Message from the USENIX ATC '25 Program Co-Chairs

Introduction

We are thrilled and honored to be holding the all-time largest USENIX ATC program, which, unfortunately, will also be ATC's last. The joint USENIX ATC and OSDI conference brings together top academic researchers, industry practitioners, and newcomers in the field; we are looking forward to meeting with you all and to many great discussions during the conference. For many of us in the community, USENIX ATC has been the conference that best captured a balance between academic depth and production pragmatism, and between deep technical advances and creative new ideas. We hope the work in this year's program reflects that legacy.

The rest of this document provides some insights into the submission and selection process that culminated in the 100 accepted works that will be presented at the conference.

Submission Process

As in the recent past, USENIX ATC '25 solicited three types of papers: full-length 12-page research papers, short 6-page research papers that describe complete and well-evaluated ideas using fewer pages, and full-length "Deployed Systems" papers. The Deployed Systems submissions align with the USENIX mission of bringing together researchers in academia and systems practitioners. These papers had different criteria for acceptance from research papers; they were judged more carefully on their practical insights rather than on their new ideas.

In addition to the submission, authors were asked to provide optional supplementary materials, a description of changes that had been made to the submission since prior submissions, and, for Deployed Systems submissions, a justification for why the submission was appropriate for that track.

Program Committee Selection Process

Our program committee (PC) was assembled to meet several competing goals like past USENIX ATC PCs: good coverage across diverse computer-systems topics, balance between academia and industry, a mix of veterans of prior USENIX ATC PCs with individuals in early stages of their professional careers, geographic diversity, and adherence to the USENIX diversity and inclusion principles.

The assembled PC had:

- 172 members from 20 countries.
- Geographic distribution of 67% from North America, 11% from EMEA and 22% from APAC.
- 73% of members from academia and 27% from industry.
- 61% veteran members who served USENIX ATC at least once in the past 3 years.
- 15% female representation, similar to the 14% at USENIX ATC '24.
- And primary areas of expertise from Distributed Systems (19%), Operating Systems (19%), Storage (15%), AI/Machine Learning (14%), Cloud (10%), Security (8%), and Networking (7%).

For the PC selection process, we initially drew from a pool of experienced PC members who had served at least once in the prior 3 iterations of USENIX ATC, removing those who were concurrently serving for OSDI. We prioritized several factors in sending invitations, including: reviewers flagged as producing good reviews for previous conferences; recommendations from invitees who were unable to serve; topic matches to anticipate the need for Machine Learning expertise; and female representation. For the cases in which we needed expertise for a paper where all reviewers identified low levels of expertise, we solicited recommendations from the PC and invited external reviewers.

Review Process

USENIX ATC '25 received 634 submissions across all tracks, which was a 30% increase over USENIX ATC '24 and an 80% increase over USENIX ATC '23. Of these, 32 (5%) were deployed systems papers and 56 (9%) were short papers. The most popular topics for submissions, as specified by authors were: systems and machine learning (37% of submissions), parallel and distributed systems (26%), storage (22%), cloud computing (20%), networking (16%), and operating systems (14%).

We retained USENIX ATC's double-blind review process to minimize bias with strict anonymity rules. Eight papers were

ultimately rejected due to violations of these rules. We rejected six other submissions without review due to violations of the formatting guidelines.

To increase the quality and relevance of reviews, we ran a bidding process where PC members had 3 days to bid on papers within their expertise. USENIX ATC '25 had two double-blind rounds of reviews.

- **Round 1:** The goal was to identify early rejections and papers where reviewers lacked expertise. We assigned 3 reviewers per paper, resulting in 1857 round 1 review assignments. We notified authors of the 345 papers rejected in round 1 (56%) early to give them more time for preparing future submissions of their work.
- **Round 2:** We assigned at least two additional reviewers to the 274 remaining submissions, bringing the total to 5 reviews for each of these papers.
- **Author Response Period:** After the second review period and an online discussion period the reviews were made available for authors to respond to. Authors had 3 days to write a response. The reviewers then continued asynchronous online discussion for another 2 weeks.
- **PC Meeting:** 92 papers were pre-accepted, leaving 27 papers for discussion at the synchronous virtual PC meeting, of which 8 (30%) were accepted. The PC meeting was one day, and it provided a high-bandwidth channel to resolve discussions and select the final program.

The PC selected 100 papers for a 16% acceptance rate. Of these, 6 were deployed systems papers, 7 were short, and 87 were full-length research papers. After selecting the program, the program chairs selected the best paper awards based on nominations from the PC.

Artifact Evaluation Process

USENIX ATC '25 continued to run a joint artifact evaluation process with OSDI '25. The authors of all accepted papers were invited to submit an artifact for an evaluation, and 47 out of the 100 USENIX ATC papers did so.

- 98% of artifacts received an "Available" badge.
- 94% received a "Functional" badge.
- 77% received a "Reproduced" badge.
- 77% of papers received all three badges.

Acknowledgements

Putting on a conference of USENIX ATC's scale is a massive task that requires the help of hundreds of individuals, most of whom are volunteers. First, we thank our Program Committee who bore the spike in submissions, wrote detailed reviews, and argued for papers both online and at the Program Committee Meeting. We also deeply appreciate the Artifact Evaluation chairs and the numerous participants on the Artifact Evaluation Committee that helped to evaluate submissions' software artifacts; this work is crucial for ensuring accountability and reproducibility in our field. Next, as always, the USENIX staff along with the USENIX ATC Steering Committee were instrumental in every step of the process. They were quick to help us when we needed it, and they kept everything organized and moving forward. Finally, we want to express our deep gratitude to the authors, whose incredible work is the bedrock of a great conference; we hope that everyone that submitted to USENIX ATC benefitted from the process.

Thank you to all of the authors and to everyone who has helped make USENIX ATC what it has been over the years—a premier venue where systems research is both principled and grounded in reality. If this is indeed the last USENIX ATC, we hope it's a fitting one.

Deniz Altınbüken, *Google DeepMind*
Ryan Stutsman, *University of Utah*
USENIX ATC '25 Program Co-Chairs

USENIX ATC '25: 2025 USENIX Annual Technical Conference

July 7–9, 2025
Boston, MA, USA

Monday, July 7

Cloud Computing: Speed, Scale, and Serverless

Fast ACS: Low-Latency File-Based Ordered Message Delivery at Scale 1
Sushant Kumar Gupta, Anil Raghunath Iyer, Chang Yu, Neel Bagora, Olivier Pomerleau, Vivek Kumar, and Prunthaban Kanthakumar, *Google LLC*

Poby: SmartNIC-accelerated Image Provisioning for Coldstart in Clouds 19
Zihao Chang and Jiaqi Zhu, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences;* Haifeng Sun, *Peking University;* Yunlong Xie, Kan Shi, Ninghui Sun, Yungang Bao, and Sa Wang, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences*

Burst Computing: Quick, Sudden, Massively Parallel Processing on Serverless Resources 39
Daniel Barcelona-Pons, *Universitat Rovira i Virgili and Barcelona Supercomputing Center*; Aitor Arjona, Pedro García-López, Enrique Molina-Giménez, and Stepan Klymonchuk, *Universitat Rovira i Virgili*

DeepServe: Serverless Large Language Model Serving at Scale 57
Junhao Hu, *Peking University and Key Lab of HCST (PKU), MOE;* Jiang Xu, Zhixia Liu, Yulong He, Yuetao Chen, Hao Xu, Jiang Liu, Jie Meng, Baoquan Zhang, Shining Wan, Gengyuan Dan, Zhiyu Dong, Zhihao Ren, and Changhong Liu, *Huawei Cloud;* Tao Xie, *Key Lab of HCST (PKU), MOE and Peking University;* Dayun Lin, Qin Zhang, Yue Yu, Hao Feng, Xusheng Chen, and Yizhou Shan, *Huawei Cloud*

***Cosmic:* Cost-Effective Support for Cloud-Assisted 3D Printing 73**
Yuan Yao, *University of Southern California;* Chuan He and Chinedum Okwudire, *University of Michigan;* Harsha V. Madhyastha, *University of Southern California*

Accelerating ML Training: Parallelism, Tuning, and Modalities

GMI-DRL: Empowering Multi-GPU DRL with Adaptive-Grained Parallelism 89
Yuke Wang, *Rice University;* Boyuan Feng, *University of California Santa Barbara;* Zheng Wang, *University of California San Diego;* Guyue Huang, *University of California Santa Barbara;* Tong (Tony) Geng, *University of Rochester;* Ang Li, *Pacific Northwest National Laboratory;* Yufei Ding, *University of California San Diego*

***m*Tuner: Accelerating Parameter-Efficient Fine-Tuning on Multi-GPU Servers with Elastic Tensor 105**
Kezhao Huang, Siqi Zhu, Mingshu Zhai, Liyan Zheng, Kinman Lei, Jiaao He, Yuyang Jin, and Jidong Zhai, *Tsinghua University*

Jenga: Enhancing LLM Long-Context Fine-tuning with Contextual Token Sparsity 123
Tuowei Wang and Xingyu Chen, *Tsinghua University;* Kun Li and Ting Cao, *Microsoft Research;* Ju Ren and Yaoxue Zhang, *Tsinghua University*

FlexPipe: Maximizing Training Efficiency for Transformer-based Models with Variable-Length Inputs 143
Hairui Zhao, *Jilin University and University of California, Riverside;* Qi Tian, and Hongliang Li, *Jilin University and Key Laboratory of Symbolic Computation and Knowledge Engineering of the Ministry of Education, China;* Zizhong Chen, *University of California, Riverside*

Optimus: Accelerating Large-Scale Multi-Modal LLM Training by Bubble Exploitation 161
Weiqi Feng, *Harvard University;* Yangrui Chen, *ByteDance;* Shaoyu Wang, *University of Southern California;* Yanghua Peng and Haibin Lin, *ByteDance;* Minlan Yu, *Harvard University*

Networking: From Cloud to In-Network Intelligence

Towards Optimal Rack-scale µs-level CPU Scheduling through In-Network Workload Shaping 179
Xudong Liao, *Hong Kong University of Science and Technology;* Han Tian, *University of Science and Technology of China;* Xinchen Wan, *Hong Kong University of Science and Technology;* Chaoliang Zeng, *BitIntelligence;* Hao Wang, *Hong Kong University of Science and Technology;* Junxue Zhang, *University of Science and Technology of China;* Mengyu Ma, *Inspur;* Guyue (Grace) Liu, *Peking University;* Kai Chen, *Hong Kong University of Science and Technology*

TGW: Operating an Efficient and Resilient Cloud Gateway at Scale 199
Yifan Yang, Lin He, Jiasheng Zhou, Xiaoyi Shi, Yichi Xu, and Shicheng Wang, *Tsinghua University;* Jinlong E, *Renmin University of China;* Ying Liu, *Tsinghua University;* Junwei Zhang, Zhuang Yuan, and Hengyang Xu, *Tencent*

MARC: Motion-Aware Rate Control for Mobile E-commerce Cloud Rendering 217
Yuankang Zhao, *Alibaba Group; University of Chinese Academy of Sciences;* Furong Yang, *Alibaba Group;* Gerui Lv, *University of Chinese Academy of Sciences;* Qinghua Wu, *University of Chinese Academy of Sciences and Purple Mountain Laboratories;* Yanmei Liu, Jiuhai Zhang, Yutang Peng, Feng Peng, Hongyu Guo, and Ying Chen, *Alibaba Group;* Zhenyu Li, *University of Chinese Academy of Sciences and Purple Mountain Laboratories;* Gaogang Xie, *University of Chinese Academy of Sciences and Computer Network Information Center, Chinese Academy of Sciences*

Accelerating Distributed Graph Learning by Using Collaborative In-Network Multicast and Aggregation 233
Zhaoyi Li, *Central South University and Nanyang Technological University;* Jiawei Huang, Yijun Li, and Jingling Liu, *Central South University;* Junxue Zhang, *Hong Kong University of Science and Technology;* Hui Li, Xiaojun Zhu, Shengwen Zhou, Jing Shao, Xiaojuan Lu, Qichen Su, and Jianxin Wang, *Central South University;* Chee Wei Tan, *Nanyang Technological University;* Yong Cui, *Tsinghua University;* Kai Chen, *Hong Kong University of Science and Technology*

Opening Up Kernel-Bypass TCP Stacks 249
Shinichi Awamoto and Michio Honda, *University of Edinburgh*

Operating Systems: Scheduling, Security, and Extensibility

GPreempt: GPU Preemptive Scheduling Made General and Efficient. 263
Ruwen Fan and Tingxu Ren, *Tsinghua University;* Minhui Xie, *Renmin University of China;* Shiwei Gao, Jiwu Shu, and Youyou Lu, *Tsinghua University*

μEFI: A Microkernel-Style UEFI with Isolation and Transparency 273
Le Chen, Yiyang Wu, Jinyu Gu, Yubin Xia, and Haibo Chen, *Shanghai Jiao Tong University*

PageFlex: Flexible and Efficient User-space Delegation of Linux Paging Policies with eBPF 291

fast-acs-wp@google.com

Abstract

Low-latency message delivery is crucial for real-time systems. Data originating from a producer must be delivered to consumers, potentially distributed in clusters across metropolitan and continental boundaries. With the growing scale of computing, there can be several thousand consumers of the data. Such systems require a robust messaging system capable of transmitting messages containing data across clusters and efficiently delivering them to consumers. The system must offer guarantees like ordering and at-least-once delivery while avoiding overload on consumers, allowing them to consume messages at their own pace.

This paper presents the design of Fast ACS (an abbreviation for Ads Copy Service), a file-based ordered message delivery system that leverages a combination of two-sided (inter-cluster) and one-sided (intra-cluster) communication primitives—namely, Remote Procedure Call and Remote Memory Access, respectively—to deliver messages. The system has been successfully deployed to dozens of production clusters and scales to accommodate several thousand consumers within each cluster, which amounts to Tbps-scale intra-cluster consumer traffic at peak. Notably, Fast ACS delivers messages to consumers across the globe within a few seconds or even sub-seconds (p99) based on the message volume and consumer scale, at a low resource cost.

1 Introduction

Low-latency message delivery is crucial for real-time systems such as advertising, dynamic pricing, retail inventory management, fraud detection, activity monitoring, online matching, and online gaming. The explosion of data is driving a corresponding growth in the size and complexity of real-time systems. These systems are often geographically distributed across numerous clusters. This distribution is essential for handling the immense volume of requests and maintaining a low-latency response. Furthermore, these systems are designed to scale horizontally, which is vital because they often handle internet-scale traffic with user numbers that can fluctuate dramatically. This also makes them vulnerable to internet-scale threats like DDoS attacks.

Consider the example of Google Ads, a large-scale online advertising system. The Ads serving system is geographically distributed across multiple clusters to handle massive user traffic. Each cluster runs numerous jobs with multiple replicas to ensure high availability and low response time. Some jobs may have thousands of replicas per cluster, while others may have tens of thousands, resulting in hundreds of thousands of replicas globally. Another example of a large-scale real-time system is online shopping serving. They need to be highly scalable to accommodate peak shopping periods when demand can increase dramatically. This requirement for dynamic scalability is common to many real-time systems that serve internet-scale traffic.

Such real-time systems rely on real-time data pipelines to receive updates for their states. These pipelines utilize real-time extractors [5, 6, 11, 56] that depend on a robust message delivery subsystem. This subsystem transports messages containing extracted data to the real-time systems. Depending on the specific needs of the real-time system, the message delivery subsystem must offer certain guarantees. For example, stateful real-time systems that can handle duplicate messages require *in-order* sequencing (messages delivered in the order they were produced) and *at-least-once* delivery (each message delivered at least once to all consumers). Ordered delivery encompasses unordered delivery and at-least-once delivery subsumes at-most-once delivery. While exactly-once delivery is desirable too, it requires two-phase commit, which is challenging for cross-cluster delivery and hence beyond the scope of this paper. Beyond delivery guarantees, low latency is paramount for these messaging systems, as is the ability to handle a massive number of consumers.

Existing Message Delivery System Message delivery systems are available in two variants: *push-based* and *pull-based*. Pioneered by systems like Scribe [42], Siena [12], and Gryphon [49], push-based asynchronous message delivery has found widespread adoption in RabbitMQ [19],

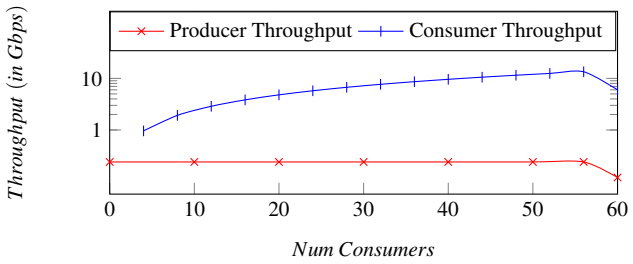

Figure 1: Results for Kafka consumer-scaling experiment. As consumers scaled, the consumer throughput went up to 14 Gbps, after which the performance degraded.

Facebook's Wormhole [44], Google Cloud PubSub [34], and Apache ActiveMQ [14]. However, relying on a push-based model presents challenges for many systems. When a diverse set of consumers, with their varying latency-sensitive backends, needs to be supported, push-based delivery becomes impractical. Handling push messages can block critical CPU cores, leading many systems to prefer pulling messages at their own pace. Moreover, pull-based messaging systems can deliver higher throughput that push-based systems.

Systems such as Apache Kafka [33] have implemented pull-based models, employing brokers to store messages in files on their local file system. Each broker handles one or more *partitions* of a *topic*. Within a partition, messages are totally ordered, while across partitions, they are partially ordered. The throughput of brokers, for both writing and reading, is constrained by the capabilities of the storage medium (like SSDs, currently maxing out at about 4.84 Gbps). Kafka performs well when message volume is high (in the Gbps range) and consumer count is limited. However, it is not optimized for scenarios with a large fan-out; tens of thousands of consumers can lead to potential meltdown, at the very least cause a significant increase in latency. There are ongoing efforts to replace local file system with Hadoop Distributed File System (HDFS) [47]. However, low-latency delivery to several consumers requires enormous tail-reading of file bytes, and so HDFS data node servers with a 64 MB file block size can still face throughput issues. In-memory caching of "hot" messages within brokers offers a potential workaround for storage bottlenecks. However, hot-spotting and network congestion can occur even within a single partition, for instance, when global total order is required.

To demonstrate consumer throughput issues, we conducted an experiment on Google Cloud [15]. The experiment involved a Kafka cluster with the following specifications: 3 brokers in a zone, each configured with 8 vCPUs, 32 GB of RAM, and NVMe SSD; and one topic with 9 non-replicated partitions.The partitioning ensured even distribution of load across brokers, preventing hot-spotting. A producer was initiated, sending 1 KB-sized messages at a rate of 240 Mbps. Then, consumers were scaled up incrementally, adding four at each step. Figure 1 shows the results. Initially, consumer throughput scaled linearly, reaching a peak of 14 Gbps. However, beyond this point, we observed a drop in the write rate due to throughput conflict between writes and reads. The producer byte rate decreased to 120 Mbps, consequently causing a drop in overall consumer throughput. The maximum consumer throughput achieved in this Kafka setup was 14 Gbps, after which performance degraded.

Apache Pulsar [32] is a geo-replicated message delivery system. It uses Apache BookKeeper [21] for storage. BookKeeper persists messages in distributed write-ahead logs, and indexes them in a cache for fast retrieval. These logs are segmented to optimize performance. However, their large segment size (typically 128 MB) can lead to throughput issues when several consumers tail-read from them.

Our Contributions To the best of our knowledge, there are no messaging systems that can handle large consumer fan-out and provide low-latency ordered message delivery. Our contribution lies in the development of such a system.

In summary, our system utilizes files on a distributed file system, namely Colossus [27] (formerly Google File System [22]). Producers append messages to these files, while consumers poll and read them. We introduce an in-memory layer on top of Colossus specifically designed for low-latency message delivery at scale. The system leverages one-sided network primitives, namely Remote Memory Access (RMA), for intra-cluster reads, while utilizing traditional two-sided communication, namely Remote Procedure Call (RPC), for inter-cluster byte transfer. The system provides essential guarantees for message delivery: *in-order* sequencing and *at-least-once* delivery to all consumers. Additionally, it enables consumers to pull messages at their own pace.

Our contributions are fourfold: 1) We demonstrate how RMA-based in-memory caching overcomes tail-read throughput limitations, enabling low-latency message delivery. 2) We show that proper chunking and distribution eliminate hot-spotting, even with global total ordering constraints. 3) We demonstrate that scaling out resources horizontally effectively mitigates network limitations. 4) We highlight the resource efficiencies achieved by leveraging RMA.

Our contribution targets real-time systems with high consumer throughput requirements, rather than systems that need extremely low latency, say, under 50ms. While achieving such low latency is possible with enhanced resources, it can be expensive. The ideas discussed in this paper can be adapted to enhance the consumer scalability of existing systems, leading to improvements in their benchmark performance.

We have materialized the design to build Fast ACS (an abbreviation for Ads Copy Service). Fast ACS has been deployed in production, consistently delivering messages to thousands of consumers across dozens of production clusters within a few seconds or even sub-seconds (p99). Fast ACS is adopted by systems that demand ordering, at-least-once delivery and low-latency on a large scale.

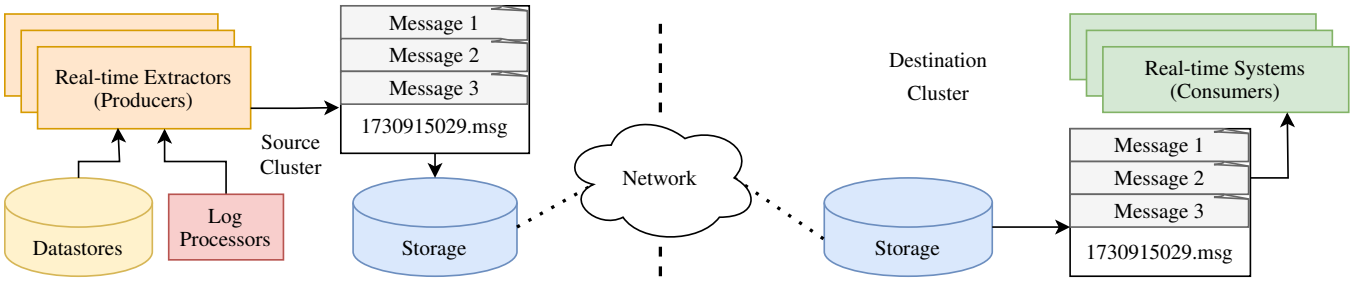

Figure 2: File-based ordered messaging for a real-time systems. Each message stream can have multiple destination clusters based on its consumers. Message files are tail-copied from the source cluster's storage to the destination clusters' storage.

2 Design Overview

We will begin by outlining how our system achieves ordered message delivery through files. Starting from Section 2.2, we will detail our system's core components.

2.1 File-Based Ordered Message Delivery

Files provide a mechanism for ordered message delivery. Producers append messages to *message files* and consumers read from them. To limit their size, the message files undergo periodic rollover. Each message file includes its creation timestamp in its name, enabling chronological sorting.

This file-based messaging approach is agnostic to the underlying message formats, focusing primarily on the storage and delivery of bytes. Consequently, producers and consumers can define their own protocols for serializing and deserializing messages to and from the files.

Producers write messages into distinct *message streams* in the source cluster, each representing an individual bundle of messages, analogous to *topics* in pub-sub systems. Producers can write to multiple message streams, while consumers can read from multiple ones as well. Each message stream is sharded for scalability, with each shard comprising a set of chronological message files containing the messages. A message stream shard resides within a single directory of the file system, simplifying organization. Thus, all ordered messages for a single message stream shard can be found in chronological files under one directory.

To accommodate geographically distributed consumers, message files must be copied from the source cluster's storage to the destination cluster's storage. Consumers in the destination cluster can then tail-read the file from their cluster-local storage system. Figure 2 provides an illustration of our cross-cluster file-based ordered message delivery for a real-time system.

2.2 Multi-Layer Storage

As illustrated in Figure 3, the message files are stored in a multi-layered storage system: Colossus [27], a distributed file system, serves as the primary layer, while a replicated in-memory cache acts as the secondary layer. This additional layer ports minimal Colossus features and operates in parallel to it. All message stream bytes are replicated to both layers. Given its finite capacity, the in-memory cache layer only stores the most recently written, "hot" bytes for the files. The layer absorbs the majority of queries for tail-reads, with Colossus serving as a fallback. This offers a low-latency, high-throughput path for message delivery.

