gray failure detector, and Zookeeper's FD for reference.

6.4 FiDe for key-value stores and distributed synchronization (RQ3, RQ4)

FiDe's main goal is to be used as a reliable building block for efficient and simpler coordination protocols. To showcase the benefit of using FiDe beyond failure detection, we evaluate our novel algorithms proposed in § 4 integrated into Redis and Zookeeper. We refer to our variants as RedisFiDe (RedisFiDe)-HSUC/HUC and Zookeeper-HSUC/HUC respectively. We evaluate the SET request latency and throughput performance to address **RQ3** and **RQ4**. We do not evaluate GET requests since all approaches would simply return the requested value, adding no overhead to native performance.

Methodology. We use the official redis-benchmark [63] utility for Redis and custom Zookeeper native client [83] with the following settings: 50 concurrent clients, for a total of 1 million SET requests. For every approach, all requests are sent to the leader which is the only possible option for both RedisFiDe and RedisRaft. The latter uses batch optimization. In Zookeeper, we use Oracle quorum setting [83] and configure the ensemble to reproduce the complexity of our algorithms substituting Zab's atomic broadcast with consensus instances ordered by the leader. In HUC's implementations, the leader

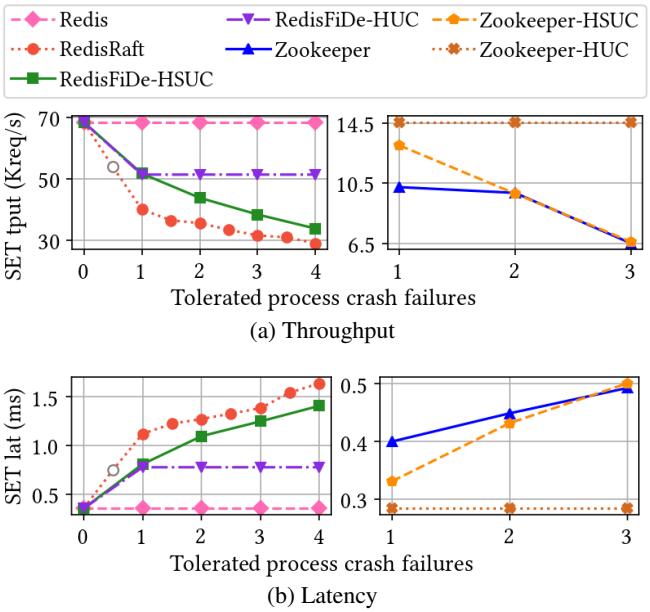

Figure 6: SET request performance of Redis and Zookeeper with different replication algorithms for given numbers of tolerated process failures (except for "Redis" reported as baseline). The values in between points on the x axis for RedisRaft are due to its use of a larger number of processes for tolerating the same number of failures cf. Tab. 1.

orders and batches concurrent requests which fit in the piggyback payload in a given FiDe heartbeat interval (at least multicast period and in the benchmarks $HB_i = 100\,\mu s$ for every p_i). We scale up to five and three tolerated failures, respectively 9 Redis instances and 7 Zookeeper instances, large sizes for a replication cluster (§ 2.3). Note that no method benefits from traffic prioritization: HUC-based services immediately return after piggybacking the decision message, hence only exploiting FiDe's accuracy and not latency enhancements. We evaluate HSUC-based services without traffic prioritization.

Results. Fig. 6a and Fig. 6b show throughput and latency of the compared approaches respectively. The metrics are plotted against the number of tolerated process failures corresponding to Tab. 1. The number of points equals to the number of processes. Since RedisRaft requires at least 3 processes to run, we put a "null" point as a placeholder for two processes (empty circle). All FiDe implementations almost always outperform the native performance, except for Redis which does not provide consistency guarantees. HUC has the highest throughput, 1.22× on average and 1.7× at maximum better than RedisRaft, and 1.71× on average and 2.23× at maximum for Zookeeper. It also has the lowest latency, respectively, reduced by 0.79× on average, 0.46× at maximum against RedisRaft, and 0.64× on average, and maximum 0.57× against Zookeeper. This is expected: the leader in HUC

uses only one heartbeat multicast to piggyback its decision directly, making FiDe's heartbeat interval (HB_i) and piggyback size limit (σ) the major factors affecting throughput. Considering $HB_i = 100\,\mu s$ for all p_i and $\sigma \approx 400\,B$, we can estimate the max throughput to be around $32\,Mbit/s$, largely sufficient for this benchmark. HSUC implementations show typical downtrend in both latency and throughput when the number of involved processes increases.

6.5 Network faults and deployment (RQ5)

We evaluate the network fault tolerance mechanism by estimating the probability of a critical compound failure, i.e., both redundant multicast trees failing withing a short time (cf. § 3.3), at different scales.

Methodology. We assume the widely-deployed multi-rooted fat tree topology [48] as defined by Al-Fares et al. [5], which uses multiple rooted trees to approximate a classical fat-tree (e.g., see Fig. 8 in App. C). We consider trees with $height = 1,2,3$ which we define as half the diameter of the tree. Note that multi-rooted fat trees always have an even number of nodes. We deploy FiDe in the multi-switch Cloudlab setup to analyze the effect of increased latency on previously measured application and OS failure detection time as well as RedisFiDe SET request latency. We apply the network and CPU load of § 6.2. We estimate the probability of *critical compound failure* by taking empirical failure probabilities from a popular study [22]; see App. C for a detailed breakdown.

Results. As expected (see Tab. 3), we observe an increase on the average application failure (A_{avg}) and OS failure (OS) detection times due to the added network distance, with latency overheads roughly equivalent to the additional switch forwarding latency of 5-10µs for larger fat trees. The impact on RedisFiDe HSUC and HSUC variations is instead minimal, due to the latency being dominated by Redis' request processing. Note that results for 1 switch vary compared to previous tests due to the different hardware setup (cf. Fig. 6b). The expected frequency of 1 critical compound failure every 22.7 years in the ideal deployment shows that FiDe is extremely likely to guarantee reliability for any realistic uptime. A back-of-the-envelope estimation of the probability of packet corruption in Ethernet + TCP (cf. App. C and [69]), widely regarded as reliable and used as such [29], shows that we could observe one packet corruption every 2.3 days at best, making FiDe more than 3 orders of magnitude more reliable.

6.6 FiDe in the bigger picture

Implementation costs. FiDe meets Non-intrusiveness: no application-specific failure detection code is required for the implementation of RedisFiDe modules apart from the necessary API calls, which amount to 6 lines of code including the imports. FDs using internal observation (§ 3.4) can have a much larger impact in similar contexts: applications based on Pidgeon [43] require 68 and 414 integration lines of code, while Falcon requires up to 159 for replication protocols [45].

Table 3: Consequences of deployment at larger scale. $freq_{\text{CCF}}$ is the expected frequency of a critical compound failure, A_{avg} and OS respectively denote average application and operating system failures, RF= average latency of RedisFiDe deployed on 2 processes (1 tolerated process failure).

Tree height	A_{avg} (µs)	OS (µs)	RF_{HSUC} (µs)	RF_{HUC} (µs)	$freq_{\text{CCF}}$
1 (ideal)	6.34	45	531	518	1 / 22.7 years
2	13.62	65	580	530	1 / 11.3 years
3	20.89	80	621	541	1 / 6 years

Combination with other FDs. FiDe can be combined out-of-the-box with other, more comprehensive (i.e. multi-level/gray) FDs through its API (§ 3.1). This would allow for performance gains and wider coverage, e.g., terminating processes that are out of control such as through deadlocks, getting the best of both worlds. For example, integrating FiDe into Panorama would improve Panorama's average crash failure detection by ca. 400×. Moreover, piggybacking probes' observations on FiDe's fast communication substrate could be exploited to accelerate remote detection of other types of failures, e.g., by more than 2 orders of magnitude for Panorama's reported propagation delay of 776.3µs [27] and more than 3 orders of magnitude for Falcon.

Overhead. FiDe's impact on the system consists in process and network resources reserved to enable reliable interactions (§ 5). We reserve one CPU core fully utilized during peak performance. This might impact performance differently depending on the processor's core count; in our case, it constitutes only $1/56$ (1.79%) of overall server processing power. The overhead introduced by the kernel watchdog, specifically `kprobes`, is in the order of ns thus negligible. In the network, we reserve highest priority queues (where needed) and consume bandwidth proportional to the periodic multicast protocol parameters (§ 3.3). In our setup, bandwidth consumption amounts to $\approx 50\,Mbit/s$ for links adjacent to endhosts, and *at most* $k \times 50\,Mbit/s$ inside the network, for k FiDe processes.

Mitigation and future work. Highly available core services targeted by FiDe are usually placed in a way to guarantee performance in practice, avoiding co-locating too many other compute intensive processes, achieving the effects of FiDe resource reservation by deployment [19, 83]. Furthermore, both processing and networking costs are mitigated by the efficiency of FiDe-based services, namely the smaller

number of nodes to tolerate same amount of failures as traditional quorum-based fault-tolerant services. We propose the following methods to mitigate energy consumption. Increasing FiDe's heartbeat interval, e.g. to hundreds of µs, would greatly reduce core utilization and only compromise failure detection time for passive failure detection. While we did not test kernel/system upgrades, FiDe simply treats them as failures and requires no particular upgrade strategy. We assume such updates are infrequent and also always provide a degree of backward compatibility. Combining FiDe with one of the state-of-the-art interference-aware CPU schedulers [21, 57], could provide stable processing without reserving a full core. Priority queues can be shared with other applications, as long as the resources needed are accounted by FiDe controller.

7 Related Work

FDs. Being able to detect failures promptly and reliably can tremendously improve distributed systems performance [4]. One of the most prominent works is Falcon [45], which aims to implement a reliable FD using *system-tailored* design with a web of layer-specific probes (spies). Falcon allows programmers to define failures but pays with intrusiveness, complexity, and observation overhead. Several FDs use a system-tailored design [7, 24, 43, 44], including gray/partial failure detectors [27, 49, 50, 52, 58] which enhance system availability by detecting subtle failures. FiDe uses a ground-up *system-driven* approach focusing on crash-stop process failures, gaining in reliability, usability, and detection timeliness.

Accelerating µs services. Many real-world distributed applications require operations at the µs scale [9, 10, 67], for which they rely on fast fault-tolerant distributed services built on top of FDs. State-of-the-art works here include Mu [2], Hovercraft [39], and DARE [60] for SMR, and uKharon [24] for group membership. Mu and DARE employ heartbeat-based FDs and assume stable interaction but fail to guarantee reliability respectively by not considering jitter sources. uKharon puts a stronger focus on reliability and implements a multi-level FD, achieving the fastest performance to our knowledge with a 50 µs full membership change. However, it fails to tackle the unpredictability of the network and optimizes heavily for RDMA on Infiniband, strongly limiting deployment. FiDe proposes a different approach with strong focus on reliability and timeliness, improving over uKharon by 7.2× on worst-case failure detection, on generic Ethernet.

Stable communication in datacenters. An ever-growing number of systems optimizes tail-latency for datacenter remote procedure calls through specialized networking stacks in hardware/software co-design [30, 71] and software only [11, 16, 21, 37, 38, 46, 57, 59, 61, 81]. These works achieve ns [30] and µs tail-latency through optimal endhost packet processing but do not consider sources of jitter in the network, hampering stability at the tail end. QJump [23] leads the way to achieve minimal, stable tail-latency in networks but does not consider jitter at the endhost, leading to the same issue. To our knowledge, the only comprehensive approach for end-to-end stable latency is given by X-Lane [35]. FiDe leverages network and process execution à-la X-Lane, but introduces more efficient and reproducible packet processing, critical novel design features including TE tailored for redundancy, reliability towards network failures and a ground-up, robust design tailored to failure detection (non-intrusive, prompt monitoring, active detection) offering dramatic improvements in throughput (50× from the values reported [35]) and reliability. Seminal work on deterministic distributed processes was introduced by DDOS [28]. However DDOS has significant overhead in remote process interaction, which FiDe's communication substrate could significantly reduce. Several prior works simply take stable interactions as given for, e.g., optimal weaker FDs [3], coordination primitives like leader election [66], or even synchronous BFT and blockchain protocols [1, 26] on top of a commodity software stack, without any concrete implementations to enforce such assumptions.

Clock synchronization protocols such as PTP [31] and TrueTime in Google Spanner [15] provide a very accurate global clock to support synchronous systems. Since gains in clock drift accuracy (ns-scale) are so small compared to interaction/communication latency (µs-scale), FiDe focuses on the latter leaving possible integration with accurate clock synchronization mechanisms for future work.

8 Conclusions

An increasing number of highly available, distributed applications are being deployed in datacenters. A key challenge in building such applications is detecting failures quickly and reliably, to ensure liveness and safety. Yet, existing failure detectors (FDs) fail to provide reliability at the µs scale, leading to inefficient, quorum-based coordination services built on top. Such FDs and are also often intrusive, making it hard for programmers to use them. FiDe fills this gap by providing reliable failure detection accelerated with respect to the state of the art by up to 7.2×, and 3.8× on average. To this end FiDe introduces a novel split system design, built ground-up, for timely interactions (communication and processing). Beyond failure detection, FiDe can be used as building block for simpler, faster algorithms. We propose 3 novel coordination primitives, accelerating replication in Redis and Zookeeper.

A FiDe-based Algorithms

The reliability of FiDe allows for the implementation of a particular set of distributed algorithms based on a reliable FD primitive, referred to as perfect FD ($\mathcal{P}$) in the widely know Chandra&Toueg classification [14]. While $\mathcal{P}$ is provably impossible to implement, we find the probabilities of FiDe to break its strong completeness and strong accuracy properties to be negligible, hence our motivation for the adoption of $\mathcal{P}$ for our novel algorithm.

Such algorithms are simple and, most importantly, reliable as they can tolerate a larger number of failures ($N-1$) compared to their pure asynchronous counterparts. In traditional timeout-based FDs, those gains may come at the of cost performance degradation due to the time spent waiting for failure notifications. Instead, the µs-scale detection times provided by FiDe enables the adoption of $\mathcal{P}$-based algorithms in practice, which in many cases can improve the system performance considerably even in failure-free runs.

A.1 Primitives overview

In this work, we propose one reliable broadcast primitive, OSRB (§ A.2), and two FiDe-based novel algorithms to solve the uniform consensus problem. The first algorithm, HSUC (§ A.3), relies directly on $\mathcal{P}$ and the OSRB primitive. The second algorithm, HUC (§ A.4), exploits the piggyback feature of FiDe to implement a heartbeat broadcast primitive which is optimal in message complexity for consensus. All algorithms assume an asynchronous system with a reliable FD primitive in the crash-stop process model. We present the uniform consensus specification taken from [13] below.

Termination: Every correct process eventually DECIDEs some value.

Validity: If a process DECIDEs v, then v was PROPOSEd by some process.

Integrity: No process DECIDEs twice.

Uniform agreement: No two processes DECIDE differently.

All the handlers are assumed to execute atomically, and, if multiple handlers are enabled at the same time, they are triggered in a fair manner.

A.2 Optimistic Stabilizing Reliable Broadcast

We start by presenting specification of a reliable broadcast primitive and our implementation of that primitive, dubbed OSRB, which we later use in our consensus algorithm.

Properties. The reliable broadcast has BROADCAST downcall and DELIVER upcall that must satisfy the following.

Validity: If a correct process p BROADCASTs a message m, then p eventually DELIVERs m.

No duplication: No message is DELIVERed more than once.

No creation: If a process DELIVERs a message m from p, then m was previously BROADCAST by process p.

Agreement: If a message m is DELIVERed by some correct process, then m is eventually DELIVERed by every correct process.

Algorithm. Like other lazy reliable broadcast primitives [13], OSRB optimistically implements BROADCAST using a multi-send and buffering received messages, which it may need to retransmit later upon detecting a process failure via $\mathcal{P}$. The reception of a message for the first time triggers the DELIVER. As a novel performance improvement, OSRB introduces an additional downcall called STABILIZE, which takes a message *id* as an argument. STABILIZE gives the possibility to apply a stabilization criterion to limit the messages buffered in *retransmit* and therefore lazy message relay upon failure.

Stabilility: If any process STABILIZEs *id*, then every correct process has RECEIVEd *msg* s.t. $id = \text{ID}(msg)$.

Note, it is the responsibility of a user of OSRB to ensure that the stabilization criterion is satisfied as otherwise, the *agreement* property can be violated.

Algorithm 2: Optimistic stabilizing reliable broadcast (OSRB). Executed by every process p_i

```
1  correct ← {1,2,...,N} /* set of process ids */
2  retransmit ← {} /* set of messages */
3  delivered ← {} /* set of message ids */
4  to BROADCAST(msg)
5      for p_j ∈ correct do
6          SEND(msg) to p_j
7  upon RECEIVE(msg)
8      if ID(msg) ∉ delivered then
9          retransmit ← retransmit ∪ {msg}
10         DELIVER(msg)
11         delivered ← delivered ∪ {ID(msg)}
12 upon CRASH(j) from P
13     correct ← correct \ {j}
14     for k ∈ correct do
15         for msg ∈ retransmit do
16             SEND(msg) to p_k

18     if ∃msg ∈ retransmit | id = ID(msg) then
19         retransmit ← retransmit \ {msg}
```

Correctness OSRB keeps track of the delivered messages in the *delivered* variable to guarantee *No duplication* since a process can receive messages it has already seen upon failure detection. The *Validity* and *No creation* properties are guaranteed by the reliable links abstraction and the fact that we send to all correct processes. The *Uniform agreement* property is derived from *Validity*, $\mathcal{P}$'s accuracy, and the message retransmission upon failure detection when STABILIZE has not been called for that message's id. If STABILIZE has been called, then it is the stabilization criterion that ensures *validity*. We demonstrate a concrete example of the use of stabilization in the HSUC Alg. 3.

A.3 Hierarchical Stabilizing Uniform Consensus

Alg. 3 called hierarchical stabilizing uniform consensus (HSUC) solves uniform consensus using a hierarchy among the processes, a reliable FD detector and the previously defined OSRB primitive.

Algorithm. The algorithm is re-adapted from the hierarchical uniform consensus algorithm in [13], originally taken from [42]. It assumes asynchronous communication, reliable links, unique message ids and sequential execution of consensus instances. The latter means that at any given process,

Algorithm 3: Hierarchical stabilizing uniform consensus (HSUC). Uses OSRB. Executed by every process p_i

```
1  correct ← {1,2,...,N} /* set of process ids */
2  leader ← MIN(correct)
3  proposal ← ⊥
4  proposer ← ⊥
5  acks ← ∅
6  lastid ← ⊥
7  to PROPOSE(v)
8      if proposal = ⊥ then
9          proposal ← v
10     if i = leader then
11         for j ∈ correct do
12             SEND(v) to p_j
13 upon RECEIVE(v) from p_j
14     if proposer = ⊥ or j ≥ proposer then
15         proposal ← v
16         proposer ← j
17         SEND(ACK) to p_j
18 upon RECEIVE(ACK) from p_j
19     acks ← acks ∪ {j}
20 upon acks ⊇ correct
21     BROADCAST(proposal)
22     acks ← ∅
23 upon CRASH(j) from P
24     correct ← correct \ {j}
25     if j = leader then
26         leader ← MIN(correct)
27         if i = leader and proposal ≠ ⊥ then
28             for k ∈ correct do
29                 SEND(proposal) to p_k
   upon DELIVER(v)
30     STABILIZE(lastid)
31     lastid ← ID(v)
32     DECIDE(v)
33     proposal ← ⊥
```

between any two PROPOSE invocations, there is exactly one DECIDE event. We also assume two kinds of implicit behaviors for all handlers in HSUC. First, a process buffers messages corresponding to future consensus instances until the process has made a decision for all the previous instances. Second, it ignores messages from all the consensus instances for which it has already decided. The consensus instance can be identified by attaching and propagating a consensus instance number inside every message. HSUC can tolerate up

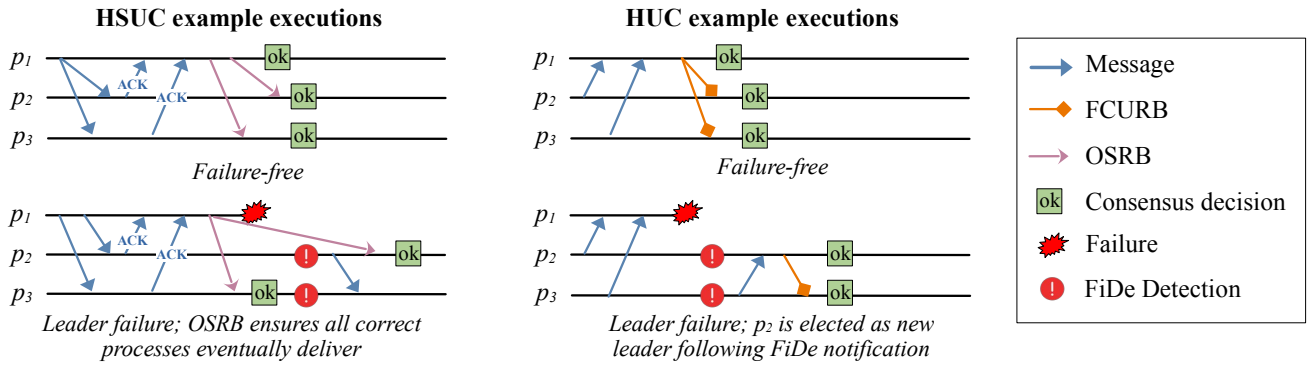

Figure 7: HSUC and HUC execution diagrams. Black lines represent timelines for each process increasing from left to right. HUC enforces message-then-failure ordering through FCURB (bottom right diagram) while HSUC allows the safe delivery of a decision message through OSRB even after a failure detection event (bottom left diagram).

to $f = N - 1$ failures where N is the number of total processes in the system.

The algorithm is round-based, with every round lasting until at least one failure is detected. The leader of every round is deterministically chosen to be the correct process with the lowest id.

In failure-free runs, the algorithm requires only one round and uses three communication messages: ① the leader multi-SENDs its proposal to all correct processes, which then ② adopt the proposal as their own and SEND an ACK to the leader upon reception. ③ Once the leader has collected ACKs from all alive processes, it reliably disseminates the decision using the OSRB primitive. The algorithm goes through these same three phases if up to $f = N - 1$ non-leader processes fail.

If the leader of a round fails, all correct processes detect it and proceed to a new round in which a new deterministically elected leader starts multi-sending the proposal message (line 11 and line 28). Note that even if the leader fails after sending its decision, all the alive processes have their *proposal* set to the leader's so any future leader would broadcast the same proposal as the failed leader. If the leader decides on v and then crashes before its decision can reach any other process, any of the following leaders will propose v as it was adopted as own proposal.

The reception of the next round's decision defines the stabilization criterion of OSRB. Once this phase of the algorithm is reached, STABILIZE($lastid$) [Alg. 3, line 30] can be safely called so that the message from the previous consensus will not be retransimitted by OSRB upon future failure detections [Alg. 2, line 15].

Process diagrams in Fig. 7 depict example executions of HSUC. Upon failure of the leader, the OSRB primitive ensures that the decision message is eventually delivered. The delivery can occur even after another process detects a failure and proceeds with the leader election. HSUC ensures that correct processes which receive a decision message (p_3 in the bottom-left diagram) will not ACK future proposal by another leader preventing mismatched decisions.