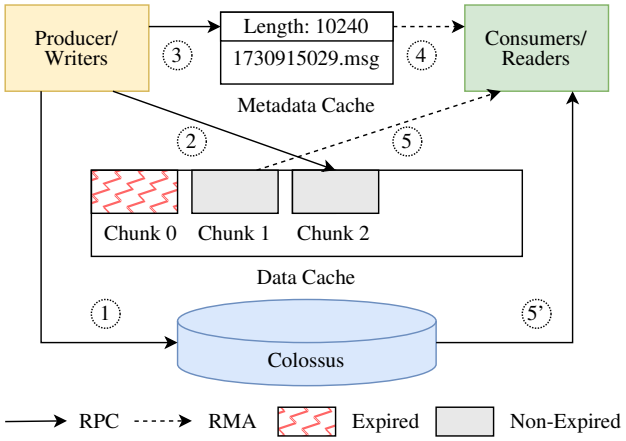

Figure 3: The multi-layer storage design. The producers/writers write the bytes to the Colossus file (1) and shadow the bytes as chunks to the data cache (2), and then update the length of the file in the metadata cache (3). The consumers/readers poll the metadata cache for the latest length of the file (4) and read the chunks from the data cache preferably (5), with Colossus acting as a fallback (5'). All the reads from caches happen over RMA. In this illustration, chunk 0 has expired while chunk 2 is only partially-filled. The length stored in the metadata cache points to the current position within this last, partially-filled chunk.

The In-Memory Cache Layer Files are segmented into a series of fixed-size chunks, each 4 KB in size. These chunks are then represented as key-value pairs. The key for each chunk is a hash of two components - the absolute Colossus file path, which is globally unique across Colossus, and the chunk's sequence number. The value comprises the corresponding chunk bytes. The 4 KB chunk size is partly based on the observed message size and partly on the maximum transmission unit in the cluster fabric, allowing a chunk to be read in a single packet.

We employed CliqueMap [4] as the underlying system for the in-memory storage layer. CliqueMap is a remote in-memory key-value cache that facilitates writes through RPC and intra-cluster reads via RMA. The latter proves advantageous given the read-heavy nature of our intra-cluster consumer traffic. Each key-value pair in the cache is subject to garbage collection (GC) upon either the expiration of its Time-To-Live (TTL) or when the cache approaches its storage capacity limit. CliqueMap employs consistent hashing [31] for key distribution among replicas. Within a replica, CliqueMap divides its memory into fixed-size *slabs*, and key hashes are divided into *buckets* via set-associative mapping.

CliqueMap supports r=3.2 replication, which provides resilience against single-point failures. With replication, CliqueMap offers a range of read consistency modes, two of which we leverage: the *consistent* mode, which reads values from at least 2 out of 3 replicas, thereby delivering the most recent value, and the *relaxed* mode, which reads from a random replica that may provide a stale value.

In constructing a file system atop CliqueMap, we employ two instances per cluster: a *data cache* and a *metadata cache*. These are analogous to the Colossus *chunkservers* and *metadata servers* respectively, except lacking processing capabilities. As a result, unlike Colossus, the data and metadata for a file cannot be atomically written to the cache layer. The data cache acts as the repository for file chunks while the metadata cache stores file metadata, particularly (a) the current *length* of the file and (b) the *file lock*. The current length, a monotonically increasing number, reflects the file length of the append-only file, stored as chunks, in the data cache, while the file lock serves to prevent concurrent writers in a best-effort manner. As elaborated subsequently, locks primarily contribute to performance optimization and do not impact the system's correctness. While both file chunks and metadata stored in such volatile caches remains vulnerable to data loss, our system is designed to withstand such occurrences, as detailed in the subsequent sections.

The data cache has two types of chunks for each file: *complete* chunks and a *last, partially filled* chunk (if any). Each chunk in the data cache possesses the following property: reading any part of a chunk will always yield the correct bytes, if present, for the corresponding file positions, even if the chunk is partially filled. This is guaranteed by always writing a chunk starting from its beginning and never from any other position, as detailed later. TTL expiration automatically removes older, non-hot chunks.

2.3 Routing

Directly streaming bytes from the source cluster to all the destination clusters of a message stream would be prohibitively expensive. To address this, we utilize a Prim-based [41] optimizer to construct a minimum spanning tree (MST), hereafter referred to as a *copy tree*, for each message stream, as illustrated in Figure 4. While prioritizing bandwidth cost, the optimizer is also fine-tuned to minimize both, the tree's depth and the fan-out per node. Minimizing the tree's depth is essential, as each hop along the copy tree introduces some delay. The first hop from source typically traverses continental boundaries, followed by a hop across metro boundaries. A typical copy tree has a maximum of 4 hops from the source cluster which can accommodate a few hundred clusters.

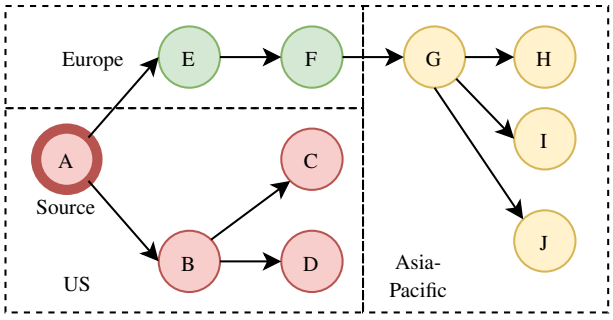

Figure 4: An MST for a message stream. The source cluster is in the US, and the stream is copied to three clusters within the US, two clusters in Europe, and four clusters in the Asia-Pacific region.

Outages in a cluster, often caused by factors such as bad releases, connectivity problems, or bulk maintenance events, can delay all descendant clusters in the copy tree. Such disruptions frequently led to significant Service-Level Objective (SLO) misses, which prompted us to automate the outage handling process. We employ a breadth-first search algorithm to penalize the problematic nodes and links, and then delegate reconstruction of the copy tree to the optimizer. The reconstruction usually sets the problematic nodes as leaf nodes in the copy tree. Consumers in the affected cluster are re-routed to a nearby healthy cluster, sacrificing the ability to perform RMA reads. Similarly, when a new cluster is added to a message stream, it starts as a leaf node with rate-limited delivery and is then promoted to a regular node once the catch-up to the head is complete.

Along each hop of the copy tree, we have a pair of worker jobs - *readers* and *writers*. Readers are responsible for polling, reading, and sending bytes from the current hop to the next hops of the copy tree while writers write the bytes to the destination storage. This design provides the necessary decoupling for the jobs to scale independently. The readers scale based on the egress bandwidth demands, which depends on the fan-out from the current cluster, and the writers scale based on the ingress bandwidth demands.

Each file is tail-copied independently through an *operation*, identified by the Colossus target file path and the storage type - either Colossus or cache. As a result, for each file, the operations for Colossus and cache are independent along the entire copy tree, which also doubles the bandwidth utilization. While pairing them was technically feasible, it led to additional complexity in implementation and introduced avoidable latency. For example, invoking the Colossus *Open* file func-

tion in the write mode is prohibitively expensive as it needs to acquire lock on the file. The cache operation bypasses such costly Colossus operations and is heavily-optimized for parallelization, enabling the fastest possible byte delivery rate.

Finally, operations are scheduled by a cluster-local *scheduler*, which is triggered by a notification from the producer. The schedulers establish a continuous stream along the tree.

2.4 Components

Producers Producers (i.e., real-time extractors) are responsible for generating update files and appending serialized messages to them. Our *File* interface implementation writes the serialized messages to the underlying Colossus file and then asynchronously shadows (copies) the bytes to the data cache. The length of the Colossus file and the length of the file in the data cache are then recorded in the metadata cache. This allows for low-latency retrieval of the file lengths from the metadata cache via RMA, especially for Colossus, where Colossus Bigtable [13] often runs into hot-spotting issues when several consumers poll it simultaneously.

Flushing messages to Colossus establishes a single source of truth, with all other copies (in other Colossus clusters and caches) reflecting this committed state. To amortize disk write costs, producers typically buffer messages before flushing.

In order to shadow the bytes to the data cache, the file implementation tracks the last partially-filled chunk (if any) for the append-only file. When new bytes are flushed to Colossus, the file implementation computes the chunks for the data cache and performs a bulk-write operation on the corresponding key-value pairs. Since a write to a chunk is atomic, slow-growing files often end up overwriting the same bytes to the same chunk multiple times, thereby increasing intra-cluster bandwidth usage unnecessarily. This can be partially resolved by reducing the chunk size to fit the file's byte rate.

Readers For each operation, a reader replica in an upstream cluster initiates a long-lived streaming RPC connection [24] with a writer replica in a downstream cluster. The operation polls the file systems for file length changes and subsequently reads and sends the bytes downstream.

File length is periodically polled from the metadata cache, which stores lengths for both the data cache file and the Colossus file. To reduce overhead, a single background thread performs consistent bulk reads from the metadata cache on behalf of all the operations scheduled on the reader replica. The polling interval for the metadata cache is set to 50ms, and can be reduced to 10ms or less based on latency requirements. Additionally, the Colossus file length is also polled from Colossus Bigtable, albeit less frequently. This serves as a fallback, in case the metadata cache becomes unavailable.

The data cache reads employ a two-step process. Initially, a relaxed read for chunks is performed, followed by consistent reads for those chunks that return fewer bytes than expected — a scenario that may occur when reading from a lagging data cache replica, as illustrated in Figure 5. Empirical observations show that consistent reads are infrequent. Hence, relaxed reads contribute to saving substantial intra-cluster bandwidth and processing resources. An alternative approach could involve using *2xR*, where a quorum on the version number of the key-value pair is first established. However, this necessitates two round-trips, which introduces latency. The relaxed read is hedged after a short delay of 30ms.

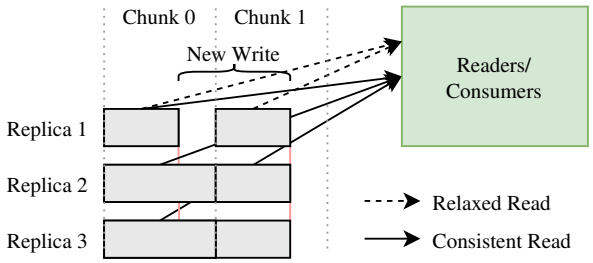

Figure 5: An illustration of relaxed reads followed by consistent reads. Suppose new bytes are written across multiple chunks, filling up the previously partially-filled chunk 0. The new chunk 1 is successfully written to all replicas, but the updated chunk 0 is only written to replicas 2 and 3. When a reader detects a new length from the metadata cache and performs a relaxed read for chunk 0 from replica 1, it will receive fewer bytes than expected. The reader will then perform a consistent read to obtain the complete chunk 0.

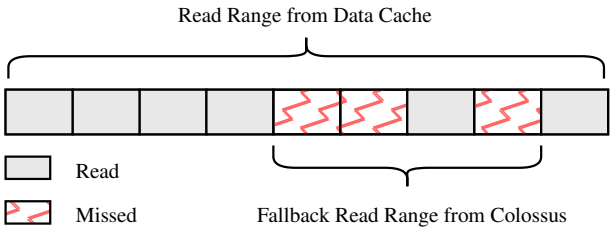

Figure 6: An illustration of fallback reads to Colossus in the event of misses from the data cache. All missed chunks are fetched in a single Colossus read to amortize the RPC cost.

Note that because the data cache is volatile, it is possible to encounter a missing chunk even after a consistent read. A missing chunk is retrieved from Colossus by reading from the positions corresponding to the chunk. In scenarios where multiple chunks are missing, the corresponding read from Colossus spans the combined positions of all the missing chunks as illustrated in Figure 6.

For a Colossus operation, the bytes are retrieved opportunistically from the data cache first and then from Colossus upon a miss, as described above. Opportunistic reads from the data cache in Colossus operations are best-effort but save valuable disk time. The Colossus Flash Cache [53] is ineffective as it only caches immutable blocks, which is not useful for tail-reading growing files. The read bytes are relayed to the downstream cluster sequentially, in line with Colossus's append-only operation support.

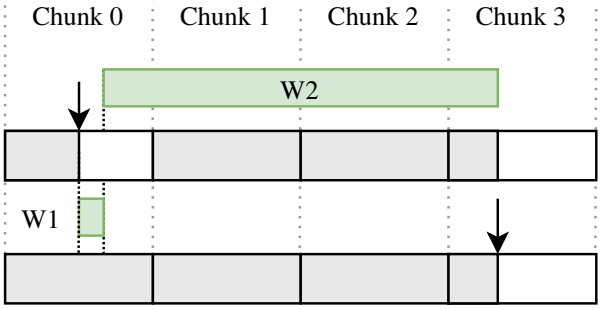

Figure 7: An illustration of writes to data cache. Consider a scenario where the 0th chunk is partially-filled and there are two concurrent write requests: W_1 with a few bytes (not enough to fill the 0th chunk) and W_2 with large bytes (spanning over the 0th, 1st and 2nd chunk fully, and the 3rd chunk partially). It is possible for W_2 to arrive before W_1, leading to the 1st, 2nd chunk and 3rd chunk being written before the 0th chunk. Consequently, the W_2th write for the 0th chunk needs to be serialized after W_1 is received and the chunk is complete. The length, shown as pointer, is updated only after all bytes up to the pointer are filled.

Similarly, for a cache operation, chunks are fetched from the data cache first, followed by a fallback to Colossus upon a miss. However, unlike a Colossus operation, the bytes are read and sent to the writer in parallel, i.e., the processing of the next file length delta does not wait for the previous one to complete.

Astute readers may notice a circular dependency between Colossus and cache operations. However, this circularity is resolved by the fact that actual byte reads are limited to the length of the file in the corresponding storage only. The cache reads by Colossus operations are *opportunity-based* while the Colossus reads by the cache operations are *fallback-based*.

Writers For a Colossus file, the operation employs single-threaded appends, which also updates the metadata in Colossus Bigtable, constituting an atomic step.

For the data cache, the operation differentiates between complete chunks and the last partially-filled chunk. Complete chunks are written in parallel as they will only be written once. On the other hand, writes to partially filled chunks are serialized to ensure that the prefix of bytes in the chunk is always correct, as illustrated in Figure 7. This creates per-chunk dependencies between write requests and the operation maintains a map of such write relationships for each chunk. Once all writes are complete, the length in the metadata cache is then updated to reflect the position up to which all complete chunks and the last partially-filled chunk have been written to the data cache. As noted earlier, unlike a Colossus file, the writes to the data and the metadata cache do not constitute an atomic step.

Note that this out-of-order parallel-write scheme for the data cache interferes with evictions based on TTL where chunks with higher sequence number may be evicted before chunks with lower sequence number. In practice, this has not been a significant problem because consumers rarely fall behind enough to be impacted by chunk expiration.

Algorithm 1 Delayed Colossus Reads for a File

```
1:  maxDelay ← 1s                          ▷ Maximum tolerable read delay.
2:  cfsSizeRec ← queue()                   ▷ Colossus file size historian.
3:
4:  procedure ShouldReadFromColossus
5:      cacheSize ← cache.size()
6:      cfsSize ← colossus.size()
7:      cfsSizeRec.push({time: time(), size: cfsSize})
8:
9:      while !cfsSizeRec.empty() do
10:         if cfsSizeRec.front().size > cacheSize then
11:             break
12:         cfsSizeRec.pop()               ▷ Remove caught-up positions.
13:     if cfsSizeRec.empty() then
14:         return false                   ▷ Cache is caught-up.
15:     if time() > cfsSizeRec.front().time + maxDelay then
16:         cfsSizeRec.clear()
17:         return true                    ▷ Cache is delayed.
18:     return false                       ▷ Cache may catch-up soon.
```

Consumers Consumers (i.e., real-time systems) are responsible for reading bytes from the storage and deserializing the messages in a sequential manner. Our design guarantees eventual progress for the consumers, regardless of the volatile state of either the metadata or data caches. This is due to the persistent, append-only nature of Colossus files.

Like readers, consumers actively poll the metadata cache to get the file length for both the Colossus file and the data cache file. Consumers then have the option to read from either of the two storage layers. A naive approach would be to read the chunks from the storage which is ahead of the other in order to minimize latency. Typically, the data cache file leads the Colossus file, making this strategy suitable for most cases. However, we have observed that Colossus files can often overtake the data cache intermittently, particularly when a data cache stream is interrupted along some copy tree hop. This used to result in a significant reads from Colossus, leading to increased latency penalties when Colossus throttled the requests. To address this, our objective was to prioritize reading from the data cache as long as latency requirements are met. This is achieved by postponing reads from Colossus unless message delivery latency is at risk. The implementation for delayed Colossus reads is illustrated in Algorithm 1. Our *File* interface implementations makes this process transparent to the consumer jobs.

Sometimes, some consumers might start late or fall behind. In such cases, past reads from the data cache will fail as the chunks would have expired, and the consumers are forced to fallback to Colossus until they catch up to the head and can resume reading from the cache. Upon cache miss, the fallback

mechanism is same as that described for readers.

Lastly, each consumer passively rate-limits the reads to cap the read bandwidth in the event that the producer restarts and writes a large backlog to the cache. Without the rate limit, the read amplification would overwhelm the data cache.

3 Implementation Details

Start Position for Cache Copies In essence, the data cache is designed to serve only non-lagging consumers. Consumers who have fallen behind are expected to catch up using Colossus file before reading chunks from the data cache. This simplification allows us to help keep the data cache stream ahead of the Colossus stream. In cases of cache outages and subsequent recovery, the data cache stream jumps to the chunk where the Colossus file is currently positioned, and the length in the metadata cache is updated accordingly.

Dueling Writers The scheduler employs Slicer [2] for sharding, which, like many sharding schemes, provides weak consistency guarantees. While strong consistency could have been achieved by employing a lock service like Chubby [10] or ZooKeeper [28], or by utilizing Slicer's strong consistency mode, these approaches compromise availability. Prioritizing availability, we opted for Slicer's weak consistency model. Consequently, multiple operations can exist for the same target path and storage.

For Colossus files, multiple writers are prohibited since the *Open* operation on a file invalidates all existing file handles used by other processes. This allows a new operation to automatically supersede an older one for a target path.

However, such a mechanism is not available for cache operations as the cache storage layer cannot execute logic. This can result in multiple writers competing, causing clobbering of key-value pairs in both the data and the metadata caches. For instance, complete chunks would be overwritten with partial chunks or the file length would intermittently go backwards. This would negatively impact performance, forcing consumers to frequently fallback to Colossus. Note that the correctness remains unaffected, and appendix A provides a formal specification verifying the system's correctness.

To address the performance issue, we utilize locks stored in the metadata cache. These locks are essentially leases that can be marked as *poisoned*. Each lock is a key-value pair, where the key is derived from a hash of the Colossus file path, and the value is a unique signature for each operation. This signature consists of a unique identifier for the writer replica and a random nonce to distinguish the operation on that replica. A lock for a file is obtained at the beginning of an operation and released when the operation completes. After acquisition, the writer continuously checks the lock for poisoning. When another operation for the same file is scheduled, it *poisons* the existing lock. Upon detecting the poison, the existing operation is then forced to terminate, allowing the new operation to acquire the lock. Additionally, if a writer terminates without releasing the lock, the new operation seizes the lock after a small delay.

Tuning the Caches We tuned both data and metadata caches for low-latency. These caches operate within the standard shared Borg [52] environment, where various jobs compete for resources. Network bandwidth is the most critical resource for the caches due to the high fan out within each cluster. Both data and metadata caches scale horizontally [43] based on the bandwidth and QPS usage.

I. Data Cache: A 1-minute TTL is assigned to the chunks, accommodating most, if not all, consumers. GC is configured to start once the cache reaches 80% of its capacity. The initial RAM for each replica and the minimum number of replica per cluster is configured to accommodate a minute worth of most recent chunks. The slabs and buckets for key-value pairs are pre-allocated to avoid delays caused by resizing. Chaining is enabled to accommodate overflowing buckets to prevent undesired forced evictions. Furthermore, the data cache utilizes a least-recently modified policy, prioritizing the removal of the oldest written chunk.

II. Metadata Cache: The TTL is set to 24 hours which is much larger than the usual rollover time for update files. Since the number of key-value pairs in metadata cache is inherently restricted by the number of files, most capacity and GC settings were deemed unnecessary.

CPU usage on the caches is typically minimal, as most traffic is read-heavy that utilizes a highly efficient software RMA implementation running on Pony Express [38].

To ensure low latency, clients set strict sub-second deadlines on cache operations. Additionally, we tuned the CliqueMap client-side executor for high parallelism by increasing both the number of threads and the buffer space allocated per thread. The underlying execution of operations can be parallelized because we manage concurrency at the application layer. However, as a side-effect, this also increased RAM usage on the consumer side. We then performed manual tuning to optimize for a low resource footprint without impacting latency. In the future, we wish to automate this based on the read traffic pattern.

Finally, to avoid potential server-side resource conflicts with write operations, reads are deliberately configured to never resort to using RPC mode, except for overflowing bucket reads. However, this still does not prevent OS network buffers and bandwidth conflicts between reads and writes.

Fault Tolerance The caches can handle single point failures, though multiple failures may impact performance. Both readers and writers can tolerate multiple failures, but this can create temporary imbalance due to operation rescheduling, potentially slowing down operations and increasing latency. To mitigate this, new operations are throttled and existing operation are periodically shed to restore balance.

The scheduler manages the entire life cycle of an operation.

During transient periods of scheduler unavailability, such as restart, an operation can continue running in an *orphaned* state thereby maintaining stream continuity. Once the scheduler is back online, it can schedule a new operation for the same file and storage, which will force the existing orphaned operation to terminate, as detailed previously. This straightforward design, inspired by the *make-before-break* strategy, ensures that the stream flow remains uninterrupted.

When scheduler and workers are both unavailable, delays are inevitable. A stream might be disrupted and will need to be re-established.

4 Evaluation

In our evaluation, we aim to address several key questions:

I. Ideal Performance: How does the system perform under ideal conditions?

II. Abrupt Load Management: What happens to the system when an abrupt consumer load is exerted on it?

III. Fault Tolerance: How does the system handle faults and ensure resilience?

IV. Scalability: How effectively does the storage layer scale in response to egress bandwidth demands?

V. Backlog Recovery: How does the system recover from large message backlogs?

All evaluations were performed within the shared Borg [52] environment. Each cache replica was allocated 1 CPU core and 8 GB RAM. Consumers were assigned 1 CPU core and 4 GB RAM. Readers and writers were assigned 2 CPU cores and 4 GB RAM, and were configured to scale both vertically and horizontally based on the demand. All jobs were configured to utilize high-priority CPU resources and ran on machines with Pony Express [38], providing highly-efficient software RMA. We used the B4 network [23, 30] for WAN traffic, which is designed for cheaper, low-priority, non-user-facing traffic.

Producers generated messages in data-index format, appending messages into two files: the *data* file, containing message contents, and the *index* file, which primarily stored the offsets of the message contents within the data file. Additionally, producers had a buffering interval of 100ms.

For evaluation purposes, monitoring jobs were turned up alongside consumers. These jobs mimicked consumers and exported performance metrics. The key metric exported by the monitors was *message delivery delay*, calculated as the difference between the producer's time on message production and the consumer's time on message consumption. The delay was comprehensive as it included the time taken by the producer to serialize and write the message, the time taken by the transport layer to copy the message to the destination, and the time taken by the consumer to read and deserialize the message. Although Google's TrueTime [16] could have facilitated cross-cluster measurements, we opted to use smeared UTC [45] instead. This decision was based on the observation

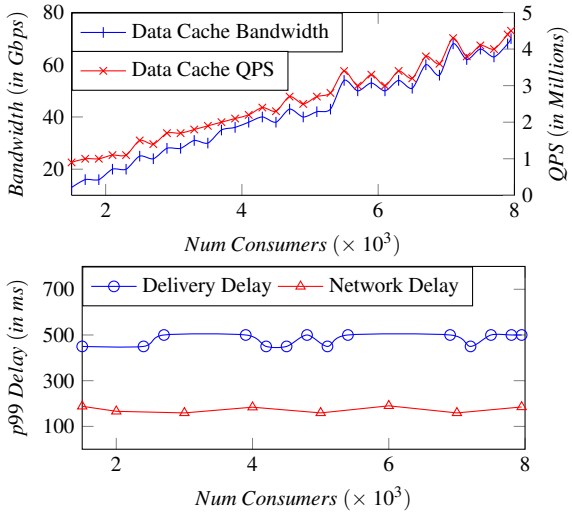

Figure 8: Results for experiment 1(a). The fluctuations in data cache bandwidth and QPS are attributed to repeated reads for last partially-filled chunk and the execution of consistent reads when relaxed reads fail. The message delivery delay exported by monitors remained relatively stable regardless of the number of consumers.

that clock drifts were negligible compared to the actual delays we encountered. All reported delays have a relative error margin of less than 7%. Metrics were exported to Monarch [1] a few minutes into steady-state after startup to avoid capturing noise generated during the initial read up to head.

4.1 Experiment 1

In this experiment, we fixed the number of cache replicas. We turned up 9 replicas for the data cache and 6 replicas for the metadata cache in each cluster. To generate workload, we enabled two message streams originating from clusters in the us-central and euro-west regions. These streams were then replicated to 15 destination clusters. The combined producer write rate was 240 Mbps on average. Using r=3.2 and chunk size of 4 KB, this configuration yielded a data cache write QPS of approximately 22,500 in each cluster. The message streams were 120-way sharded, and each shard contained their own data-index file pairs. Each consumer was assigned to read from 4 shards, resulting in a read rate of 8 Mbps per consumer. The polling interval was set to 50ms for readers and 100ms for consumers.

Experiment 1(a) - Ideal Case We started with 1,500 consumers in one of the leaf clusters of the copy tree, which was 3 hops away from each source, located in asia-east region. We scaled-up the number of consumers to see how it affects the latency. The consumers were scaled up smoothly adding 5 replicas every 5 seconds. Throughout the experiment, all upstream clusters reported stable delays. This represents a fairly ideal scenario.

Observations: The experiments concluded with 7,950 ac-

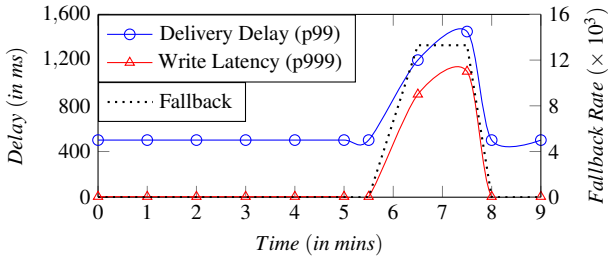

Figure 9: Results for experiment 1(b). The elevated cache write latency led to a substantial increase in fallbacks to Colossus by consumers, consequently impacting delivery delay.

tive consumers. Figure 8 shows the results. Notably, no fallback to Colossus was observed during stable state of consumers. Peak read bandwidth from the data cache reached 70 Gbps, exceeding the anticipated 62 Gbps by approximately 13%. A similar trend was noted for QPS, although the deviation from expectations was more pronounced. The peak QPS to the data cache was 4.5M, surpassing the expected 2M by 2.25x. The elevated bandwidth can be attributed to two factors. First, the last partially-filled chunk is read multiple times until it reaches its full size. Second, the chunks that fail relaxed reads are followed up with consistent reads. The latter results in elevated QPS as well.

Monitors consistently reported a p99 message delivery delay of approximately 500ms. This delay stemmed from several factors: producer-side buffering and serial flushing of data and index (120ms), network transit (180ms), and consumer-side periodic polling followed by serial reading of index and data (100ms). Our system added only around 25ms of processing delay along each hop, which included source read I/O, network transmission/receive queuing, and destination write I/O, with the majority of the delay attributed to I/O.

In the following experiments, we capped the number of consumers at 4,000 to ensure we stayed within the resource constraints allocated for each cache replica.

Experiment 1(b) - Abrupt Consumer Spike Utilizing the same cluster setup as in Experiment 1(a), we abruptly scaled the number of consumers from 0 to 4,000 to observe the system's response. This simulates an atypical scenario, like during incident mitigation, where the consumer size surges unexpectedly, putting the system under stress.

Observations: The data cache experienced a sharp increase in read QPS, reaching as high as 4.7M, due to numerous requests for trailing bytes of files stored in non-expired chunks. This surge in read QPS created back pressure on writes because both read and write operations shared the same OS network buffers and bandwidth (lacking isolation at that level), temporarily increasing write latency. Consequently, cache operations encountered failures, forcing consumers to fallback to Colossus to retrieve the necessary bytes. This resulted in a noticeable delivery delay increase of approximately 1s for about 150 seconds as shown in Figure 9. The system eventually recovered and resumed normal performance.

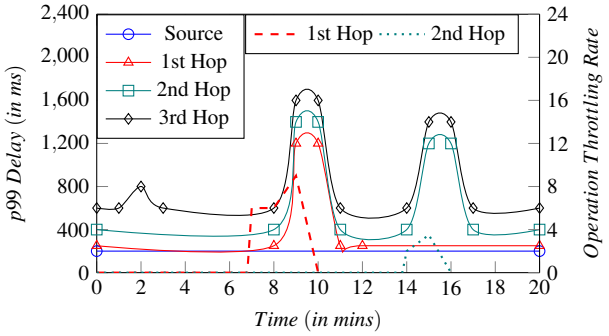

Figure 10: Results for experiment 1(c). The solid lines represent p99 delays and non-solid lines represent throttling caused by imbalance. Delay in a hop impacted the delay in downstream hops.

Experiment 1(c) - Multi-hop Abrupt Consumer Spike We repeated experiment 1(b), but along all the hops of the longest branch of the copy tree of one of the message stream. We turned up 4,000 consumers in 4 clusters, including source.

Observations: The results are shown in Figure 10. We noticed spikes in write latency in the affected clusters, similar to experiment 1(b), which occasionally resulted in operation failures. Although the scheduler rescheduled the operations within 100ms, this rescheduling led to imbalances that caused operation throttling. As a consequence, throttled cache operations triggered Colossus fallbacks. The impact was amplified as a delay in a parent hop affected the entire subtree. The p99 message delivery delay stayed mostly below 600ms, with spikes up to 1.8 seconds coinciding with Colossus fallbacks.

Experiment 1(d) - Fault Tolerance Similar to experiment 1(b), we turned up 4,000 consumers within a single leaf cluster. Additionally, we turned up two backup replicas for both the data cache and the metadata cache. Subsequently, we terminated the cache replicas, followed by the readers and writers, to analyze the resulting impact.

Observations: Data caches demonstrated resilience to single-point failures, maintaining quorum and experiencing no read/write failures when one replica was terminated. However, unavailability and cache operation failures occurred when two replicas of a key-shard were terminated. The backup replica's CPU utilization spiked as it replicated key-value pairs from the remaining replica. This further elongated the unavailability, causing significant Colossus fallbacks of 60,000 reads/seconds and a spike in latency up to 2 seconds as shown in Figure 11. A similar pattern emerged for metadata cache when two replicas of a key-shard were terminated, although recovery was faster due to the significantly smaller number of key-value pairs.

In contrast, terminating readers and writers had a negligible impact on latency (not shown), as operations were swiftly rescheduled by the scheduler within 50ms. However, there was a minor effect on load distribution among the remaining

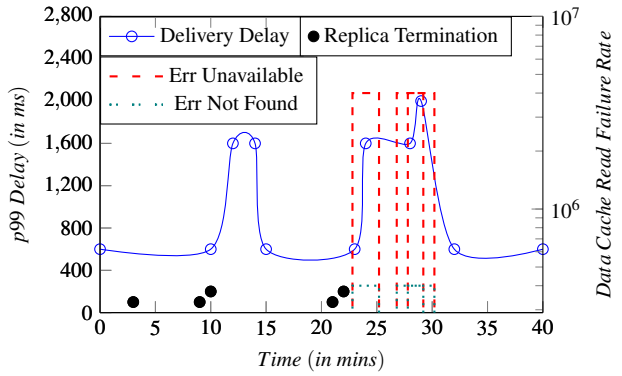

Figure 11: Results for experiment 1(d). Scatter points represent the specific times when a data cache replica for a particular key-shard was terminated. A significant increase in failures was observed, primarily attributed to key-shard unavailability during the repair process.

replicas, which was gradually resolved through load shedding and operation rescheduling.

4.2 Experiment 2

In this experiment, we enabled horizontal scaling for caches, triggered by bandwidth and QPS pressure. We turned up 18 replicas for the data cache and 6 replicas for the metadata cache in one of the leaf cluster. Scaling was configured to trigger whenever a replica breached either 4 Gbps of bandwidth or 400,000 QPS. We simulated a heavier workload by enabling two message streams from clusters in the us-central and euro-west regions. Together, these streams had an average producer write rate of 480 Mbps. The data cache write QPS in each cluster reached approximately 45,000. The message streams were 120-way sharded, and each consumer was assigned 20 shards to read from. Thus, each consumer had a read rate of 80 Mbps. The polling interval was set to 50ms for readers and 500ms for consumers, as a shorter duration led to metadata cache overload.

Experiment 2(a) - Smooth Scaling We began with an initial 1,000 consumers and ramped up to 20,000 consumers, incrementally adding 50 replicas every 10 seconds.

Observations: The maximum read bandwidth observed from the data cache reached 1.8 Tbps as shown in Figure 12. Meanwhile, the metadata cache experienced a peak QPS of 19.2M (20,000 consumers x 2 message streams x 20 shards x 2 files per shard x 2 keys per file x 2 polls per second x 3 replicas). In response to the workload, the data cache scaled up from its initial 18 replicas to 481, surpassing the expected 460 replicas by 4%. This scale-up led to chunk migrations due to re-sharding, causing transient unavailability of the data cache. This, in turn, forced fallbacks to Colossus, resulting in intermittent drops in data cache bandwidth. Despite this, the p99 message delivery delays exported by monitors remained under 2.5 seconds.

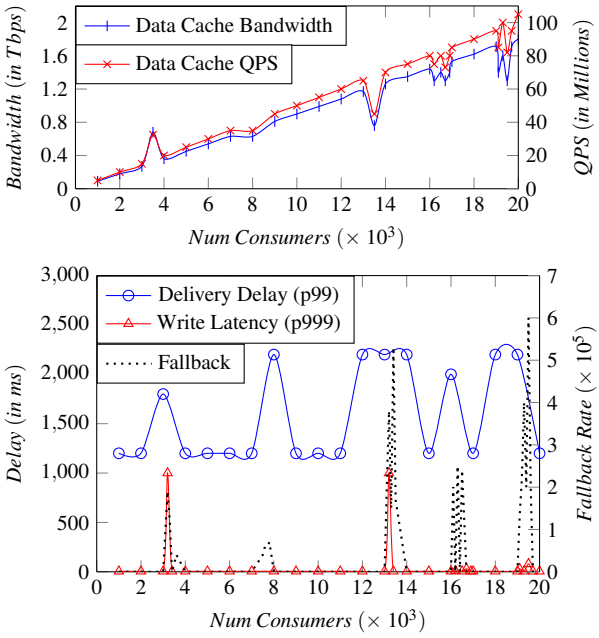

Figure 12: Results for experiment 2(a). Dips were observed in data cache bandwidth and QPS, attributed to two factors. First, the spikes in cache write latency. Second, the transient unavailability of the data cache during scale-ups. These dips were accompanied by fallbacks to Colossus.

The metadata cache also expanded, growing from 6 replicas to 81, which was 68% higher than the anticipated 48 replicas. This steeper-than-expected increase in the metadata cache was due to an uneven distribution of key-value pairs, particularly during scale-up events. This imbalance potentially overloaded certain replicas, triggering further scaling. Increasing the replication factor from r=3 to, say, r=10 could address the metadata cache overload issue, but it would come at the cost of increased tail latency during writes. Unfortunately, CliqueMap's current limitations only allowed for a replication factor of 3.

Another interesting observation is the fact that with 27x more data cache replicas after scale-up, we also increased the chunk storage capacity by 27x and so the TTL of chunks could have been as large as 30 minutes. However, in practice, consumers rarely experience such significant delays. We are exploring strategies to vertically scale-down the caches as they are horizontally-scaled.

Experiment 2(b) - Abrupt Scaling We scaled up the consumers suddenly from 0 to 6,500. While such large-scale increases in consumers are infrequent, they can occur in certain clusters during regional outages.

Observations: The peak data cache bandwidth surged to 645 Gbps, and the metadata cache QPS reached 6.24M. This abrupt increase triggered aggressive scaling in both caches, leading to a significant imbalance that necessitated further scaling. The data cache expanded from 18 to 406 replicas,

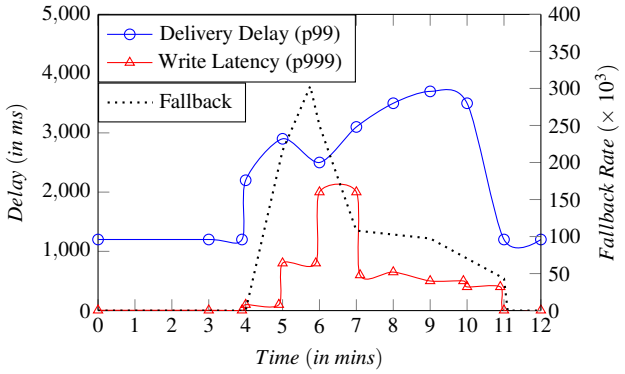

Figure 13: Results for experiment 2(b). The delivery delay was adversely affected for a period of several minutes. A significant number of Colossus fallbacks were observed during this time. Ultimately, the system stabilized and achieved a consistent delivery delay.

while the metadata cache grew from 6 to 29 replicas. During this period, prolonged cache read and write failures were observed, causing a substantial number of fallbacks to Colossus, peaking at 300,000 reads/second. Consequently, the p99 latency exported by monitors spiked beyond 3 seconds as shown in Figure 13. The system eventually recovered after 7 minutes, with delays subsiding to under 1.5 seconds. Once stabilized, the data and metadata caches scaled back down to 171 and 19 replicas respectively, to save resources.

Experiment 2(c) - Backlog Recovery Building on scenario 2(b), we initiated the test with 6,500 consumers, each passively capped at a read rate of 160 Mbps. We then stopped the producer for one of the message stream and started it after a 15-minutes delay. This action resulted in a substantial accumulation of messages awaiting extraction and delivery. Such scenarios can occur when a backlog of messages accumulates due to producer downtime.

Observations: After the producer restart, the peak bandwidth surged to over 1.6 Tbps as shown in Figure 14. This peak was temporary, lasting for only 2 minutes before settling down to 600 Gbps. Due to the transient nature of the spike, the data cache experienced only a minor scale-up from 171 to 184 replicas. The imposed limit on the read rate effectively managed the fan out. However, a significant delivery delay was observed, which eventually resolved once a steady state was reached.

5 Experiences

Development From early design to deployment, the system required an investment of 8 SWE-years. The development process added 17,500 lines of new, non-test C++ code.

The system underwent extensive testing before production deployment. We run regression tests in the pre-production environment before releasing to production. In production, we monitor the metrics outlined in the evaluation and offer

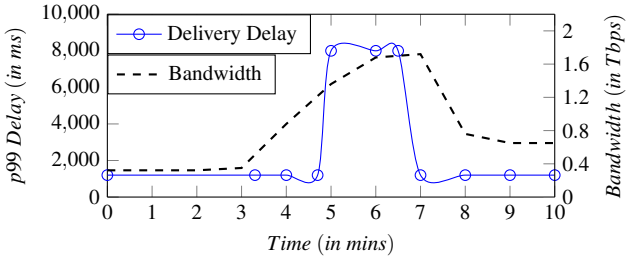

Figure 14: Results for experiment 2(c). A sudden surge in read bandwidth was observed, which lead to high delivery delay.

SLOs on latency and cache byte availability.

We have correctness monitors that ensure the bytes read by consumers exactly match the bytes written by producers. While incorrect bytes in compressed message streams would lead to decompression failures, some message streams are uncompressed where it would be particularly concerning if consumers successfully parse malformed messages.

Rollout Strategy Our system spans dozens of clusters, consisting of numerous jobs (with 3 to 400 replicas each) across scheduler, worker, and storage layers. This complexity necessitates a meticulous rollout strategy. During cache rollouts, we adopt a cautious approach, updating only one replica of a given key-shard at a time. After an update, the replicas are given time to repair their state by retrieving key-value pairs from other replicas.

Worker rollouts cause delay spikes due to throttling and reschedules. Fast rollouts (updating half the replicas at a time) can reduce reschedules but may cause hot-spotting. Conversely, slow rollouts (updating one replica at a time) increases reschedules. We have found that updating one-third of the replicas at once strikes a good balance between hot-spotting and reschedules.

Finally, we never rollout the scheduler and worker jobs together, ensuring scheduler availability during worker rollouts. The rollout strategy discussed so far is slow, sometimes taking several hours. We are continually refining our rollout strategy to strike a better balance between deployment speed and system stability.

Integration with Google Ads The Ads infrastructure relies on an Extract, Transform, and Load [51] pipeline. Extraction and transformation are intra-cluster operations primarily consisting of MapReduce [18, 55] jobs. They extract data from various sources such as transactional databases (e.g., Ads F1 [25, 46]), data warehouses (e.g., Napa [3] and Mesa [26]), and real-time log processors (e.g., Ubiq [48] and Photon [7]), and produce data that is loaded into the serving systems. The extraction and transformation jobs are replicated across a few selected clusters. For instance, each replica of real-time extractors resides in a cluster on a different continent.

The serving systems, on the other hand, are geographically distributed across dozens of clusters. Each job in the Ads

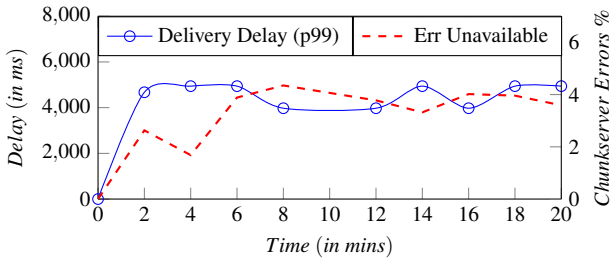

Figure 15: Case of data cache unavailability. Colossus chunkservers throttled read requests resulting in unavailability.

serving system has an in-memory state represented as key-value pairs that is used to serve requests efficiently.

An additional 7,600 lines of non-test C++ code was added for integration with the Ads infrastructure. Each shard of a Google Ads message stream contains two types of entities: *snapshots*, which are compact summaries of a message stream shard up to a logical time [36], and *updates*, which are continuous, ordered sequences of messages on top of the snapshots. The snapshots are used to build an initial server state and the updates are applied on top of it. Each message updates the value for a particular key. Snapshots are atomically copied across clusters by a batch system, while updates are handled by our system. Update files older than the recent snapshots are garbage-collected.

We migrated several Ads message streams to the new stack. The message delivery delay exported by monitors, measured over a day, shows p95, p99, p999, and p9999 latency of 500ms, 630ms, 730ms, and 5.71s respectively. These latency vary depending on the byte rate of the message stream. The largest message stream experienced a p9999 latency of 8.59s over a day. Even within a single message stream, some shards occasionally experience higher delays. The opportunistic reads in Colossus read operations have 96% hit rate, saving disk time on the read path.

We have also noticed latency spikes in certain message streams, some lasting several hours. A few of them were caused by bugs, often introduced due to code complexity. Deadlocks have been particularly challenging to debug because of their latent nature and inability of our cluster-local monitors to distinguish between producer-stopped streams and streams stopped due to worker deadlocks. Occasionally, our jobs were scheduled on bad machines, significantly impacting tail latency [17] without clear symptoms. In such situations, we resort to rescheduling such jobs based on system metrics. Other delays stemmed from infrequent intercontinental network issues caused by link outages. Although the routing process has automations to address this, the passive nature of the actions still results in delays.

Ablation Study In one scenario, the data cache was unavailable, whereas the metadata cache was available. We recorded a substantial QPS to Colossus chunkservers for several hours. Chunkservers throttle based on CPU, memory, and network time usage, in addition to disk time usage. Consumers experienced throttling resulting in unavailability for 3-5% of read requests, thereby resulting in a higher delivery delay (Figure 15). The slight delay intentionally introduced before reads from Colossus (Algorithm 1) proved effective in managing the QPS thereby resulting in a negligible CPU-related unavailability. The vast majority of unavailability (over 99%) stemmed from network congestion.

On another occasion, a faulty configuration push rendered both the data and metadata caches unavailable. We observed latency in the order of minutes, as the Colossus file length was polled directly from Bigtable at a much lower frequency.

Comparison with Predecessor The system before Fast ACS lacked the capability to handle large consumer fanout. With limited fanout, Fast ACS demonstrates greater tail latency stability due to the use of RMA. Furthermore, the adoption of RMA has led to a significant reduction in server-side CPU usage, resulting in cost savings exceeding one-third of the previous total cost.

6 Key Takeaways

This work yielded several valuable insights for designing scalable, low-latency messaging systems:

1. NIC capacity will be the bottleneck of future network-intensive computing: Given the limited near-term prospects for widespread terabit NIC deployment, achieving ordered data delivery at scale requires designs that efficiently utilize existing NIC capabilities. Our system addresses this by horizontally scaling resources to maximize cluster's NIC capacity utilization.

2. Ordered byte delivery does not need in-order transmission across the network: Instead, parallel out-of-order fetching of data chunks, followed by client-side reassembly, can effectively overcome server-side throughput constraints for low-latency delivery. This concept is already employed in web clients that perform parallel download of file chunks from multiple servers. Our system leverages this principle by chunking message files, pulling these chunks out-of-order, and then assembling and delivering them to consumers in the correct sequence. Through consistent chunk distribution, we also avoid hot-spotting in all scenarios.

3. RMA offers a powerful paradigm for building highly efficient software by minimizing server-side processing overhead: Our implementation strategically utilizes RMA on the client side, reserving server-side computation for fallback scenarios, thus providing significant resource savings.

7 Related Works

Distributed storage systems are evolving to leverage modern hardware capabilities. For example, NVM- and RDMA-aware HDFS [29] provides remote SSD reads for file bytes.

Octopus [57] enhances this further with low-latency file metadata access. Colossus also supports similar functionality with SSDs and CliqueMap, too, can use SSDs as the underlying storage. However, SSDs are not ideal for our needs for several reasons. First, their lifespan would be limited due to wear-leveling caused by continuous writes. Second, they offer lower read throughput and higher latency compared to RAM. Third, our hot storage requirements are minimal, not justifying the capacity of SSDs.

Tachyon [37] is an RMA-based in-memory file system available for big data processing. However, it is not optimized for tail reading due to its large block sizes, which can lead to hot-spots on the tail block servers. Reducing the block size can help, but it may lead to latency hits on read path since block metadata access still relies on RPCs. Our approach of distributing 4 KB chunks as key-value pairs significantly reduces hot-spotting during tail reads.

Memcache [40] is a popular productionized distributed in-memory key-value store. It provides low-latency storage and lookup and integrates well with external sharding engines like Slicer [2] to offer scalability. However, we decided to use CliqueMap due to two reasons. First, CliqueMap supports replication out-of-the-box, which makes it resilient to a single point of failure and makes our rollout process simple, unlike Memcache, which requires certain wrappers to support replication. Second, CliqueMap makes use of RMA on the read path, achieving significantly higher throughput and saving valuable server-side CPU while maintaining a comparable median latency. Other RMA key-value systems like FaRM-KV [20] could provide serialized consistent lookups using primary/backup architecture; however, serialization-based consistency was not required in our design, and so we opted for a simpler quorum-based system. Pilaf [39] is one such RMA KV-store with quorum-based support and resembles performance similar to CliqueMap. However, CliqueMap is already productionized at Google and serves as a backend for critical infrastructures in Ads, Maps, and YouTube.

Lastly, while there is extensive research on userspace file systems like FUSE [50] and its extension, extFUSE [8], which provide a VFS-like interface for creating custom file systems, we chose not to use them. First, our needs were limited to dealing with files, not directories. This allowed us to utilize hash-based addressing instead of a hierarchical file system and a key-value store was a natural fit. Second, our caching file system was essentially a reflection of the underlying Colossus file system supporting append-only files. Implementing a full file system was unnecessary.

8 Future Work

To ensure fair and efficient caching for a growing number of message streams, we are exploring key-space isolation to prevent resource contention. Currently, the shared data cache can be overused by individual streams, impacting others. By providing dedicated cache space, each stream can independently manage its usage and chunk expiration, improving overall system stability and fairness.

Each Google cluster has a capacity limit ranging from hundreds to tens of thousands of machines. During experiment 2, we observed that multiple consumers were running on the same machines, sometimes up to 10. One effective technique to limit intra-cluster bandwidth would be to implement a sidecar ambassador process [9] that retrieves messages onto local machines and relays them to consumers. This approach would allow us to scale up to millions of consumers per cluster while enforcing a limit on anticipated data cache bandwidth and metadata cache QPS.

In experiment 2, we observed that the primary factor driving up the latency was the increased consumer polling interval. Reducing the polling interval can help bring down latency but can cause QPS limits breach on the metadata cache. There can be many strategies to mitigate the QPS problem. First, the bandwidth utilization per metadata cache replica is low and so the network is essentially non-constraining; the QPS limits can be raised by increasing the number of software RMA endpoints. Second, because the write QPS is much lower than read QPS, we can combine metadata for multiple files into a single key-value pair. This combination can be automated based on the consumer read pattern.