Correctness. The *validity* property follows trivially from the algorithm and from the no-creation properties of communication abstractions. The *integrity* follows from our assumption that all the messages from earlier consensus instances are ignored once the decision is made. For *Termination*, it is sufficient to show that at least some *correct* process DELIVERs, for OSRB's agreement ensures that then every correct process DELIVERs and, hence, decides. Assume no correct process DELIVERs, consider then correct process p_{i*} with the lowest process id i^*. Eventually, due accuracy and completeness of $\mathcal{P}$, p_{i*} will become and always remain a leader. Right at that point (on line 11 or line 28), p_{i*} will multisend its proposal. Note that due to accuracy of $\mathcal{P}$, no process p_j with $j > i*$ will become a leader, and, hence, will multisend its proposal or set its *proposer* variable to j. Hence, no *proposer* variable will ever get set to $j > i^*$, implying that eventually all the correct processes will respond to p_{i^*}'s proposal triggering p_{i^*} to BROADCAST, and hence, DELIVER, contradicting our assumption. The fact that processes ignore messages from older instances does not hinder termination as advancing to the next instance is only possible after DELIVER, hence all correct processes continue to participate under our assumption that no correct process DELIVERs. To show *Uniform Agreement* we argue that all the BROADCASTs necessarily carry the same value. This is guaranteed by phase ① and ② of the algorithm that ensure that every process will propose hence decide on the same value even if a leader fails before delivering a decision. Specifically, the moment process p_i receives all the ACKnowledgements all the alive processes must have their *proposal* equal to that of p_i. First of all, no proposal has been sent by p_j, $j > i$ as no such p_j could have become a leader for i is still alive. Hence, all the processes

that have received p_i's proposal have ACKnowledged it and could not yet have changed their *proposal* value. We also need to show the *Stability* criterion of OSRB since it could be violated by an unsafe call to STABILIZE and violation of the *agreement*. Stability of *lastid* is guaranteed as if a process receives a decision, then a leader must have collected all the ACKs for the *current* consensus instance, meaning that all the correct processes have responded with those ACKs and they have decided in the *previous* instance on some proposal v with $\text{ID}(v) = lastid$ as otherwise ACK requests would be buffered instead.

Complexity. In the failure-free cases, HSUC uses 3 message delays and exchanges $O(N)$ messages. Each failure of a leader adds 2 additional delays and $O(N)$ messages for consensus and $O(N^2)$ for the OSRB retransmission upon failures [Alg. 2, line 15]. If we used a lazy RB instead of OSRB , e.g. "Lazy Reliable broadcast" in [13], the added complexity overhead of the RB would be $O(M \times N^2)$ where M is the number of messages sent in all previous instances of consensus. This performance improvement is achieved through message *stabilization* logic.

A.4 Heartbeat Uniform Consensus

The second implementation of uniform consensus that we propose is called heartbeat uniform consensus (HUC) and is shown in Alg. 4.

Overview. Once again we assume asynchronous communication and reliable links. HUC uses a leader-driven decision logic with a new leader elected deterministically by selecting the process with the smallest ID upon failure of its predecessor. Here FiDe is used both as $\mathcal{P}$ and as the means to piggyback decision messages. As for HSUC, we assume that messages pertaining to old consensus instances are ignored and future ones are buffered. This simple algorithm is meant to showcase the reduced logical and message complexity that can be achieved in failure-free executions when using FiDe as backbone of distributed systems. Enabling such reductions is arguably the most relevant contribution of this work.

Fail-consistent uniform reliable broadcast. We abstract FiDe's piggyback feature into a primitive called fail-consistent uniform reliable broadcast (FCURB). Since there is a limit on the message size for the piggyback method, we assume small message sizes. A practical implementation of this assumption is to reliably disseminate the messages in advance, using FiDe piggyback for message ids only. The properties of fail-consistent uniform reliable broadcast are:

Validity: If a correct process p BROADCASTs a message m, then p eventually DELIVERs m.

Algorithm 4: Heartbeat uniform consensus (HUC). Uses FCURB. Executed by every process p_i

```
1  correct ← {1,2...N}
2  leader ← MIN(correct)
3  proposals ← [⊥]^N
4  acks ← ∅
5  to PROPOSE(val)
6      proposals[i] ← val
7      SEND(val) to p_leader
8  upon RECEIVE(val) from p_j
9      proposals[j] ← val
10     acks ← acks ∪ {j}
11 upon acks ⊇ correct
12     val ←DET(proposals)
13     acks ← ∅
14     BROADCAST(val)
15 upon CRASH(j) from FiDe
16     correct ← correct \ {j}
17     proposals[j] ← ⊥
18     if j = leader then
19         leader ←MIN(correct)
20         if proposals[i] ≠ ⊥ then
21             SEND(proposals[i]) to p_leader
22 upon DELIVER(val)
23     DECIDE(val)
```

No duplication: No message is DELIVERed more than once.

No creation: If a process DELIVERs a message m from p, then m was previously BROADCAST by process p.

Uniform agreement: If a message m is DELIVERed by some process, then m is eventually DELIVERed by every correct process.

Fail-consistency: If process p DELIVERs a message from process q, then p has not yet received CRASH notification for q.

Validity, *uniform agreement*, and *fail-consistency* are guaranteed by FiDe's reliability: a heartbeat message m BROADCAST by p is guaranteed to be either (i) DELIVERed by all correct processes *and* confirming that p is still alive, hence *fail-consistency*; or (ii) being lost for all processes as a result of p failing before actually sending out m. *No creation* and *no duplication* are guaranteed by underlying guarantees of the links and the fact that no re-transmission are needed. We use FCURB to implement Alg. 4, heartbeat uniform consensus.

Algorithm. HUC uses two communication steps in failure-free executions: ① every process sends its proposal to the

leader, ② once the leader has collected a proposal from every correct process it deterministically decides using the DET function (Alg. 4, line 12) and then disseminates the decision by using FCURB. If the leader fails, every alive process correctly detects and proceeds with the next leader (line 19). Note that the delivery of a decision can never follow a failure detection event thanks to *fail-consistency* properties of our FCURB i.e., FiDe piggybacking mechanism. A leader can fail and not broadcast a decision message (scenario depicted in Fig. 7) or broadcast and immediately fail, in which case the decision is reliably delivered to all processes by FCURB..

Correctness. *Validity* follows from the validity of underlying communication abstractions, and *integrity* follows trivially from the assumption of ignoring old consensus messages after the decision is taken. *Termination* for Alg. 4 is guaranteed once *any* process DELIVERs due to FCURB's *uniform agreement*. Assume, similar to HSUC that never happens, and consider again the correct process p_{i^*} with the lowest i^*. Eventually every process would recognize p_{i^*} as a leader (due to $\mathcal{P}$'s completeness and accuracy) and, hence, will eventually send their proposals to p_{i^*} either on line 21 or on line 7, which would be collected by p_{i^*} and, hence BROADCAST, and hence DELIVERed. *Uniform agreement* follows easily once we show that only one successful BROADCAST every happens. To see that, assume that process p_i and p_j, $j > i$ both successfully broadcast, for that to happen, p_j should have received a proposal from some *correct* process p_k. That implies that p_k thought p_j was the leader and, hence, must have received a failure notification from p_i, but due to *fail-consistency* p_i must have DELIVERed p_i's decision first, and, hence, should have advanced to the next instance, a contradiction.

Complexity. In the failure-free cases, HUC uses 2 message delays and exchanges $O(N)$ messages. Each failure of a leader adds 1 additional delays and $O(N)$ messages for consensus. HUC has better performance than HSUC (Alg. 3) and other asynchronous with $\mathcal{P}$ algorithms in literature [13]. It also has equivalent or better performance than widely known partially synchronous consensus algorithms (e.g. Paxos [41], Raft [56]), but higher fault tolerance: Typical quorum-based algorithm can tolerate $f = N/2 - 1$ failures compared to $f = N - 1$ of the algorithms proposed in this section. The downside is that the throughput and message size are limited FiDe's periodic multicast protocol which may be a bottleneck in very large systems. To overcome limited message size, clients might need to broadcast messages to replicas in advance.

B FiDe Traffic Engineering Algorithm

The key responsibility of FiDe traffic engineering is to construct the multicast trees and derive the parameters of the *periodic multicast protocol*, while incorporating global view on the behavior of network nodes provided made available by SDN, namely bandwidth, latency and jitter of network devices. Latency and jitter parameters of the network subsystem at endhosts are estimated empirically using a purpose-built tool. Crucially for FiDe's reliability, there must be K multicast trees for the same sender/receivers pair and those tree must be *vertex-disjoint in their internal nodes* (leaves are always the same) providing necessary redundancy in case of link or switch failures; henceforth we use *vertex-disjoint* to mean "vertex-disjoint in internal nodes".

To decouple optimization process from ensuring latency guarantees, we employ a similar high-level approach as in [35], namely, first, we find the most promising set of multicast trees, and only then we compute the protocol parameters. For the latter, we take the *adjustment* phase from [35] and extend it to account for redundant trees: given a set of vertex-disjoint trees $\mathcal{T}$ for sender p_i^* and receivers $\{p_j^*\}_{j\in J}$, the parameters for $\mathcal{T}$ are derived from tree parameters as:

$$\sigma_{\max}(i,J) = \min(\sigma_{\max}(T) : T \in \mathcal{T})$$
$$\pi_{\min}(i,J) = \max(\pi_{\min}(T) : T \in \mathcal{T})$$
$$\lambda_{\min}(i,j) = \min(\lambda^T_{\min}(i,j) : T \in \mathcal{T})$$
$$\delta_{\max}(i,j) = \max(\lambda^T_{\min}(i,j) + \delta^T_{\max}(i,j) : T \in \mathcal{T}) - \lambda_{\min}(i,j)$$

The tree-finding task is more challenging as we need to ensure vertex-disjointness. The main building block is finding the set of trees for a single request, represented by a FiDe sender process p_i^*, receiving processes $\{p_j^*\}_{j\in J}$, requested packet size $\sigma_{\max}(i,J)$, and desired sending period $\pi_{\min}(i,J)$. The key observation that we make to enable practical algorithm for finding a set of *vertex-disjoint* paths is that datacenter networks have regular structure. Let us denote the network graph as $G = (V,E)$, the distance between $u,v \in V$ as $d(u,v)$, the set of endhosts as $H \subseteq V$, for a FiDe process p_k^* we let h_k denote the endhost where p_k^* is running and let $H_J = \{h_j\}_{j\in J}$. We also define the set of all nodes at distance exactly r from v as $N^r(v) = \{u \in V : d(v,u) = r\}$, and the set of all endhosts h' such that there exists a shortest path from $h \in H$ to h' through v as $N_H(h \rightsquigarrow v) = \{h' \in H : d(h,h') = d(h,v) + d(v,h')\}$. Now, the regularity of the network topology is expressed by the assumption that for any endhost $h \in H$, and any two nodes $v,v' \in G^r(h)$, either $N_H(h \rightsquigarrow v) = N_H(h \rightsquigarrow v')$ or $N_H(h \rightsquigarrow v) \cap N_H(h \rightsquigarrow v') = \emptyset$; moreover for any $h' \in H$, $h' \neq H$ we have $N_H(h \rightsquigarrow h') = \{h'\}$.

The core idea of the algorithm is to produce a set of multicast trees $\mathcal{T}$ bottom-up, each step being identified by $r \in \{0,\ldots,r^*\}$, where r^* is the largest satisfying $N^{r^*}(h_i) \neq \emptyset$. At layer r, we consider $G^r(h_i) = V_1^r \cup \ldots \cup V_{l_r}^r \cup V^r$, each V_k^r representing an equivalence class w.r.t. $N_H(h \rightsquigarrow -)$, so $N_H(h \rightsquigarrow V_k^r)$ is well-defined, and $N_H(h \rightsquigarrow V_k^r) \cap H_J \neq \emptyset$. We call V_k^r *leaf* if $V_k^r = \{h_j\}$ for some $h_j \in H_J$. For each V_k^r, for each $X \subseteq V_k^r$, s.t., $X = V_k^r$ for leaf V_k^r or $|X| = K$ for non-leaf V_k^r the algorithm constructs set $\mathcal{T}_k^r(X)$ of $|X|$ rooted

vertex-disjoint trees, s.t. (1) the set of roots must be exactly X; (2) each tree must have exactly $N_H(h \rightsquigarrow V_k^r) \cap H_J$ as leaves; and (3) all paths from the root must be shortest in G.

The base case corresponds to V_k^r being leaf, where $\mathcal{T}_k^r(X)$ has a single trivial tree. For the inductive case, we want to build $\mathcal{T}_k^r(X)$ for non-leaf V_k^r. To that end, we consider all $V_{k'}^{r+1}$ such that $N_H(h_i \rightsquigarrow V_{k'}^{r+1}) \subseteq N_H(h_i \rightsquigarrow V_k^r)$. Each such $V_{k'}^{r+1}$ would give a separate child to each of the K trees in $\mathcal{T}_k^r(X)$ as due to our assumption of $N_H(h_i \rightsquigarrow V_{k'}^{r+1})$ being disjoint and the constraint on all the paths being the shortest makes the branching necessary at this point. Concretely, to build $\mathcal{T}_k^r(X)$, the algorithm loops over each $V_{k'}^{r+1}$, at each iteration trying all possible $Y \subseteq V_{k'}^{r+1}$ and trying all possible ways of attaching each tree from $\mathcal{T}_{k'}^{r+1}(Y)$ as a child of some $v \in X$, finding one that minimizes the *cost*, to be defined shortly, of the resulting tree. Note, since the overall *cost* of a tree is monotone with respect to each child, the choices for each $\mathcal{T}_{k'}^{r+1}(Y)$ are independent. The overall complexity is $O(|V|^{2K} \cdot K! \cdot d)$, where d is the G's diameter.

The cost of a set of trees is computed as the sum of two components, one measuring the maximum latency of the current set of trees, the other being an upper bound on the maximum latency increase of existing trees. The former is defined simply as $\lambda_{\min}(r,j) + \delta_{\max}(r,j)$, where $j \in J$ and r is the root of the tree, while the latter is defined as a sum of queuing delays $\sigma_{\max}(i,J)/\beta(u,v)$ introduced by the new tree at each of the links for each of the other trees using the same link, where $\beta(u,v)$ is the bandwidth of the (u,v) link.

C Critical Compound Failure Probability Estimation

This section details the procedure used to estimate the probability of a *critical compound failure*, i.e., a combination of network failures not tolerated by FiDe. This type of failure is outside the scope of FiDe's model, hence monitoring processes can possibly misinterpret it as a remote process failure (false suspicion). Recall that the two-fold redundancy and the tree recovery mechanism are robust towards a single network failure, since processes can rely on the other (healthy) tree, and also tolerates multiple failures in the redundant trees given they allow FiDe TE to recover. We will shortly see how the recovery time is in fact not influential for critical compound failures. Moreover, we assume that FiDe terminates gracefully, when one of the two trees is still alive and there are no more healthy links available for tree recovery.

In what follows, we consider all events with respect to a given operational *year*. We define two auxiliary events:

- f^l: link l fails at least once;
- $f^{l,l'}$: links l and l', $l \neq l'$, fail at least once within the tree recovery time.

Now we can define a critical compound failure event:

$f_{\text{CCF}}^{\mathcal{T}}$: at least two distinct network failures occur within the tree recovery time interval affecting all multicast trees in multicast tree set $\mathcal{T}$ (in FiDe, we have $|\mathcal{T}| = 2$).

Formally, for redundancy level two $f_{\text{CCF}}^{\{T_1,T_2\}} = \{\exists\ l_1 \in T_1, l_2 \in T_2 : f^{l_1,l_2}\}$.

We use switch and link failure statistics from a seminal large scale analysis of datacenter network failures from Gill et al. [22]. Note that, while FiDe's failure model defines a network failure as a more generic packet drop, we restrict the scope to switch and link failures only because packet drops caused by congestion are prevented by FiDe's TE-driven periodic multicast protocol. We report probability estimates relevant to our topology from [22] below (marked with $'$).

- If l is a "trunk" link, then $p(f^l) \leq p'_{tr} = 0.054$ (probability of a "trunk" link failure) [22, Fig. 5].
- If l is a "core" link, then $p(f^l) \leq p'_{cr} = 0.095$ (probability of a "core" link failure) [22, Fig. 5].
- If $p(\exists\, l' \neq l : f^{l,l'} | f^l) \leq p'_g = 0.41$ (probability of a given failure affecting a group of links) [22, Fig. 10].

Gill et al. [22] report that (a) switch failures do not show correlation and that (b) link failures are either "simultaneous" (without giving an exact quantification) or the time between them is too large to indicate a meaningful correlation. Finding (a) suggests that FiDe is very likely to always tolerate switch failures since the trees in $\mathcal{T}$ are disjoint on inner nodes. For finding (b), consider that FiDe adopts a conservative tree recovery time of several seconds (our measurements indicate a recovery time ms-range similar to several studies [25,40,77]), which, for the purposes of this evaluation, we can confidently assume to be much smaller than the "large grouping thresholds" evaluated in the empirical study. We therefore consider only simultaneous link failures as potential causes of a critical compound failure and do not delve into a detailed quantification of the tree recovery time.

We compute an upper bound on $p(f_{\text{CCF}}^{\mathcal{T}})$ for multi-rooted fat trees of different *height*, which we define as half the diameter of a fat tree. Fig. 8 provides a visual example of a multi-rooted fat tree, showing how deployment of FiDe processes can create "sub-trees" withing a broader topology. The formulas below are used to derive the upper bound on the probability of critical compound failure.

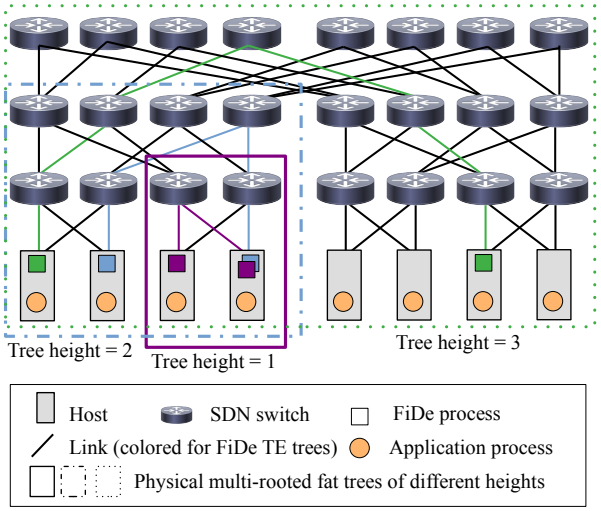

Figure 8: Widely-adopted multi-rooted fat tree topology with three different FiDe deployments (color-coded) showcasing different tree heights.

$$
\begin{aligned}
p(f_{\mathrm{CCF}}^{\{T_1,T_2\}}) &\leq \sum_{l_1 \in T_1} p(\exists\, l_2 \in T_2 : f^{l_1,l_2}) && (1)\\
&= \sum_{l_1 \in T_1} p(\exists\, l_2 \in T_2 : f^{l_1,l_2} | f^{l_1}) \cdot p(f^{l_1}) && (2)\\
&\leq \sum_{l_1 \in T_1} p(\exists\, l' \neq l_1 : f^{l_1,l'} | f^{l_1}) \cdot p(f^{l_1}) && (3)\\
&\leq p'_g \cdot (p'_{tr} \cdot n_{tr}(T_1) + p'_{cr} \cdot n_{cr}(T_1)) && (4)\\
&= p'_{\mathrm{CCF}}(\{T_1,T_2\})
\end{aligned}
$$

where $n_{tr}(T)$ and $n_{cr}(T)$ denote the number of "trunk" and "core" links, respectively. In (1) we use a union bound over links in T_1, in (2) we use the fact that $f^{l_1,l'} \subseteq f^{l}$ and we can use the definition of conditional probability, in (3) we use the fact that any link T_2 contains only a subset of links different from l_1, and, finally, in (4) we apply the bounds.

For a practical example, consider the topology with height $H = 1$ from Fig. 8, which has only two trunk links in each tree, i.e. $n_{tr}(T_1) = 2$ and $n_{cr}(T_1) = 0$. We obtain the upper bound on the failure probability $p'_{\mathrm{CCF}}(\{T_1,T_2\}) = p'_g \cdot p'_{tr} \cdot 2 \approx 0.044$. In general, for a set of multicast trees $\mathcal{T}$ connecting n FiDe processes and having height $H \in \{1,2,3\}$ we have $p'_{\mathrm{CCF}}(\mathcal{T}) = p'_g \cdot n \cdot (\max(H-2,0) \cdot p'_{cr} + \max(H-1,0) \cdot p'_{tr})$. Concretely, if $n = 2$, then for $H = 2$ we get $p'_{\mathrm{CCF}}(\mathcal{T}) \approx 0.089$ and for $H = 3$ we get $p'_{\mathrm{CCF}}(\mathcal{T}) \approx 0.17$.

Critical compound failure probability in perspective. The expected frequency of a critical compound failure ($freq_{\mathrm{CCF}}$) based in the smallest (ideal) topology is 1 every *22.73 years*, hence extremely likely to outlive any realistic service uptime. To put this number in perspective, we compare it against the probability of packet corruption in TCP, widely regarded and used as reliable communication layer by coordination services such as Zookeeper [29]. A popular study [69] reports that "the Ethernet CRC + TCP checksum will fail to detect errors for roughly 1 in 16 million to 10 billion packets", with recent real-world cases being reported [72, 73]. If we assume equivalent TCP traffic as FiDe's throughput when set with the lowest possible sending period of $T = 20\mu s$ (500Mbps) used in our evaluation, the reported error rate would translate to one packet corruption every 320 seconds to 2.3 days, making it several orders of magnitude more reliable. Considering that error reports [22, 69] are from decades ago, we expect both probabilities to be significantly smaller in modern networks, challenging the common misconception that any network is unreliable.

LEOCraft: Towards Designing Performant LEO Networks

Suvam Basak*, Amitangshu Pal*, Debopam Bhattacherjee†
*Indian Institute of Technology Kanpur, †Microsoft Research India

Abstract

Low Earth Orbit (LEO) satellite constellations have revolutionized Internet access for millions of users. OneWeb and SpaceX are already operating constellations of hundreds and thousands of satellites, offering Internet service directly from space across 100+ countries. These exceptionally large networks come at a cost – thousands of routers (satellites) need to fly at ∼22× the speed of sound, thus making network design a non-trivial challenge. While the systems research community with decades of deep networking expertise has a relatively short window to influence the design of these networks, there is a serious lack of the right tools to enable such efforts. To address this, we introduce LEOCraft – an LEO network design framework to help the community visualize and evaluate the performance of different choices. LEOCraft offers integrated optimization techniques tuned upon the domain knowledge acquired from thousands of LEO constellation design's performance evaluations to optimize a new constellation design ∼5× faster than other off-the-shelf black-box optimization techniques. LEOCraft scales up seamlessly, tested for 83K satellites across multiple shells (more than 2× SpaceX's long-term proposal) with 1K ground stations, thus making it feasible for the community to explore LEO trajectory and topology design for even the largest of *mega*-constellations.

1 Introduction

In the past few years, thousands of satellites have been deployed in Low Earth Orbit (LEO) to serve worldwide high-speed Internet broadband service directly from space [44]. The early movers of this new networking landscape, SpaceX's Starlink and OneWeb, initially relied upon bent-pipe connectivity in the first generation of constellations [58]. Further technological advancements have introduced robust laser Inter-Satellite Links (ISLs), enabling space-borne mesh networks with high bandwidth and speed-of-light grade latency [55]. Such a LEO satellite network can carry long-haul Internet traffic over the satellite network, thus reducing the requirement for denser Ground Station (GS) deployment across the globe [2]. This development enabled Starlink and Amazon's Project Kuiper to propose a 2nd generation mega-constellation of 30,000 [3] and 3,236 satellites [1] respectively, to wrap the Earth with a dense mesh of LEO satellites. However, the FCC approved only 7,500 satellites of Starlink across three different altitudes [3]. SpaceX started launching these new generation satellites in December 2022 [61]. In contrast, Kuiper was recently in the testing phase of the optical mesh network in space [5]. Therefore, none of the operators has achieved the true scale of ISL-enabled mega-constellations yet, keeping the *brief window* open for the networking community to influence such design.