Finally, we are investigating the potential of RMA and other network enhancements to improve performance in broader scenarios, such as cross-cluster RMA-based reads. However, current network deployment limitations prevent us from supporting this functionality in all cases.

9 Conclusion

This paper presents the design of Fast ACS, a file-based ordered message delivery system. At its core is a multi-layer storage that has been demonstrated to be a valuable component, helping the system achieve Tbps-scale consumer fan-out per cluster and deliver messages with minimal latency. This system has been widely deployed in production.

Acknowledgments

We gratefully acknowledge contributions to the design and implementation of the system from many colleagues at Google. Special mention for Aman Shaikh, Apar Madan, Ayush Jha, Ben T. Harper, Bin Lyu, Chen-Han Ho, Connor Quagliana, Erin Rovelstad, Florentina I. Popovici, Hongchen Li, Lily Chen, Manav Prajapati, Mengjie Xia, Nick Golob, Paul D. Bartlett, Serafi Zanikolas, Sucharitha Vasudevan, Tao Huang, and Youer Pu. We also thank Jeff Mogul, Tao Huang, and Ashish Gupta for their helpful suggestions on the presentation of the work. Finally, we thank the anonymous reviewers and our shepherd, Fernando Pedone, for their feedback.

A Formal Specification for Dueling Writers

We developed a formal specification for the system, which consists of multiple writers for the cache file and a single writer for the corresponding Colossus file. The system was modeled using TLA+ [35]. The goal was to check for correctness of the system, manifested in the following way:

- *Safety*: Consumers receive bytes strictly in the order they were produced. This is formally expressed by the following invariant:

  $Invariant ==$

  $$\wedge\ readBytes = [i \in 1..Len(readBytes) \mapsto kBytes[i]]$$

  where *readBytes* are the bytes read by the consumer and *kBytes* are the bytes written by the producer in source.

- *Eventual Progress*: The consumers eventually receives all the bytes. Formally, the following property is satisfied:

  $Termination ==$

  $$\Diamond\ ((pc = \text{“}done\text{”}) \implies (readBytes = kBytes))$$

  where *pc = "done"* is the termination marker.

The system's safety is intuitively clear: data cache chunks always contain the correct bytes, if present, corresponding to the file positions, and each chunk write is atomic. The corresponding Colossus file serves as a safety net for partially-filled or missing chunks.

Eventual progress is ensured because the Colossus file continually grows in length, eventually forcing consumers to fall back and fetch bytes directly from Colossus.

We used the TLA+ Model Checker [54] to verify the specification under two configurations:

- *Configuration 1*: 4 chunks, each with 4 bytes, and 2 cache writers. This resulted in 85,690,897 distinct states.

- *Configuration 2*: 2 chunks, each with 2 bytes, and 4 cache writers. This resulted in 12,062,699 distinct states.

In both runs, the model checker successfully verified the system's safety and eventual progress.

Abstract

Coldstart introduces a significant latency penalty in cloud computing. While several previous works have proposed mechanisms such as warm start, fast snapshot recovery, lightweight isolation, and fast image download to avoid or mitigate this issue, image provisioning remains underexplored despite being critical.

In this paper, we propose `Poby`, a software-hardware collaborative system that offloads and accelerates critical operations of image provisioning using SmartNICs. Specifically, `Poby` embodies a disaggregated architecture that offloads different image provisioning operations to the appropriate hardware such as embedded CPUs and domain-specific hardware accelerators for optimal performance. It uses a pipeline-based, data-driven workflow to eliminate delays caused by the serial execution of image provisioning operations. Moreover, it contains a distributed image provisioning scheme to alleviate the performance bottlenecks of conventional centralized registries. We implement the entire `Poby` system using BlueField SmartNICs and evaluate its performance using various microservice and FaaS benchmark suites. The results demonstrate that `Poby` outperforms two industry-standard container platforms, containerd and iSulad, with speedups of 13.2× and 8.0×, respectively. In addition, compared to iSulad, it reduces host CPU usage by 87.5%.

1 Introduction

Cloud computing has long promised on-demand scaling since its inception. This feature allows the cloud system to automatically adjust hardware resources to meet the dynamic needs of cloud applications, eliminating the need for human intervention. However, this convenience also presents significant challenges in cloud management. The coldstart problem is one of the prominent performance issues [5, 64, 83]. When an incoming request triggers an on-demand container creation and runtime initialization, the response time can be significantly longer - almost 10× compared against a warm startup [41], which negatively impacts the user experience.

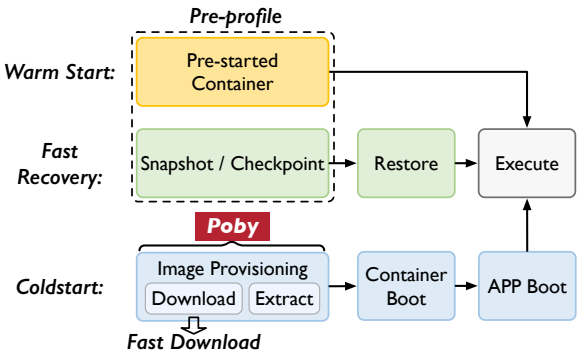

Figure 1: Overview of optimizations for coldstart.

Within coldstart, the most time-consuming step is *image provisioning*, which involves *downloading* and *extracting* large images from remote storage into local memory. Therefore, as shown in Figure 1, state-of-the-art (SOTA) work towards coldstart mainly focuses on the image provisioning part. The *warm start* method [1, 8, 51, 60, 61, 64, 68] prestarts containers before invocation and keeps them running continuously. However, this introduces considerable resource overhead and breaks the promise of on-demand scaling. The *fast recovery* method [3, 11, 19, 54, 62, 73, 80], which relies on snapshots or checkpoints to boot containers, avoids the time-consuming image provisioning process. Still, this approach incurs substantial storage overheads and requires containers to be stateless, which is challenging in production environments.

Both warm start and fast recovery methods attempt to *bypass* the image provisioning part. However, in fact, it is impossible to completely avoid coldstart in the production environment, such as warm start prediction errors, the first request to a newly uploaded function, and so on. In such scenarios, some work directly *accelerates* the image provisioning part, such as accelerating image download through a peer-to-peer approach [10, 39, 72, 76] (*fast download*). Nevertheless, we identify a counter-intuitive issue where *image extraction* takes more time than *image download*. The *extraction* step, which

†Corresponding authors.

decompresses and unpacks image files to initiate the container booting process, consumes over 68.8% of the overall image provisioning latency (details in §2.2).

To accelerate the entire image provisioning process for coldstart, we propose a software-hardware collaborative system named Poby. Instead of consuming valuable host CPU resources for compute-intensive tasks such as image compression and extraction, we offload those tasks directly onto modern SmartNICs with specific hardware accelerators for better performance and reduced CPU usage. In addition, most modern SmartNICs natively support zero-copy network protocols such as RDMA [14, 16, 48, 53], thus enabling low-latency and high-bandwidth image downloads.

However, porting image provisioning to SmartNIC is a nontrivial task due to the following three reasons. Firstly, the embedded CPUs of existing SoC-based SmartNIC lack sufficient computing power. Naively offloading the entire image provisioning process to SmartNIC can be counterproductive. Secondly, the sequential execution of the image provisioning operations causes significant waiting delays. This issue worsens on SmartNIC because images must be transferred between the NIC memory and the host memory. Finally, the high-bandwidth image download via RDMA could also overload the centralized image registry, potentially creating a new performance bottleneck.

To address these challenges, we design and implement a *disaggregated architecture* in Poby, which offloads various image provisioning operations, including control of image provisioning, image downloads, image decompression, and image unpacking, to optimal hardware such as the embedded SmartNIC CPU, the RDMA logic, the decompression accelerator, and the host CPU, accordingly. Poby features a *pipeline-based data-driven workflow* to eliminate the waiting delay introduced by serial execution of image provisioning operations. Furthermore, Poby *decentralizes the image registry* to alleviate the potential performance bottlenecks of the conventional centralized registry.

In this paper, we implement Poby using the Nvidia BlueField-2 SmartNIC [14], which is equipped with eight ARMv8 A72 CPUs and various domain-specific hardware accelerators for network and storage. We build a dual-card prototyping system to evaluate the effectiveness, efficiency, and scalability of the proposed design. Our evaluation shows that in comparison to the SOTA implementations containerd [23] and iSulad [55], Poby achieves 13.2× and 8.0× speed-ups, respectively. Furthermore, compared to the SOTA image download works Kraken and FaaSNET, which use high-performance host CPUs, Poby achieves comparable scalability using the embedded SmartNIC CPUs.

To the best of our knowledge, Poby is the first software-hardware collaborative system to accelerate the complete image provisioning process for coldstart. In summary, we make the following contributions:

- We observe that image extraction is critical but time-consuming for image provisioning. Accelerating the entire image provisioning process is essential to mitigate the coldstart overhead.
- We propose a novel software-hardware collaborative system named Poby, which features disaggregated architecture, pipeline-based data-driven workflow, and decentralized image registry to accelerate the end-to-end image provisioning process.
- We prototype and evaluate Poby on BlueField-2 SmartNICs with realistic cloud workloads and demonstrate that Poby achieves up to 13.2× performance improvements over prior works.

2 Background and Motivation

2.1 Coldstart and Prior Optimizations

Coldstart is a classic problem in cloud computing, especially in container-based microservice architecture and serverless computing. For flexible service management, large-scale online service providers deploy single-purpose microservices or fine-grained function instances into containers, which offer a lightweight and isolated virtualization environment. In such cases, a coldstart refers to the delay caused by inactivity when a microservice instance or function is first invoked. In addition, a surge in service requests will also trigger a large number of coldstarts. A complete coldstart process consists of three steps: (i) preparing the container images (including download, decompress and unpack), (ii) launching the container, and (iii) initializing the application. Unfortunately, the coldstart process can be time-consuming and may potentially bottleneck the overall system performance.

The container image encompasses all the necessary components for a container to operate. According to the OCI Image specification [27], the image is composed of an image manifest and a collection of filesystem layers. The manifest is a general description and a list of layers contained in the image. The layers themselves are compressed filesystems and changes of the filesystem. These layers can be serialized to a container filesystem according to the manifest.

Limitations of prior optimizations. As shown in Figure 1, various optimization technologies have been proposed to alleviate the coldstart overhead. However, these solutions still suffer from different limitations:

- *Fast download.* Some works [39, 72, 76] focus on optimizing the image download. They apply a peer-to-peer (P2P) approach to accelerate image download and improve the scalability. Although image download is one of the most time-consuming operations within coldstart, they ignore the overhead of image extraction, i.e., decompressing and unpacking the downloaded images before launching the container. Note that image extraction is also a critical phase in coldstart (see details in §2.2). Works like [10, 39, 76]

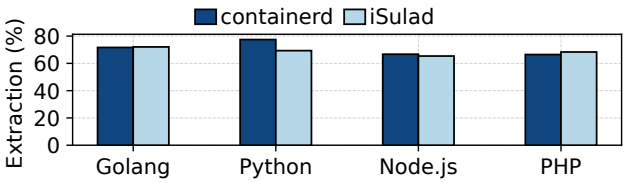

Figure 2: Relative extraction time in image provisioning.

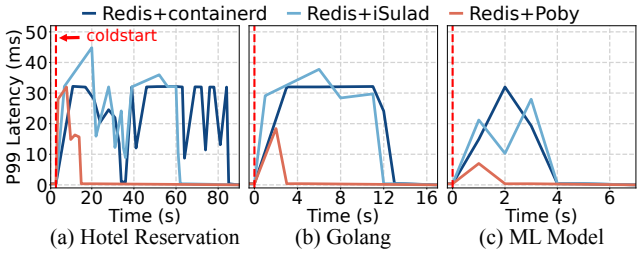

adopt new image formats to enable on-demand downloading and decompression, but this makes them completely incompatible with traditional image distribution systems.

- *Fast recovery.* Some studies maintain the *snapshot* / *checkpoint* of a booted container in memory [11, 54, 80–82] or storage [3, 19, 33, 62, 73] for *fast recovery*. In this way, these systems bypass the image provisioning when starting a previously launched container. However, the diversity of microservices and function instances poses considerable challenges for the management of numerous snapshots. Firstly, it requires a substantial amount of memory or storage to create and maintain snapshots of booted containers. Secondly, the application in the container snapshot must be *stateless*. This means that it cannot retain any information about previous interactions. Because recovering stateful data (e.g., timestamps, statistics, and request data) from the snapshot can introduce anomalies and privacy concerns.
- *Warm start.* Prior works [6, 13, 49, 75] adopt the *keep-alive* strategy to avoid the coldstart penalty. However, such approaches incur additional overhead for running containers even when there are no requests. On the one hand, such overhead is unacceptable for platforms that manage a large number of containers. On the other hand, it breaks the fundamental promise of *pay-as-you-go* in cloud computing. To reduce the keep-alive overhead, several studies [1, 8, 61, 64] predict the occurrence of coldstart and preemptively start containers. But this approach requires much effort to learn coldstart patterns for high prediction accuracy, and is ineffective for newly deployed images. Other works [51, 60, 68] maintain a shared container pool to reduce overhead, while this approach is not applicable to user-provided images.

2.2 Motivation

When looking into the coldstart process, the following three observations motivate us to completely address this issue.

① **Coldstart from image provisioning is inevitable.** Existing approaches such as fast recovery and warm start aim to bypass image provisioning at the cost of massive memory caching. However, (i) it is not cost-effective to cache *all* containers in memory. For example, CodeCrunch [6], a SOTA warm start work, achieves an 80% warm start rate with surprisingly over 90 TB peak memory usage. Thus it is impractical and inefficient to cache all the containers in limited memory resources, since requests are concentrated on a subset of hot containers [64, 76, 81]. (ii) Some works [1, 8, 61, 64] try to predict the upcoming needs for containers and provide on-demand

(a) Hotel Reservation (b) Golang (c) ML Model

Figure 3: Tail latency of Redis when colocated individually with containerd, iSulad, and `Poby` during the coldstart.

memory caching to reduce memory costs. However, these predictions are by no means completely accurate, especially in production. According to the trace of Alibaba Cloud [17], the average coldstart frequency for each container in the platform still exceeds 130 times in one day.

② **Image provisioning is the most time-consuming step of coldstart.** According to the statistics [76] of 712,295 coldstart operations for containerized functions within 15 days from Alibaba Cloud, over half of function requests spend at least 72% of the total time on image provisioning. And more than 57% of these operations take at least 45 seconds. Although factors such as image size, compression rate, and the number of layers may impact the processing time, image provisioning remains the most time-consuming step of coldstart [51, 68, 74].

③ **Recent efforts ignore the image extraction process.** Existing works only focus on accelerating the image download [39, 72, 76], overlooking the extraction process of image provisioning. Remarkably, we find that image extraction (i) is not only the de facto performance bottleneck in image provisioning (ii) but also introduces severe performance interference to other applications.

- *Performance bottleneck.* Figure 2 evaluates the image extraction time of two well-known container solutions, containerd [23] and iSulad [55], across language runtimes of different sizes. Notably, the image extraction takes more than 68.8% of the image provisioning time in all kinds of runtimes.
- *Performance interference.* Figure 3 evaluates the performance interference of Redis when colocated with containerd and iSulad, respectively. We measure the latency of Redis during the extraction of three image sizes (see Table 1). The latency of Redis increased by over 110 × due to colocation. This is attributed to the resource-intensive nature of image extraction, which involves decompression and file writing. Firstly, decompression is CPU-intensive, as it executes intricate decoding operations to reverse complex encoding patterns. Secondly, the unpacking operation requires writing a large number of small files in images, which demands frequent CPU involvement.

Thus, we argue that the image extraction should be carefully re-examined and accelerated.

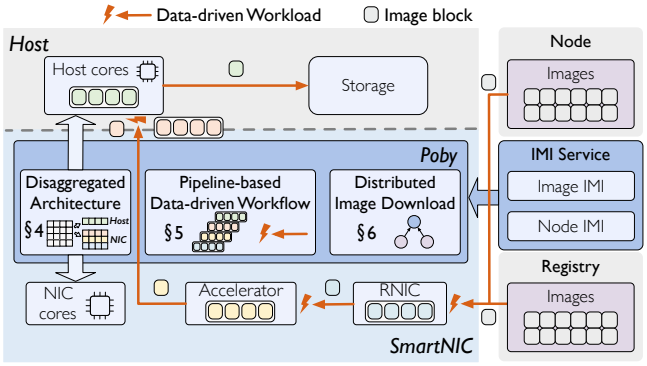

Figure 4: Overview of the Poby system.

3 Poby Overview

Poby is a novel software-and-hardware collaborative system designed to accelerate image provisioning of the coldstart process. The overall architecture is shown in Figure 4. As can be seen, a key feature of Poby is its ability to offload critical tasks related to image provisioning onto modern SmartNICs, thus achieving hardware acceleration using domain-specific accelerators, as well as saving valuable host CPU resources from processing cloud infrastructure tasks.

We define the following main ***goals*** for Poby:

- ***Performance*:** Poby aims to complement existing mitigation methods by accelerating the overlooked decompression process, and fundamentally resolve the coldstart issue.
- ***Resource*:** Poby offloads coldstart to SmartNIC for reducing resource contention and datacenter *tax* [29].
- ***Compatibility*:** Poby provides an optional auxiliary acceleration capability for coldstart, it does not refactor the original design and software stack of container platforms.

In recent years, SmartNICs have been widely adopted in data centers [21, 28, 69] and many researches apply SmartNIC to offload applications such as storage [38, 50], distributed system [31, 63], and network protocol [4, 32, 52, 65]. In this work, we take advantage of several key features of modern SmartNICs. For example, they natively support zero-copy network protocols such as RDMA, potentially enabling low-latency and high-bandwidth image download. In addition, SmartNICs embody hardware accelerators and computing engines for various scenarios including data compression and management, thus ideally suitable for accelerating image extraction and addressing resource contention issues.

3.1 Challenges

Although accelerating the image provisioning by the SmartNIC seems intuitive, it is non-trivial to put into practice due to the following Challenges.

C1: Offloading dilemma. The strawman solution that offloads the complete image provisioning onto the SmartNIC cannot achieve good performance. The reasons accounting for this include two aspects. Firstly, the on-NIC CPU of existing SoC-based SmartNICs is wimpy, which is only suitable for offloading applications with low IPC (instructions per cycle) or high cache MPKI (misses per kilo-instruction) [31, 44, 78]. That is to say, the performance of image extraction on the NIC is much lower than on the host. Secondly, even if we offload the image extraction to the specific hardware accelerator or customized FPGA module, the transmission of numerous extracted files becomes the new bottleneck. Here, most container images are comprised of many layers.

C2: Serial execution of image provisioning. The serial execution of image provisioning operations is a typical store-and-forward workflow, which results in significant waiting delays. Specifically, each operation must suffer a delay of waiting for the previous operation to complete, even if the preceding operation is a time-consuming operation like downloading and decompression. This issue is particularly severe for latency-sensitive and large containers. In addition, offloading image provisioning to the SmartNIC introduces an additional operation of transferring image data from the NIC memory to the host memory, which exacerbates the problem.

C3: Centralized image registry. Although RDMA can boost image download performance, the classic centralized image registry remains a bottleneck. Our tests reveal that concurrent downloads from eight nodes to one registry cause a 10× and 6× increase in latency with TCP and RDMA, respectively. Traditionally, cloud providers mitigate this by scaling registry nodes and using the load balancer. However, prior research shows that requests to a single service can spike dramatically, incurring hundreds of nodes to pull the same images simultaneously [10, 64, 76]. This necessitates deploying numerous additional registries, contradicting our design goal. Moreover, the centralized registry struggles with RDMA scalability. The RDMA NIC (RNIC) of the registry has to frequently switch the queue pair information in its cache to transmit images to different hosts, which seriously impacts the performance.

3.2 Poby Design

As shown in Figure 4, Poby integrates three solutions to accelerate image provisioning. The key insight of Poby is to orchestrate appropriate hardware resources of the entire cluster to accelerate different operations within image provisioning. In a nutshell, Poby executes the fine-grained operations of image provisioning atop the RNICs, on-NIC CPU, hardware accelerators, and host CPU. In addition, Poby assumes that images are compressed in gzip format, which is the most widely used format, accounting for as much as 96.3% of all images in Docker Hub [85]. The design of Poby is orthogonal to the compression format and compatible with other formats.

Disaggregated architecture (§4). Poby devises a *disaggregated architecture* to offload different operations of image provisioning to appropriate places (**C1 addressed**). Firstly,

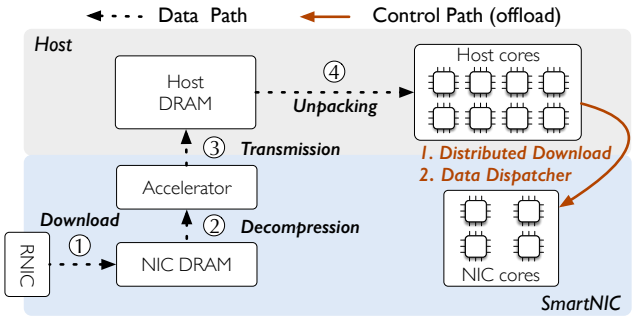

Figure 5: Disaggregated architecture of Poby.

we offload the control of the entire image provisioning to the on-NIC CPU, whose computing overhead is acceptable for its wimpy CPU. Secondly, we download the image via RDMA to fully utilize the high-bandwidth transmission capability of modern SmartNICs. Thirdly, we decompress the downloaded images at the hardware decompression accelerator to achieve better performance. Finally, we transmit the decompressed images from the NIC to the host via PCIe and unpack them by the host CPU, which eliminates the performance bottleneck of transmitting numerous small files.

Pipeline-based data-driven workflow (§5). Poby adopts a *pipeline-based data-driven workflow* to eliminate the waiting delay introduced by the classic sequential execution of coldstart (**C2 addressed**). To enable the pipeline-based data path, images are downloaded, decompressed, transmitted, and unpacked at the granularity of blocks (e.g., 16 MB) in Poby. Thus, the download, decompression, transmission, and unpacking for different data blocks can be executed at the same time, improving the efficiency of image provisioning. However, the finer-grained data path introduces more control information to manage all pipeline blocks. For example, a 37-layer image with a total size of 2.45G can be divided into 189 pipeline blocks (16MB). Poby further utilizes data-driven workflow to reduce the overhead of additional control information. Specifically, we integrate the control command into data blocks. Then, each component in Poby executes the subsequent operations based on the control command in its received data block. This minimizes the transmission of control command and execution status.

Distributed image download (§6). Poby decentralizes the image registry to alleviate the performance bottlenecks of the conventional centralized registry (**C3 addressed**). Specifically, Poby adopts a *best-effort* strategy to currently download the image from multiple nodes who happen to own the required images. In this way, Poby avoids the significant storage overhead of distributed nodes *actively caching images*. To enable this, we first devise the *image metadata index* (IMI) to hold the available image locations and node transmission workload. Poby makes the download plan based on the IMI to ensure the load balance between distributed nodes. Here, our best-effort strategy allows Poby to download images from the original registry when no node contains the required image or the retrieved IMI is inconsistent.

Discussion. The design of Poby, based on workflow accelerating, is orthogonal to most existing studies as it focuses on optimizing the inherent processes of coldstart. For example, the disaggregated architecture and pipeline-based data-driven workflow can accelerate *warm start* and subsequent processes of *fast download*. Even for *on-demand download* works that adopt new image formats, Poby can still accelerate image processing for the lazy download process.

4 Disaggregated Architecture

Poby proposes a disaggregated architecture that orchestrates resources of the entire cluster to accelerate image provisioning for coldstart. Figure 5 illustrates the details of the architecture, composed of a *data path* (§4.1) and a *control path* (§4.2).

4.1 Data Path

The key idea behind Poby data path is to put different operations into the right hardware components to maximize performance gains. Existing container solutions are typically monolithic, with a single server responsible for the entire image provisioning process. In contrast, Poby disaggregates this monolithic architecture into separate components and offloads them to specialized hardware units, including on-NIC CPU, decompression accelerator, and host CPU. Furthermore, we decouple the image extraction into *image decompression* and *image unpacking*. Along with the image transmission between the NIC and host memory (discussed in **C2**), the entire data path of image provisioning currently includes four operations: image download, image decompression, image unpacking, and image transmission. Here, this decoupling between image decompression and image unpacking brings three benefits.

① **New execution order bypassing bottleneck.** The decoupling enables reordering the execution of image unpacking and image transmission. Specifically, Poby executes the data path in the following order. Firstly, Poby downloads the images via RDMA to its SmartNIC memory. Secondly, Poby decompresses the downloaded images using the hardware accelerator. Thirdly, Poby directly transmits the decompressed images from the accelerator to the host memory. Finally, Poby unpacks the decompressed images on the host CPU.

Note that this execution order bypasses the performance bottleneck discussed in **C1**. On the one hand, image unpacking on the host can avoid the overhead of unpacking on the weak on-NIC CPU. On the other hand, transmission for a large decompressed file is much more friendly to PCIe than numerous small unpacked files. Because each file writing operation involves multiple PCIe transactions (such as DMA transfers and interrupt requests). When unpacking a file with numerous small files, writing these files to disk can saturate

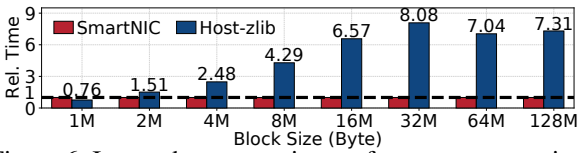

Figure 6: Image decompression performance comparison.

the PCIe bus with a large number of transactions and small data, thus reducing the effective bandwidth utilization.

② **Network-wide collaborative enhancement.** This decoupling permits the architecture to be further disaggregated across multiple nodes. Therefore, we can perform image decompression at the hardware accelerator of remote hosts and then download the decompressed images via RDMA. Here, our on-NIC controller can distinguish whether the received image data is raw or decompressed according to block_status (detail in § 5.2). It then dispatches the data to the local hardware accelerator or directly to the host memory depending on the data type. This collaborative architecture can be applied to the following two scenarios: (1) the local hardware accelerator is busy or occupied by other tasks; and (2) nodes in the cluster are only equipped with RDMA NICs but no SmartNICs. This approach is in line with our design principle, i.e., orchestrating hardware resources of the entire cluster to accelerate image provisioning. As a result, this further reduces the demands of `Poby` for SmartNIC and increases the utilization of accelerators.

Although decompressing the image first greatly increases the amount of data transferred, this is acceptable for two reasons. Firstly, current RDMA hardware offers up to 200 Gbps of transmission bandwidth with μs-scale latency, which significantly reduces the transmission latency of images. Secondly, the hardware accelerator decompresses images much faster than the host (Figure 6), reducing the additional overhead introduced by transmitting decompressed images.

③ **Performance benefits for decompression.** The image decompression itself can benefit from the hardware decompression accelerator of existing SmartNICs. Figure 6 compares the time that decompresses images of different sizes using the hardware accelerator and the classic `zlib` [47] on the host. As the block size increases, the decompression time of `zlib` increases significantly, far exceeding that of the accelerator. Furthermore, for blocks larger than 16 MB, the accelerator reduces the decompression latency by 7× on average. Note that the decompression time of blocks varies depending on the data pattern, leading to fluctuations (e.g., 32 MB).

4.2 Control Path

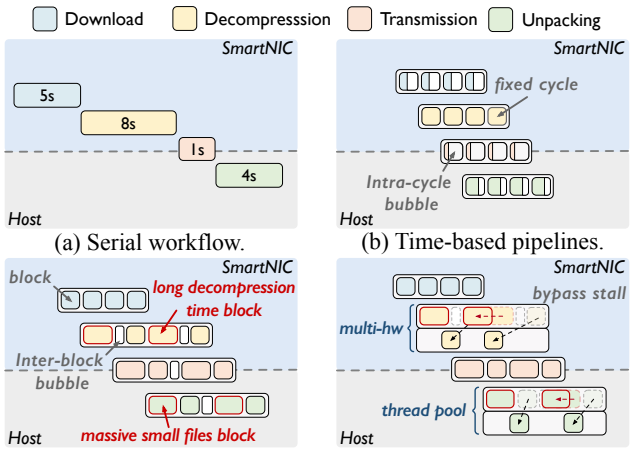
The control path of `Poby` coordinates the execution workflow of image provisioning. Specifically, the control path includes an *application programming interface (API) agent* running on the host and an *on-NIC controller*.

API agent. The API agent ensures compatibility with the original interface of the existing container service (e.g., Docker API). When the host issues a command to perform a coldstart, our API agent sends this request to the on-NIC controller. When the image provisioning ends, the agent returns the control back to the container service to launch the container.

On-NIC controller. The on-NIC controller is responsible for two functionalities. (1) It manages the distributed image download, including the maintenance of RDMA contexts, the retrieval for IMIs, and the decision-making (i.e., download layer from which host) for distributed downloads (see §6). The on-NIC controller adopts a lazy destruction strategy to reuse existing RDMA connections, minimizing the overhead of frequent connection creation and teardown. (2) It dispatches different types of downloaded image data to the corresponding places in the data path (see §4.1).

The offloaded on-NIC controller brings the following three benefits. Firstly, it decreases host resource usage, allowing hosts to run more business applications. Secondly, the on-NIC controller further reduces the transmission delay of commands for the control path. Finally, the operations of the control path are not compute-intensive, offloading them to the weak on-NIC CPU will not cause overload.

5 Pipeline-based Data-driven Workflow



`Poby` introduces a pipeline-based data-driven workflow to enhance the efficiency of classical serial execution (Figure 7a). This section investigates two critical questions: (i) What is the best way to split the pipeline? (§5.1) and (ii) How should the pipeline execution be scheduled? (§5.2).

5.1 Pipeline-based Data Path

Strawman solutions. `Poby` decomposes the original data path into four operations: download, decompression, transmission, and unpacking. These operations support streaming processing, where the partial output of one operation can serve as the input for the next. Thus, `Poby` executes them in a pipeline-based manner to enhance parallelism. However, common pipeline designs face significant performance issues when applied to image provisioning.

- *Layer-based pipelines:* Common in prior studies [23, 55, 72], they parallelize image provisioning at the layer granularity. The small number of image layers and the substantial size variations between them result in overly coarse granularity, limiting parallelism.
- *Time-based pipelines:* This approach segments processing into fixed-length time periods (Figure 7b). Variability in hardware performance introduces pipeline bubbles, as some stages must wait for others to finish. For example, the 100 Gbps RDMA wastes most of each cycle waiting for the 30 Gbps decompression accelerator.

Block-based redundant pipelines. `Poby` proposes block-based redundant hardware pipelines to enhance pipeline par-

(a) Serial workflow. (b) Time-based pipelines.

(c) Block-based pipelines. (d) Redundant pipelines (Poby).

Figure 7: Different designs of pipeline-based workflow.

allelism and address pipeline bubbles. Poby divides images into fixed-size data *blocks*, which are simple subdivisions of layers, requiring no additional processing. This enables parallel processing of blocks within a layer, tackling the low parallelism of layer-based pipelines. However, this approach still faces two significant issues.

Issue 1: Pipeline bubbles. Block-based pipelines still encounter pipeline bubbles. The primary factors contributing to these bubbles (Figure 7c) are:

- Differences in compression ratios cause varying sizes of decompressed blocks, leading to inconsistent decompression times. Figure 8 shows that the decompression time can vary by over 3.5× for 128 MB blocks from different images.
- Data blocks with massive small files take considerably longer to unpack, increasing processing time compared to blocks with fewer files.

To alleviate these bubbles, Poby constructs *redundant* hardware pipelines. Figure 7d illustrates the redundant hardware mechanism. For the decompression stage, Poby prioritizes the round-robin strategy to schedule blocks to local accelerators. When no local accelerators are available, Poby notifies the sender via the existing connection to decompress blocks before transmitting. For the unpacking stage, Poby maintains a dedicated unpacking thread pool on the host side and exploits the kernel scheduler to manage it. If a new block arrives while the previous one is still being unpacked, the new block will be scheduled to available cores.

Issue 2: Block size. Block-based pipelines face the classic pipeline cycle decision dilemma.

- A small block size wastes most of the time switching and setting environments, reducing pipeline efficiency. Figure 8 shows that the accelerator incurs a 6.9 ms startup time.
- A large block size reduces the parallelism of pipelines or even degenerates into layer-based pipelines.

To achieve high efficiency, Poby adopts an empirical value, 16 MB, as the block size. Firstly, a 16 MB block can amortize the startup time of decompression (Figure 8), which we speculate is related to hardware configuration and the minimum data processing granularity of the accelerator. Secondly, over 80% of the small layers are less than 16 MB [85], a 16MB block strikes a balance between the pipelining of large layers and the switching overhead of small blocks. In addition, the efficiency of the 16 MB block is also confirmed by *Exp#5*.

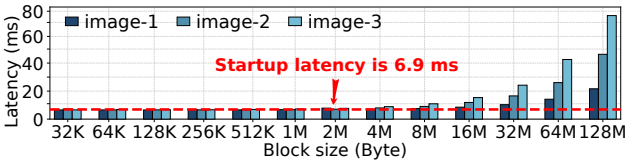


Figure 8: The decompression latency of SmartNIC with different block sizes and images.

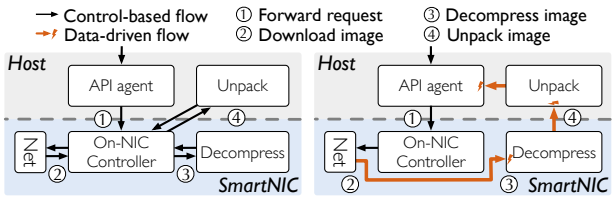
5.2 Data-driven Workflow

Issues with control-driven workflows. The block-based pipeline introduces a significant amount of control information into the conventional *control-driven workflow*. Figure 9 illustrates such a workflow, where the centralized on-NIC controller coordinates the execution of each decomposed image provisioning operation. The controller uses control messages to interact with hardware components, determining the start, completion, and downstream of operations. In block-based pipelines, images are split into numerous blocks, each requiring control information for orchestration. This consumes substantial resources and limits the concurrency of pipelines.

Data-driven workflow in Poby. Poby proposes a *data-driven workflow* to schedule the execution of block-based pipelines, eliminating the overhead of control messages. Instead of relying on centralized control, Poby integrates state information into data blocks and dynamically updates the information during execution. Each block contains two pieces of state information. (i) The block_index specifies the position of a block in the layer and image, along with the total number of blocks in the corresponding layer. (ii) The block_status indicates whether the block is compressed or not.

The complete pipeline-based data-driven workflow of Poby is as follows:

(1) The API agent parses the requests from users and sends them to the on-NIC controller.



(2) The on-NIC controller retrieves the locations of the image and establishes network connections to get image blocks.

(3) The download operation receives the block and assigns it based on block_status to (i) available decompression queues (round-robin strategy) and (ii) transmission queue.

(4) The accelerator decompresses the blocks in its queue and assigns them to the transmission queue when completed.

(5) The transfer engine sends the blocks in its task queue to the host side and notifies the unpacking thread pool.

(6) The unpacking thread pool assigns worker threads to process blocks, updates progress and completion to the API

(a) Control-driven workflow. (b) Data-driven workflow (Poby).

Figure 9: Different designs of workflow models.

agent according to the block_status.

(7) All operations perform as above until its queue is empty.

This data-driven workflow of Poby provides two major advantages. (i) The pipeline becomes self-driven, removing dependency on the on-NIC controller. In this workflow, hardware components track block statuses and pass them to subsequent stages upon completion. As shown in Figure 9b, the pipeline autonomously operates without requiring control-path intervention after initialization. (ii) Each block is uniquely identified, enabling precise tracking of provisioning. Firstly, Poby leverages block_index to assess provisioning progress. For example, when the final block of a layer is processed, the corresponding image step is considered complete. Secondly, using the block_status, Poby can bypass the decompression accelerator by sending remotely decompressed blocks (see §4.1) directly to the host for unpacking.

6 Distributed Image Download

The distributed image download of Poby is transparent to the host and incurs no additional overhead. Existing distributed image download studies [7, 39, 72, 76, 86] effectively address the performance bottlenecks of centralized registries. However, these studies introduce significant synchronization and storage overhead to actively cache images. As noted in [85], the total size of all publicly accessible images already exceeded 47 TB in 2017, and this number has undoubtedly grown larger since then. Go beyond existing works, Poby proposes *best-effort distributed download* and *image metadata index* to minimize cache overhead. Furthermore, Poby offloads distributed image management to SmartNIC, freeing the host from concerns about the management overhead.

Best-effort distributed download. The best-effort design only allows coldstart requests to download images from nodes that happen to contain the required image. Note that images on other nodes are from previous runs, rather than proactive caching. Only when no node contains the required image, Poby downloads it from the registry. Additionally, our distributed download operates at the image layer granularity, coldstart can download different layers from other nodes concurrently. The best-effort strategy offers two benefits: (1) It avoids the significant storage overhead of proactively caching. (2) It reduces the network bandwidth consumption needed for frequent synchronization of image updates across nodes. Note that Poby does not introduce additional coldstart latency,

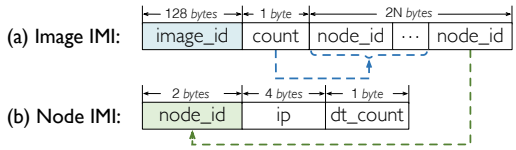


Figure 10: Format of IMI.

since it retains the original centralized image registry download scheme as a fallback. Once any error occurs during the processing of a layer, Poby immediately hands over the task to the original process without blocking the execution flow.

Image metadata index (IMI). To enable best-effort distributed image download, we propose the image metadata index (IMI). On the one hand, the IMIs track the available locations of each image and the image transmission workload of each node. Here, we use the number of active image download tasks on each node to quantify the transmission workload. On the other hand, the IMIs associate the image digest with the image manifest to obtain all necessary image metadata (e.g., the number of image layers). Leveraging the IMI, the node initiating the coldstart can arrange the most efficient download plan by considering image locations, the number of layers, and each node's workload. In short, it prioritizes downloading layers from nodes with fewer download tasks.

IMI format. As shown in Figure 10, we devise two data structures to hold the image and node information, respectively.

- *Image_IMI.* The key of the Image_IMI is the image digest image_id, which uniquely identifies images. According to the OCI Image Format Specification [27], we use the SHA-512 algorithm to generate the 128-byte digest. The Image_IMI value contains the available image locations referenced by the node_id. Each Image_IMI holds up to *N* node_id slots, where *N* is a pre-configured constant. We use the count field to track the number of valid node_id.
- *Node_IMI.* Each node in Poby corresponds to a Node_IMI, identified by the node_Id field. The Node_IMI values include the node IP address (ip) and the current number of active download tasks on this node (dt_count). Each time the IMI service responds to an IMI query, it increments the dt_count in the associated Node_IMIs by one to indicate a new download task. When the download task is over, the node initiating the coldstart must notify the IMI service to decrement the dt_count in the corresponding Node_IMIs.

It is trivial to keep all IMIs in memory. Consider a system consisting of 50,000 nodes and 1,000,000 images. An image_IMI records require 139 bytes if N is set to 5. Thus, it will take 0.35 MB for Node_IMIs and 139 MB for Image_IMIs in total.

IMI management. The IMI service manages all the IMI data, including IMI querying, node load tracking, and image location tracking. (1) For IMI querying, the IMI service returns the manifest and IMI of the required image to the node initiating the coldstart. (2) For node load tracking, the IMI service automatically increments the dt_count in the Node_IMIs when responding to an IMI query, indicating a new download

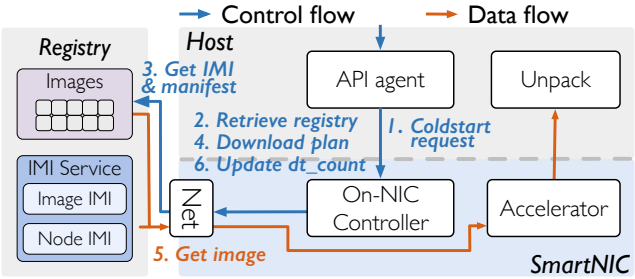

Figure 11: Workflow of distributed image download.

task on these related nodes. Upon receiving a completion notice from a node, it updates the `dt_count` accordingly. (3) For image location tracking, the IMI service simultaneously adds the node to the available locations in the Image_IMI. If the number of available nodes exceeds N, we use the least recently used algorithm to update the `node_id` list in Image_IMI. If a node deletes a local image, it notifies the IMI service to remove its `node_id` from the corresponding Image_IMI. Here, our IMI service is colocated with the original registry, which just provides the required images when unavailable on any node (best-effort strategy). Since the IMI is far smaller than images, this prevents the IMI service from becoming a bottleneck in transmission and managing IMI.

Workflow. Figure 11 shows the complete workflow of the distributed image download. (1) The on-NIC controller receives the coldstart request from the API agent on the host. (2) The on-NIC controller sends the request for the desired image (image name and tag) to the registry. (3) The registry looks up the image digest based on the provided name and tag. Then, it retrieves the manifest and IMI using the image digest and returns them as a response. (4) The on-NIC controller makes the download plan based on Algorithm 1. (5) The pipeline-based data path downloads data blocks within each image layer from the planned nodes. (6) The on-NIC controller notifies the IMI service on the registry of the completion of the download task to decrease the `dt_count` of the corresponding Node_IMIs.

Algorithm 1 presents the pseudo-code to generate the most efficient distributed download plan. The algorithm assigns a provider for each layer according to the response (manifest and IMIs) from the IMI service. It achieves load balancing through the following steps: (1) Sort nodes containing the images in ascending order according to dt_count (line 2). (2) Assign the node with the lowest image download load to the current layer (lines 5-6). (3) Switch to the next node when the load of the current node is greater than the next node (lines 7-10). (4) Repeat *steps 2-3* to assign nodes for all layers (lines 4-10).

Discussion. We explore how `Poby` handles unexpected cases. Firstly, `Poby` can function even with inconsistent IMI. If a node deletes a local image and this change is not synchronized with the IMI service, inconsistencies may arise. In this case, the on-NIC controller verifies with planned nodes during

Algorithm 1 Download plan for distributed image download

Input: *manifest, image_imi, node_imi[list_len]*
Output: *download_plan<layer_id, ip>*

```
1:  function GENERATE_DOWNLOAD_PLAN( )
2:      nodes = sort_by_dtcount_ascend(node_imi)
3:      node_id = 0
4:      for all layer in manifest.layers do
5:          download_plan[layer.id] = node_imi[node_id].ip
6:          node_imi[node_id].dt_count ++
7:          if node_id == list_len − 1 then
8:              node_id = 0
9:          else if nodes[node_id].dt_count > nodes[node_id + 1]
    then
10:             node_id ++
11:     return download_plan
```

RDMA connection setup that they have the required image. If a node is missing the image, the controller updates the download plan or pulls the image from the registry if none of the nodes have it. Secondly, `Poby` can handle unexpected image deletions. If a host deletes the image during the transmission, and the NIC remains unaware, corrupted data may be transmitted. `Poby` checks the checksum for each downloaded layer, and if a mismatch is detected, the controller identifies that node as faulty and re-downloads the layer from another node.

7 Implementation

We implement a prototype of `Poby` with NVIDIA BlueField-2 SmartNIC [14] and open-source it*. We implement the disaggregated architecture with cross-hardware pipelines and a data-driven framework. These two works are mainly deployed on SmartNIC. For the IMI management, we integrate with existing components.

SmartNIC. BlueField-2 consists of three parts: (i) RDMA NIC, (ii) multi-core SoC, and (iii) hardware accelerators. According to the specifications, the total maximum power consumption of BlueField-2 is 150W. Considering the low-power characteristics of ARM cores and dedicated hardware accelerators, its power efficiency exceeds that of general-purpose host CPUs. Besides, the hardware vendor provides a software library called DOCA to support interactions with these hardware components. We encapsulate the library to build the disaggregated architecture of `Poby`.

Cross-hardware pipelines. The pipeline of `Poby` consists of two parts: data storage and processing. We implement the two parts with memory pool and thread pool.

- *Memory pool.* `Poby` pipelines the data path at block granularity. We implement a memory pool to manage blocks. It supports adjusting the size and number of blocks dynamically. `Poby` configures them according to image characteristics. The image characteristics include layer size and the

*Available at: https://github.com/ACS-Innov/ATC2025-Poby.

Table 1: Workload images adopted from benchmark suites.

	Name	Specification	Source
Micro Service	Social Network (*SN*)	9 layers, 90.6MB	DeathStar Bench [24]
	Media Service (*MS*)	23 layers, 286.6MB	
	Hotel Reservation (*HR, small*)	18 layers, 39.6MB	
FaaS	Python (*PY*)	30 layers, 155.1MB	OpenWhisk [22]
	Node.js (*JS*)	21 layers, 356.3MB	
	Golang (*GO, medium*)	20 layers, 281.6MB	
	PHP (*PP*)	37 layers, 192.7MB	
	pyaes (PS)	33 layers, 169.9MB	Function Bench [30]
	linpack (*LP*)	33 layers, 214.6MB	
	chameleon (*CL*)	33 layers, 170.1MB	
	matmul (*MT*)	33 layers, 214.6MB	
	ML Model (*ML, large*)	37 layers, 2.45GB	

number of layers. Poby gets them from the image manifest, which is the initial download in the entire workflow.

- *Thread pool.* To improve the efficiency of pipelines, Poby concurrently performs time-consuming steps such as downloading and unpacking. Specifically, Poby implements a thread pool for unpacking on the host with folly [20], a high-performance C++ library that provides a thread-pool API. The workers in the thread pool process different layers concurrently. Downloads also employ layer-grained concurrency. The scheduling of all pipeline threads is managed by the scheduler of Linux.

Data-driven workflow. We implement an RDMA-based remote procedure call (RPC) framework for data-driven workflow. The workflow uses two-sided RDMA verbs to support gRPC-like communication, and epoll to monitor multiple events occurring in pipelines (e.g., RDMA events, compression hardware events). To transmit data blocks with control messages, we place control messages into RPC parameters.

IMI management. The IMI service is a centralized component for managing IMI data and supporting retrieval. To ensure availability, we integrate it into the registry server and use leveldb [25] to store the IMIs. For the coldstart node, we implement the IMI logic into the on-NIC controller. When the on-NIC controller receives requests to coldstart or deletes images, it notifies the update of images to IMI service.

8 Evaluation

We evaluate the performance benefits of Poby with various images, and aim to answer the following questions.

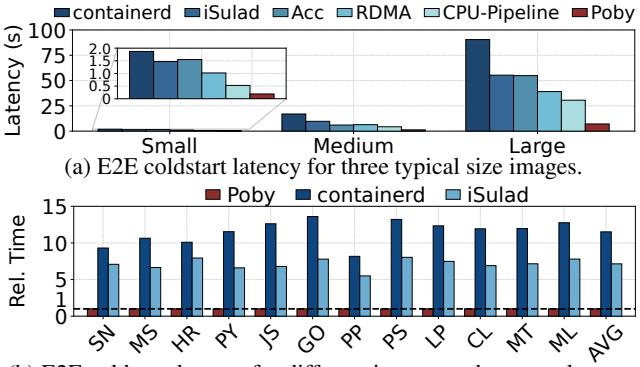
- **Q1 (End-to-end performance):** How much can Poby speed up coldstart (§8.2)?
- **Q2 (Concurrency and scalability):** How does the latency of Poby change as the number of nodes and concurrent requests increase (§8.3)?
- **Q3 (Latency breakdown):** How much do the individual processes of Poby contribute to overall latency? (§8.4)?
- **Q4 (Resource demand):** What is the resource demand of Poby (§8.5)?
- **Q5 (Architecture optimization):** Is it possible to disaggregate Poby to different nodes (§8.6)?

8.1 Experimental Methodology

Testbed. We deploy our Poby prototype on two servers. Each server is equipped with two Intel Xeon Gold 6226R CPUs, 256 GB of memory, and an NVIDIA BlueField-2 SmartNIC. These servers run Ubuntu 22.04 LTS with the 5.15.0 Linux kernel. In addition, we use another server with a dual-port 100Gbps NVIDIA ConnectX-5 NIC [15] to run the image registry and IMI service.

Baselines. We compare Poby with two baselines.

- *containerd* [23] is the runtime of Docker, the most popular open-source containerization platform. It is an industry-standard container runtime and supports managing the life cycle of containers.
- *iSulad* [55] is a new container solution that has the advantage of being light, fast, and applicable to multiple architectures. The performance of iSulad is much better than containerd for pulling images, including download, decompression, and unpacking.