The secret of constellation design: The success of Starlink's early launches sparked researcher's interest in exploring various aspects of LEO networks. Such recent works [44–46, 50, 54–56, 58, 64, 67, 68, 76] have used Starlink, OneWeb, and a few other constellation designs in their experiments since details are publicly available in the FCC filings [1, 3, 8, 12, 21, 31]. However, none of these existing works include the complete set of design parameters determining the satellite's trajectory as well as topology [45, 72, 92, 93]. Most of these efforts are restricted to a single shell, considering the inter-shell connectivity and aggregated performance measurement of multiple independent shells as *"an open problem"* [93].

Furthermore, Starlink and OneWeb, the biggest constellation operators, rely on proprietary systems, making their LEO networks function like black boxes. Why they chose a particular design, and what traffic matrices it targets, is unknown to the community. Therefore, in this work, we aim to unveil the subtle crux of designing an optimized LEO network from scratch. Our effort will help networking researchers understand these 'new space' networks better.

Why constellation design is non-trivial?: Designing a satellite network is not a new problem. In the 90s, serious efforts [37, 41, 52, 65, 66, 89, 90] have been devoted in studying constellation design. However, the current scale and design objectives have significantly transformed over time, imposing new challenges. Optimizing a satellite constellation in the 90s emphasized coverage with a limited budget of a few 10s of

satellites, ensuring availability worldwide [42]. In contrast, now, with the scale of a few thousand or more satellites, network performance has become comparable to the terrestrial networks [53]. Therefore, optimizing a constellation today is no longer a geometrical optimization of overlapping satellite coverage [51], but rather, an optimization of the satellite's orbital trajectories and their ISL topology for a given Internet traffic demand matrix. Therefore, given the number of satellites, the design problem is to decide upon several parameters describing ISL topology and each satellite's orbital trajectory at $\sim$22$\times$ the speed of sound, such that network performance is maximized. A network design is already a hard problem [62]; further joint optimization of orbital parameters with added dynamics of satellite motion makes it a non-trivial high-dimensional optimization problem. A naive brute-force grid search approach looking for maximum network performance measurement could take years due to the curse of dimensionality. A few previous efforts explored the aspect of improving constellation performance with better ISL topology [45, 72]; however, the approach [45] suffers from scalability issues hence could not be extended to the direction towards superior constellation design, i.e., optimization of satellite's trajectory at scale to enhance the network performance.

Missing the right tools: An in-depth study of trajectory and ISL topology optimization of the LEO network requires the execution of tens of thousands of simulations while varying one or more orbital/design parameters to measure how these choices impact the network performance. Therefore, an LEO network evaluation framework must offer the flexibility to (i) rapidly implement different ideas (topology, ISL connectivity, routing strategy, etc.), (ii) plug and play with various optimization strategies, (iii) evaluate the effectiveness of optimization strategies and further tuning these implementations. Existing platforms, i.e., *Hypatia*'s [64] packet-level simulator, or *StarryNet*'s [67] *Docker* container-based emulator, suffer from fundamental scalability issues [63]. Hence does not go well for large-scale (tens of thousands of satellites) trajectory simulation. Another LEO network emulation platform *xeoverse* [63] is built upon a lightweight process-based network emulator platform *Mininet* [20] and claims to outperform *Hypatia* and *StarryNet* by large margins; however, their source code is not public for community use. Therefore, the community lacks the right tools to approach large-scale trajectory and topology optimization problems.

Our contributions: In this paper, we address these gaps with `LEOCraft` – an LEO satellite constellation design exploration, optimization, and visualization framework. `LEOCraft` relies upon process-based parallelism [14], thus bypassing the Global Interpreter Lock, a major computational bottleneck [17] in the existing platforms [64, 67]. It is designed to be a modular framework that allows rapid implementation of new design ideas with minimal code change (typically 100 lines of code), which helps to run new experiments quickly. It operates at the flow level, computes network measurements from the intuitive mathematical model of the LEO network instead of resource-intensive packet-level simulations. For instance, the performance evaluation of Starlink's Gen1 three shells of 3,888 satellites (S-1 to S-3 in Table 1) in `LEOCraft` takes $\sim$2.5 minutes on a standard Desktop PC. Whereas with *Hypatia*, it takes hours for only RTT measurement of Starlink's single shell of 1,584 satellites. We also tested `LEOCraft` on a hypothetical mega-constellation of 83+ satellites across multiple shells (as shown in Table 1). Thus, `LEOCraft` enables rapid evaluation of design choices at a large scale. The visualization module also generates interactive views of the constellation, showcasing topology evolution and end-to-end route changes to augment the intuition of LEO dynamics.

We use `LEOCraft` to rigorously study the constellation design for given traffic demand matrices across a set of GSes and illustrate how the choices of design parameters impact the performance of these LEO networks. Since Internet traffic demand is skewed towards specific regions of the Earth with higher populations, the performance measurements of constellation designs exhibit common trends irrespective of the satellite budget. We use this domain knowledge and predictable characteristics of network performance measurements to prune the search space drastically. This reduces the running time by $\sim$5$\times$ as compared to the naive off-the-shelf black-box optimization techniques. We also demonstrate how inter-shell ISL can improve the throughput of a constellation and highlight some shortcomings of such ISL usage. We made `LEOCraft` publicly available [35] for community use.

Paper outline: The remaining paper is organized as follows – §2-3 summarize our overall background and problem overview. Then §4-6 discusses the development, optimization, and system design strategies used in `LEOCraft` framework. §7-8 present the experimental evaluation. §9 summarizes the related works. The paper is concluded in §10.

2 Background

Building an LEO constellation is a relatively new topic, so this section aids the reader with the relevant background.

2.1 LEO constellation design parameters

A satellite's trajectory around the Earth can be described by six parameters given by Kepler's law of interplanetary motion [84] using Two Line Element set (TLEs) [59], which is a standard format of defining the position, velocity, and trajectory of any Earth-orbiting object at a specific time (epoch). Since establishing an ISL takes a few 10s of seconds [45], satellites in a constellation follow a similar trajectory to sustain the ISL connectivity for a longer period of time. `LEOCraft` automatically generates the TLEs for each satellite for the given six parameters defined in the following:

Altitude (h): The height of the LEO satellites from the sea level typically falls between 500 to 2,000 km. These satellites need to orbit the Earth at a fixed velocity to maintain an orbit

Table 1: Constellation parameters of well-know space players [1, 3, 8, 12, 21, 31]. In this table *S-x* denotes *x*-th shell.

S-2	32	720	40°	5°	1,200 km
S-3	32	720	55°	5°	1,200 km

at a particular height; hence, the orbital period of a satellite is also fixed for a particular height. For instance, satellites at 500 km of altitude need to orbit the Earth at $\approx$ 27,000 kmph; therefore, the orbital period would be $\approx$ 90 minutes. Increasing the altitude of the satellites will decrease the orbital periods, as these two factors are inversely proportional.

Angle of inclination (i): The angle between the orbital plane and the Earth's Equatorial plane (when satellites are moving towards the north). Hence, a satellite with inclination 90° orbits the Earth over the north pole. Meanwhile, a lower inclination tilts the trajectory; hence, the satellite orbits through the lower latitudes.

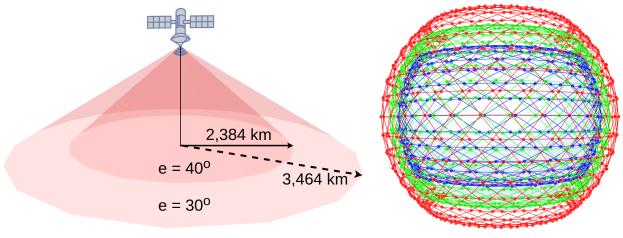
Number of satellites per orbits (n): Each orbit in a LEO satellite constellation contains a fixed n number of satellites placed equidistantly across the orbit. All the satellites of fixed altitude orbit the Earth at the same velocity; hence, the in-between distance of $360°/n$ is maintained consistently.

Number of orbits (o): Similarly, the constellation would have o orbits, each with n satellites, uniformly spaced along the Equatorial line to ensure even coverage of Earth's surface.

Phase offset (p): Determines the relative positioning offset between satellites of adjacent orbits. In our implementation, p varies from 0 to 0.5. A phase offset of 0.5 denotes that the n-th satellite of $(o+1)$-th orbit is positioned at the middle of n and $(n+1)$-th satellites of o-th orbit.

Angle of elevation (e): The satellite's coverage area on Earth's surface depends on the minimum elevation angle e as shown in Fig. 1(a). This parameter depends upon the capability of space- and ground-based communication hardware. LEO satellites use software-defined phased array antennas to create spot beams on Gateway Ground Stations and User Terminals [1, 3, 8]. Hence, the onboard software can regulate the coverage area with the elevation angle. Table 1 summarizes the constellation parameters of major space players.

Furthermore, the LEO satellite mega constellation design comprising a few thousand or more satellites goes one step ahead, where the satellites are divided into groups that may have different designs; the satellites within a group follow similar trajectories that help sustain the ISLs for longer periods, as shown in Fig. 1(b) using Kuiper's proposed design. In LEO constellation terminology, these groups are known as *shells*. We assume that the satellites within a shell establish



(a) (b)

Fig. 1: (a) Low elevation e covers larger areas on the Earth's surface. (b) Kuiper design of three shells at altitudes of 630, 610, and 590 km with inclination 51.9°, 42°, and 33°, respectively.

four ISLs, two in the same orbit with leading and trailing satellites, while the other two with satellites of two adjacent orbits. Hence, each shell creates a layer of + shaped mesh network, defined as +Grid topology [45]. The `LEOCraft` takes six parameters to describe the design of each shell and automatically generates the TLEs for all the satellites for these shells, as illustrated in Fig. 1(b).

2.2 LEO network modelling and assumptions

The proprietary nature of the LEO constellation prohibits public disclosure of key details, such as satellite connectivity policies, user terminal associations, and bandwidth distribution mechanisms, etc. Thus, we base our assumptions on standards widely adopted in prior literature.

Network model: In `LEOCraft`, given a set of design parameters, we model the LEO satellite constellation as a big network graph, where nodes represent the satellites and GSes, and edges represent Ground to Satellite Links (GSLs) and ISLs. Unavailability of precise geospatial information prevents the modelling of individual user terminals [88]. Therefore, we assume the GS located in a city serves as a proxy for the demands of all the users in that city. Consequently, we allow a GS to establish GSLs with all the satellites available above the minimum angle of elevation e (from the horizon) at that particular time.

GSL budget model: In the above network, capacities of GSLs C are calculated from Shannon's channel capacity theorem [82]. The atmospheric path loss is estimated using the Free-Space Path Loss (FSPL) model [60]. With these, the channel capacity is expressed as $C = B\log_2\left(1+\frac{P_t G_t \lambda^2}{(2\pi d)^2 k_B B}\times\frac{G_r}{T}\right)$, where, P_t is the Tx power

(EIRP), G_t and G_r are the Tx and Rx antenna gains respectively, λ is the wavelength, and antenna gain-to-noise-temperature ratio G_r/T are taken from Ka-band specification available in FCC filling [50]. d denotes the distance between the Tx and Rx antenna, i.e., the distance between the satellites and GSes, k_B is Boltzmann's constant, and B is the transmission bandwidth. Note that, in our implementation, B is divided equally among the GSes under the coverage of each satellite.

ISL budget model: The laser ISLs are expected to have extremely low beam divergence properties and narrow beam widths, minimizing interference issues [4]. Currently, ISLs are in the early phase of deployment [30] or the testing phase of different operators [5, 11]. Since the largest LEO network operator Starlink's satellites use 4 ISLs [43] and subsequently all the prior work [45, 64, 67, 92, 93] made this a de facto standard, this work assumes and extends the same with capacity of each ISL conservatively set to 50 Gbps [6, 7, 9]. Although it is a configurable parameter in `LEOCraft`.

2.3 Internet traffic demand matrices

Since a geospatial dataset of individual Starlink users is not public [88], we use the following intuitive traffic demand matrices (TM) that follow the gravity model [79].

High population TM: We use World Cities Database [34] for the population dataset, where GSes are located in 100 most populous cities around the globe. We assume that 10% of a city's population is the targeted customer, with average data usage per head of 300 Kbps [76]. The traffic demand across the GSes is inversely proportional to their geodesic distances.

High GDP population TM: Apart from the city population, typically, the Internet traffic is also proportional to the city's GDP [38]. So, in this demand matrix, we assume that the targeted market is 10% of the total population of the 100 most populous cities. However, the data usage is weighted based on the city's GDP. We keep the mean data usage to be 300 Kbps. Similar to the previous matrix, the demand across the GSes is inversely proportional to their geodesic distances.

Country capital TM: In this matrix, the GSes are located in the capital of 233 countries. The demands across the GSes are weighted proportionately to the country's population and in inverse proportion to the geodesic distances between GSes.

Global flight TM: In-flight Wi-Fi market is already a billion-dollar industry, forecasting an annual growth rate of 11.8% [18]. Therefore, domestic and international airlines are also potential target markets for the in-flight high-speed Wi-Fi service [80]. For that, we use *FlightRadarAPI* [33] to collect details of the in-flight aircraft worldwide. Then we assume 50% of passengers of each flight above 10,000 feet of altitude are communicating with GSes located at the 100 most populous cities via satellite network. We weighted the demand matrix between the flights and the GSes using the gravity model discussed above, whereas the weights are directly proportional to populations/passengers and inversely proportional to the distance between the flights and the GSes.

Moreover, notice that the TMs are subject to the target market. A satellite constellation designed to serve the shipping industry might weight the demand matrices analogous to the busiest trade routes in the ocean. Hence, many such intuitive TMs can be formulated. However, our study is focused only on the TMs discussed above.

2.4 Network performance metrics

We evaluate the constellations on the following three performance metrics.

Throughput: We measure the throughput of the LEO satellite constellation as a multi-commodity flow across the GSes. We compute n shortest routes between the GSes at any given time using Yen's algorithm [91]. Then, we use the following linear program to maximize the flow between all pairs of GSes.

$$\text{Maximize: } \sum_{f \in \mathbf{F}} D_f \times \sum_{r}^{n} R_r^f \tag{1}$$

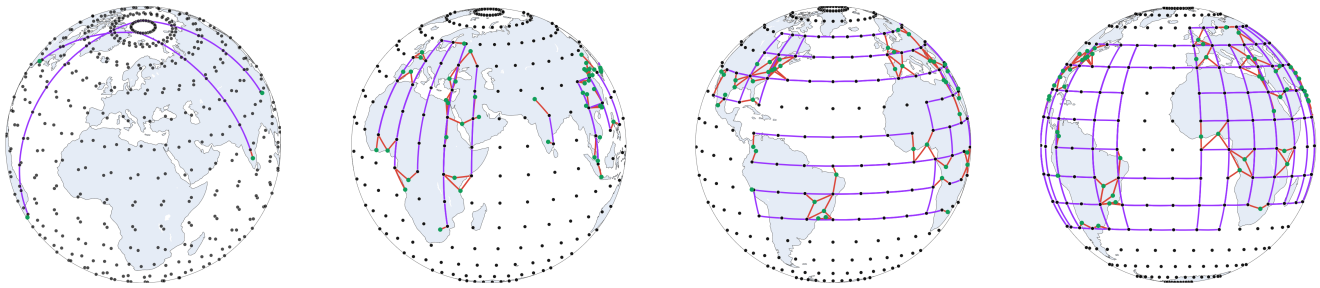
$$\text{Subject to: } \quad 0 \leq \sum_{r}^{n} R_r^f \leq 1 \quad | \, \forall f \in \mathbf{F} \tag{2}$$

$$\sum_{(f,r) \in \mathbf{S}_l} D_f \times R_r^f \leq C_l \quad | \, \forall l \in \mathbf{L} \tag{3}$$

Here, $\mathbf{F}$ is the set of flows, where a flow is defined as an ordered pair of GSes denoting traffic flow between one GS pair. D_f is the traffic demand for the flow f (demand between two GS). Since we have n shortest routes between each pair of GSes, R_r^f denotes the fraction of demand D_f flowing through the r-th shortest route. Therefore, $\sum_r^n R_r^f$ the sum of n continuous variable bounded within zero and one in constraint (2), which ensures n shortest routes together can accommodate at most 100% of the demand D_f of any flow $f \in \mathbf{F}$. Finally, the links could be shared by more than one flow in the network. Therefore, aggregated traffic flows sharing a particular link are constrained by the capacity of that link. Hence, in constraint (3), $\mathbf{L}$ is the set of all the links in the network, and $\mathbf{S}_l$ denotes a set of flows f and their r-th shortest route that shares link l. Therefore, $\sum_{(f,r) \in \mathbf{S}_l} D_f \times R_r^f$ denotes total traffic flow via link l, which is constrained by the C_l, the capacity of link l. For all our simulations, we use $n = 20$.

Stretch (latency): We measure *stretch* between source and destination GS pair as the ratio of the distance between two locations over the satellite network through ISLs and their geodesic distance. This metric demonstrates the inflation in the length of the end-to-end routes. Since the scope of this work is a comparative performance study of constellation design, lower stretch and lower hop counts for end-to-end routes are expected to give better network latency.

To understand the generalized nature of latency worldwide across diverse routes, we classify all the routes into five categories based on their nature. The first two categories are based on the distance between the source and destination



(a) HG routes (b) NS routes (c) EW routes (d) NESW routes

Fig. 2: Illustration of the route categories based on the path orientation and distance, where red lines are *GSLs*, violet lines are *ISLs*, black dots are the *satellites*, and green dots are the *GSes*.

GSes. Therefore, (a) any pair of GSes located within a distance of 2,000 km falls in the *Low Geodesic (LG) distance* class. Such routes will always come with higher stretch because of the route overhead of going up from the source GS to a satellite and coming down from a satellite to the destination GS, only to use one satellite hop (most of the time). (b) Any source and destination pair of GSes located far apart in different hemispheres ($\geq$ 8,000 km) falls in the class of *High Geodesic (HG) distance* routes as illustrated in Fig. 2(a). All other routes that do not fall into the above two classes are classified based on the orientation of the path. Therefore, the routes between the GSes pairs oriented with (c) angle above 75° shown in Fig. 2(b) are classified as *North-South (NS)* routes, (d) angle below 15° shown in Fig. 2(c) are classified as *East-West (EW)* routes, and (e) angle within 15° and 75° shown in Fig. 2(d) are classified as *NorthEast-SouthWest (NESW)* routes. For overall stretch tendency, we report the median stretch and hop counts of each category.

Coverage: One of the unique potentials of the LEO satellite constellation is to offer genuinely global high-speed Internet service irrespective of geographical challenges. However, to sustain the business, the obvious choice of a constellation operator would be to optimize the satellite trajectories to provide higher availability where the volume of customers is high. Therefore, we measure the coverage of a constellation as $\sum_{t=0}^{T}\sum_{g=0}^{G}\log_{10}(n_{t,g})/T$, where G is the number of GSes, T is the number of epochs, and $n_{t,g}$ denotes the number of satellites visible from the g-th GS at t-th epoch. The $\log(.)$ function models the diminishing returns as the number of visible satellites per GSes increases.

3 LEO network design from scratch

With the preceding background, we now delve into the LEO trajectory design problem, along with the research challenge of high dimensionality.

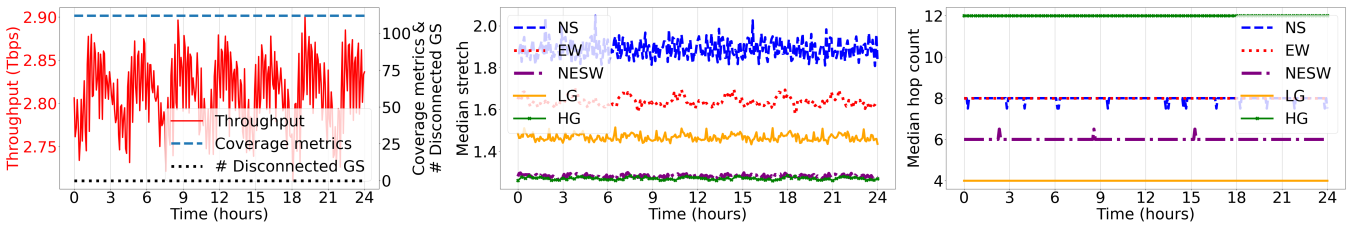
Problem statement: We define our problem statement as follows – given the number of satellites (which is our network budget), location of GSes, and traffic demand matrix across these GSes, we need to find the constellation design parameters of one or more shells (s) and their operational altitude (h), inclination (i), minimum elevation angle (e), number of orbits (o), satellites per orbit (n), and the phase offset (p) between satellites in adjacent orbits that maximize some objective function such as throughput, coverage, latency, or a combination of these. However, in this work, we focus on a performant constellation that maximizes the throughput. Higher throughput produces more salable bandwidth, which might fetch higher revenue for the constellation operator.

The curse of dimensionality: Therefore, in a mega-constellation of multiple shells, a brute-force grid search approach to find near-optimal design parameters will require the execution of $|s| \times |h| \times |i| \times |p| \times |o| \times |n| \times |e| \times |t|$ simulations, where $|x|$ means number of distinct choices of parameter x, and $|t|$ denotes the number of epochs over 24 hours (one complete rotation of Earth) to estimate the performance fluctuation for LEO dynamics. Each simulation involves generating a network graph, calculating link budgets, computing routes globally, and evaluating network performance. That could take from a few minutes to hours or even days, depending on the number of satellites and GSes in the constellation. Therefore, executing these many simulations with many computational cores could take years.

Can we prune the search space? Given the large search space, meta-heuristic methods like *Simulated Annealing* [85], *Differential Evolution* [83], and *Adaptive Particle Swarm Optimization* [81] can offer near-optimal solutions. In addition, we leverage domain knowledge and heuristics related to the design parameter's impact on network performance to reduce the search space significantly. Our comprehensive analysis of design parameters highlights their performance characteristics and inter-dependencies. This insight refines meta-heuristic approaches. Further enables tuning of local search strategies to outperform out-of-the-box meta-heuristics.

4 Exploring the search space

We first explore the search space by conducting a single-dimensional analysis and extend the understanding to higher dimensions. Therefore, first, we focus on the single shell analysis; to characterize the effect of different design parameters, we use Starlink's first shell, which consists of 1,584 LEO satellites operating at 550 km of altitude. The satellites are



(a) Throughput and coverage (b) Stretch (c) End-to-end hop counts

Fig. 3: The propagation of satellites over time leads to fluctuation in (a) throughput (left Y-axis), (b) stretch, and (c) hop counts within certain bounds. However, (a) coverage is consistent (right Y-axis).

distributed among 72 orbits inclined at 53°, each with 22 satellites. The elevation angle of Starlink's first shell is chosen as 25°. Unless otherwise mentioned, we use a phase offset of 0.5 in our simulations. All these parameters and upper Ka-band specifications are taken from the FCC filing [10, 50]. Performance characteristics of other proposed constellations are discussed in §A.1. We use the *High population TM* for this section; however, in §A.2, it shows that the findings are generalizable to other traffic metrics as well.

Performance impact of LEO dynamics: We begin by measuring network performance fluctuations due to LEO dynamics. We simulate Starlink's first shell for 24 hours with 5 minutes of granularity. The network performance metrics from the simulation are shown in Fig. 3. Notice that in Fig. 3(a), the constellation gives consistent coverage, and none of the GSes experience an outage within 24 hours. However, throughput shows a periodic pattern of fluctuation of $\sim$ 150 Gbps, which is up to 7% of the maximum recorded throughput. Similar behavior is also noticeable for other performance metrics, i.e., stretch fluctuates within a small margin, and hop counts are mostly stable, sometimes changing by at most two hops, as shown in Fig. 3(b)-(c), respectively. It is essential to notice that due to the Earth's rotation, one orbit will eventually take the position of the next. Also, within each orbit, one satellite will take the position of the next satellite after a specific time. Hence, the fluctuation rate of performance metrics will be within a relatively small margin.