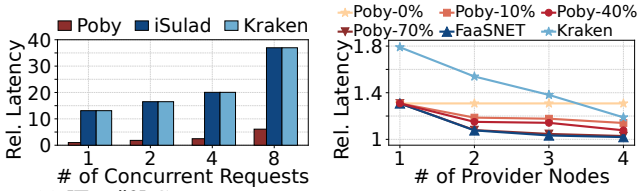


Workloads. We use a collection of images from real-world applications and two cloud benchmark suites as workloads for evaluation. Firstly, we use DeathStarBench [24] to represent microservice images. Secondly, we select Functionbench [30] images and four widely used language runtime images from OpenWhisk [22] as FaaS workloads. Thirdly, we choose three images of typical sizes from those images for detailed analysis. They are hotel-reservation (*small*), OpenWhisk-Golang (*medium*), and ML Model (*large*), with compressed sizes of 39.6 MB, 281.6 MB, and 2.45 GB, respectively. Table 1 displays all the information of workloads in detail.

Latency metrics. In this work, we measure the end-to-end coldstart latency to evaluate the performance of different systems. Poby focuses on image provisioning and all evaluated works adopt the same container runtime. Hence, the end-to-end latency does not take the boot time of coldstart into account, as the boot time is the same across all systems.

8.2 End-to-end Performance

This experiment evaluates the performance of Poby with different images. We choose latency as a key performance metric and configure Poby with 2 unpacking threads (see §8.4). These images, which cover small, medium, and large sizes, can effectively illustrate the performance of Poby for different sizes of images.



[Exp#1] Performance improvement: Poby can speedup coldstart by 11.5× and 7.1× than containerd and iSulad on average. Figure 12a shows the coldstart latency of the three typical-size images on different systems. Poby reduces the latency of coldstart by up to 92.7%, and it outperforms two

(a) E2E coldstart latency for three typical size images.

(b) E2E coldstart latency for different images and average latency.

Figure 12: **[Exp#1]** E2E coldstart latency.

(a) **[Exp#2]** Concurrency. (b) **[Exp#3]** Scalability.

Figure 13: Latency of Poby and baselines with different (a) concurrent numbers and (b) provider nodes. Poby-N% represents Poby with a N% distributed download hit ratio.

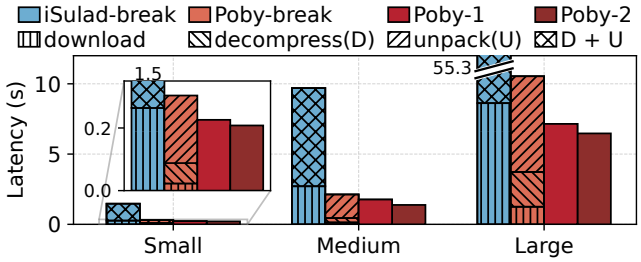
industry-standard container platforms, containerd and iSulad, with maximum speedups of 13.2× and 8.0×, respectively. Containerd takes more than 90 seconds for large images due to serial execution, while iSulad still takes 55.3 seconds with multi-threads. To further evaluate the acceleration of Poby for various containers, we compare the latency of containerd, iSulad, and Poby for all the images (Table 1) in Figure 12b. Poby is 11.5× and 7.1× faster than containerd and iSulad on average. The values of containerd and iSulad are relative latencies to Poby.

To detail the performance improvements of our design compared to the original host CPU solution, we implemented two prototypes with RDMA (RDMA) and hardware accelerator (Acc) based on the original workflow. Furthermore, we implement a host CPU-based pipeline prototype (CPU-Pipeline) based on the RDMA version to demonstrate the performance gains from pipelines. Figure 12a shows that the direct utilization of hardware features (Acc and RDMA) only reduces coldstart latency by 20% compared to the host CPU solution, while pipeline (CPU-Pipeline) further reduces it by 34%. However, they still have a significant gap compared to Poby. Because the disaggregated pipelines of Poby efficiently leverage RDMA and accelerators on SmartNIC while addressing the issue of pipeline bubbles and small file transfer.

8.3 Concurrency and Scalability

We evaluate the concurrency and scalability of Poby and compare them with two baselines.

- *Kraken* [72] is a P2P-powered registry designed for image managementand distribution in cloud environment. Kraken has been in production at Uber, which can distribute 20K 100MB-1G blobs in 30 seconds.
- *FaaSNET* [76] is a SOTA fast download work. Due to the lack of open-source access and unavailable details of the new image format, we simulate a simplified version without on-demand fetching using the distributed image download part in its paper.



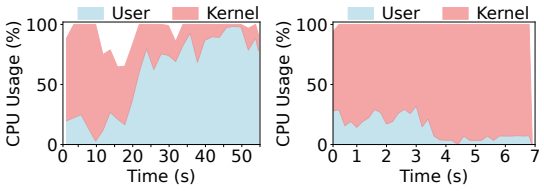


Figure 14: **[Exp#4]** Latency and statistics of each process for iSulad and Poby. The overall latency includes unpacking with one (Poby-1) and two (Poby-2) threads. Poby-break represents the time accumulated by each step of the poby-1.

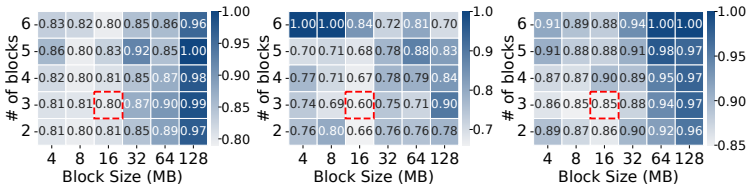

[Exp#2] Concurrency: ***Poby is 4.8× faster than Kraken under 8 concurrent coldstart requests.*** We simultaneously generate coldstart requests on the same machine to evaluate the concurrency performance of Poby and iSulad. Figure 13a shows the average relative latency of Poby, iSulad, and Kraken under different numbers of concurrent requests. All latencies in the figure are relative to the latency of Poby under one request. In this experiment, Kraken gets the same latency as iSulad. Since in the scenarios of concurrent coldstart multiple images, Kraken cannot take advantage of P2P download. Meanwhile, Poby remarkably outperforms iSulad and Kraken from one to eight concurrent requests. As the number of concurrent connections increases to eight, the latency of Poby increases by 6×. Because the network bandwidth limits the performance of disaggregated pipelines of Poby. However, the latency of Poby is still 4.8× faster than that of iSulad and Kraken. It is worth noting that we do not limit the CPU resource (up to 96 cores) of iSulad. Because network bandwidth and the non-parallelizable portion (e.g., each layer) limit concurrency and infinite time reduction.

[Exp#3] Scalability: ***Poby performs much better than Kraken at a distributed download rate of only 10%, and achieves comparable scalability to FaaSNET at 70%.*** This experiment evaluates the scalability of Poby with our RDMA cluster, which consists of 5 nodes. We compare the average coldstart latency of Poby, FaaSNET, and Kraken. In each experiment, all 5 nodes simultaneously initiate one coldstart request, with the number of image providers ranging from 1 to 4. For example, the N providers experiment of Poby indicates that 5 nodes simultaneously initiate coldstart request once through Poby to download the image from N providers. Since Poby employs a best-effort distributed download strategy, with the hit rate balancing coldstart latency and storage overhead. This hit ratio represents the probability that Poby

(a) iSulad. (b) Poby.

Figure 15: **[Exp#5]** CPU usage of iSulad and Poby for coldstarting the large image.

(a) Small. (b) Medium. (c) Large.

Figure 16: **[Exp#6]** Latency of Poby for small, medium, and large images with different sizes and numbers of blocks.

downloads the image from multiple nodes in one experiment. We measured the latency of Poby under different distributed download hit rates (e.g., Poby-10%). Figure 13b shows the latency of these systems in different cases. The values in this figure are the relative values of the corresponding system and images compared to Exp#1. The latency of Poby-0% shows that 5 concurrent requests exceeded the capacity of one provider, resulting in a 30% increase in latency. The decentralized image download alleviates image provision bottlenecks, and even a single additional provider can improve coldstart performance by 22%.

8.4 Latency Breakdown

We conduct latency analysis to quantify the execution time of each step for iSulad and Poby. Since Poby adopts pipelines to accelerate the data path, we cannot directly obtain the time consumption of each step. Here, we accumulate the time to process blocks for each step as the total time (Poby-break), though the time of these steps overlaps. Note that the decompression time of Poby consists of two parts: decompression on SmartNIC and data transmission to the host. This is because Poby integrates these two steps into a single SmartNIC operation to improve performance. iSulad does not require cross-hardware transmission, but the decompression and unpacking operations are integrated (e.g., libarchive). Therefore, we measure the total time of the two operations (iSulad-break).

[Exp#4] Latency analysis: ***Poby can reduce the extraction time by 76.1%, and adding an additional unpacking thread can further reduce it by 11.0%.*** Figure 14 shows the latency breakdown for the typical-size images, where image extraction is the most time-consuming step for both iSulad and Poby. Poby reduces the extraction time by 76.1% than iSulad on average. This indicates Poby achieves an efficient architecture on the SmartNIC (§5). In addition, the unpacking process of Poby retained on the host still occupies an average of 71.6% of the total time. To further evaluate Poby with concurrent unpacking (storage backend support), we measure the latency of Poby with one (Poby-1) and two (Poby-2) unpacking threads. The 2-thread unpacking reduces the latency by 9.1% on average. Even for a small image, which is only 39.6 MB, it still reduces the latency by 4.4%. While for medium and large images, 2-thread reduces the latency by more than 11.0%. Besides, we measure Poby with more unpacking threads, but it does not gain further improvement. Because 2-threads unpacking already reached the bandwidth bottleneck of storage.

8.5 Resource Demand

In the experiments, we evaluate the CPU and memory resource demand of Poby. The software and hardware environment for this experiment is the same as § 8.2.

[Exp#5] CPU usage: ***Poby offloads 45.3% of user-mode CPU usage on the host side to SmartNIC, and reduces CPU usage by 87.5%.*** Poby is designed to minimize the kernel-mode execution. Specifically, Poby reduces the overall host-side CPU workload by offloading intensive user-mode tasks, such as decompression, to the SmartNIC. As a result, only the non-offloadable file-writing operations remain in kernel mode. For CPU usage, we measure the CPU utilization of Poby and iSulad on the host side. Figure 15a and 15b details the CPU usage of iSulad and Poby in kernel and user mode. Poby takes 6.8s for coldstart of the large image while iSulad takes 54.6s. Poby reduces 47.8s (87.5%) of CPU time than iSulad. The low utilization of iSulad from 14s to 19s is due to waiting for a large layer (> 1 GB) to finish downloading. Besides, Poby spends only 14.1% of CPU time in user mode, while iSulad spends 59.4%. It offloads 45.3% of user-mode tasks to SmartNIC, including control path and decompression. This indicates that Poby offloads most tasks to SmartNIC (except for unpacking), leaving only 5% of user-space CPU usage on the host side.

Additionally, offloading image provisioning to the SmartNIC similarly encounters performance interference issues. Poby delegates the time- and resource-consuming decompression to the hardware accelerator, leaving the on-NIC CPU solely responsible for the control path. We evaluate the on-NIC CPU demands of Poby during the coldstart of all workload images, observing a peak on-NIC CPU usage of only 16.3% and an average usage as low as 3.0%. Given the low resource demand, we believe it feasible to reserve resources on the on-NIC CPU for Poby, effectively mitigating potential interference from other applications.

[Exp#6] Memory configuration: ***Poby achieves the lowest coldstart latency when configured with three 16MB blocks.*** Poby maintains a memory pool on the host side, which includes several pre-allocated blocks for receiving the decompressed data. The size of the blocks in the memory pool is

consistent with the block-based pipelines. To obtain an optimal memory pool configuration, we measure the coldstart latency of Poby with different sizes and numbers of blocks. As we mentioned in §5, blocks larger than 2 MB can overcome the startup latency of accelerators on SmartNIC. Here, we vary the block size from 4 MB to 128 MB and the number of blocks in the memory pool from 2 to 6. Figure 16 illustrates the latency of coldstart for small, medium, and large images with different memory configurations. The following two observations confirm the analysis in § 5.1 and guide our configuration of the block size. For the small image, it aligns better with smaller block sizes. Because a single small block is sufficient to accommodate layers of the small image. Increasing the block size and number does not improve performance and may even lead to performance degradation due to worse data locality (blocks larger than the cache). For the medium and large images, 16 MB is an efficient block size for pipelined execution. As for the number, three blocks are sufficient for 2 unpacking threads, and increasing the number of blocks brings no additional benefit.

8.6 Architecture optimization

As mentioned in §4, Poby can alleviate local SmartNIC contention via network-wide offload. This experiment evaluates the performance of disaggregating Poby to different nodes.

[Exp#7] Network-wide offload: *Poby achieves network-wide decompression offload with only 18.0% latency increase.* This experiment configures one node as the coldstart requester and the other node as the decompression assistant. The requester sends image requests to the assistant for decompressing the image. Figure 17 compares the coldstart latency of local and remote decompression for Poby. It reveals that disaggregating Poby to remote nodes with RDMA is feasible for SmartNIC contention scenarios. The remote decompression only introduces 18.0% latency overhead compared to local decompression. Moreover, although the average compression ratio of images is as high as 2.7, the remote decompression only results in 2.2 Gbps network bandwidth overhead. Because Poby employs a block-based pipeline, the capability to decompress and unpack limits the excessive use of network bandwidth. As a result, the network bandwidth overhead of remote decompression is amortized across the entire coldstart process, preventing a surge in network bandwidth demand.

9 Related Work

Lightweight isolation. Some efforts propose lightweight isolation mechanisms to accelerate the container startup with coldstart [2,9,34,46,66]. We divide these works into two categories. Firstly, some systems [2,34] employ sensitive data protection techniques to share isolation environments. Secondly, other approaches utilize fine-grained isolation techniques (e.g., application- [46], language- [66], and thread- [34] level).

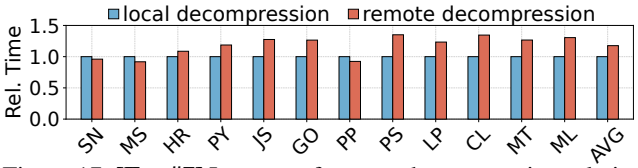

Figure 17: **[Exp#7]** Latency of remote decompression relative to local decompression for Poby.

These methods completely update the existing isolation mechanism of cloud platforms, effectively mitigating the coldstart issue. Poby optimizes the pre-processing steps of creating isolation environments, which is orthogonal to lightweight optimization works and can be integrated together.

SmartNIC offload. Previous works [70,79] characterize the performance of SmartNIC. Due to the integration of RDMA network cards, extensive researches continue on leveraging SmartNIC to enhance network performance. However, with the introduction of programmable hardware, most of the researches [4,21,32,37,43,52,56–59,65] focus more on offloading tasks such as network functions, network protocol stacks, and package processing to SmartNIC. In addition, some works attempt to offload a broader range of applications. AlNiCo [40] accelerates transaction processing within a single node, while Xenix [63] applies to distributed scenarios. Similarly, LineFS [31] offloads distributed file systems with pipeline parallelism. Moreover, other studies apply SmartNIC to storage [36,50,57,69,84], microservice [12,44,45], remote function call [35,67], and others [18,26,28,42,71,77]. Specifically, Poby offloads FaaS coldstart to SmartNIC and uses on-NIC CPU to manage RDMA links and hardware acceleration to decompress layers.

10 Conclusion

Existing approaches ignore the most time-consuming step of coldstart. We complete the coldstart puzzle with SmartNIC offloading and data-driven pipelines. We propose Poby, a software-hardware collaborative system that leverages emerging hardware SmartNICs to accelerate image provisioning directly. Poby disaggregates the architecture of coldstart and orchestrates appropriate hardware resources of the entire cluster to accelerate different operations within image provisioning. It achieves efficiency with data-driven pipelines. Our experiment with BlueField-2 shows that Poby performs well with different benchmark images.

Burst Computing: Quick, Sudden, Massively Parallel Processing on Serverless Resources

Abstract

We present burst computing, a novel serverless solution tailored for burst-parallel jobs. Unlike Function-as-a-Service (FaaS), burst computing establishes job-level isolation using a novel group invocation primitive to launch large groups of workers with guaranteed simultaneity. Resource allocation is optimized by packing workers into fewer containers, which accelerates their initialization and enables locality. Locality significantly reduces remote communication compared to FaaS and, combined with simultaneity, it allows workers to communicate synchronously with message passing and group collectives. Consequently, applications unfeasible in FaaS are now possible. We implement burst computing atop OpenWhisk and provide a communication middleware that seamlessly leverages locality with zero-copy messaging. Evaluation shows reduced job invocation and communication latency for a 2× speed-up in TeraSort and a 98.5% reduction in remote communication in PageRank (13× speed-up) compared to standard FaaS.

1 Introduction

The cloud offers compute infrastructure on demand, but provisioning, adjusting, and managing these resources for large-scale data processing applications is an arduous task, especially for non-experts. Furthermore, when the load is unpredictable, dynamic, with varying volumes of data, user-driven, and sometimes interactive, finding the right scale to avoid misprovisioning [25, 39, 54] becomes very complex.

Function-as-a-Service (FaaS) has gained traction as a solution to the resource provisioning problem as it offers rapid, on-demand, no-ops scaling and a pay-as-you-go billing model at very fine granularity (MB per ms). Users do not need to set up a cluster, but the service simply accepts function invocations and fully manages the rest. Moreover, its resource *burstability* has set FaaS aside from traditional engines like Spark or Dask, allowing to start thousands of short-lived functions in seconds instead of minutes (see Table 1). Several research works [15, 16, 23, 44] have used FaaS for a myriad of data- and compute-intensive tasks.

Table 1: Time to provision cloud compute resources on different services and technologies.

Technology	Total vCPUs	Nodes[a]	Start-up time
EMR Spark	96	6	296 s
		24	431 s
Dataproc	96	6	95 s
		24	113 s
Dask	128	8	184 s
		64	253 s
Ray	128	8	187 s
		64	229 s
Knative (Kubernetes)	960	960	54 s
OpenWhisk	960	960	21 s
AWS Lambda (2 GiB)	960	960	6 s
Burst Computing	960	960	1.7 s

[a] AWS EMR Spark and GCP Dataproc use m5 and E2-standard VM families, respectively. Dask and Ray are deployed on user-managed m6i family EC2 VMs. Knative, OpenWhisk, and Burst deployed on 20 c7i.12xlalrge VMs but start 960 functions/workers.

This has brought a new concept in cloud computing that refers to the ability to quickly respond to sudden, parallel workloads without provisioning a cluster in advance. Fouladi et al. [16] talk about a "burstable supercomputer-on-demand" and a "burst-parallel swarm of thousands of cloud functions, all working on the same job." However, literature admits that the current FaaS model is too narrow and precluding for massively parallel data processing programs (MPP) [24].

In this work, we highlight that the key issue of FaaS hindering burst-parallel jobs is its lack of group awareness. Indeed, FaaS users need multiple independent service calls to spawn a fleet of workers, which become strongly isolated from each other. We note that such fine-grained isolation is damaging and unnecessary for collaborative jobs, and thus propose to raise the multi-tenant boundaries to the job level.

We present *burst computing*, a new cloud computing model to deal with quick, sudden, massively parallel workloads, which we call *bursts*. To this end, we offer a *group invocation* primitive to handle the whole job as a unit. To the best of our knowledge, we are the first to implement this feature

in a FaaS platform, clearly differing from all other research efforts that suffer the burden of handling and orchestrating individual function invocations. A group invocation allows to optimize resource allocation, ensure worker parallelism, and perform *packing*: running multiple workers co-located in the same environment. In addition to speed up worker start-up latency, this enables *worker locality* and *simultaneity*, which can be exploited to improve code and data loading, and to aid powerful worker-to-worker communication patterns (e.g., broadcast, all-to-all) that seamlessly leverage shared memory channels with zero-copy mechanisms.

From the user side, a burst spawns a fleet of workers that communicate with message-passing, a simple but very powerful abstraction that creates a novel serverless substrate versatile to many applications beyond what is feasible in FaaS. This gives extensive control of the job to advanced users and allows to design compute engines or frameworks on top (e.g., DAG-based) to simplify development, manage the execution, and handle failures. Massively parallel computations are prime burst applications, especially when sudden, unpredictable, and user-driven in nature. Batch-like jobs are also good candidates when run interactively. Some examples are data processing, analytics, and machine learning workloads like exploratory model tuning, SQL, *k*-means, and large-scale sorting. Bursts may be stateless (e.g., grid search or Monte Carlo simulations) or stateful (e.g., table joins and aggregations).

We make the following contributions:

- We present burst computing, a novel cloud service model for short, sudden, massively parallel jobs (bursts). We believe that no cloud vendor or research effort has created the necessary substrate to support them.
- Burst computing evolves FaaS with a key novel group invocation primitive (a flare) that raises multi-tenant isolation from a single function invocation to the whole job. In consequence, the system launches massive process groups faster, with guaranteed parallelism, and packs workers together to exploit locality.
- We implement a burst computing platform by extending OpenWhisk, a state-of-the-art FaaS system. Our implementation includes a specialized Rust worker runtime and a burst communication middleware that seamlessly leverage worker locality with collective code/data loading and zero-copy messaging.
- Under evaluation on several burst-parallel workloads against FaaS, burst computing improves job invocation latency (up to 11.5× faster), worker simultaneity (up to 26.5× lower median absolute deviation), and group communication (up to 98% in a broadcast), for a speed-up of 13× in PageRank and 2× in TeraSort.

2 Motivation: in search of burstability

Many works are leveraging serverless services for massive data processing [3, 7, 9, 15, 16, 23, 40, 60] despite current (FaaS) hindrances [5, 18, 24] due to the resource *burstability*

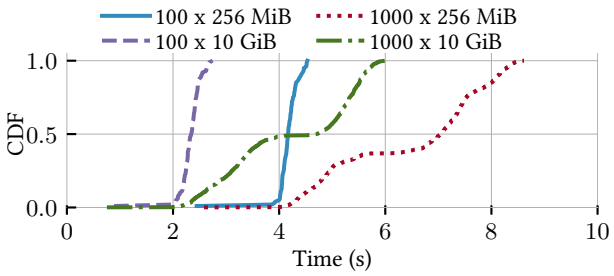

Figure 1: Start-up time (cold start) of 100 and 1000 FaaS functions in AWS Lambda for two memory sizes.

of this model [17, 38]. Applications benefit from quick, on-demand, no-ops resources at very fine granularity, and pay precisely for what they need, when they need it.

This has brought what we call *bursts*, massively parallel processing (MPP) workloads that appear suddenly and process large, variable volumes of data in a very short time (under 1 or 2 minutes). Such applications have dynamic resource needs that cannot be predicted easily, thus serverless burstability becomes essential [49, 50, 52, 56]. Consider, e.g., an interactive, scientist-driven workflow in a Jupyter Notebook, where the user dynamically explores large datasets and modifies parameters that significantly impact the workload size. Although they may resemble batch jobs, they are characterized by their sudden, sporadic occurrence, highly dynamic and unpredictable data volumes, and the expectation of low-latency execution. Representative use cases include interactive model tuning via grid search, exploratory data analysis with SQL queries and algorithms such as logistic regression, and data preparation operations like filtering and sorting. The MilliSort and MilliQuery benchmarks [31] exemplify such short-running workloads. Additional scenarios include real-time data stream or video feed processing, where both data volume and analytical complexity may fluctuate dramatically over time.

Current data processing solutions such as Spark, Dask, Flink, or Ray fail to support bursts. A long-lived deployment of these engines is impractical, as it would easily become misprovisioned. They are not offered *as a service* by any cloud either, which could palliate the issue by multiplexing jobs from multiple tenants, and thus forces per-user deployments that are too slow to set up [38], even on cloud-managed offerings (e.g., Amazon EMR). Table 1 shows that starting one of these technologies is intolerable for critical sporadic or dynamically sized applications.

In contrast, FaaS services provide a large-scale compute substrate much faster. Fig. 1 shows that AWS Lambda may spawn a fleet of 1000 functions in 6 s; a much more appropriate time range for bursts.[1] FaaS is also more attractive than Container-as-a-Service (CaaS) or managed Kubernetes ser-

[1]Note that small functions (256 MiB) incur higher invocation latency than large ones (10 GiB). Also found on other providers (e.g., GCP), it is likely due to the overhead of scheduling finer-grained resources.

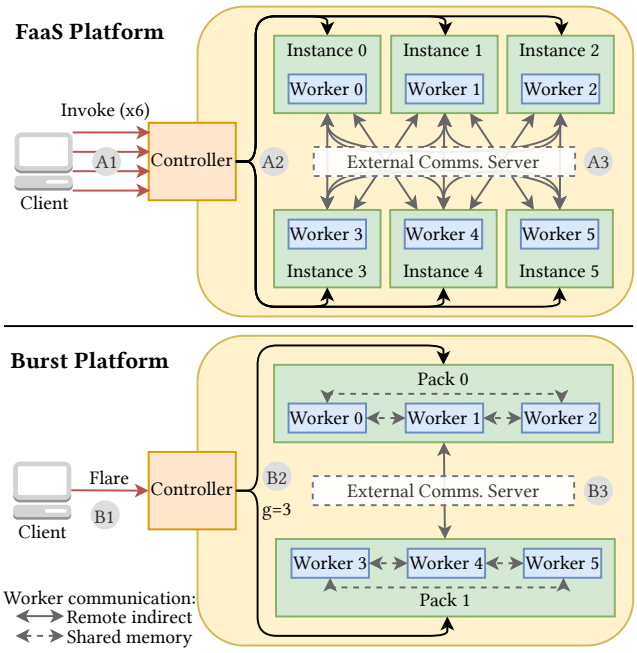

Figure 2: Running a data processing job of 6 workers in FaaS and burst computing with granularity (g) 3.

vices due to simpler abstractions [26] and quicker resource allocation. For example, Knative, a Kubernetes-based FaaS-like implementation, is noticeably slower in spawning workers than dedicated FaaS platforms (Table 1).

2.1 FaaS is holding us back

A review of the literature will show us that running bursts atop FaaS brings many challenges [18, 24, 38]. We highlight three friction points: (**F1**) worker isolation, (**F2**) job fragmentation with complex orchestration, and (**F3**) huge data movement.

To illustrate them, Fig. 2 follows the execution of a parallel job on a FaaS platform. It shows a parallel job with 6 workers. The job could be embarrassingly parallel (stateless) such as a data filtering, or require the workers to coordinate at some point (stateful) such as a table join or, more intensively due to its iterative nature, PageRank.

F1 appears because multi-tenant isolation is at the level of a function invocation. FaaS spawns function instances independently, one at a time, requiring multiple HTTP requests A1 to obtain the 6 workers. Besides the added latency of several requests, this is an issue for parallel jobs because the platform is not aware of these workers being collaborators, and thus cannot guarantee their parallelism. This creates delays or skews between workers that potentially harm job execution. Take, for instance, Fig. 1, where the last function starts up to 6 s after the first one.[2] Even more, the platform populates identical environments (instances) for each invocation A2, which stresses the system with code, dependency, and data[3] loading that creates memory duplication [41, 53].

F2 occurs when workers need to coordinate. For instance, TeraSort *à la* MapReduce includes a data shuffle amidst the job, and PageRank iteratively globally aggregates a vector. Workers cannot communicate effectively because they may not exist at the same time (**F1**). Instead, workers read and write intermediate data asynchronously through an external storage solution. This pattern (depicted in Fig. 3) creates job fragmentation (function stages) and complicates its orchestration, especially in iterative algorithms like PageRank (unfeasible with this approach [6]). First, it increases data movement and requires worker recreation at each stage (adding code and data loading overhead). Second, it needs an active workflow orchestration process to monitor the state of workers and oversee the overall job progress.[4] Centralized solutions add a mostly-idle driver component while decentralized task scheduling adds a layer of complexity to applications [9, 29, 32]. Neither can solve the underlying problem of worker isolation.

These issues are emphasized by **F3**. With so many tiny isolated workers, most communication patterns (e.g., a shuffle) require numerous remote connections A3. In data processing workloads, this may result in very large data transfers, precluded by the (FaaS) lack of direct communication [10, 35].

3 Burst Computing

Burst computing is a novel paradigm for running *bursts* in the cloud. It overcomes the above frictions with two key principles that evolve FaaS: group awareness and locality exploitation. Fig. 2 shows how this changes job invocation.

FaaS hinders worker collaboration because multi-tenant isolation is at the level of a single function (**F1**). Because a job belongs to a single tenant, it makes sense to raise isolation to the job level and handle all its workers as a group. To this end, burst computing provides a group invocation primitive, which we call *flare* B1, to instantly launch massive process groups with guaranteed parallelism. To the best of our knowledge, we are the first to implement this kind of primitive in a serverless system. Flares bring group awareness to the service, which is key to perform worker *packing* B2, i.e., running multiple workers of a job in the same isolated environment. Packing establishes *worker locality* and enables several optimizations discussed below.

In a flare, all workers have guaranteed parallelism and access to the job context (e.g., the burst size, IDs, or locality), which allows them to communicate synchronously in patterns unfeasible in FaaS, such as worker-to-worker message passing and collectives, that simplify job orchestration and avoid **F2**. This difference is depicted in Fig. 3. **F3** is addressed because communication B3 can seamlessly exploit locality and use shared memory mechanisms between workers in the same pack, which reduces remote transfers.

[2] Further evaluation (not shown in the plot) reveals that this dispersity may increase to 44 s in GCP, or 20 s in an OpenWhisk deployment.

[3] For instance, hyperparameter tuning uses the same data in all workers.

[4] This can be painful since FaaS does not provide monitoring mechanisms.

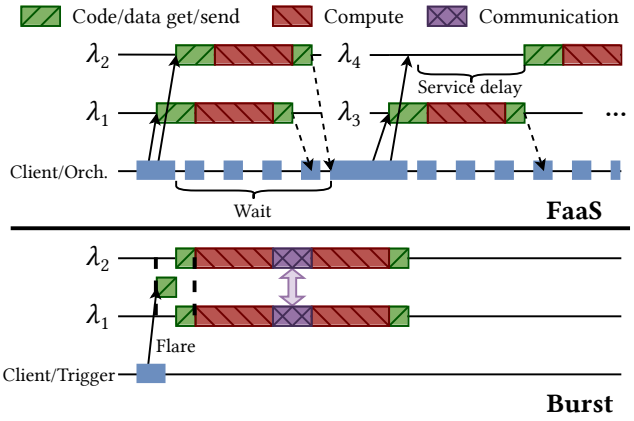

Figure 3: Timeline comparison of a parallel job with FaaS and burst computing.

3.1 Worker packing and communication

Worker packing To run a flare, the burst platform allocates n workers into m packs; we say that n is the *burst size*. The number of workers per pack is the burst's *granularity* ($g = n/m$). Thus, Fig. 2 shows a burst of size $n = 6$ where, by setting $g = 3$, the platform only spawns 2 packs, each with 3 workers. The higher g, the lower m, reducing the number of environment creations, which is a critical part of function invocation time in FaaS. Then, worker code and dependencies are loaded only once per pack and shared by all co-located workers. This further helps with initialization time (especially when dependencies are large) and optimizes resource usage (e.g., avoiding memory duplication [41]). A similar reasoning applies for data loading: workers processing the same data (like in hyperparameter tuning) download it just once per pack and utilize their aggregated resources to speed up the transfer (i.e., with parallel downloads).

Choosing g is a trade-off between ease of system management and locality maximization. To illustrate that, we identify three strategies[5] for worker packing: (i) *heterogeneous*, where workers are placed in containers as big as possible in the underlying system machines; (ii) *homogeneous*, where workers are placed in fixed-size containers; and (iii) *mixed*, where workers are put in fixed-size packs, but if multiple packs fall onto the same machine, they are merged into a single container. The first approach maximizes locality, but it can become a resource scheduling problem, as it is prone to fragmentation. The homogeneous packing mitigates that issue, but it restricts worker locality. The third strategy is the compromise that allows a fast and flexible management while still maximizing locality (see §5). Given this complexity, we argue that the responsibility for setting the granularity should lie with the platform rather than the user, enabling better control over resource scheduling and providing a more streamlined and user-friendly service.

[5] Strategies must consider how many resources we assign to each worker. For simplicity, this paper considers only vCPUs and applies 1 vCPU per worker, but the strategies work for any such assignment.

Worker communication Burst applications are *elastically distributed and collaborative*. They are coded as a single function run by all workers that accepts any worker multiplicity transparently. Then, because workers are guaranteed to be parallel, they may coordinate synchronously by sending messages and with common communication patterns.

To simplify this, burst computing includes a worker-to-worker, message-passing communication middleware readily available to workers. The middleware seamlessly identifies messages between workers placed in the same pack for local communication (zero-copy). Only messages between packs are transferred remotely, and the middleware optimizes these connections (e.g., a broadcast only sends one message per pack). Remote delivery may be implemented with several technologies. Our contributions are independent of this choice because burst computing reduces any remote communication through packing. In this work, we follow the usual approach in FaaS and only consider indirect solutions using an external communication server B3.

4 Design and implementation

We put the above ideas into a prototype burst computing platform and communication middleware. Here we provide the design details and implementation. Fig. 4 shows an overview of the main components and their interactions.

The burst platform extends the design of a FaaS platform to implement group invocation and worker packing. Built atop Apache OpenWhisk, our platform shares its components with important modifications (see §4.4). The *controller* manages user interaction with the platform, it handles inbound HTTP requests to deploy and invoke bursts, oversees system resources, and performs worker packing. A *database* stores the burst definitions and configuration, as well as the results and execution metadata. Computational resources in the platform are provided by the *invokers*, a set of machines with capacity for burst *packs*. Packs are run in containers that isolate a custom runtime environment to run workers.

Our burst communication middleware (BCM) has two main components: the core communication library and the remote backends. The *library* exposes message-based communication to workers, and it is extensible with *backends* to use different remote message delivery solutions.

4.1 Life cycle overview

Fig. 4 depicts the life cycle of the system. To deploy a new burst definition, the user first sends (1) a `deploy` HTTP request. The controller receives it and registers (2) the new definition in the database. Later, when the user desires to trigger the execution of the burst, they send (3) a `flare` HTTP request with specific parameters. The controller handles the invocation and decides worker allocation (4) based on the current state of the invoker machines. The affected invokers

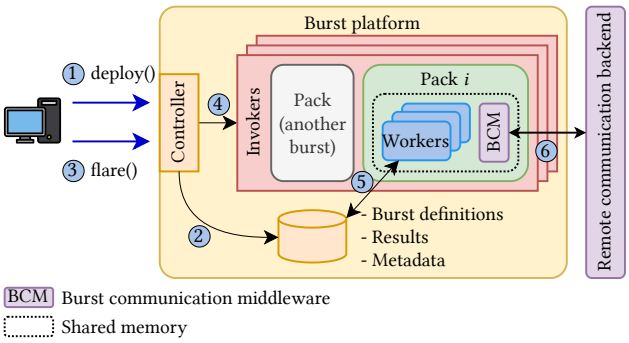

Figure 4: Burst computing platform overview.

receive the task to spawn the required runtime environments (packs) with space for as many workers as needed. When the environments boot, their host invoker tells them which burst definition and parameters to load (5) from the database. Then, each pack spawns its workers internally, which will execute the user-defined function (`work` in Table 2) in parallel. Workers may use the BCM to coordinate and share data. This seamlessly uses shared memory or remote connections to communicate workers (6) in the same or a different pack, respectively. Additionally, workers may read or write data to external storage systems (e.g., object storage) or produce a result that is stored back to the database, where it may be retrieved later by users through another HTTP request.

4.2 Developing and running bursts

User experience is key for burst computing. As a serverless service, all resource management remains hidden. Users interact with the service through a simple interface that allows to define bursts with resource-agnostic code and to schedule their execution. This is similar to FaaS services that allow users to upload their function definitions and then set up triggers or invoke them as needed. The interface and abstractions are summarized in Table 2.

Deployment Similar to functions in FaaS, developers package and upload their burst definitions (code) to the cloud, giving them a name and configuration. The configuration includes runtime parameters and worker characteristics (such as language and memory size).

Invocation Burst definitions are triggered for execution like functions in FaaS: an event or HTTP request notifies the intent to execute a burst with specific input parameters. We call each burst invocation a *burst flare* (Table 2). The main difference with FaaS is that a flare will spawn a group of parallel workers (instead of a single function instance). The service ensures that all workers run simultaneously and applies packing. In our prototype, the burst size is explicit on the size of the *inputParams* array. Hence, users have direct control over it. We believe this to be important because parallelism is strictly application-specific and depends on data volume (e.g., ETL tasks), data content (e.g., dimensionality or sparsity), or algorithm configuration (e.g., the number of clusters in *k*-means). Smart burst sizing is left for future work, i.e., the platform may automatically calculate the number of workers based on application and data information.

Table 2: Burst computing abstractions and API.

Interface	Functions
Burst Service	**deploy**(*defName*, *package*, *conf*) upload and deploy a burst definition **flare**(*defName*, [*inputParams*]) invokes a burst
Burst Function	abstract **work**(*inputParams*, *burstContext*) function to run on each worker
Burst Context	**workerID** → unique ID of this worker within the flare **burstSize** → number of total workers in the flare **packID** → unique ID of the current pack **packSize** → number of workers in the current pack **numPacks** → number of packs within the flare **belongToPack**(*workerID*) → packID returns the pack ID to which a worker belongs to **isPackLeader**() → bool returns true if this worker is its pack's leader
Comm. Primitives	**send**(*data*, *dest*) → none **recv**(*source*) → data **broadcast**(*data*, *root*) → data **allToAll**(*[data]*) → [data] **reduce**(*data*, *f*(*data*, *data*) → *data*) → data

Coding Burst definitions are coded as a single function that is run by each worker in the burst (`work` in Table 2). This function must be programmed elastically so that it accepts and runs correctly for any burst size. The code is also agnostic to the packing performed by the service. To that end, the `work` function receives a burst context object through which each worker may obtain information about the worker distribution within the particular flare. For example, a worker can query its own unique ID, the burst size, granularity, or which workers belong to each pack (*Burst Context* in Table 2). With this information (provided by the platform invoker), the code can implement logic to apply locality optimizations at the pack and burst levels (see an example in §5.4.1). This context object also gives access to the BCM.

Communication interface The BCM offers simple yet powerful worker-to-worker communication through message passing similar to MPI. The abstractions are elastic (adapt to the burst size) and available through the burst context. Burst computing programs make use of two basic primitives to connect workers: send and receive. These primitives enable point-to-point communication between workers and are designed to send arbitrary volumes of data efficiently within the burst. To facilitate common communication patterns in parallel jobs, bursts may also use group collectives. As listed in Table 2, our prototype implements broadcast, all-to-all, and reduce. Primitives and collectives are locality-aware, although the

```rust
fn work(params: Input, burst: &BurstContext) -> Output {
  let num_nodes = params.num_nodes;
  let mut page_ranks = vec![1.0 / num_nodes; num_nodes];
  let mut sum = vec![0.0; num_nodes];
  let adjacency_matrix = get_adjacency_matrix(&params);
  while err < ERROR_THRESHOLD {
    page_ranks = burst.broadcast(page_ranks, ROOT_WORKER);
    for (node, links) in graph {
      for link in links {
        sum[*link] += page_ranks[*node] / out_links(*node);
      }
    }
    let reduced_ranks = burst.reduce(sum, |vec1, vec2| {
      vec1.zip(vec2).map(|(a, b)| a + b).collect()
    });
    if burst.worker_id == ROOT_WORKER {
      err = calculate_error(&page_ranks, &reduced_ranks);
      page_ranks = reduced_ranks;
    }
    err = burst.broadcast(err, ROOT_WORKER);
    reset_sums(&mut sum);
  }
  Output { page_ranks }
}
```

Figure 5: Simplified source code of the PageRank *work* function for burst computing. The accesses to the burst context to obtain the worker ID or communicate are highlighted.

programs remain agnostic to it, i.e., co-located workers (same pack) communicate on shared memory and only remote workers hit the network.

4.3 Application example

Fig. 5 shows an example in Rust code (simplified) of the `work` function that implements the PageRank application. The algorithm consists of an iterative process in which each worker holds a portion of the adjacency graph (relating links between web pages). In each iteration, the new global ranks are computed in parallel, aggregated, and reduced in a tree structure, then broadcasted from the root worker to the rest of them. The algorithm runs until it converges past a threshold or reaches a limit of iterations.

Similarly to the MPI computing model, all workers execute the same code but perform different logic based on the worker ID (the *rank* in MPI). The example highlights the worker accesses to the `BurstContext` object to perform collectives and obtain information about the current flare. For example, it is used to perform a collective *broadcast* to share the updated ranks vector, and later a *reduce* to aggregate the partial ranks computed among the workers. It also shows how a worker checks its ID when it needs to calculate the convergence, since this is only done by the root worker after collecting the aggregated vector in the reduce.

4.4 Burst platform implementation

The prototype implementation is built on top of the popular Apache OpenWhisk platform (v1.0.0). We used OpenWhisk as the basis because it is a well-known, open-source, production-tested FaaS implementation and provides higher burstability than other platforms like Knative (Table 1). Our changes amount to approximately 2K SLOC. They affect the main components of the platform, including the controller, the invoker, and the runtime environment.

The controller now supports two new HTTP endpoints for bursts: `deploy` and `flare`. It also implements the logic to handle them (§4.1). This includes the packing strategy in the three flavors (§3): heterogeneous, homogeneous, and mixed. Granularity can be configured. In any case, the controller calculates the number and size of the packs based on the specific burst size and the resources available in the invokers.

Invokers run a new monitoring logic that can be adjusted to report their load to the controller based on CPU instead of RAM. Our prototype is set to assign 1 vCPU per worker because bursts tend to be compute-intensive jobs and we do not consider parallelism within a worker,[6] but other configurations are possible. Invokers also implement new logic to support the creation and execution of packs, spawning Docker containers of the appropriate size for each burst (by specifying resource limits) and telling each container/runtime the number of workers to run, plus their IDs and context. Containers are currently not reused across bursts.

For the runtime, we adapted the official OpenWhisk Rust environment, but it is possible to support others. The new logic allows to spawn multiple workers within it as requested by its host invoker. In particular, the Rust runtime spawns one thread per worker to provide parallelism. Finally, the runtime also includes our BCM built-in.

4.5 BCM implementation

The burst communication middleware (BCM) is coded in Rust in about 5K SLOC. It is readily available for our custom Rust runtime and we are working on a binding for Python.[7] It enables the transmission of intra-pack (zero-copy) and inter-pack (via remote backend) messages. The BCM is instantiated by the runtime (once per pack) and made available to workers as a parameter (in the `work` function as shown in Table 2).

For local communication, BCM uses in-memory queues to send and receive data between workers in the same pack. In the Rust runtime, workers are threads and reside in the same memory space, so shared memory mechanisms are not necessary (e.g., `shm_open` or `mmap`). Instead, workers just pass memory pointers between them. Thanks to Rust's memory safety guarantees, access to shared data is thread-safe. Rust also provides a reference-counting mechanism for immutable data, so shared data is released when it is no longer used at runtime. For example, the root worker in a *broadcast* sends a read-only memory pointer to its local workers, and they safely access the message concurrently. To modify the data, one may use mechanisms such as copy-on-write.

For remote communication, each pack has a shared connection pool to the remote backend, which allows each worker within the pack to send and receive messages concurrently, with the goal of maximizing the container's bandwidth. This

[6] The burst size (number of workers) determines total job parallelism.

[7] Other languages may be supported through bindings (Java, C++, Go…).

is especially useful in primitives like *all-to-all*, where all workers must open channels with all the others. For large messages, the data is split into smaller chunks that are sent and received concurrently. This maximizes network utilization and allows readers to start receiving data from the first chunk, instead of waiting for the full message to be available at the backend.

The BCM is extensible, allowing the implementation of more remote backends. Currently, we support Redis, DragonflyDB, RabbitMQ, and S3. The backend interface differentiates between sending direct messages (one-to-one) and broadcast messages (one-to-many). The reason is that direct messages are read only once, while broadcast messages multiple times, so we want to optimize this particular case. For instance, in RabbitMQ, one-to-one messages use direct brokers, while one-to-many use fan-out brokers.

To ensure that no messages are lost (*at-least-once* delivery semantics), the BCM relies first on the backend delivery guarantees (e.g., RabbitMQ uses durable queues to avoid dropping messages). Additionally, the BCM keeps a count of direct messages sent between each pair of workers, and for each collective operation. The middleware handles duplicate and/or out-of-order messages. For that, messages include a header with the source and destination worker, collective type, counter, and, if chunked, the number of chunks and chunk number. Messages with a counter lower than the expected value are ignored and assumed as already processed. Those with a counter greater than expected are cached locally until needed. For chunked messages received out-of-order, a memory region is reserved for the total payload and chunks are written to their respective offset as they come in.

5 Evaluation

Our evaluation aims to assess burst computing against current FaaS on the three friction points described in §2.1. Importantly, we show and analyze the effects of worker packing and locality. All experiments run on Amazon Web Services (AWS) in the `us-east-1` region.

5.1 Burst group invocation

Group invocation is the key element against friction **F1**. Here we evaluate how job-level isolation improves worker readiness time (invocation latency), ensures their simultaneity, and provides locality for collaborative code and data loading.

Setup: The burst platform runs on an Amazon EKS cluster, with the control plane on a `t4i.xlarge` VM (4 vCPUs and 16 GB RAM), and the invokers on up to 20 `c7i.12xlarge` VMs (48 vCPUs and 96 GB RAM). This gives us space to accommodate up to 960 workers with 1 vCPU each.

Impact on burst invocation latency First, we use the homogeneous packing policy to evaluate how assigning different granularity (g) affects burst invocation latency. The exploration is depicted in Fig. 6 for two bursts of sizes 48 (left) and 960 (right).[8] It is quickly apparent that as g increases (up to

[8]We conducted experiments with similar results for burst sizes in-between.

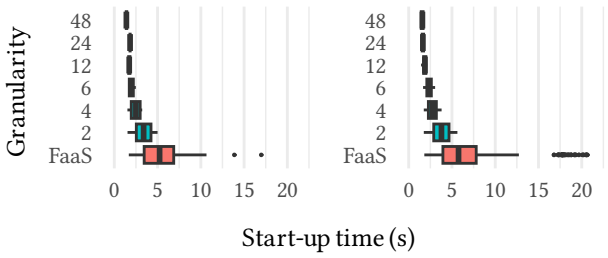

Figure 6: Worker start-up latency distribution within one job for burst computing with different packing granularity and FaaS (equivalent to $g = 1$). Left and right show, respectively, burst sizes of 48 and 960.

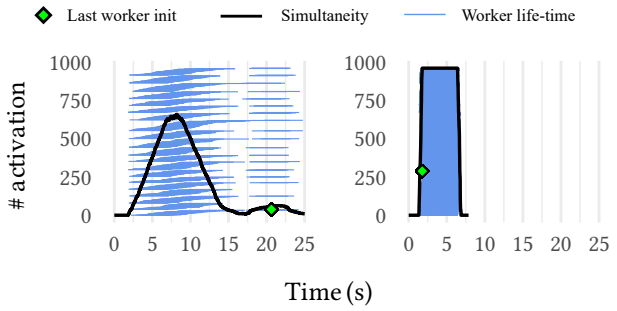

Figure 7: Simultaneity (number of workers running at an instant) in FaaS (left) and Burst with $g = 48$ (right). Each bar represents the life-time of a worker.

48 in both cases), the start-up time decreases, and generally becomes more consistent across workers for all burst sizes. For instance, the latency of having all workers ready in a burst of size 960 reduces by 11.5× from $g = 1$ (FaaS) to $g = 48$. We found that container creation dominates invocation latency, hence higher g performs best. This proves that creating the biggest possible containers, and thus the less amount of them (heterogeneous packing), achieves the best start-up latency, since it creates a single container per invoker per flare. By extension, the mixed packing strategy exhibits the same results, but allows the system to manage resources more effectively in small portions to facilitate allocation and avoid resource fragmentation. To assess the impact of granularity, the rest of the evaluation uses homogeneous packing.

Impact on worker simultaneity We run a burst with size 960 on FaaS against burst computing with $g = 48$. For demonstration purposes, each worker performs a 5-second sleep and we plot their execution timeline in Fig. 7. The plot shows that burst computing achieves faster resource allocation and quicker readiness of workers. This ensures worker parallelism. Analyzing dispersity of worker start-up time (also in Fig. 6), the FaaS execution evinces a range of 18.8 s between the start of the first worker and that of the last one, with a median absolute deviation (MAD) of 2.65 s. In contrast, the range

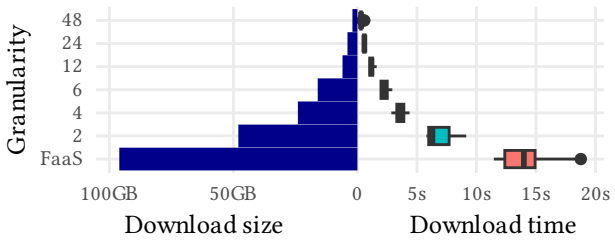

Figure 8: A burst of 96 workers loading the same 1 GiB object from S3 with different granularity.