Key takeaway(1):- The network performance remains stable, fluctuating within 6.5% due to LEO dynamics.

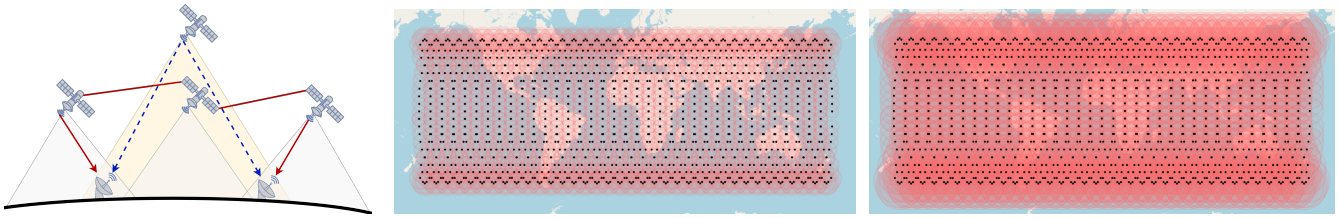
Performance impact of altitude (h): Operating a satellite at a higher altitude with the same elevation angle e will increase the coverage area on the Earth's surface as illustrated in Fig. 4(a). Therefore, operating a shell at higher altitudes of 600 km gives much denser coverage than operating the same at an altitude of 300 km, as shown in Fig. 4(b)-(c), respectively. We simulate Starlink's first shell by gradually increasing the altitude h of the shell from 300 to 2,000 km, while all the other parameters are kept constant. The results of the simulation are shown in Fig. 5. At higher altitudes, the availability of satellites per GS increases, which is visible in the coverage metrics of the constellation in Fig. 5(a). This higher availability of satellites per GS gives higher end-to-end path diversity, leading to a throughput hike up to a certain point. However, beyond a certain point, increasing h results in longer GSLs with higher atmospheric loss. Also, at higher altitudes, many GSes connect to the satellites, which results in low bandwidth for each GSL. As a result, throughput eventually starts falling.

Next, we discuss the effect of h on network latency. Notice that the shells at lower altitudes limit satellite availability per GSes. For that, the shortest path has to take a few more hops to reach the satellites above the destination GSes, as illustrated in Fig. 4(a). This behavior is also visible in our simulation results in Fig. 5(b)-(c). Apart from the LG routes, when the altitude of the shell is increased beyond 300 km, the stretch and hop count decrease drastically. The stretch starts inflating beyond 700 km because of longer GSLs. For LG routes, source-destination pairs are close to each other; a higher h results in longer GSLs, leading to increased stretch.

Key takeaway(2):- A fixed number of satellites at lower altitudes could lead to coverage gaps and higher latency, while higher altitudes reduce aggregated throughput. Slight altitude changes have minimal impact.

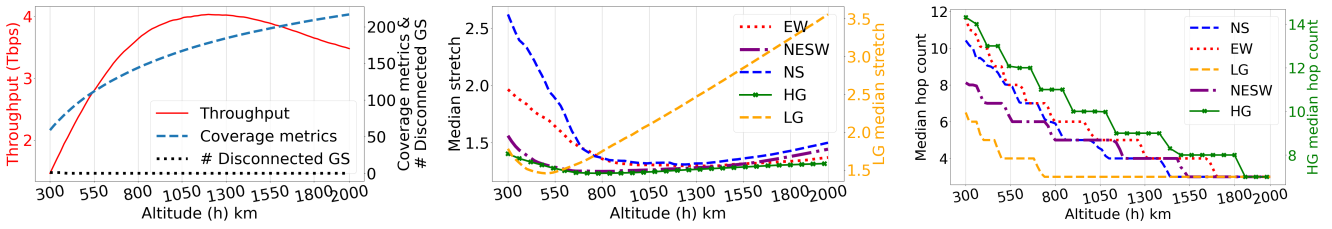
Performance impact of inclination angle (i): Similarly, we simulate Starlink's first shell with the angle of inclination i ranging from 5° to 175°. The results are shown in Fig. 6. From Fig. 6, we can observe that the network performance corresponding to inclination 5° to 90° is completely symmetric to the performance from 90° to 175°. This is because when a shell is inclined at 45°, the satellites that move towards the north at the angle of 45° in one hemisphere are the same satellites that move towards the south at an angle of 135° in the opposite hemisphere. Thus, a shell inclined above 90° is symmetric to an inclination below 90°. Therefore, we focus on the first half of the performance metrics (5° to 90°) to understand the inclination's impact on the network performance.

In Fig. 6(a), we can observe that the throughput and coverage peak arise around 40° of inclination. This is because, if we look at the 100 GSes locations at most populated cities in Fig. 7(a), then we can observe that 40° of inclination restricts the satellite trajectories exactly above these 100 GSes, as shown in Fig. 7(b). However, moving towards the polar inclination (towards 90°) reduces the coverage since satellites spend a certain amount of time in the polar regions, where not a single GS is located in our setup, as illustrated



(a) (b) At $h = 300$ km (c) At $h = 600$ km

Fig. 4: (a) Higher altitude increases coverage areas, resulting in route changes with fewer hops. (b) and (c) illustrate coverage footprint expansion of Starlink's first shell when the altitude is increased.



(a) Throughput and coverage (b) Stretch (c) End-to-end hop counts

Fig. 5: (a) Increasing altitude h improves the coverage (right Y-axis) and throughput up to a certain point (left Y-axis). (b) Very high/low h negatively impacts stretch (left Y-axis), LG routes are most affected (right Y-axis) (c) high h reduces hop counts for all routes (HG routes in right Y-axis).

in Fig. 7(c). Thus, it negatively impacts the throughput. In contrast, a too-low inclination squeezes all the satellites close to the equatorial region. Therefore, most GSes at relatively higher latitudes go out of coverage, as illustrated in Fig. 7(d), and as a result, the throughput falls, whereas the number of disconnected GSes rises in Fig. 6(a).

Fig. 6(b)-(c) shows the performance of stretch and hop counts. Here, polar orbits give better results only for the NS routes because constellations with lower inclinations can not provide any straight path over ISLs in the north-south orientation. This is illustrated in Fig. 8. From Fig. 8, we can observe that the shortest path from St. Petersburg to Johannesburg is stretched with a lower inclination. On the other hand, lower inclination provides better stretch and hop count for EW and NESW routes, as observed for the routes between Dar es Salaam to Kabul and Khartoum to Hong Kong, respectively.

Key takeaway(3):- The orbit's inclination should align with GSes placement and route orientation to enhance coverage and throughput and minimize latency.

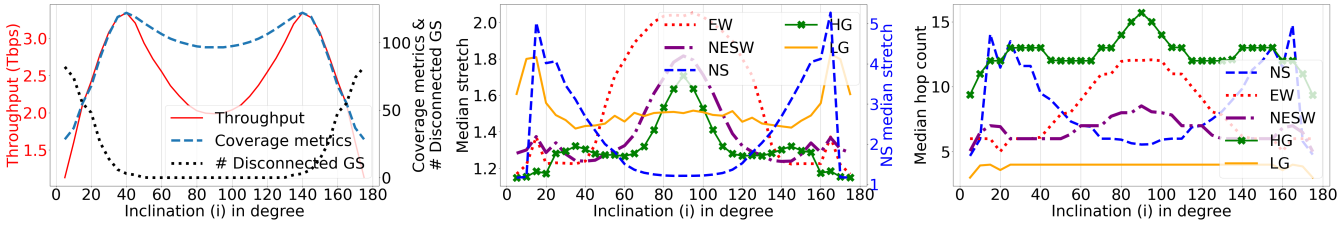
Performance impact of elevation angle (e)**:** As illustrated in Fig. 1(a), a reduction in e increases the coverage area of the satellites on the Earth's surface. That is clearly visible in Fig. 9(a), where e is varied from 5° to 50° for Starlink's first shell. As higher coverage results in more available satellites per GS, the end-to-end path diversity and throughput increase. However, after 13° of elevation, even though coverage increases, throughput starts falling drastically. This is because such a small value of e ($e < 10°$) results in GSLs over the Earth's horizon and therefore experiences enormous atmospheric path loss. This is illustrated in Fig. 10, where we can observe that at 5° elevation, the routes between two continents go through a single satellite hop, as compared to a few 10s of hops for 30° and 50° elevation. Thus, a lower e provides excellent hop counts and stretch results for all categories of routes, as shown in Fig. 9(b)-(c).

However, line-of-sight GSLs with a very low e may not be feasible without obstruction in urban areas (unless antennas are placed at higher elevations). However, a low value of e may be useful for providing connectivity over a long distance in less obstructed areas, such as oceans or polar regions. For instance, OneWeb FCC reports [8] mention that OneWeb satellite can reach up to 5° of elevation on the ocean to reach gateway GSes on the land area, compromising on power density, as they do not have plans of using ISLs yet.

Key takeaway(4):- While too extreme values are unfavorable, e should be tuned based on other parameter values to unleash better performance.

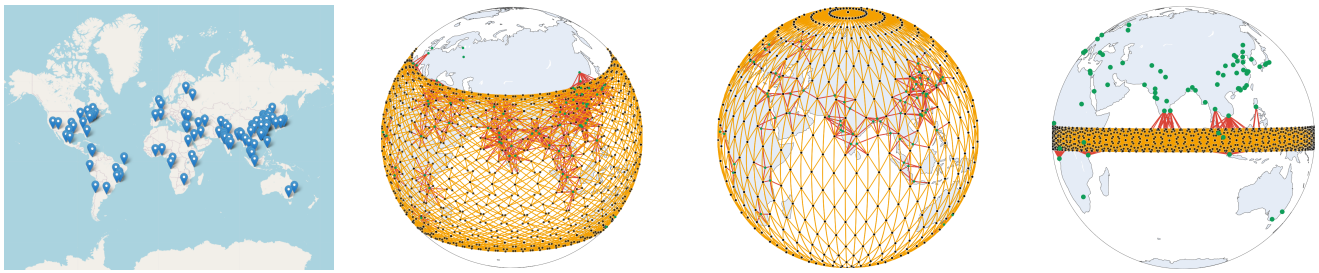
Performance impact of the number of orbits (o) **and phase offset** (p)**:** Since all the orbits have the same number of satellites, changing the number of orbits o inherently means adjusting the number of satellites n per orbit to maintain a fixed number of satellites. These orbits are equally spaced on the Earth's equator. Hence, a design with few orbits generates high east-west path diversity due to the large number of ISLs between satellites in adjacent orbits, as shown in Fig. 11(a). On the other hand, routes with high geodesic distances experience higher hop counts, as these routes follow intra-orbital ISLs to reach the destination GSes. Similarly, a design with many orbits reduces both hop counts in the high geodesic distance and east-west path diversity, as shown in Fig 11(b).

The phase offset p decides the relative positioning of satellites between adjacent orbits, i.e., in a constellation with 0.5 phase offset, a satellite n in orbit $(o+1)$ will be in the middle of satellite n and $(n+1)$ of orbit o, hence creating zigzag



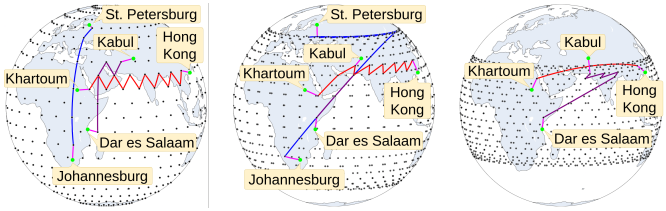
(a) Throughput and coverage (b) Stretch (c) End-to-end hop counts

Fig. 6: Performance measurement of i from 0° to 90° is symmetric to the measurement of 90° to 180°. (a) 40° provides best throughput (left Y-axis) and coverage (right Y-axis), too low/high i impacts negatively. (b), (c) Polar i provides better stretch (right Y-axis) and hop counts for *NS routes* and lower i provides better stretch (left Y-axis) and hop counts for other routes.



(a) GS locations (b) At $i = 40°$ (c) At $i = 90°$ (d) At $i = 5°$

Fig. 7: (a) Location of the GSes at the most popular cities. (b) $i = 40°$ restricts the trajectory of satellites on main population centers. (c) Higher i provides denser coverage at the polar region, whereas (d) lower i leaves most of *GSes* out of coverage.



(a) At $i = 90°$ (b) At $i = 50°$ (c) At $i = 30°$

Fig. 8: (a) Higher i provides better stretch with straight *NS* routes and zigzag ISLs for *EW* and *NESW* routes inflate the stretch. (b) Inclined trajectory provides better stretch for *NESW* and slightly improves *EW* stretch, whereas (c) very low i provides better EW stretch, leaves end-to-end *GSes* of *NS* out of coverage.

EW routes as shown in Fig. 11(d). On the other hand, with 0 phase offset, the ISL creates a precise +Grid shape network, as shown in Fig. 11(c). Hence, it is essential to note that these three parameters o, n, and p together describe the topological structure of the satellite mesh network. Therefore, after deeply exploring and analyzing the high-dimensional search space, our key discoveries are as follows:

(i) When the values of h, i, and e are close to optimal values, any number of orbit o which is sufficiently larger than the number of satellites per orbit n ($o >> n$) at a phase offset $p = 0.5$ produce higher throughput for any sufficiently large constellation. This behavior is shown in Fig. 12(a) for Starlink's first shell, where 100 GSes are located across most populated cities and the optimized value of i and e is chosen to 40° and 15° (§4) respectively. Notice that when the number of orbits is sufficiently large ($o > 66$), it gives a clear trend of increase in throughput with higher p.

(ii) This behavior is consistent across all the shells of Starlinks and Kuipers where the number of satellites is sufficiently large (≥ 300 satellites). The reason behind this behavior is demonstrated in Fig. 12(b)-(c). Notice that as we move towards higher o and p, median hop counts reduce, and the path diversity increases for HG routes without impacting other routes (i.e., NS, EW, NESW, LG); as a result, the constellation accommodates more traffic demands. The same is demonstrated between two GSes located in South Asia and North America in Fig. 13. When the constellation is designed with large o at $p = 0.5$, these two GSes experience high path diversity. Reducing either o or p negatively impacts the path diversity.

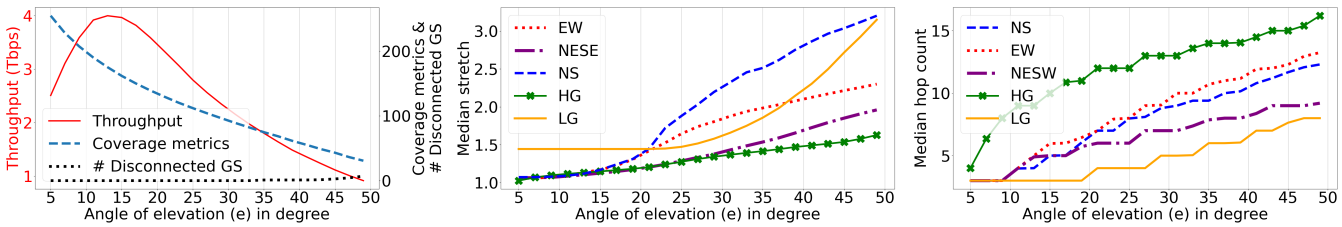
(iii) Change in the value of o or p essentially tweaks the mesh network at space, i.e., changes the ISL topological structures, which is illustrated in Fig.11. Therefore, when h, i, and e are fixed, any combination of o (hence n) and p produces consistent coverage.

> Key takeaway(5):- For a sufficiently large constellation (≥ 300 satellites), using larger o ($o >> n$) with a phase offset of 0.5 increases throughput.

5 Shaping an optimization strategy

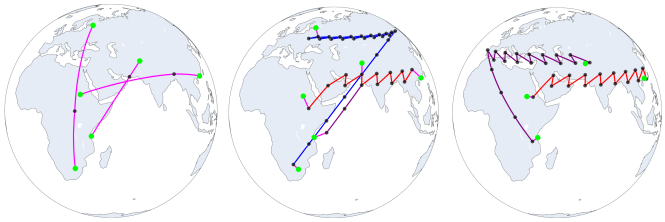
Now, we narrow down the search space using domain knowledge and key takeaways from the previous section. The outlined strategy helps optimization techniques converge faster.

Reducing the search space: As discussed earlier, the design of a single shell of a constellation deals with six parameters, i.e., h, i, e, o, n, and p. Since the topological structure is consistent and performance fluctuation is not significant over time, t could be ignored (takeaway (1)). Based on the observation of



(a) Throughput and coverage (b) Stretch (c) End-to-end hop counts

Fig. 9: Lower e provides better (a) coverage (right Y-axis) and throughput up to a certain point (left Y-axis). (b), (c) Lower e also provides better stretch and hop counts, whereas higher e (≥ 50) start creating coverage gaps.



(a) At $e = 5°$ (b) At $e = 30°$ (c) At $e = 50°$

Fig. 10: (a) Too low e enables cross-continent single hop routes with over the horizon *GSLs*, whereas (b) higher e reduces coverage area, thus, cross-continent *NS*, *EW*, and *NESW* routes increase up to 10s of *satellite* hops. (c) Too high e creates coverage gaps, hence, leaves *GSes* of *NS* routes out of coverage.

coverage metrics, these six parameters can be classified into two groups:

- GROUP-I: Set of parameters that impacts the constellation's coverage, i.e., h, e, and i.
- GROUP-II: Set of parameters that do not impact coverage, i.e., o, n, and p.

Now, notice that when the parameters of GROUP-I are optimized, then in GROUP-II, any number of orbits o which is sufficiently larger than the number of satellites per orbit n at phase offset $p = 0.5$ produce higher throughput than any other combinations (takeaway (5)). Hence, in our search strategy, we keep o to its maximum value (which will determine the value of n as well), $p = 0.5$, and then optimize the values of h, e, and i. Therefore, the search space is reduced to these three parameters of GROUP-I.

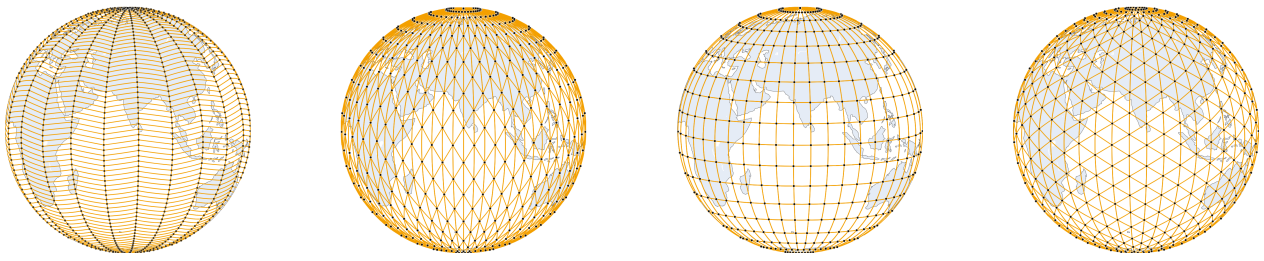
Furthermore, the scope of varying h is limited by various non-networking factors, i.e., FCC, ITU regulation [19, 24], radiation hazards [73, 78], rate of orbital decays [86], etc. Apart from that, because of symmetric performance outcomes (takeaway (3)), we restrict the parameters i up to 90°. It is also desirable to avoid too low inclination to reduce the interference with GEO satellites that operate over the Equator [26]. The range of e is also limited by the satellites and GSes communication hardware, which is not incorporated in our implementation.

Proposed search strategy: After trimming down the search space, `LEOCraft` tries to optimize the values of i, e, and h by using *Variable Neighborhood Search (VNS)* [57, 74] strategy. VNS starts with an initial solution x; in every iteration, it discovers the neighborhood of the current solution $N(x)$ and takes the best neighborhood. The process is repeated until the convergence criteria are reached (i.e., the solution starts saturating). In `LEOCraft`, we use a random step size at every iteration. While choosing the initial solution, we observe that $i \approx 30°$ and e between 10° to 20° converge faster. The intuition behind this is that the median latitude of the 100 most populous cities is 29.6°, and lower elevation gives good throughput for high path diversity (takeaway (4)).

6 Designing of `LEOCraft`

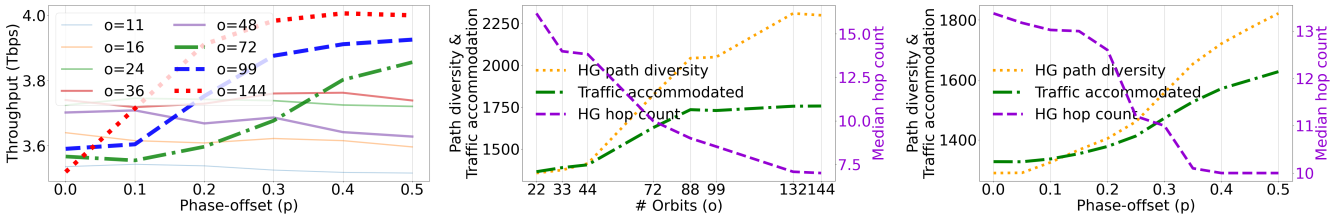
Overview of other simulation platforms: The well-known LEO network simulation and emulation platforms in the community are *Hypatia* [64], *StarryNet* [67], and *xeoverse* [63]. *xeoverse* is a relatively new LEO network emulation platform built upon network emulation platform *Mininet* [20]. *xeoverse* claims to outperform *Hypatia* and *StarryNet* by large margins [63]; however, *xeoverse* is not public for community use. On the other hand, *StarryNet* is a data-driven emulation platform partially available [70] to the community. *StarryNet* uses *Docker containers* [15] to emulate each node (satellites, GSes, user terminals) and Python's thread-based parallelism [32] for updating the state of virtual links (ISLs and GSLs) connecting containers [63]. Thus, *StarryNet* is resource-intensive, and scalability by default is constrained by the Docker engine's upper limit of its bridge interface (up to 1,023 containers [13] on a single machine [63]). Due to CPython's Global Interpreter Lock (GIL) [17], the link state update procedure of *StarryNet* with thousands of threads experiences a bottleneck, too. *Hypatia* is based upon ns-3 packet-level simulation platform [22]; hence, the scalability is constrained by the ns-3's limitations. Since *Hypatia* fails to utilise multiple CPUs, simulation execution drastically slows down with larger constellation [63, 64].

System design: After exploring the implementation of the above platforms, we found that a significant portion of the performance bottleneck arises from the software layer. This is because the LEO satellite constellation is treated as a single, monolithic block. However, within this block, most computations are independent of one another. For example, determining the coverage area of one satellite does not depend on calculations for other satellites. Similarly, computing a route from one GS to another is independent of the routes



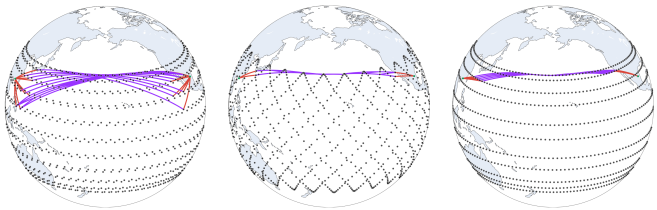
(a) $o = 22, n = 72$ (b) $o = 72, n = 22$ (c) $p = 0$ (d) $p = 0.5$

Fig. 11: Parameter o, n, and p together determine the *ISL* topological structures. (a), (b) n and o manipulates height and width to deform +Grid topological structure to rectangular grid cells. (c) Lower p forms a perfect +Grid topology, (d) higher p transforms +Grid to diamond ($\diamond$) shaped cells.



(a) Changing o and p (b) Changing o while $p = 0.5$ (c) Changing p while $o = 72$

Fig. 12: When i and e are set to 40° and 15°, (a) larger o (≥ 66) at a higher p provide better throughput. (b), (c) Such combinations reduce the *hop counts* (right Y-axis) and increase the *path diversity* for HG routes, and therefore accommodates *more traffic* for both parameter o in and p.



(a) $o = 144, p = 0.5$ (b) $o = 48, p = 0.5$ (c) $o = 144, p = 0$

Fig. 13: 20 shortest *HG routes* from South Asia to North America (a) have way higher path diversity with $o = 144$ and $p = 0.5$ than (b) lower o at $p = 0.5$ and (c) lower p at $o = 144$.

between other pairs of GSes, and so on. We exploit this in the implementation of `LEOCraft` [35], where each component (such as satellites and GSes) operates as an independent block with format-restricted data exchange APIs. This allows us to distribute workloads uniformly across all available CPUs, effectively shifting the performance bottleneck from the software layer to the underlying hardware.

In Fig. 14, we represent `LEOCraft`'s simulation workflow. In `LEOCraft` *LEO constellation builder* creates a top-level instance of *LEO constellation* based on specified design parameters and GS locations. This *LEO constellation* instance consists of all LEO network component instances (GSes, satellites, and ISLs) in it. The *LEO Constellation Simulator* acts as an execution framework in `LEOCraft`. It accumulates *LEO constellation* instances in the *Task queue* and evaluates the given batch of instances in parallel. This parallelism is at the functional level across all the *LEO constellation* instances in the *Task queue*. For that, *LEO Constellation Simulator* creates a pool of worker processes corresponding to each available CPU [14]. These worker processes remain active for the entire duration of the simulation execution, thus minimizing process creation overhead too. Each worker receives data (instances of LEO network components) and function references, executes these functions on the data, and sends the results back to the respective *LEO Constellation* instance through the dispatcher. The *LEO Constellation* accumulates the results of each asynchronously called function. Once all the function calls return, it writes back the evaluation results. Then *LEO Constellation Simulator* removes the instance from the *Task queue*.

This process-based concurrency [14] effectively bypasses the GIL [17], the primary performance bottleneck for CPU-bound tasks, allowing uniform use of all CPUs even for a single *LEO Constellation* instance in the *Task queue*. As a result, `LEOCraft` evaluates a large constellation within a few minutes. For the interested readers, §A.5 provides an overview of `LEOCraft` APIs for simulating any LEO constellation.

7 Performance evaluation of `LEOCraft`

We now evaluate the performance of `LEOCraft` to examine constellation-scale behavior. We compare the effect of different traffic matrices, optimization strategies, inter-shell connectivity, etc., using `LEOCraft`. In addition to these, we also compare and evaluate the performance of `LEOCraft` against existing platforms in §8.

Comparison with other optimization techniques: We now evaluate `LEOCraft` with different optimization strategies while scaling the constellation sizes. Specifically, we compare the network performance and running time of `LEOCraft` with four optimization techniques, i.e., *Simulated Annealing (SA)* [85], *Differential Evolution (DE)* [83], *Adaptive Particle Swarm Optimization (A-PSO)* [81], and *Variable Neighbourhood Search (VNS)*. The implementations of *A-PSO* and *VNS* are integrated into the `LEOCraft` framework, whereas for *SA* and *DE*, we use *SciPy*'s `optimize` APIs [25]. We use a max-

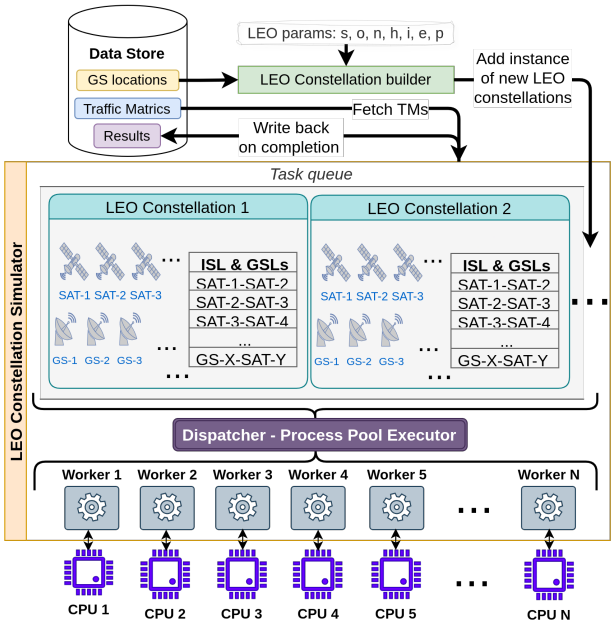


Fig. 14: LEOCraft's simulation framework.

imum iteration of 100 (60) for *SA* when domain knowledge of the search space is not in use (domain knowledge in use[1]). Similarly, for *A-PSO*, the number of iterations and particles is 25 and 20 (25 and 10), respectively, when domain knowledge is not in use (domain knowledge in use). These hyperparameters are empirically decided upon through a series of trials of synthetic constellations of different sizes. We evaluate the running time of these optimization techniques on a workstation powered by 16 core (24 thread) 12th Gen Intel(R) Core(TM) i9-12900 with 64 Gigabytes of memory.

The time taken to optimize the design parameters of different constellation sizes using different optimization techniques is shown in Fig. 15(a). Notice that when the same optimization techniques are used after pruning the search space using domain knowledge (§5), the average running time is reduced by ∼2.1×, ∼4.2×, ∼2.2×, and ∼13.7× for *SA*, *DE*, *A-PSO*, and *VNS*, respectively. Interestingly, *VNS* with domain knowledge outperforms all three metaheuristic techniques, as shown in Fig. 15(a). *VNS* is on average ∼2.2× times faster than the fastest metaheuristic technique when the search space is pruned with domain knowledge and at least on average ∼4.9× faster than the naive approaches. It is worth noting that *DE*, *VNS*, and *A-PSO* evaluate the cost function in parallel (evaluation of different design parameter combinations). In contrast, *SA* executes serially. However, if the running time is not the constraint, then the optimized design parameters produced by these four techniques are pretty similar. This is observed from Fig. 15(b)-(c), where we compare the throughput and stretch of NS routes of these optimized designs. Notice that the measured throughput varies marginally (standard deviation ±60 Gbps for 3,888 satellites) in Fig. 15(b), and the median stretch of NS routes deviation remains within 0.3, which is negligible variation as compared with the LEO dynamics (takeaway (1)).

> Outcome(1):- Insights drawn from extensive simulations can greatly reduce the search time for suitable constellation parameters.

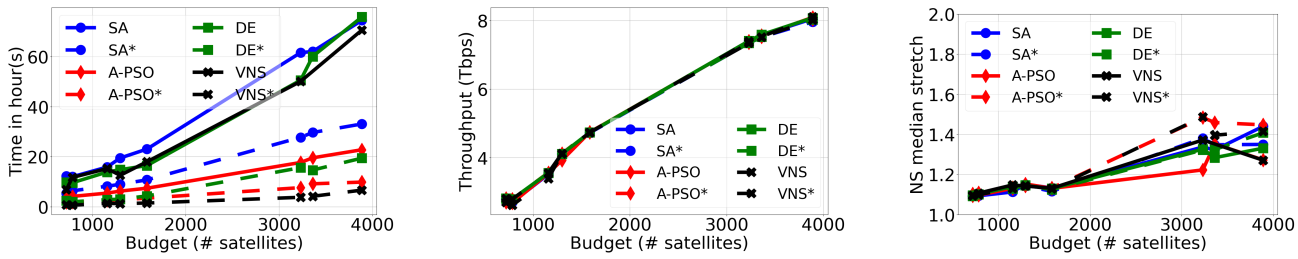
Single-shell vs Multi-shell design: We now explore the impact of multiple shells on the network throughput. For that, we take Starlink's first three shells, where the first two have 1,584, and the last one has 720 satellites, with altitudes of 540, 550, and 570 km [21], respectively. We do not consider inter-shell connectivity in this set of experiments. The results are shown in Fig. 16(a). Since these shells are independent of each other, we optimized the design of these three shells separately for our 100 GSes for the *High population TM*. The optimized Starlink constellation with three shells produced a throughput of 7.5 Tbps. Then, we merged the total budget of satellites into one shell, i.e., a single shell with 3,888 satellites produces a throughput of 8 Tbps when optimized. Further, we test the same while merging the satellite budget of any two shells out of three; thus, the constellation with two optimized shells produced throughput between 7.5 and 8 Tbps as illustrated in Fig. 16(a). We also test the same with a Kuiper budget of three shells with 1,156, 1,296, and 784 satellites, respectively, at altitudes 590, 610, and 630 km, respectively [1]. The observations are similar, i.e., the throughput observed when three shells are separately optimized is 6.6 Tbps, and when all satellites are merged and optimized in one shell, it is 7.4 Tbps. And any other combination falls in between these two measurements illustrated in Fig. 16(b).

> Outcome(2):- A single dense shell is more beneficial when higher throughput is the objective. A dense mesh network provides better path diversity for n shortest routes than multiple shells with sparser satellites.

Inter-shell ISL connectivity: However, designing a large constellation in one shell for higher throughput may increase the risk of collision [69,75]. This motivates us to explore inter-shell ISLs where we maintain the same +Grid ISL topology across the satellites deployed in different shells. Therefore, in LEOCraft, we simulate three shells of Starlink and Kuiper with inter-shell links. After optimizing the design, the throughput of these constellations reaches 8.01 and 7.34 Tbps for Starlink and Kuiper, respectively. This is almost equal to the throughput of merging the entire budget of a satellite into a single shell since a few 10s of km difference in altitude has a negligible impact on throughput (takeaway (2)).

The main drawback of this inter-shell connectivity is the variation of phase offset with time. Since the orbital periods of satellites at higher altitudes are slightly lower than those at

[1]Here "using domain knowledge" refers to running meta-heuristics within the reduced search space discussed in §5. In contrast, "without domain knowledge" excludes evaluations over 24 hours, as they fail to converge.



(a) (b) (c)

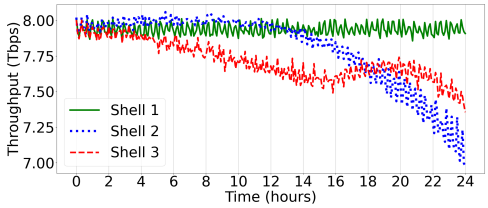

Fig. 17: Throughput measurement with inter-shell ISL connectivity over 24 hours without hand off.

lower altitudes, the phase offset will gradually deviate with time, and therefore, periodic hand-offs are needed to maintain the ISL connectivity and topological structure across the neighboring shells. However, we observe that the hand-off frequency for such a slight altitude difference (in 10s of km) is low. Fig. 17 shows the throughput measurement over a day when Starlink's 3,888 satellites are deployed in different shells, and inter-shell ISL connectivity is established in case of multiple shells. As expected, the throughput remains mostly consistent with minor fluctuation over time for the single shell design. For multi-shell design, deformation of the ISL topology due to the phase offset shift with time negatively impacts the throughput. We can also observe that a handoff after $\sim$ 13 and $\sim$ 4 hours may be needed for maintaining the inter-shell ISL topology across two and three shells, respectively.

Outcome(3):- Inter-shell ISLs enhance throughput slightly but require occasional handoffs to maintain connectivity and topology between shells.

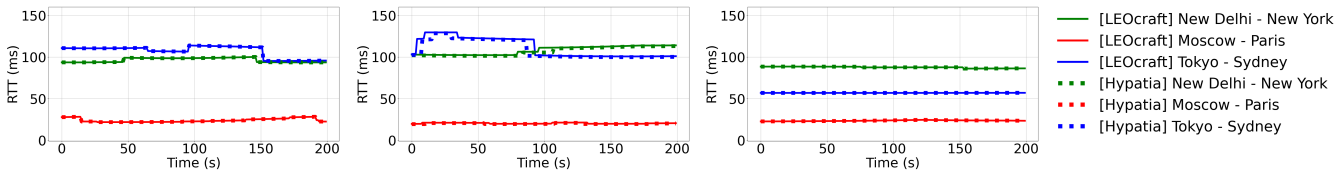
Visualization features: `LEOCraft` provides a range of visualization features, such as routes, satellite coverage, and constellation topologies. Some figures such as Fig. 1, 2, 7, 8, 10, 11, 13 are snapshots of the LEO network design's interactive and responsive visualization. Multi-shell mega constellations can be insanely dense networks that make it difficult to visualize particular areas of interest. `LEOCraft` visualization APIs allow cherry-picking of the components of interest (set of satellites, GSes, ISLs, GSLs, routes, etc.) for rendering. `LEOCraft` also generates frame-by-frame evolution of the network at the granularity up to nanoseconds to demonstrate how network topology and end-to-end routes change over time due to the LEO dynamics. Some additional details of visualization features are available in §A.3.

8 Comparing `LEOCraft` with other platform

Since *StarryNet* [67] does not scale up to a few thousand satellites on a single machine, and *xeoverse* [63] is not public, we choose to compare `LEOCraft` with *Hypatia* [64].

Packet-level vs. flow-level simulation: First, we highlight the scope of comparison and the fundamental differences between flow-level and packet-level simulations to avoid any misinterpretation for the readers. Notice that *Hypatia* is well-suited for analyzing detailed network protocol behaviors, like packet drops, retransmissions, or reordering due to handovers. A flow-level simulation like `LEOCraft` is more appropriate for examining architectural and policy-level trade-offs, such as the effects of ISL topologies, routing choices, and GSes placements on overall performance. Consequently, `LEOCraft` and *Hypatia* are not competitors; rather, they complement each other. A future simulation pipeline could utilize `LEOCraft` to uncover systematic design issues in LEO networks at scale, which could then be closely examined using *Hypatia*.

Latency comparison with *Hypatia*: In *Hypatia*, we simulate '`pings`' at 1 second interval between three GS pairs, i.e., Delhi to New York, Moscow to Paris, and Tokyo to Sydney through the shortest route over the first shell of Kuiper, Starlink, and Telesat for a duration of 200 seconds. Then we compute the round-trip time (RTT) in `LEOCraft` between the same pair of GSes over the same constellations. The results are shown in Fig. 18. From this figure, we can observe that the measured RTT obtained from *Hypatia* closely matches with the '`computed`' RTT of `LEOCraft`. The RTT of Moscow to Paris is one-third of the latency of Delhi to New York since the distance between Delhi to New York is $\sim 5\times$ than the distance between Moscow and Paris. In contrast, Tokyo to Sydney



(a) Kuiper first shell of 1,156 satellites (b) Starlink first shell of 1,584 satellites (c) Telesat first shell of 351 satellites

Fig. 18: *Hypatia*'s `Ping` closely matches with `LEOCraft`'s computed RTT for (a) Kuiper, (b) Starlink, and (c) Telesat.

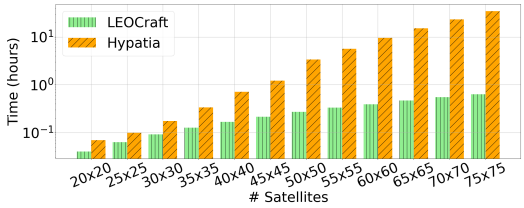


Fig. 19: Comparison of simulation times with *Hypatia* and `LEOCraft` for different constellation sizes.

routes experience latency equivalent to the HG route Delhi to New York, despite these two endpoints being relatively close to each other. This is because the orbital inclination of Starlink and Kuiper are 53.0° and 51.9° do not generate the straight route in the north-south orientation. In contrast, Telesat's inclination of 98.98° generates a straight route in a north-south orientation, hence Tokyo to Sydney latency is reduced by $\sim$ 50% as compared to Starlink and Kuiper.

Simulation time comparison with *Hypatia*: We now compare the simulation time of *Hypatia* and `LEOCraft` in Fig. 19, where we simulate the end-to-end latencies between 50 most populous cities while increasing the size (number of satellites) of a synthetic single shell +Grid constellation. The inclination angle, elevation angle, and altitude of the satellites are kept as 90°, 30°, and 1,000 km, respectively. From the figure, we can observe that the `LEOCraft` is $\sim$ 1.7 to 54.5$\times$ faster as compared to *Hypatia*, and this difference keeps increasing with the size of the constellation. While having more CPUs will further speed up the simulation in `LEOCraft` due to its design, which is not the case with *Hypatia*.

Additionally, to evaluate the scalability of `LEOCraft` with a hypothetical mega-constellation consisting of 20 highlighted shells in Table 1[2], which comes out to be a mega-constellation of 83K satellites. We have observed that `LEOCraft` manages to simulate this mega-constellation within a week on a system powered by Intel Xeon Silver 4309Y (16) @ 3.6GHz and 128 Gigabytes of memory. This shows that `LEOCraft` is well-suited for simulating mega-constellations consisting of tens of thousands of satellites within a reasonable time.

9 Related work

Simulation and measurement: Several efforts [47, 63, 64, 67, 68] have focused on creating simulation platforms for measuring LEO networks. Notable examples include *Hypatia* [64], *StarryNet* [67], and *xeoverse* [63], their strengths and limitations has been briefly discussed in §6. Additionally, [46] explores RTT fluctuation using intuitive mathematical modeling, avoiding resource-intensive simulations.

LEO topology: Most of recent studies [40, 47, 63, 64, 67, 68, 92, 93] have widely adopted the +Grid topology as the de facto standard for LEO networks. In contrast, [45] proposed an improved ISL topology to minimize hand-offs and enhance throughput latency. Meanwhile, [72] highlighted the drawbacks of +Grid, advocating for $\times$Grid topology to reduce packet drops and hop counts. A recent study [92, 93] used *Hypatia* [64] to analyze single-shell LEO topologies with a limited set of design parameters. This work extends the analysis to all parameters, including multiple shells, optimizing satellite trajectories based on the traffic demand matrix between GSes.

10 Conclusion and future work

In this paper, we introduce `LEOCraft` [35], an open-source, modular, and scalable framework for evaluating and visualizing LEO constellations. `LEOCraft` analyzes high-dimensional search spaces to uncover the crux of LEO trajectory design that enables trimming of search space to optimize constellation design quicker. We also present findings on the performance gain for inter-shell ISL connectivity.

In the future, we plan to extend the `LEOCraft` towards topology and trajectory joint optimization [45, 72]. While this work focuses on maximizing throughput, mega-constellation operators with humongous budgets often target diverse sectors. For instance, Starlink's deployment of two polar-orbit shells improves connectivity in the polar region [27–29]. Additionally, seeks FCC approval for VLEO deployment to enable low-latency applications like fin-tech and gaming [16]. Optimizing mega constellations for multiple objectives presents another promising research direction.

A Appendix

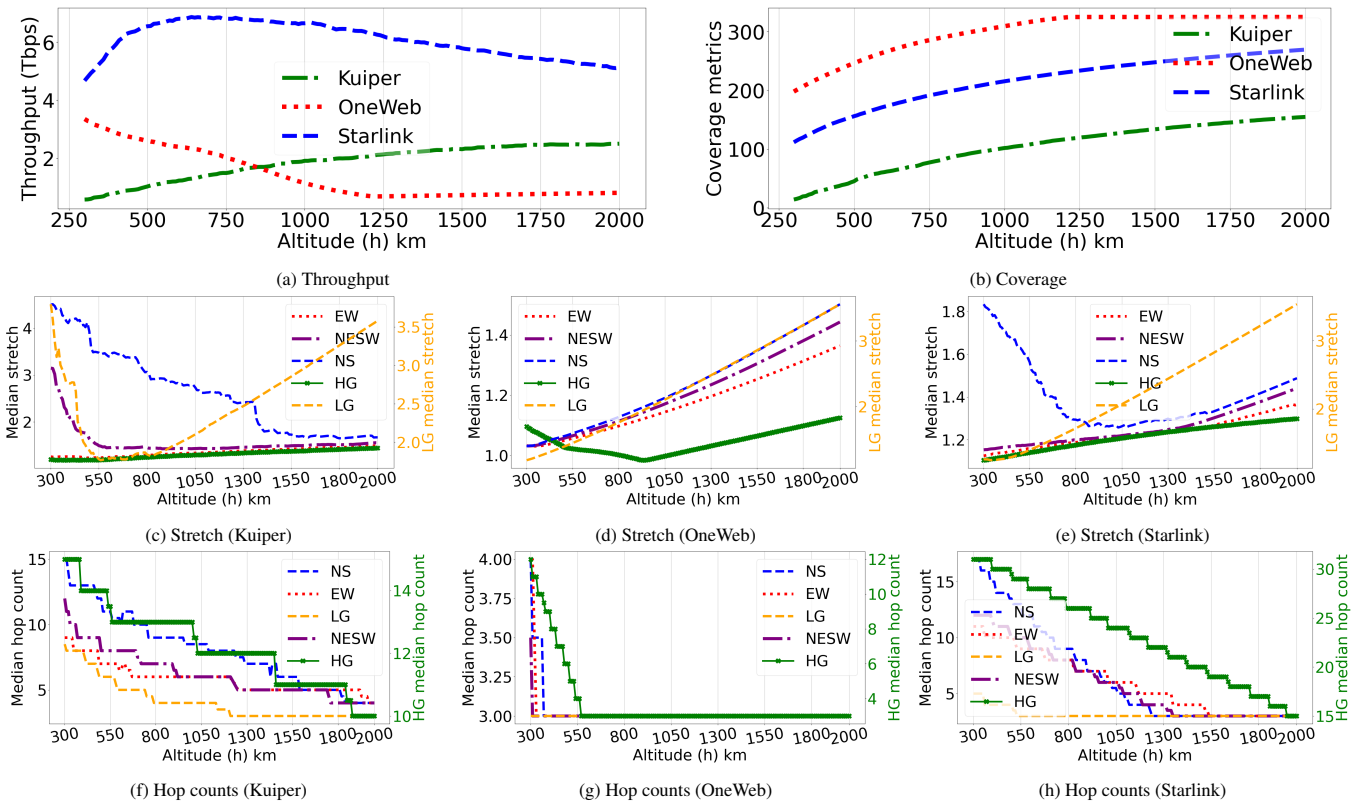
A.1 Comparison across various constellations

All LEO satellite network operators have proposed a wide variety of constellations so far. So, in this section, we evaluate the performance characteristics of different constellation designs to illustrate how different types of constellation designs impact performance. For that, we pick three shell configurations of different LEO operators shown in Table 1, i.e., (a) Kuiper's third shell, which is a relatively smaller shell of 784 satellites at a low inclination of 33°, (b) OneWeb's first shell[3], which is a moderate size shell of 1,764 satellites at polar inclination of 87.9° and relatively higher altitude of 1,200 km, and (c) Starlink Gen2's first shell, which is a large shell of 5,280 satellites at VLEO of altitude 340 km. These three shells cover a wide variety of constellation design choices at different altitudes and inclinations. Through detailed simulations, we observed that the performance characteristics of these shells with different TMs (§2.3) are consistent with each other, while varying one or more constellation design parameters, whereas others are kept at their default value as mentioned in Table 1. Therefore, for brevity, we restrict the following discussion to *High-population TM* only.

Altitude (h): The throughput, coverage, stretch, and hop count characteristics of these three shells while varying altitude h are shown in Fig. 20. For most of these performance metrics, all these constellations show similar characteristics. The only difference that we can observe is how the throughput trends change with altitude. Notice that Kuiper, with a low satellite budget of 784, produces higher throughput at relatively higher altitudes with larger coverages. In contrast, Starlink Gen2 shell, with a large satellite budget of 5,280, starts experiencing a decline in throughput and inflation in stretch (latency) above 500 km (900 km for NS routes) of altitude. This is evident since these large VLEO shells are focused on low-latency connectivity [16].

Interestingly, for OneWeb, the throughput trend is a bit odd as compared to others. This is because their operational altitude is as high as 1,200 km, whereas the elevation is too low at 5°. Since their target is the commercial sector and maritime market [23], their design is inclined towards offering globally reachable connectivity rather than achieving high performance for the population density.

[3] Notice that OneWeb does not have a plan for using ISL yet, but is open to incorporate it in future generations of satellites [8]. Therefore, in our analysis, we study +Grid ISL topology for OneWeb as well.



(a) Throughput (b) Coverage

(c) Stretch (Kuiper) (d) Stretch (OneWeb) (e) Stretch (Starlink)

(f) Hop counts (Kuiper) (g) Hop counts (OneWeb) (h) Hop counts (Starlink)

Fig. 20: (a) Throughput, (b) coverage (c)-(e) stretch and (f)-(h) hop counts measurement across most populous cities with varying altitude (h).

Inclination (i): The performance metrics of three constellations while varying inclination i are shown in Fig. 21. Notice that, except for OneWeb's stretch, coverage, and hop count, all other performance characteristics are consistent. Due to OneWeb's higher altitude with a low elevation angle, coverage and hop count do not show any noticeable impact due to the inclination change. However, a low angle of inclination restricts the availability of satellites near the equatorial regions and inflates the stretch of NS and LG routes.

Elevation (e): We show the performance characteristics while varying elevation e in Fig. 22. The performance metrics are consistent. Only LG routes of OneWeb experience higher stretch than usual due to a single satellite hop at an altitude of 1,200+ km between the nearby GS pairs.

Number of orbits (o) **and phase offset** (p): Similarly, the performance characteristics while varying the number of orbits o and phase offset p, are also consistent in Fig. 23 with our previous discussion in §4.

Outcome:- The characteristics of various performance metrics of different constellation sizes are pretty similar and predictable. Thus, knowledge of the search space in §4 could be used to intuitively trim the search space for different constellation sizes as well.

A.2 Comparison of traffic metrics

All the results discussed previously in §4 and in §A.1 are simulated with *High population TM*. In Fig. 24, we illustrate how performance characteristics change with other TMs for the first Starlink shell (Table 1). Since demands are concentrated in the regions with higher population density, we have observed that overall performance measurement characteristics are similar for all TMs across all the constellation design parameters. Therefore, we only demonstrate the impact of inclination i and elevation angle e here for brevity. Notice that the throughput for *High population TM* and *High GDP population TM* overlaps for both i and e in Fig. 24(a)-(b) except for the lower inclination. Since countries with high populations and lower GDP are mostly located close to Earth's Equators (i.e., lower latitude lines), lower inclination provides slightly higher throughput for *High population TM*. Whereas for *Country capital TM*, the constellation consistently provides higher throughput than the other TMs irrespective of the values of i and e. The GSes for *Country capital TM* are sparsely located across the capital of 233 countries, they do not experience much congestion around multiple high population/GDP cities located closely in China, India, USA, and Europe.

On the other hand, *Global flight TM* throughput measurements are consistently lower than other TMs. Our dataset includes total 8,384 flights on the air (> 10,000 feet altitude)

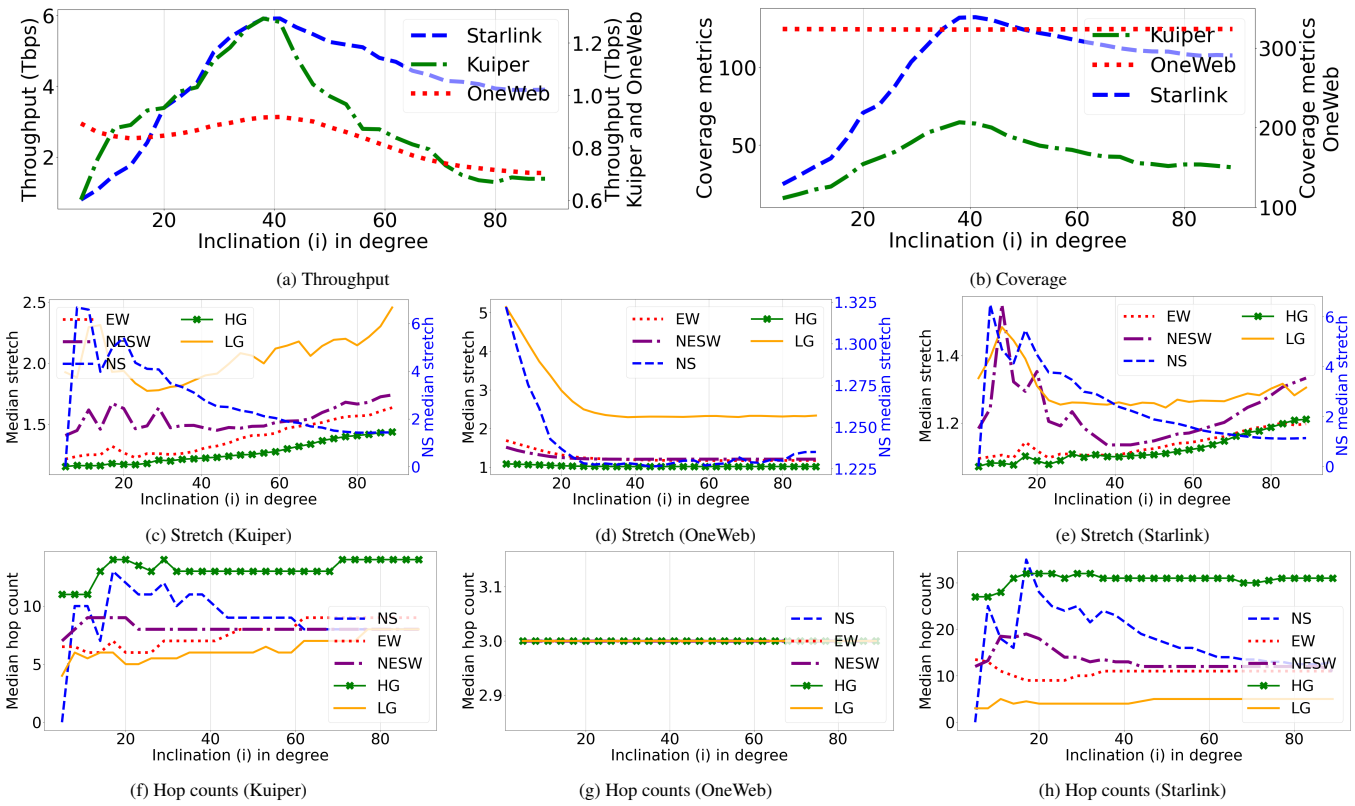


Fig. 21: (a) Throughput, (b) coverage, (c)-(e) stretch, and (f)-(h) hop counts measurement across most populous cities while varying inclination angle (i).

worldwide. Therefore, in regions with a high air traffic density, each satellite serves the demand of 100+ flights, and the GSL bandwidth is divided among these; thus, the throughput deteriorates. Only Starlink's first shell of 1,584 satellites could not cope with this many flights. Nevertheless, the overall behaviors of the throughput measurement are the same, as most flight densities are of the domestic flights in the USA, Europe, and the eastern part of China within the airspace of 20° N to 55° N latitude lines. All international air traffic follows a few specific flight corridors [49] to cross the Atlantic and Pacific oceans within latitude lines 70° N to 5° N and 60° N to 30° S, respectively, where the flight density is significantly sparser than domestic flight. Thus, the throughput is relatively low towards lower and polar inclinations.

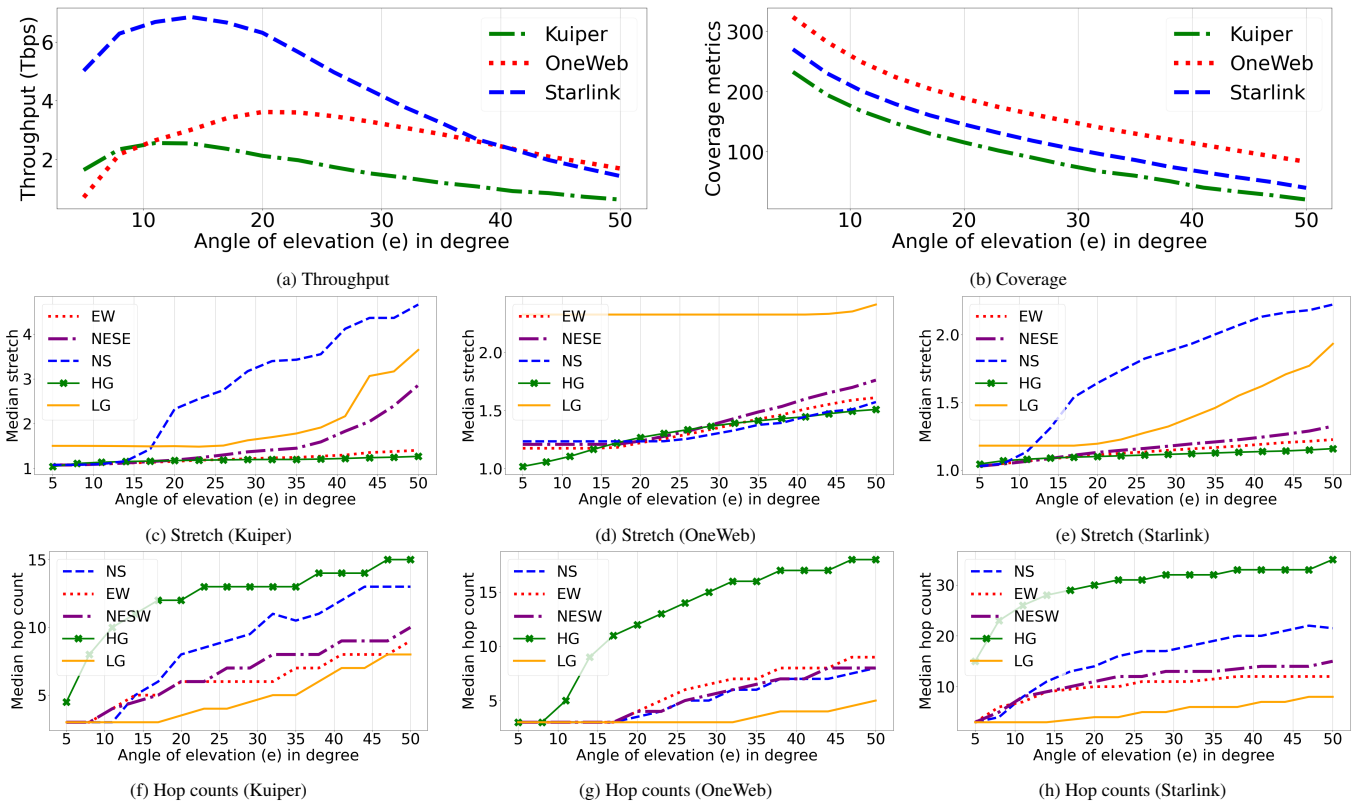
Apart from throughput, characteristics of other performance metrics are also consistent across all the orbital parameters. Again, for brevity, we only show the coverage and NS routes median stretch measurement with i and e in Fig. 24(c)-(d) and Fig. 24(e)-(f), respectively.

Outcome:- The characteristics of various performance metrics with different constellation parameters remain consistent with different traffic demands. Therefore, the proposed search strategy in (§5) is also generalizable and applicable to different target markets.

A.3 Visualization with `LEOCraft`

In this section, we provide an overview of the visualization capabilities of `LEOCraft`. Ideally, `LEOCraft` generates 2D and 3D interactive views to inspect LEO constellations. However, we use some snapshots of interactive views to demonstrate various features and aspects of LEO constellation networks.

Multi-shell LEO constellation: `LEOCraft` can generate a multi-shell LEO network topology. Fig. 25 shows some snapshots of the Starlink [10] and Telesat [12] constellations, whereas Kuiper [1] constellation is already depicted in Fig. 1(b). In these figures, the color distinguishes different shells in the constellation, where the dots represent satellites, and the lines represent the ISLs. Notice that the characteristic of having one shell at a relatively higher inclination ($\geq 60°$) is consistent for most of these proposed designs. For example, in Fig. 25, Starlink Gen1's blue shell and Telesat red shell have inclinations of 70° and 98.98° respectively. OneWeb's and Starlink Gen2 also have shells at inclinations of 87.9°, and 96.9° respectively, as shown in Table 1. Our simulation results in §4 discuss the effects of inclination angle to demonstrate the trade-off between throughput and global coverage, i.e., higher inclination gives more Earth surface coverage at higher latitudes, whereas lower inclination provides better throughput to the well-populated areas with limited coverage at higher (polar) latitudes. We speculate that the LEO constel-



(a) Throughput (b) Coverage

(c) Stretch (Kuiper) (d) Stretch (OneWeb) (e) Stretch (Starlink)

(f) Hop counts (Kuiper) (g) Hop counts (OneWeb) (h) Hop counts (Starlink)

(a) Kuiper (b) OneWeb (c) Starlink

Fig. 23: Changes in the number of orbits (o) and phase offset (p) for all shells with GSes across the most populous cities show similar throughput characteristics.

lation operator tries to address the issue by deploying multiple shells for targeting different regions of interest. They deploy a shell at a higher inclination ($\geq 60°$) to address the coverage at higher latitudes, whereas multiple shells are deployed at lower inclinations to address the demand at densely populated areas.

Route evolution over time: LEO satellites orbit the Earth at a very high velocity of $\sim$ 27,000 kmph [45]. Therefore, the route between two endpoints (i.e., user terminal or gateway ground station) on the Earth's surface continuously evolves over time. `LEOCraft` can be used to visualize such evolution of routes between any pair of GSes over a granularity of nanoseconds. In Fig. 26, we show the snapshots of the evolving shortest paths between Bengaluru, India, and Tokyo, Japan, at different time instances. In this particular example scenario, we can observe that the shortest route between the end-points experiences a route length variation of above 1000 km over just 100 seconds. This leads to abrupt RTT changes, which are also visible for other routes, as discussed previously in Fig. 18(a)-(b).

Coverage and route change due to altitude variation: `LEOCraft` allows inspection of the coverage area of a constellation at individual satellite levels with red-shaded circles beneath it. In Fig. 27, we illustrate the same with the shortest route between Bengaluru, India, and Tokyo, Japan, over the ISL of Starlink's first shell. In this illustration, we only focus on the coverage of ingress and egress satellites. As we increase the altitude of the shell from the default height (i.e., 550 km) to 1,000 km, the coverage area of the satellite (highlighted for ingress and egress points only) increases. Thus, the two endpoints choose satellites closer to each other to form the shortest route, reducing the end-to-end hop length from

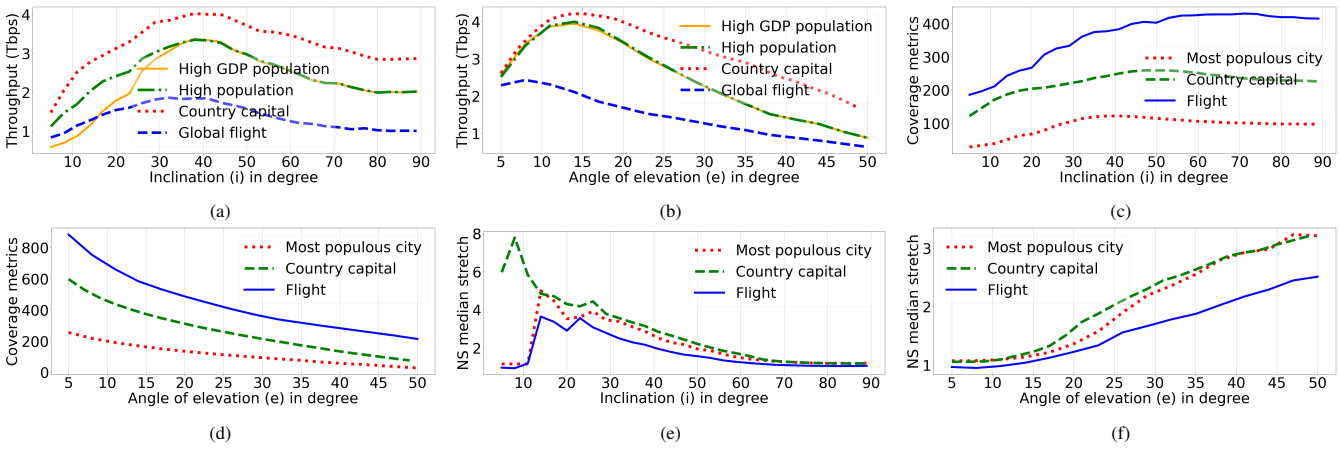

Fig. 24: (a)-(b) Throughput, (c)-(d) coverage, and (e)-(f) stretch measurements with different TMs while varying inclination and elevation angles show similar characteristics.

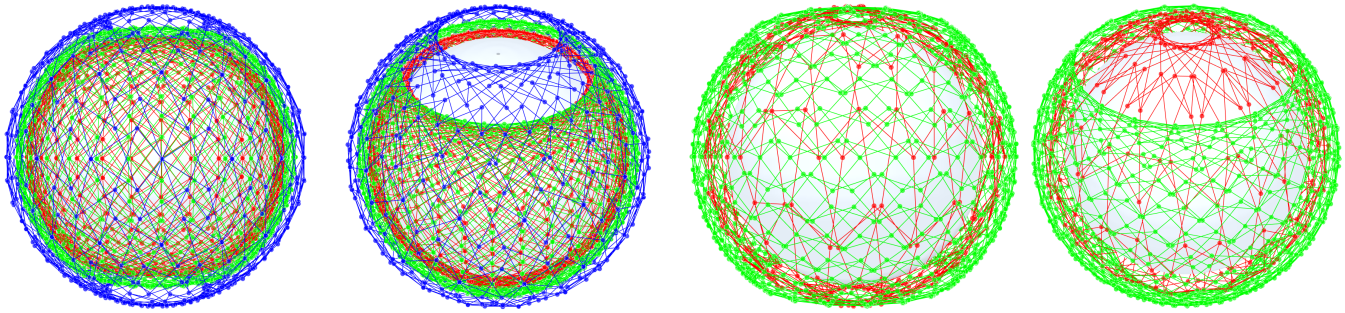


(a) Equatorial view (b) Polar view (c) Equatorial view (d) Polar view

Fig. 25: Visualizing multi-shell LEO network topology proposed by (a)-(b) Starlink Gen1 [4] and (c)-(d) Telesat [12].

6 satellite hops to only 2 hops. Notice that in Fig. 27(b), the coverage area of the satellite at the higher latitude appears to be larger than at the lower latitude due to the 2D Mercator projection [36].

Ground track of satellites: `LEOCraft` also helps in visualizing the ground track [48] of the satellites. Fig. 28 shows the nadir, i.e., 90° projection of the satellites on the Earth's surface with the inclination of 50° and 80°. The tracking for 120 minutes of both satellites starts at the same point. The figure shows how these two satellites deviate from the starting location after one orbit due to the rotation of Earth. From such visualizations, we can also observe how the coverage regions vary with the inclinations.

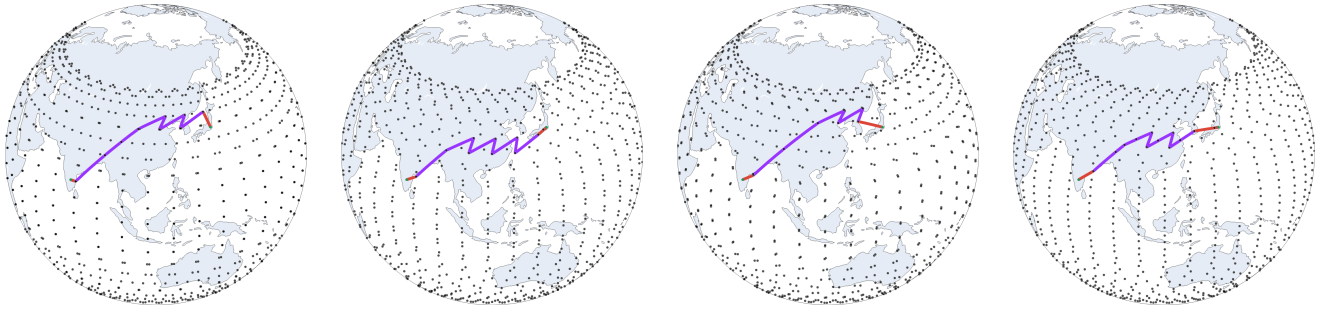
ISL utilization: `LEOCraft` can also be used to visualize the ISL utilization of individual constellations. For example, Fig. 29(d)-(f) shows the link utilization of Starlink's first shell, when the 100 populous cities communicate over the 20 shortest routes. We can extract the link selections and respective link usages in `LEOCraft` to render an interactive view of link utilization using color codes, i.e. *Unused*, *up to* 20%, *up to* 60%, *up to* 80%, *above* 80%.

From Fig. 29(d)-(f) we can observe that many ISLs above the oceans are *unused*, especially over the Pacific Ocean in Fig. 29(f). In general, ISL utilization is *up to* 20% since GSLs are the main bottleneck in these LEO networks. However, ISL utilization in the northern Pacific Ocean is pretty high (*up to* and *above* 80%.) as these ISLs are carrying the traffic between the US and the two most populated areas, i.e., India and the Chain in Fig. 29(f).

We next repeat the same study with 233 GSes located sparsely across the globe in the capital of countries, the results are shown in Fig. 29(g)-(i). From these figures, we can observe that the ISL utilization is increased, whereas the number of *unused* ISLs decreases significantly. A few ISLs are under pretty high utilization above the oceans (such as the center of the Atlantic, or the northwestern area of the Pacific) as they carry the traffic between cross-continent population centers. Such visualizations provide valuable insights about the links or regions that experience network bottlenecks.

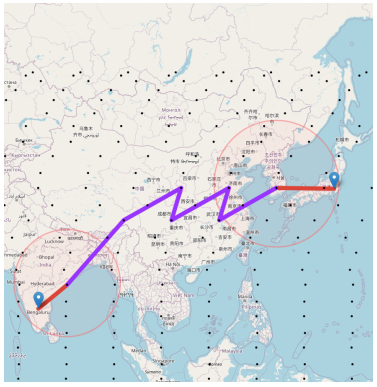
A.4 Additional comments

LEO Constellation design types: Previous works have classified satellite constellation designs into two types based on their geometry [89]. The first one is *Walker Star*, where all satellites in one hemisphere move towards the north pole,

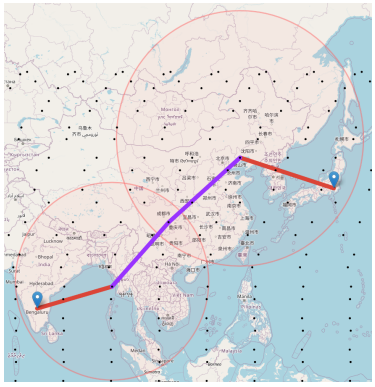


(a) At epoch (b) After 47 seconds (c) After 60 seconds (d) After 100 seconds

Fig. 26: The shortest route from Bengaluru, India, to Tokyo, Japan, changes over time due to satellite movement, leading to the RTT fluctuations.



(a) $h = 550$ km



(b) $h = 1{,}000$ km

Fig. 27: The shortest route from Tokyo to Bengaluru is reduced to two satellite hops as increasing the altitude of the shell expands the coverage area of satellites, shown with ingress and egress satellite.

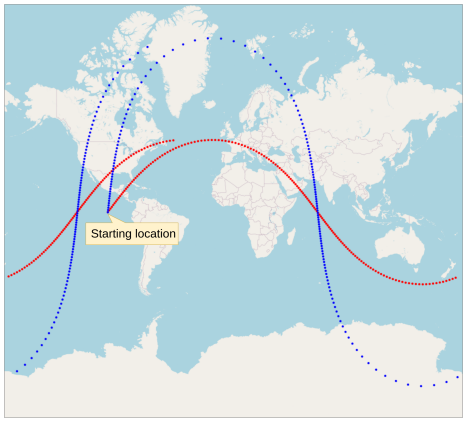


Fig. 28: The ground track over 120 minutes of two satellites orbiting at inclinations of 50° and 80°.

whereas in another hemisphere, these satellites move towards the south pole. Hence, in the polar region, the movement of the satellites creates a star shape while viewing from the top [71, 77]. Satellite constellations are also designed in *Walker Delta* structure, where orbits of less than 90° (likely) inclination are equispaced across the entire Earth's equatorial plane; therefore, northwards and southwards movement of satellites overlap across the globe. Such a design with three orbits creates a triangular shape like the Greek alphabet Δ at the polar region while viewing from the top [39, 87]. Therefore, the *Walker star* configuration provides dense coverage in the polar region; on the other hand, the *Walker delta* configuration creates a coverage gap (if inclined below 90°). Since the main population centers are in lower latitudes, most of the LEO constellations proposed for global Internet broadband fall under the category of *Walker delta* types. Therefore, this work mainly focuses on the *Walker delta* types of constellation design. However, extending `LEOCraft` to study the *Walker star* design is possible with minimal effort due to its modular design.

Impact of interference: In `LEOCraft`, we do not account for the impact of interference since satellite constellations deploy a multitude of interference mitigation techniques to maximize the throughput offered per satellite. Well-known schemes include dividing the terrestrial coverage area into tessellation shapes or spots and then reusing frequencies by assigning adjacent spots different non-overlapping frequency bands. Starlink and Kuiper have extensive plans [1,26] beyond such simple mitigation, which include (a) many steerable, shapeable beams with varying bandwidth, (b) multiple antennas per satellite, each with multiple beams, (c) beam splitting and merging to address interference as well as spatially varying demands, etc.

A.5 Simulation using `LEOCraft`'s APIs

We provide a concise overview of evaluating the LEO constellation using `LEOCraft`'s APIs, along with some code snippets. Additionally, we illustrate the framework's extensibility. For readers interested in further details, `LEOCraft`'s repository [35] includes comprehensive documentation.

Building a LEO constellation: To build a LEO constellation, first create a path loss model for the GSLs with `FSPL` instance as shown in Lst. 1, which uses the Ka band specification available in Starlink's FCC filing [50]. Then, using `LEOConstellation` API, build a LEO constellation in-

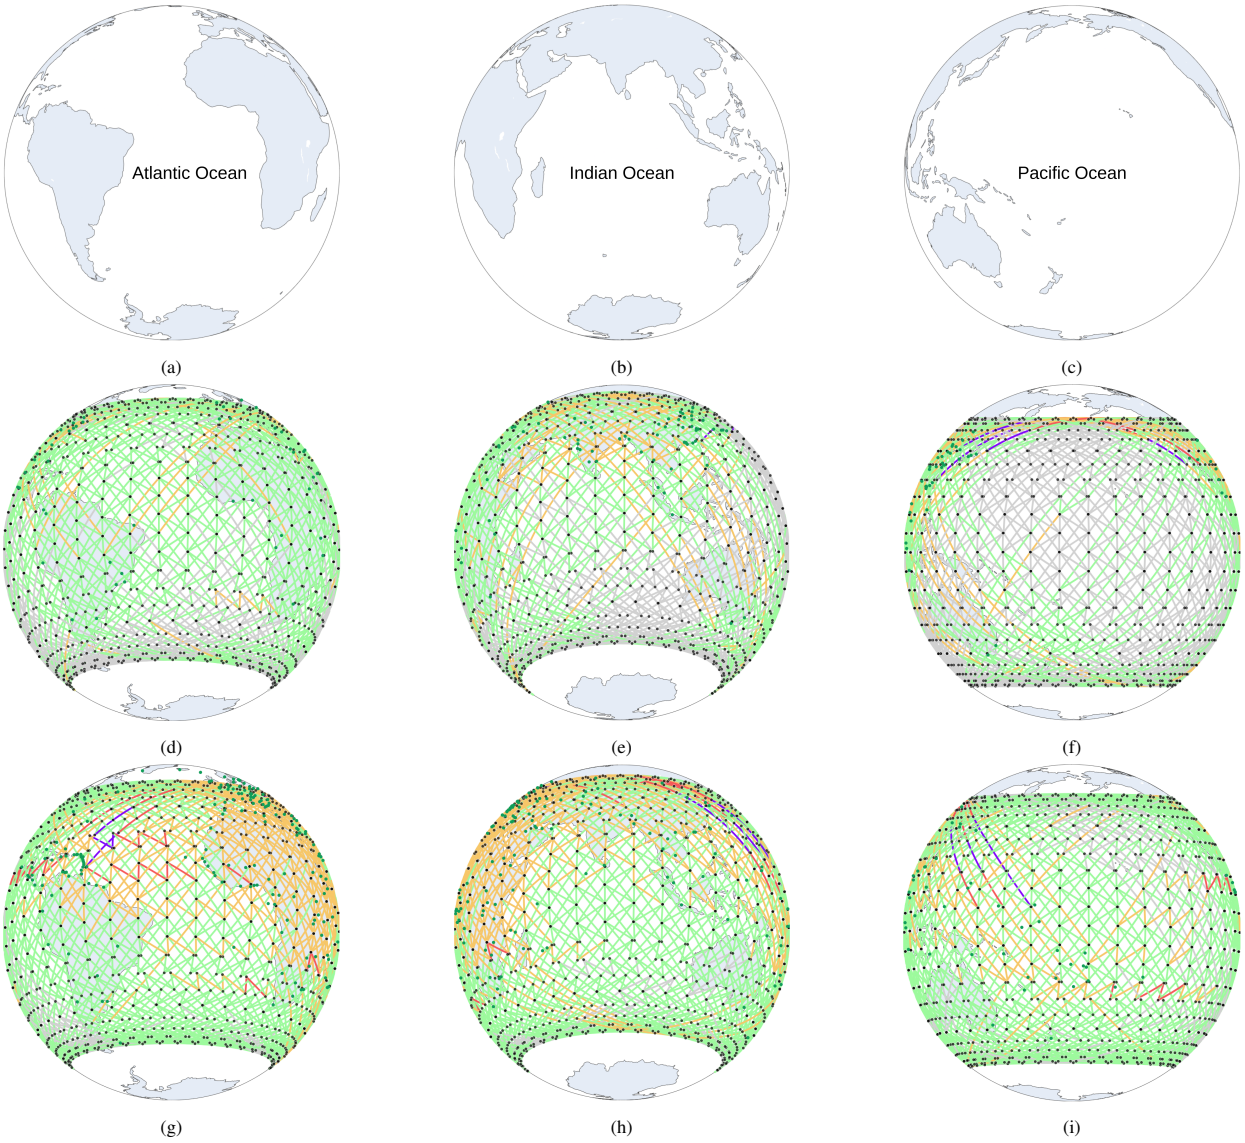

Fig. 29: ISLs utilization above the (a) Atlantic, (b) India, and (c) Pacific Ocean show that most of the ISLs are Unused for (d)-(f) high population TM across 100 cities, whereas the utilization (up to 20%, 60%, 80%, and above 80%) has increased for (g)-(i) the country capital TM across the capital of 233 countries.

```python
from LEOCraft.attenuation.fspl import FSPL

loss_model = FSPL(
    28.5*1000000000,    # Frequency in Hz
    98.4,               # Tx power dBm
    0.5*1000000000,     # Bandwidth Hz
    13.6                # G/T ratio
)
loss_model.set_Tx_antenna_gain(gain_dB=34.5)
```

Listing 1: Building loss model

stance and add all the LEO network component instances like `GroundStation` (builds GSes across cities), `PlusGridShell` (builds all LEO satellites and +Grid ISLs) as shown in Lst. 2. To simulate a multi-shell constellation, repeat the `add_shells()` method with design parameters of the other shells while increasing the `id` for each one. Followed by this, add the instance of the path loss model created in Lst. 1, and set the epoch before building and computing the routes across all the GS pairs.

Evaluating a LEO constellation: Once the routes computation is complete, the instance of `LEOConstellation` can be used to evaluate the throughput, stretch, and coverage using the performance evaluation APIs of `LEOCraft` as shown in Lst. 3. Notice that, unlike stretch and coverage, the throughput instance needs the TMs across the GSes.

Evaluating a cohort of LEO design: In addition to the above approaches, `LEOCraft` also provides a high-level API – `LEOConstellationSimulator` to evaluate a batch of LEO constellation designs. As shown in Lst. 4,

```
from LEOCraft.constellations.LEO_constellation import \
    LEOConstellation
from LEOCraft.dataset import GroundStationAtCities
from LEOCraft.satellite_topology.plus_grid_shell import \
    PlusGridShell
from LEOCraft.user_terminals.ground_station import \
    GroundStation

leo_con = LEOConstellation('Starlink')
leo_con.add_ground_stations(
    GroundStation(
        GroundStationAtCities.TOP_100
    )
)
leo_con.add_shells(
    PlusGridShell(
        id=0,
        orbits=72,
        sat_per_orbit=22,
        altitude_m=550000.0,
        inclination_degree=53.0,
        angle_of_elevation_degree=25.0,
        phase_offset=50.0,
    )
)
leo_con.set_time(second=3)
leo_con.set_loss_model(loss_model)
leo_con.build()
leo_con.create_network_graph()
leo_con.generate_routes(k=20)
```

Listing 2: Building a LEO constellation

```
from LEOCraft.dataset import InternetTrafficAcrossCities
from LEOCraft.performance.basic.coverage import Coverage
from LEOCraft.performance.basic.stretch import Stretch
from LEOCraft.performance.basic.throughput import \
    Throughput

th = Throughput(
    leo_con,
    InternetTrafficAcrossCities.ONLY_POP_100
)
th.build()
th.compute()

sth = Stretch(leo_con)
sth.build()
sth.compute()

cov = Coverage(leo_con)
cov.build()
cov.compute()
```

Listing 3: Evaluating throughput, latency/stretch, and coverage

`LEOConstellationSimulator` serves as the simulation execution framework in `LEOCraft`. It queues all instances of `LEOConstellation` and uses all the available CPUs on the system to build the constellation and compute the routes, throughput, stretch, and coverage. Finally, on evaluation completion, `LEOConstellationSimulator` writes back the results of each `LEOConstellation` in a file for further analysis.

Modularity: `LEOCraft` framework's design offers superior

```
from LEOCraft.simulator.LEO_constellation_simulator import\
    LEOConstellationSimulator

leo_1= LEOConstellation('LEOCON_1')
leo_1.add_ground_stations(
    GroundStation(
        GroundStationAtCities.TOP_100
    )
)
leo_1.set_time(second=3)
leo_1.set_loss_model(get_loss_model())
leo_1.add_shells(
        PlusGridShell(
            id=0,
            orbits=72,
            sat_per_orbit=22,
            altitude_m=1000.0*550.0,
            inclination_degree=53.0,
            angle_of_elevation_degree=25.0,
            phase_offset=50,
    )
)
# ... repeat for leo_2, leo_3, ..., leo_n
simulator = LEOConstellationSimulator(
    InternetTrafficAcrossCities.POP_GDP_100,
    'output.csv'
)
simulator.add_constellation(leo_1)
# Repeat above line for leo_2, ..., leo_n
simulator.simulate_in_parallel(max_workers=3)
```

Listing 4: Evaluating a cohort of LEO constellation

extensibility. For instance, one can inherit `PlusGridShell` and override just one method – `build_ISLs()`, to create a `XGridShell` that evaluates the performance of the LEO constellation with a $\times$Grid ISL topology [72]. Similarly, `Throughput`, `Stretch`, `Coverage` can be inherited to overwrite the `compute()` method to implement other approaches for the computation of these metrics. Hence, `LEOCraft` enables further exploration of LEO design and optimization strategies, addressing a wide range of objectives such as routing policies, bandwidth allocations, traffic patterns, ISL topologies, the number of antennas and their capabilities, weather conditions, and much more.

B Artifact Appendix

Abstract

This artifact provides detailed instructions for setting up `LEOCraft` simulation environments on Linux and macOS platforms. The primary focus is on verifying the claims made in the paper and reproducing the figures presented throughout. Additionally, it offers guidance on extending the `LEOCraft` project to experiment with traffic metrics, topology, routing, and connectivity policies.

Scope

This artifact includes straightforward steps to validate four major claims of the paper – (i) execute a flow-level LEO network simulation, (ii) optimize LEO constellation design using search space heuristic, (iii) evaluate and simulate designs for multi-shell LEO constellation, and (iv) interactive visualization the LEO constellation network. In addition to that, the `GitHub repository` hosts the `LEOCraft`'s source code under the MIT License.

Contents

The `GitHub repository` provides the complete source code for `LEOCraft`, accompanied by thorough documentation. The `Artifact Evaluation` page documents the steps to execute all experiments supporting the major claims of this paper. Additional available contents are outlined below:

Examples: The repository contains a handful of `example Python scripts` illustrating how `LEOCraft` can be programmed for different LEO network simulations and visualization.

Evaluation of constellation with all TMs: The Fig. 20– 24 presents a summarized overview of the performance measurements for various LEO constellations against different TMs. The repository contains all the detailed performance measurements for the proposed constellation, as highlighted in Table 1, against all the TMs discussed in §2.3 for `GSes` and `flights`.

Interactive visualization: The repository also contains an interactive versions of LEO constellation design (Fig. 1(b), 25), satellite coverage (Fig. 1(a), 4(b)-(c)), GSes location (Fig. 7(a)), routes (Fig. 2, 8, 10, 13, 26, 27), ISL topology and satellite trajectory changes (Fig. 7(b)-(d), 11), ground track of satellites (Fig. 28), and ISL utilization (Fig. 29) inside `Visulization Examples`.

Hosting

The source code of the `LEOCraft` under MIT License is available at – `github.com/suvambasak/LEOCraft.git`. The documentation of `LEOCraft` is available at – `suvambasak.github.io/LEOCraft/`. The source code and the documentation might be updated according to the future release with new versions of `LEOCraft`. Additionally, `Artifact Evaluation` page provides the straightforward steps for reproducing the results of this paper.

Requirements

The `LEOCraft` uses the Gurobi Optimizer to solve the linear program to maximize throughput. Consequently, a valid Gurobi license is required to use `gurobipy` for solving linear programs. Additionally, we recommend using a multi-core system with a minimum of 8 gigabytes of memory; however, having more computational resources helps `LEOCraft` to execute faster.

Emulating Space Computing Networks with RHONE

Abstract – The rapid advancement in satellite technology with the adoption of commercial off-the-shelf (COTS) devices and satellite constellation networking has given rise to Space Computing Networks (SCNs). While SCN research is typically conducted on experimental platforms due to high operational costs, the unique challenges of SCNs – such as the harsh space environment (*e.g.,* power and thermal constraints) and dynamic constellation networks – require special consideration. Existing platforms cannot fully replicate the SCN operating environment with high scalability. This paper introduces RHONE, an emulator that bridges these gaps by achieving both satellite- and constellation-level fidelity (the accurate replication of satellite and constellation states, including power, thermal, and network conditions, as well as application performance characteristics) while ensuring usability. RHONE adopts a two-phase emulation approach: *i)* an offline phase builds power, thermal, orbit, network, and computation models using real satellite telemetry data and hardware-in-the-loop chip mirroring, and *ii)* an online phase executes container-based emulation integrated with these models. Key components, the *satellite COTS aligner* and the *satellite network aligner*, dynamically align the containers with real satellite conditions. Evaluation shows RHONE 's scalability to 700 satellites on a single node, with power and computation model errors under 5% and thermal model errors within 1.3 – 2.5°C. Two case studies – satellite network energy drain attack and real-time earth observation application – demonstrate RHONE's capability to emulate satellite- and constellation-level dynamics.

1 Introduction

Low-earth orbit (LEO) satellites are evolving from large, singular, and expensive nodes focused solely on communication into networked computing systems in space, which we term *Space Computing Networks (SCNs)*. Behind this are two technological trends – *i) Adoption of COTS devices.* Conventional low-performance computing components (*e.g.,* 50 MHz CPU with 64 MB RAM [1]) specialized for satellites is being replaced by commercial off-the-shelf (COTS) hardware (*e.g.,* Raspberry Pi [2], FPGA [3], GPU [4]), which has better performance and lower costs. *ii) Satellite constellation networking.* Satellites are no longer limited to low-data-rate communication, but high-bandwidth constellations providing global coverage [5, 6, 7, 8, 9, 10]. Starlink [5], with over 6,000 satellites in low Earth orbit (LEO), provides global connectivity with approximately 100 Mbps downlink and 10 Mbps uplink speeds [7]. Planet Dove constellation, comprising 150 satellites, specializes in Earth observation tasks [11].

SCNs have revolutionized two categories of satellite applications: *i) Earth observation (EO).* SCNs employ COTS devices for in-orbit image processing, such as compression, filtering, and detection [12, 13, 14, 15, 16], reducing the volume of data transmitted. Satellite constellation networking eliminates the need to wait for satellites to pass over ground stations for data transmission. Together, these enable *near-real-time* EO in both industry [11, 17, 18] and academia [19, 15, 16] with SOTA capture-to-insight latency of 6 minutes [15], while conventional approaches take tens of hours to months, as reported by [15, 18]. Academia is actively exploring EO with higher efficiency and lower latency [19, 20] jointly involving onboard processing and data transmission for captured images. *ii) Satellite-backboned global networking.* Satellites are providing global network services, where on-satellite COTS devices enable the potential of satellites as in-orbit computing nodes to perform network functions. For example, satellites can serve as meet-up servers processing and routing video streams for cross-continent video conferencing [21]. Satellites can also integrate cellular core functionalities [22, 23, 24, 25, 26], enabling the processing of heavy user traffic (*e.g.,* User Plane Function (UPF) in the 5G core) using COTS chips. Satellite network attacks and countermeasures also raise concerns [27, 28], as satellites are more susceptible to malicious threats (*e.g.,* DDoS energy drain attacks) due to their harsh operating environments and predictable orbital trajectories.

However, SCN applications are hard to design, build and evaluate. We identify two unique characteristics of SCN that distinguish it from ground-based computing and networking: *i)* satellite COTS chips, which are not originally designed for space environment, face energy and thermal constraints. Overlooking these results in low application performance or even serious harm to the satellite such as overheat or power

*Equal contribution.
†✉: chenren@pku.edu.cn.

failure [2, 29, 30, 31]; *ii)* the dynamic nature of constellation networks (*e.g.,* frequent topology changes [32, 33, 22] and node failures [2, 31, 34, 35]) leads to poor network stability and performance, and should be properly addressed.

Therefore, SCN applications must be designed, built and evaluated with careful consideration of the space environment to ensure proper operation and high performance. However, the high costs of operating or accessing a real constellation (*e.g.,* $150,000 to launch a small satellite [36]) and increasing constellation sizes make it impractical to use real satellites for SCN research. Consequently, SCN research relies on practical experimental platforms that accurately replicate the space environment, *i.e.,* achieving *i) satellite-level fidelity*, involving heterogeneous COTS devices onboard and environmental context (*i.e.,* energy and thermal) they face; *ii) constellation-level fidelity*, involving complexity and dynamics of constellation networks, in terms of both topology changes and node failures; *iii) high usability*, scaling to encompass entire constellations while being cost-effective, flexible, and user-friendly. However, existing tools fall short of meeting all these requirements (§2.3): *i) Physical setups* [5, 37] offer high fidelity but are difficult to access and lack scalability; *ii) Simulators* [38, 39, 40, 41, 42, 13] use analytical modeling to simulate the space environment but lack system/network stacks and support for real system functionalities or interactive network traffic [43]; *iii) Emulators* [44, 45, 43] incorporate constellation network models with virtualized environments (*e.g.,* containers or virtual machines). However, they overlook heterogeneous satellite COTS computing devices facing space environment, especially energy and thermal limitations, and therefore cannot mimic COTS chips' performance, as our measurement study with real in-space satellites shows.

In this paper, we present RHONE[1], an SCN emulator that meets all the requirements above to support SCN research. The challenges in building RHONE stem from a conflict: As the computation performance of onboard chips is influenced by various factors like operating environment, hardware capacity, and application workload, it requires large system overhead (*e.g.,* CPU and memory) or high cost (*e.g.,* hardware device expenses) to achieve accurate emulation for individual satellites. However, while scaling to a constellation level, the total system overhead or cost for emulating SCN constellations exceeds the requirements for scalability and affordability. To address this, RHONE adopts a *two-phased* emulation process – it builds models based on real data collected from in-orbit satellites and on-board COTS devices, and then scales the models to constellation level via a light-weight container-based architecture with the models installed. *i) Offline model building phase*: we analyze telemetry data from in-space satellites and onboard COTS chips using *(a)* an open-source dataset [2] and *(b)* processed flight data which we collected from the Tiansuan constellation[2]. We have released the processed version of the latter on GitHub[3], containing over 800000 timestamped entries spanning December 23, 2021 to July 14, 2022. We build power, thermal, orbit, and network models based on such data to replicate the space environment, and the computation model of COTS chips using *hardware-in-the-loop chip mirroring*; *ii) Online emulation phase*: we use container-based emulation integrating the models built in the first phase to mirror space environment. We design the *satellite COTS aligner* to mirror COTS computing devices through profiling and dynamic resource tuning to ensure satellite-level fidelity. We also integrate the *satellite network aligner* to manage the container network to mirror constellation-level network dynamics. We also provide a set of easy-to-use monitor and command APIs for users to run unmodified applications.

We evaluate the scalability and fidelity of RHONE. Our scalability evaluation shows that RHONE scales to 700 satellites on a single physical machine node, matching the size of Starlink shells, which is comparable to SOTA emulator [43]. In our fidelity evaluation, RHONE shows $< 5\%$ error rate in power and computation models, and $1.3 - 2.5°C$ average error in its temperature model, compared to telemetry data we collect from in-orbit satellites as ground truth.

To illustrate how RHONE can advance SCN research, we present two use cases of SCN with RHONE: *i) Satellite network energy drain attack.* We emulate an energy drain attack [27, 28] in RHONE, where a victim satellite is attacked by malicious heavy traffic load, leading to intensive power usage, rapid battery drain, and degraded network performance. RHONE emulates both satellite-level power consumption and constellation-level network characteristics. *ii) Real-time earth observation.* We emulate a real-time EO application, comparing four processing strategies (direct transmission, compression, onboard filtering, and onboard inference) in terms of power usage, data transmission volume and end-to-end latency. RHONE emulates both satellite-level in-orbit edge computing for image processing and constellation-level network for data transmission.

Contributions.

- We present RHONE, a full-fledged emulator dedicated for futuristic SCN research(§3);
- We build models of satellites' operating environment and COTS computing performance by collecting and analyzing real satellite telemetry data (§4), and integrate models with online emulation (§5);
- We conduct experiments to evaluate RHONE's scalability and fidelity (§7), and demonstrate its ability to advance SCN research by two use cases (§8).

This study does not raise any ethical issue.

[1] RHONE is named after Vincent van Gogh's painting *Starry Night Over the Rhône*, which features a reflection of the starry sky.

2 Background and Motivation

2.1 Research Challenges and Opportunities

While the rise of SCN offers numerous opportunities for the research community, the unique characteristics of satellite platforms and their operating environments present significant challenges for researchers in exploring the architecture and optimization of emerging applications.

Energy and thermal dynamics and constraints. Satellites in space operate under harsh environmental conditions, leading to significant performance degradation compared to those on the ground. Regarding energy, as both energy harvesting capability is influenced by sunlit regions and onboard battery storage is limited, real satellite measurements [2] indicate that the instability in energy supply and limitations on battery discharge depth affect the power available to onboard computing devices, thereby influencing their availability and efficiency. In terms of thermal management, as satellites generally lack active cooling mechanisms to reduce costs, chips can automatically reduce their clock speeds due to thermal throttling. Short-term overheating can reduce the satellite's computing throughput and prolong task execution latency. Long-term exposure to high temperatures can diminish the reliability and lifespan of COTS devices. As a result, there are opportunities for SCN researchers to consider energy and thermal dynamics and constraints when designing and optimizing SCN applications (*e.g.,* allocate more tasks in sunlit regions and fewer in shadows).

Constellation network dynamics. Different from terrestrial networks, constellation networks in space are highly dynamic. These dynamics manifest in two ways: *i) Topology dynamics.* The high velocities of satellites relative to each other and to fixed ground stations lead to highly dynamic connectivity and frequent topology changes. As a result, SCN researchers must develop more robust routing schemes [46], topology design [47, 48] and satellite-ground collaboration strategies [19]; *ii) Node failure.* COTS devices in space are more vulnerable than those on Earth. In addition to cosmic radiation [34], their performance can also be affected by energy and thermal issues, as mentioned above. Recent studies [27, 28] show that malicious network traffic can trigger energy drain attacks on satellites, leading to node failures. Consequently, SCN researchers must address these node failures and their impact on constellation networks.

2.2 SCN Emulator Essential Elements

The complex and dynamic operating environment of SCN, combined with the extremely high costs associated with developing a mega-constellation in space, underscores the urgent need for a comprehensive SCN emulator for the research community to optimize constellation-level applications that integrate computing and networking on real satellites. Based on the preceding discussion, a comprehensive emulator should meet the following requirements to mimic the unique characteristics of SCN:

Satellite-level fidelity. A comprehensive emulator should accurately model the operating environment, computational capability, and application performance of individual satellites. This modeling must encompass both the environment and the devices: *i) Contextual environmental awareness.* The emulator should account for the effects of real satellite operational contexts on applications. For example, energy availability and thermal control should influence computing capacity and efficiency, affecting end-to-end latency in real-time EO applications. *ii) Replications of realistic heterogeneous computing devices.* The emulator should precisely replicate the computation, storage, and communication capacities of satellite COTS hardware, such as Nvidia's TX1 and TX2 (CPU+GPU) [49], Xilinx's Zynq (CPU+FPGA) [3], and Huawei's Atlas 200DK (CPU+NPU) [2].

Consellation-level fidelity. To emulate constellation networking, the emulator must replicate the complexity and dynamics of entire constellations. This includes the impact of topology changes, satellite-ground communication handoffs, ISL bandwidth, and node failures on network performance.

High usability. The emulator must be highly usable in three aspects: *i)* scalability to support simulations of extensive satellite constellations containing thousands of satellites while maintaining accurate modeling of each satellite's performance and inter-satellite networking; *ii)* flexibility to run

Category	Platform	Fidelity						Usability

Table 1: Comparison of different platforms/simulators/emulators.

real applications and network stack provided by users; *iii)* accessibility with easy-to-use interfaces and low cost.

2.3 Limitations of Existing SCN Emulators

Although many simulators/emulators have been proposed in recent years [38, 39, 40, 41, 42, 13, 44, 45, 43], as shown in Tab. 1, they fall short of meeting all these requirements, particularly in accurately modeling the operational context's impact on networking and computing performance.

Physical setups. Commercial satellite constellations [5] and open-sourced experimental satellite platforms [37] with physical setups offer the highest fidelity for both individual satellites and constellations. However, commercial platforms do not provide researchers with experimental interfaces. Open-source platforms allow some experimentation, but lack support for freely running user-defined applications and face scalability limitations tied to constellation size.

Simulators. To address the issues of scalability, flexibility, and accessibility, the research community has turned to the development of analytical simulators [38, 39, 40, 41, 42, 13]. These simulators rely on theoretical modeling without real software and network stacks, limiting their ability to simulate the actual behavior of computing or networking devices. Additionally, most of them also do not allow users to run custom applications or algorithms.

Emulators. This widening gap highlights the growing need for emulators [44, 45, 43] that incorporate virtual environments (*e.g.,* containers or virtual machines), thus enabling real system/network stacks to maintain system fidelity. However, due to the lack of real in-orbit data from COTS devices on satellites, even the current state-of-the-art (SOTA) solutions struggle to accurately replicate the actual environmental context, including energy and thermal influences, as well as the characteristics of onboard computing devices.

Motivating examples: low emulation fidelity. We analyze the power, thermal, and computing capacity dynamics of COTS devices onboard with the open-source dataset from an in-space satellite BUPT-1 [2] running DNN inference tasks on a Raspberry Pi. The dataset includes telemetry data of power, temperature, and onboard tasks. With this ground-truth data, we highlight two motivating examples that illustrate the limitations of existing SOTA emulators in achieving high-fidelity emulation of individual satellites: *i) Inaccurate power model. Cote* [13], the SOTA satellite computing simulator, provides a power model for individual satellites. We compare it with the actual satellite harvested power trace, as shown in Fig. 1a. The power model in *Cote* assumes the harvested power in the sunlit region to be constant. In reality, the harvested power varies with the satellite's position, attitude, placement of solar panels, and the satellite's orientation. An inaccurate power model fails to simulate the effects of power fluctuations on computing or networking devices, such as reduced availability during power shortages, which *Cote* does not accurately represent. *ii) Inaccurate computation capacity. StarryNet* [43], the SOTA satellite networks emulator, uses Docker containers to emulate computing devices on individual satellites. We replicate the onboard DNN inference experiments within a container of *StarryNet* and compare the inference latency with those obtained from Raspberry Pi on BUPT-1. As shown in Fig. 1b, the execution latency of an application in its containers deviates significantly from that of an in-orbit COTS device. The YOLOv3 and YOLOv5 execution latency fluctuations of onboard chips are 330% and 160% larger than emulated, respectively. The application's average latency in the container differs by up to 15% compared to the real in-orbit COTS devices. Moreover, *StarryNet* fails to simulate the increase in inference latency caused by chip throttling due to overheating (initial 25 min in Fig. 1b). These inaccuracies arise because *StarryNet* simulates devices' capabilities by adjusting CPU core counts and frequencies. However, this method does not capture the inherent characteristics of COTS devices, which are often heterogeneous (*e.g.,* Jetson TX2's CPU + GPU). Additionally, COTS devices and containers operate on different computing architectures, leading to different performance.

3 RHONE Overview

We present RHONE, a comprehensive SCN emulator meeting all requirements discussed in §2.2. As shown in Fig. 2, the emulation process of RHONE consists of two phases: *Offline Model Building* (§4) and *Online Emulation* (§5). In

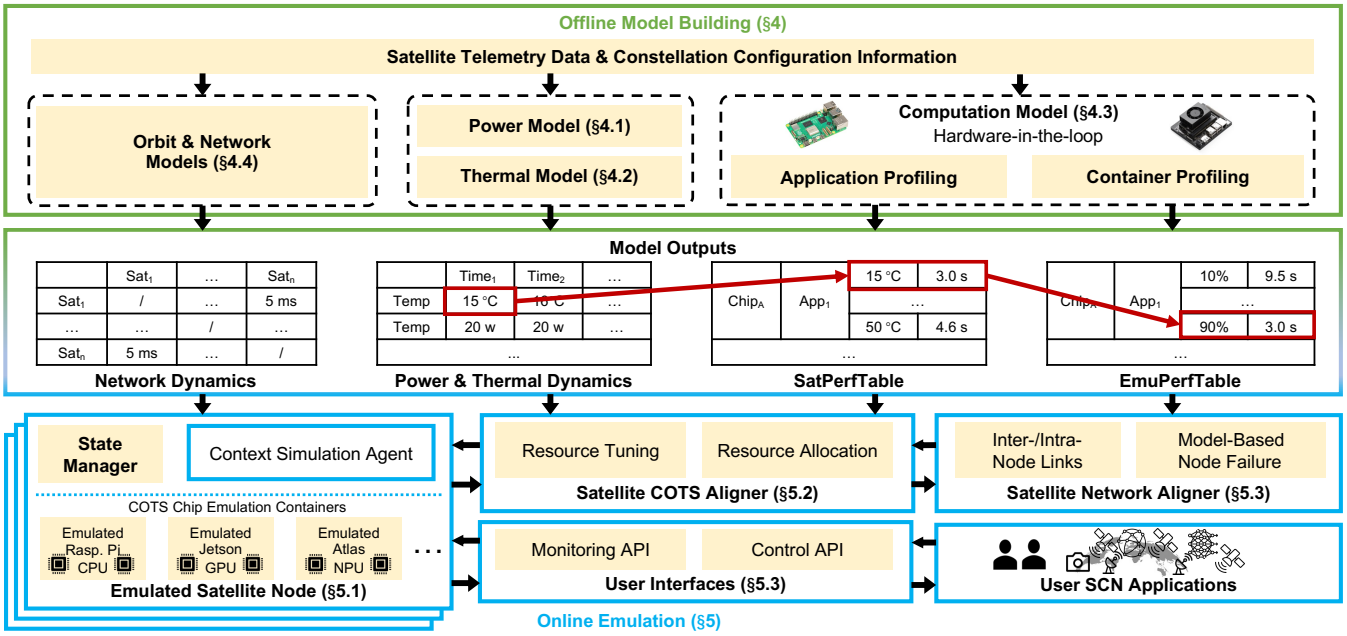

Figure 2: RHONE system overview. The red lines illustrate the query process of the resource allocation scheme.

the model building phase, RHONE initially constructs power, thermal, computation, orbit, and network models offline using telemetry and experimental data collected from real satellites and onboard COTS devices. These models replicate the complex and dynamic SCN environment, effectively mirroring the behavior of onboard chips. In the emulation phase, RHONE deploys these pre-built models into software containers to emulate each satellite node and their interactions. This two-phased design ensures high-fidelity emulation of individual satellites while scaling to the constellation level at a low cost. Users can interact with the system via monitoring and control APIs to run custom applications.

4 Offline Model Building

In this section, we propose and build the power, thermal, computation, orbital, and network models of RHONE to replicate the computation and communication capacities of individual satellites, based on real telemetry and profiling experiments conducted on devices.

4.1 Power Model

As discussed in §2.1, energy dynamics is a critical factor affecting satellite computing performance. We first collect a complete set of power telemetry data from a satellite (Fig. 3), including time series of current and voltage from the solar panels and all onboard electrical components. This dataset is sufficient for building the power models because it contains energy behaviors for all orbital working modes of the satellite (*e.g.,* Earth-pointing, Sun-pointing, etc.) during approximately 2,000 orbital cycles. Our principle is to identify general patterns of energy behavior from this dataset and build our power model. Users with satellite power telemetry can also adopt our method to fine-tune their own models.

4.1.1 Energy Harvester

Most LEO satellites regularly transition between sunlight and eclipse during their orbit, leading to cyclical energy harvesting. Additionally, the power harvested in sunlight varies dynamically, as illustrated in Fig. 1a, due to factors such as the satellite's movement and changes in its working mode. To emulate this energy-harvesting process, we adopt a widely used power model as in [29, 30, 50, 51]:

$$P_h = S \times \eta \times I_d \times L_d \times A \times \cos\theta, \quad (1)$$

where P_h represents the harvested power, such power is determined by the solar constant flux density S, the efficiency of the individual solar cells η, the inherent degradation I_d, the lifetime degradation L_d, the panel area A, and the cosine loss $\cos\theta$. The angle θ is the angle between the solar panel norm and the direction of the incoming sunlight, as shown in Fig. 3. It is primarily influenced by the satellite's orbit, geometry, the installation orientation of the solar panels, and the satellite's pointing direction. Our energy-harvesting emulation method is straightforward but effective, the accuracy of Eqn. 1 is evaluated in §7.2.2.

4.1.2 Energy Consumer

Most satellite subsystems, including the electrical power system, propulsion, guidance, attitude and orbit control, and avionics, consume electrical power. The COTS devices, acting as the computing payload, share a power supply with these systems. To determine the available electrical energy

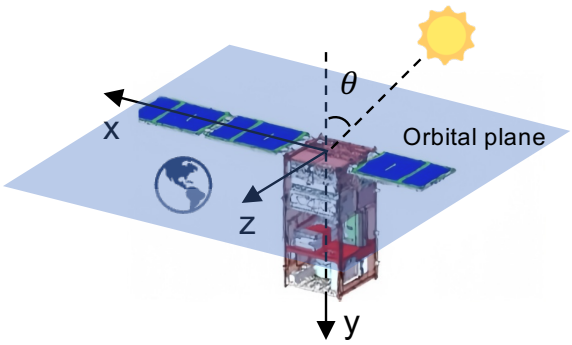

Figure 3: Satellite position and angle θ.

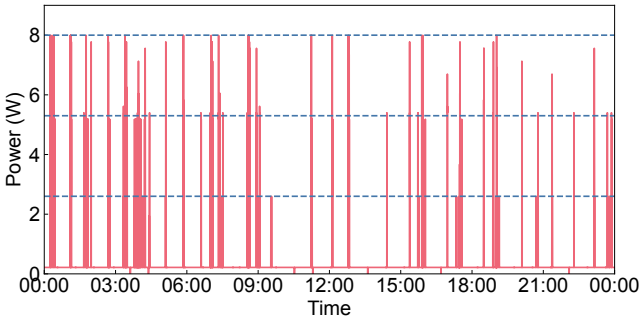
for the computing payload, it is essential to accurately characterize the power consumption of other subsystems.

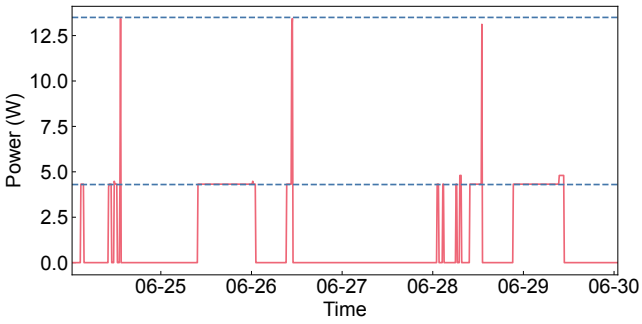
Working and power consumption patterns. In RHONE's power model, we analyze component-level power consumption and operational behavior using real satellite telemetry data, specifically current and voltage readings from various components. While components have different power shares, they follow two working patterns and two power-consumption patterns, which innovate our modeling of onboard power consumption. *i) Working pattern.* Onboard components' working patterns can be classified into two types: *continuous operation* and *intermittent operation*. Components with continuous operation, typically part of the satellite's platform system, support the satellite's normal functioning, such as the magnetic torque system. In contrast, components with intermittent operation are activated only during specific tasks, like the X-band communication component. *ii) Power-consumption pattern.* A component's power consumption can be categorized into *Markov-based* (Fig. 4a) and *function-based* patterns (Fig. 4b). Next, we detail both patterns of power consumption modeling.

Markov-based power consumption pattern. Components with a Markov-based power consumption pattern switch randomly between several power levels, resembling a Markov chain [52]. For example, the magnetic torquer switches between three power levels, as shown in 4a. To model such components, we perform clustering analysis on the power telemetry data to identify the power levels and use their occurrence probabilities to generate each power value over time. This process reveals the underlying Markov chain and its accuracy is evaluated in §7.2.2.

Function-based power consumption pattern. Some components' power consumption patterns can be modeled by specific functions, such as the X-band and computing devices. The X-band component is responsible for high-speed data downlink and receiving control commands from ground stations once the connection is established. As



(a) Markov-based pattern with three levels (magnetic torque).



(b) Function-based pattern with idle and active states (Xband).

Figure 4: Energy consumption patterns.

shown in Fig. 4b, the X-band transitions between two states: idle (approximately 4W) and active (approximately 14W). This behavior follows the classic radio link power model [27, 53, 54], which can be expressed as:

$$P_{\text{tr}}(t) = \begin{cases} P_{\text{tr}}^{\text{idle}} & \text{if } t \in \text{idle state}, \\ P_{\text{tr}}^{\text{active}} + w_{\text{tr}} dr_{\text{tr}} & \text{if } t \in \text{active state}, \\ 0 & \text{otherwise}. \end{cases} \quad (2)$$

where $P_{\text{tr}}^{\text{idle}}$ is idle power, $P_{\text{tr}}^{\text{active}}$ is baseline power in active stage, w_{tr} is a link-specific constant, and dr_{tr} is link data rate.

For COTS computing devices, we leverage the insight that their power consumption is influenced by: *i)* the operational frequency regulated by the device and *ii)* the temperature [55]. The power model can be formulated as [56],

$$P_c = P_s(f) + U \cdot P_d(f) + P_l(T_{\text{hottest}}), \quad (3)$$

where f represents the processor frequency, U is the processor utilization, T_{hottest} represents the temperature of the hottest spot on chip, P_s is the idle power, P_d is the dynamic power, and P_l is the leakage power. We use our telemetry data to tune the parameters of our power model and evaluate the model accuracy in §7.2.2.

4.2 Thermal Model

Unlike proactive cooling methods (*e.g.,* fans, water-cooling) on the ground, many cost-effective small satellites rely on passive cooling methods that depend on thermal conduction

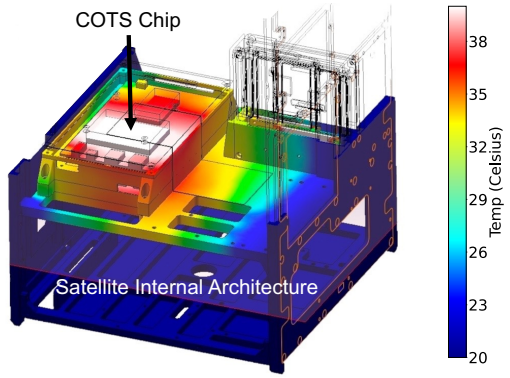


Figure 5: FEA-based thermal model illustration.

Figure 6: Temperature distribution of COTS devices under computing load.

and radiation [57]. The in-orbit temperature of COTS computing devices significantly impacts their computational performance. Therefore, in RHONE, we primarily develop a thermal model for computing devices, as shown in Fig. 5. RHONE's thermal model focuses on the chip temperature, which directly affects computing efficiency and reliability.

FEA-based thermal model. Simulating temperature variations in computing devices ideally requires real satellite data, but varying heat dissipation across different devices makes profiling costly and non-scalable. Ground-based simulations, including thermal vacuum tests, struggle to replicate external heat flux and structural thermal conduction. To overcome this, we use Finite Element Analysis (FEA) in SolidWorks [58] to model the satellite's thermal environment and heat transfer. FEA offers scalable and accurate thermal dynamics modeling, widely used in satellite engineering for designing and evaluating thermal control systems [59, 60].

The computing payload primarily dissipates heat through thermal conduction via the mounting structure. In FEA based thermal conduction simulation, the input includes the satellite's internal temperature and the energy consumption trace from the power model. The output is the chip temperature distribution over time. The thermal conduction equation used in these simulations is:

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + q''' \tag{4}$$

where ρ is the material density, c is the specific heat capacity, T is the temperature vector of the chip region, t is the time, k is the anisotropic thermal conductivity, q''' is the local volumetric heat generation rate (*i.e.,* the total amount of heat generated per unit volume), primarily due to internal heat sources such as electronic components.

The FEA model uses a piecewise-smooth approximation for the temperature field. It models heat transfer in two main ways: (i) internal conduction within component domains (*e.g.,* chips), where Eqn. 4 applies and the $\nabla \cdot (k \nabla T)$ term describes anisotropic heat conduction; and (ii) heat transfer from chips to the satellite chassis and structure, modeled through physical interfaces (*e.g.,* thermal pads, structural contact). External thermal loads on the satellite (*e.g.,* orbital solar flux, albedo) and system-level thermal context are incorporated via a boundary anchoring strategy, using interface temperatures as empirical boundary conditions. This applies appropriate thermal boundary conditions to the model's exterior surfaces and relevant interfaces, efficiently accounting for the broader thermal environment.

Then, time discretization is carried out using an implicit method [61], ensuring stability and convergence. The temperature update equation is:

$$(M + \alpha \Delta t K) T_{n+1} = M T_n + \alpha \Delta t q''' \tag{5}$$

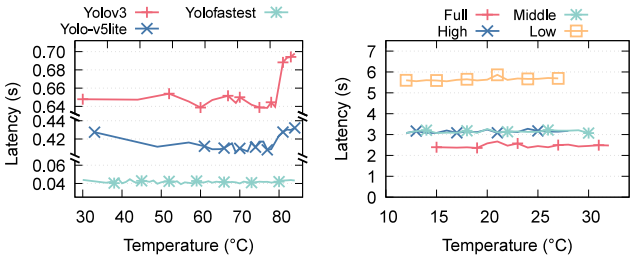
where M is mass matrix which represents thermal inertia of model, α is a coefficient, typically set to 0.5 or another appropriate value, Δt is the time step, K is Stiffness Matrix which describes the heat transfer efficiency, T_n and T_{n+1} are the temperature vectors at the current and next time steps. By integrating these steps, the thermal model accurately depicts the temperature distribution within the satellite.

Note that application workloads interact with the thermal model in two ways: *(i)* Workload drives utilization, determining chip power consumption (Eqn. 3), which serves as thermal model input. *(ii)* Application performance is determined by the output temperature of the thermal model.

4.3 Computation Model

The computation model for a COTS chip uses the current temperature to estimate the performance (execution latency) of user-defined applications. This estimation facilitates the alignment of computing performance from ground-based emulation to in-space satellites.

Challenge: heterogeneity of COTS device performance. To understand satellite COTS devices' performance, particularly under overheating, we conduct in-space experiments that complement the measurement study in [2], using a Raspberry Pi and Ascend Atlas 200 DK to run image recognition workloads. The Raspberry Pi runs YOLOv3 [62], YOLOv5lite [63], and YOLOfastest [64] for 90 minutes



(a) Raspberry Pi (b) Atlas 200 DK

Figure 8: Relative error of task execution latency between in-space and on-the-ground COTS devices.

each, while the Atlas runs YOLOv3 under four power settings (Full, High, Medium, Low) for 30, 60, 60, and 90 minutes. Data on temperature distribution (Fig. 6) and model inference latency (Fig. 7) reveal two levels of heterogeneity: *Device-level heterogeneity.* The two chips exhibit different average performance, given their differing architectures. For the same model, YOLOv3, the Raspberry Pi and Atlas show varying latency (Fig. 7a). Moreover, they respond differently to overheat-induced performance degradation. The Raspberry Pi shows increased latency for YOLOv3 and YOLOv5lite above 80°C (Fig. 7a), while the Atlas maintains stable latency (Fig. 7b) across its temperature range (Fig. 6b); *Application-level heterogeneity.* Different applications also react uniquely to overheating. On the Pi, YOLOv3 and YOLOv5lite experience increased latency above 80°C, but YOLOfastest does not (Fig. 7a). Such device- and application-level heterogeneity necessitate tailored modeling for each device and application. To model the computation performance of satellite COTS devices, one intuitive method is to directly set up real COTS devices and execute various applications on them during emulation. However, the challenges of replicating satellite thermal environments on the ground, coupled with inflexibility and high costs, make this impractical. Instead, RHONE adopts a hardware-software co-designed approach: it integrates real COTS devices into the computation model and mirrors them using software containers at scale, maintaining both fidelity and scalability.

Observation: chip overheat can be mimicked on Earth. Our design is based on the key observation that *although the space environment differs from that on the ground, the performance of COTS devices, especially the degradation due to overheating can be mimicked on Earth*. The rationale is straightforward: overheating leads to performance degradation, and at the same temperature, both satellite and ground-based COTS chips should experience similar degradation. Note that we focus on short-duration tasks (*e.g.,* object detection) where single executions induce negligible temperature changes, which are typical for satellite in-orbit computing. We validate the observation by conducting Earth-based experiments using the same COTS chips as those deployed on satellites, with their cooling fans removed to simulate the absence of active cooling in space. We cyclically stress each chip by repeatedly executing a specific task until thermal throttling occurs, then cool it, and repeat, while each task execution records temperature and execution latency. We observed that the performance degradation closely mirrors that of in-space conditions under temperatures equivalent to those encountered in space as shown in Fig. 6. As shown in Fig. 8, the relative error of task execution latency between in-space and on-the-ground devices is relatively small for most workloads, demonstrating that our Earth-based setup accurately reflects satellite performance under overheating. Note that Pi-YoloFastest's high speed and large random error resulted in a large relative error. Atlas YoloV3Full also showed high relative error, though we believe better space-simulating thermal vacuum experiments could improve this.