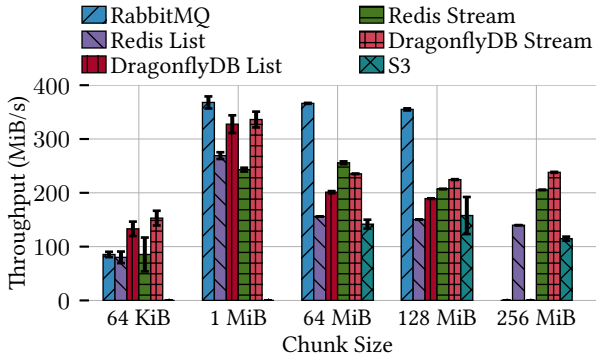
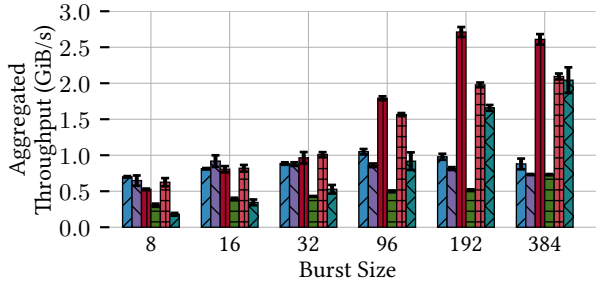
with $g = 48$ is just 0.44 s (MAD is 0.1 s). Compared, the range is 43× lower in burst computing, with MAD showing 26.5× lower dispersity than FaaS. Dispersity in worker start-up latency precludes FaaS to achieve full parallelism (all workers running simultaneously from start to finish), while burst guarantees it.



Impact on data loading Burst computing mitigates the FaaS problem of loading the same data on all functions (§2.1), e.g., in a grid search. We can leverage worker access to locality information to optimize this problem and download the data only once per pack, trivially reducing data ingestion. Specifically, each worker in a pack retrieves a part of the data based on calculations from pack information in the burst context (Table 2). Then they recreate the full data in a local shared memory region. This allows to parallelize the download and complete the process faster than choosing a leader to perform it (also possible through the `isPackLeader` function in the context, which returns true for the worker with lowest ID within its pack). We evaluate this approach on multiple g and present it in Fig. 8. Burst optimizations achieve a download time speed-up of 32.6× with $g = 48$ compared to FaaS.

Takeaway Flares eliminate friction **F1** through faster worker group initialization (11.5×) and ensured simultaneity (43× less dispersed workers) that enables locality with packing. In turn, locality may accelerate data download in applications (32.6×), tackling friction **F3**.

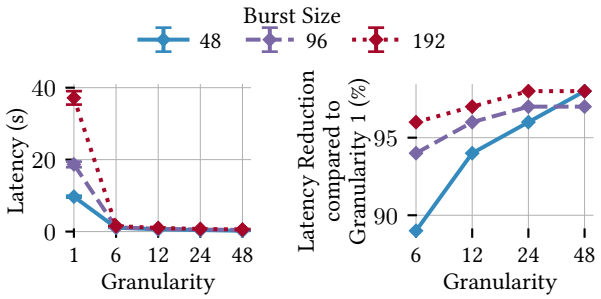


5.2 Burst inter-pack communication

Before we evaluate the effects of the BCM on frictions **F2** and **F3**, we want to ensure that an indirect communication model is feasible and to find a backend that sustains the load of bursts at scale. For this, we measure the throughput of several indirect communication backends. Specifically, we test Redis, DragonflyDB (a Redis-compatible multi-threaded alternative), RabbitMQ, and S3. Redis and DragonflyDB evaluate two flavors: using lists or streams.

Message chunk size The BCM chunks messages into several blocks to optimize network utilization and allow parallel read/write. The optimal chunk size is a trade-off between latency to first byte and operation overhead, and it varies

(a) Throughput between two remote workers sending a 1 GiB payload chunked in different sizes.



(b) Aggregate throughput of two remote packs, A and B, of varying size (g =burst size/2), where each worker from pack A sends a 256 MiB payload to another worker from remote pack B.

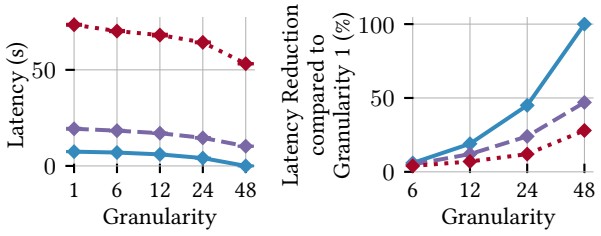


Figure 9: Throughput experiments for the different BCM backends. Median values with standard deviation (10 runs).

for each communication backend. To find the optimal configuration, we measure the throughput of sending a 1 GiB message between two remote workers. The workers run on two `c7i.large` machines (4 vCPUs, 8 GB) and we deploy a `c7i.16xlarge` (64 vCPUs, 128 GB) for the intermediate server. Fig. 9a plots the results. RabbitMQ offers a constant throughput for larger chunk sizes, but does not allow payloads larger than 128 MiB due to AMQP protocol limitations. Redis and DragonflyDB work best at 1 MiB, the latter being slightly superior. S3 offers the lowest throughput because object stores are not designed for small files (1 MiB or less exceeds the allowed service request rate limits).

Maximum throughput To understand how the different backends scale under parallel load, we measure the aggregated throughput between several pairs of workers communicating simultaneously. In this experiment, we launch a group of workers (burst size from 8 to 384) split into two remote groups. Each worker in a group A sends a fixed message (256 MiB) to a worker in the other, remote group B. As the burst size increases, so does the total data volume sent. Each backend uses the optimal chunk size assessed in the micro-benchmark above. Workers run on two VMs scaled to the burst size (from `c7i.xlarge` for 8 workers to

(a) Broadcast

(b) All-to-All

Figure 10: Latency and its reduction percentage with respect to $g = 1$ of two collectives, for varying g and burst size.

`c7i.48xlarge` for 384), and the communication server runs on one `c7i.48xlarge` instance. The results are shown in Fig. 9b. We observe that RabbitMQ does not scale beyond 1 GiB/s. For the in-memory stores, the approach with lists performs better than streams. Like RabbitMQ, Redis does not scale with parallelism because it is single-threaded. In contrast, DragonflyDB does scale and achieves the highest throughput, surpassing 2.5 GiB/s for large burst sizes. S3 also scales with parallelism but remains slower.

Takeaway The BCM achieves high throughput even with indirect communication, and some backends sustain up to the evaluated 384 workers with individual connections, suggesting a feasible approach. In view of the results, the rest of the evaluation uses DragonflyDB List with 1 MiB chunks.

5.3 Burst group collectives

We assess the impact of locality on group collectives as a means to face friction **F3**. We measure end-to-end latency, i.e., the total time it takes for all workers to complete the collective, as we vary g. We present results for *broadcast* and *all-to-all*. *Reduce* behaves similar to *broadcast* because they follow the same data movement pattern.[9]

Setup: We employ one, two and four `c7i.12xlarge` VMs (48 vCPUs, 96 GB) for bursts of sizes 48, 96 and 192, respectively. g varies from 1 to 48. Each worker uses 256 MiB of data for each collective call. The backend server runs on one `c7i.48xlarge` (192 vCPUs, 384 GB).

[9]Other collectives like *gather* and *scatter* are similar to *all-to-all*.

Overall, Fig. 10 shows that latency decreases as the granularity increases. This is because remote communication is the main bottleneck of collective operations and its volume decreases as g increases and more data movement becomes local. The cost of local communication is insignificant compared to the remote one. Broadcast sends the message once, but reads it once per pack, i.e., remote data movement is directly proportional to the number of packs: if we halve the packs, we move half the data. Thus, latency quickly decreases as we increase g; near 98% reduction with $g = 48$ (Fig. 10a). All-to-all is more intensive in data traffic because all workers have a message of 256 MiB for each of the other workers (48 GiB total with 192 workers). This means that even if we only have two packs, half the data traffic is remote. This is clearly evident in Fig. 10b. Considering $g = 48$, burst sizes 48, 96, and 192 create one, two, and four packs; thus latency reduction is ca. 100%, 50%, and 25%, respectively.

Takeaway Locality-aware group collectives heavily mitigate friction **F3** by seamlessly reducing remote data traffic.

5.4 Burst applications

We evaluate three real-world bursts: hyperparameter tuning, PageRank, and TeraSort. These (or similar) applications are commonly used in the literature to assess the performance and show the limitations of FaaS platforms for parallel jobs and serverless data analytics [4, 7, 15, 16, 28].[10] These applications clearly show all friction points while providing an overall view of the effects of burst computing compared to FaaS-based implementations. Further, they are representatives of short jobs a scientist may want to run interactively in a dynamic analysis session: sudden and quick (under 2 min).

Our baseline for comparison is thus the current FaaS paradigm available in public clouds as used in the serverless data analytics literature. Since MPI-like communication is not supported on any serverless service, we opt to use unmodified OpenWhisk and AWS Lambda as our baselines, employing external storage for communication and data sharing to align with the state of practice.

5.4.1 Hyperparameter tuning

Grid search is a machine learning technique in which a set of hyperparameter values are evaluated to find the combination that yields the best performance for a given model. This evaluation is done in parallel, with each worker processing a full copy of the training dataset. Since there are no dependencies between parallel tasks, FaaS seems suitable for this job. However, each function would download a copy of the data, regardless of whether there are functions co-located on the same node. This results in a waste of bandwidth and memory due to duplicate data downloads. Burst computing provides an optimization opportunity by exploiting locality (see impact on data loading in §5.1).

[10]We do not use FaaS benchmarks (e.g., FunctionBench [27]) because they focus on applications where FaaS already does a good job (independent function invocations and stateless or embarrassingly parallel workloads).

Table 3: Time to start 96 workers and gather input data in hyperparameter tuning for different granularity.

Granularity	1 (FaaS)	6	12	24	48	96
Ready time (s)	17.51	5.65	3.64	3.18	2.96	2.57

Setup: The grid search is applied to a stochastic gradient descent model in a `sklearn` Python application and distributed to 96 workers. We use a 500 MiB Amazon reviews dataset (CSV), available at Kaggle[11] and stored in an S3 bucket. AWS Lambda is the baseline (denoted as $g = 1$), with a memory configuration of 1769 MiB, which provides a full vCPU. The burst platform uses a `c7i.24xlarge` instance.

Table 3 collects the "ready time", meaning the time elapsed from client-side job invocation until the input data is available to all workers and they are ready to compute. We see how burst computing quickly reduces this time as g increases. This effect has two causes. First, the group invocation primitive speeds up invocation time compared to FaaS, from approx. 4 to 1.5 s with $g = 96$. Second, data download can be optimized as assessed in Fig. 8. While FaaS has to download a copy of the data on each worker, workers co-located in a pack collaborate in downloading the input in parallel. Hence, as g increases, the input download time decreases, going from 14 s in FaaS to 1 s with $g > 48$.

5.4.2 PageRank

PageRank is a well-known data analytics workload with intensive worker coordination. It involves iterative and heavy data aggregation for large datasets, which is of interest for benchmarking worker communication in burst computing. We adapted PageRank for burst computing from the Hi-Bench suite [19] (MapReduce approach). The implementation is detailed in §4.3. In this case it is not possible to make optimizations regarding data ingestion (like in §5.4.1), since each worker takes a different partition of the dataset. We skip reporting the MapReduce version atop FaaS because the number of (short) stages necessary to perform the iterative aggregations make it obviously slower. Spark has a similar problem [7]; evaluation on AWS EMR with an equal-sized deployment (needing 5 min to start up) shows that this application takes over an hour.

Setup: This experiment uses four `c7i.16xlarge` VMs (64 vCPU, 128 GB). The graph dataset is generated with Hi-Bench consisting of 50M nodes (ca. 30 GiB) in 256 partitions. The algorithm runs over 10 iterations, with a burst size of 256, varying the granularity between 1 and 64.

Fig. 11 shows the total execution time of all iterations split into phases: the time dedicated to download input data (from S3), compute the ranking, and communicate (collectives) between workers. Times for each phase are averaged across workers, and all iterations added. Table 4 shows the network traffic and % of reduction compared to $g = 1$. Communication accounts for the majority of the execution time because the rank vector must be aggregated and shared at each iteration. Our configuration uses a vector of 40 MiB that is sent, received, and aggregated in a tree pattern across the workers, and then broadcast from the root worker to the rest of them. As g increases, the remote portion of this movement decreases. For example, with $g = 2$, only the first level of the (binary) reduction tree is local (the leaves), and the rest communicate remotely. With $g = 64$, there are 4 packs, so remote communication occurs only in the last 2 tree levels. With this setup, we achieve a 98.5% reduction in data traffic and a 13× speed-up compared to $g = 1$.

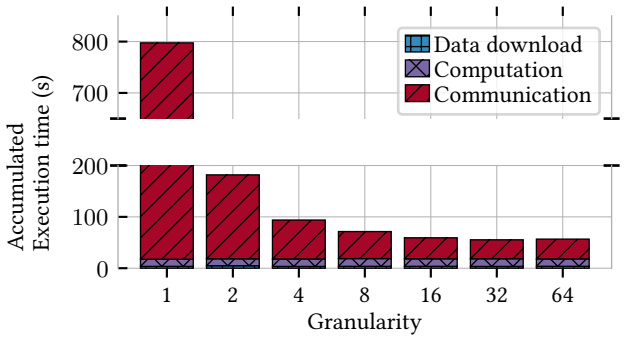

Figure 11: PageRank execution time by phase, varying g.

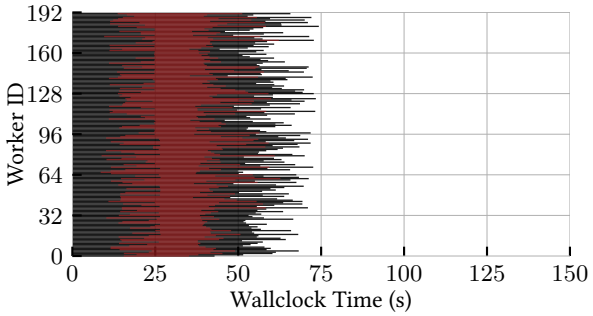
Table 4: Aggregated network traffic volume and percentage of traffic reduction compared to $g = 1$, varying g in PageRank.

Granularity	**1**	**2**	**4**	**8**	**16**	**32**	**64**
Traffic (GiB)	3068	1532	764	380	188	92	44
% Reduction	n/a	50.0	75.0	87.6	93.8	97.0	98.5

5.4.3 TeraSort



We have implemented TeraSort based on the MapReduce version in Hi-Bench suite [19]. TeraSort is of particular interest because it involves a heavy data shuffle phase. We want to compare a TeraSort following the serverless MapReduce approach [33, 40, 46], with a single-stage burst computing version where we exploit locality for the shuffle phase. The main advantages of burst are: (i) the MapReduce version requires two rounds of function invocations (map and reduce), while the burst model requires a single flare, and (ii) the MapReduce version shuffles data through object storage, while burst employs the (locality-aware) *all-to-all* collective.

Setup: This experiment sorts a 100 GiB dataset generated with Hi-Bench with 192 partitions. The burst platform runs on EKS with two `m7i.24xlarge` (96 vCPUs, 384 GB) invokers and a `c7i.xlarge` controller. The input data is in an Amazon S3 bucket located in the same region. For reference, an equal-sized Spark deployment solves this problem in 106 s average but needs 5 min to start up the cluster.

[11] https://www.kaggle.com/bittlingmayer/amazonreviews

(a) Serverless MapReduce

(b) Burst computing

Figure 12: TeraSort timeline comparison between (12a) serverless MapReduce and (12b) burst computing. MapReduce comprises two function rounds (map and reduce), with data exchange via object storage. Burst uses a single flare, exchanging data through the *all-to-all* collective.

Fig. 12 shows the timeline of two executions comparing serverless MapReduce and burst. The execution time of each worker is shown in horizontal black bars, stacked by *Worker ID* on the vertical axis. Superimposed in red, we see the time elapsed for the shuffle phase of the TeraSort algorithm. In the MapReduce version (Fig. 12a), we highlight (i) the dispersity in function start-up time, as we have seen in Fig. 7; (ii) a gap where no functions are running, caused by splitting the workload into two phases (map and reduce), with an externally-managed synchronization phase between them, adding further overhead; and (iii) an outlier in the map phase (worker #121), which slows down the entire workflow.

All these points are addressed in burst computing (Fig. 12b). First, the group invocation packs all workers into two containers of 96 workers, making start-up faster, and ensuring parallelism, which eliminates (latency-induced) outliers. Second, worker-to-worker collectives avoid splitting the job into two phases. Finally, remote communication is reduced thanks to locality (see §5.3). To wit, we achieve a 2× speed-up for this particular execution—1.91× mean across six executions.

For completeness, we also run TeraSort on Spark using AWS EMR on a cluster of equivalent resources. Best results are achieved with 74 executors of 4 GB of memory each. The total run time ranges between 100 and 110 seconds, placing it between the FaaS and Burst implementations. Although the execution times are relatively close, there are substantial differences that make a comparison and analysis of results complex. To start, the programming language changes (Scala to Rust), and Spark's execution model and its peer-to-peer communication capability impact application performance in different ways: Rust may be more performant, the burst execution model simpler and more effective, but Spark's direct communication is faster. Moreover, it is worth noting that cluster creation time on AWS EMR took over 5 minutes, adding additional overhead for an sporadic workload. Neither FaaS nor Burst require the user to set up a cluster.

Takeaway Frictions **F1**, **F2**, and **F3** appear in real-world applications. Hyperparameter tuning shows duplication in worker initialization due to friction **F1**, which also slows down worker start-up in PageRank and TeraSort. PageRank and TeraSort evidence the issues of friction **F2**: the iterative nature of PageRank makes it unfeasible in FaaS due to excessive stages, and TeraSort is hindered considerably due to slower coordination. Burst computing mitigates this by allowing workers to coordinate and share data in a single stage, instead of requiring multiple stages orchestrated externally that communicate asynchronously through storage. PageRank and TeraSort also emphasize friction **F3**: Page-Rank with iterative, large communication to aggregate the vector and TeraSort with a single, large data shuffle.

6 Discussion and limitations

Burst as a cloud service One potential concern regarding the adoption of burst computing as a public cloud service is the added scheduling complexity of packing multiple workers, along with its implications for billing. Giving burst granularity control to the provider addresses this by enabling more effective resource management. The mixed packing policy we propose further enhances scheduling efficiency by targeting small resource gaps and maximizing locality through co-located resource consolidation. Burst computing aligns with the trend toward "Big Lambda" architectures, seen in platforms such as AWS Lambda, Google Cloud Functions, and CaaS offerings like IBM Code Engine. For example, AWS already supports functions with up to 6 vCPUs, indicating that its infrastructure can already schedule resource bundles at this scale. Setting a burst granularity of 6 would thus mirror current AWS capabilities. Implementing burst computing requires the concurrent allocation of multiple such high-capacity functions, similar to existing multi-invocation FaaS handling, while optimizing locality. Though this may introduce slightly higher latency than a single function invocation, it remains more efficient than coordinating numerous remote HTTP calls. Our evaluation on OpenWhisk confirms the viability of this model, demonstrating that it preserves internal resource management and auto-scaling typical of FaaS.

We see burst computing as a natural evolution of FaaS: despite the constraint of parallel provisioning, bursts are ephemeral and may be bounded in time or concurrency, clearly distinct from long-running serverful processes. Thus, we argue that burst support in public clouds is not prohibitively complex and can follow FaaS-like billing models. Moreover, there is clear evidence that users are already willing to pay for "Big Lambdas" or containers when the workloads justify it [18].

Burst applications The suitability of burst computing versus traditional FaaS depends on an application's communication patterns, performance demands, and tolerance to execution imbalances. Burst computing is designed for massively parallel workloads with collaborating workers, enabling co-location and synchronized execution. Applications with strong locality requirements and intensive data sharing—such as PageRank, SQL queries, or large-scale sorting—are prime candidates. However, even loosely coupled workloads like grid search or Monte Carlo simulations can benefit from shared data downloads (see §5.4.1), faster initialization, and coordinated result aggregation. Burst computing also facilitates optimizations such as function fusion, where stateless functions within a dataflow are merged into a single, stateful burst to reduce communication overhead and improve locality [47]. Interactive workloads or those requiring synchronized responses across workers similarly gain from burst simultaneity. In contrast, those with minimal data sharing or high variance in execution time across workers are typically better served by conventional FaaS. While our current prototype reclaims resources per pack—leading to potential idle resources when worker durations differ—it targets short-lived, coordinated workloads (i.e., workers typically progress in lockstep) where imbalance is rare, as seen in PageRank and MilliSort/MilliQuery [31]. Addressing this limitation via dynamically sized packs is a path for future work. Ultimately, choosing between burst and FaaS depends on locality needs, parallelism requirements, and the importance of coordinated execution.

Coding limitations While burst computing introduces new capabilities for expressing parallel and stateful workloads, it also imposes certain programming constraints that must be acknowledged. The model is designed as a low-level primitive, offering developers greater flexibility rather than prescribing orchestration logic. Similar to MPI, it executes the same code across all workers while assigning each a unique identity, enabling divergence in behavior. However, unlike MPI, bursts are triggered with FaaS-like simplicity, abstracting away explicit resource management. The primary coding complexity introduced lies in inter-worker communication, yet this is mitigated by using programming primitives that are agnostic to worker count and locality, thereby simplifying development. Although multi-burst orchestration—e.g., for full DAG-based workflows—remains future work, it can leverage well-established techniques such as dependency persistence in object storage or worker reuse across flares. A higher-level framework could encapsulate this coordination, offering abstractions for DAG scheduling and state propagation across bursts [9, 36, 43]. Many real-world applications (e.g., clustering, gradient descent, aggregation queries, N-body simulations) can already be implemented within a single burst, avoiding orchestration overhead altogether. Furthermore, libraries could expose common distributed patterns (e.g., a distributed sort) via simple APIs, hiding burst-level details from end users. Thus, while the model lacks full orchestration capabilities out of the box, it provides foundational support for powerful abstractions and ensures parallel execution—a property often missing in existing FaaS-based solutions, where developers must manually coordinate parallelism without system-level guarantees [5, 9, 16].

Serverless clusters Burst computing poses a step towards redefining the boundary between serverless architectures and traditional cluster-based systems [17, 38]. Recent work has explored how to emulate cluster-like capabilities atop existing FaaS platforms [9, 57]. However, our approach takes a fundamentally different perspective: rather than adapting conventional cluster technologies to work around the limitations of current FaaS substrates, burst computing seeks to evolve serverless services themselves, introducing native abstractions and execution models that offer the parallelism, coordination, and locality benefits traditionally associated with clusters—yet within a fully serverless paradigm. This opens the door to realizing truly serverless versions of platforms like Spark, Dask, or Flink, moving beyond the managed, but still serverful, offerings available today.

7 Related work

The concept of resource burstability has already been discussed in the serverless literature. FaaS has been referred to as a "burstable supercomputer-on-demand" [16] for "burst-parallel serverless applications" [55], albeit with limitations. "Flash bursts" in HPC [31] explore the feasibility of 1 ms jobs spanning a large number of servers, which is attractive but unfeasible with existing technologies in public clouds. Granular computing [30, 42, 48] explores very similar ideas to improve cluster utilization. Müller et al. [38] pursue serverless burstability for batch jobs, highlighting that functions are too limited for the job.

Burst computing goes a step further in defining a new way of running burst-parallel jobs in the cloud. It evolves from FaaS to exploit serverless burstability, but it unlocks the limitations of working with functions to provide a compute environment tailored for massively parallel collaborative jobs. Recent works also promote the need to evolve the FaaS model to overcome important challenges [11, 13]. To our knowledge, we are the first ones to raise the unit of management from a function to the job level in a serverless service with a group invocation abstraction to pack workers together and enable locality within the job.

Several papers [12, 21, 59] tackle handling function invocations faster. They aim to respond to thousands of function calls with very low latency. Others relax function isolation to handle multiple invocations together and cut on start-up and data sharing overhead [2, 50]. Similarly, some works perform opportunistic function packing, placing multiple function invocations from the same user on the same container to improve invocation latency and resource usage [1, 8, 22, 53, 61]. This shows that burst jobs are becoming widely accepted in FaaS settings, and locality is a key enabler. All these works only consider individual function invocations and are thus limited. Burst computing further optimizes job execution thanks to group invocations and guaranteed worker parallelism. Still, the mentioned works may be combined with burst computing to accelerate resource allocation.

A different line of work handles complex computations atop FaaS through higher-level function orchestration, task schedulers, or workflow optimizers [9, 29, 32, 34, 36, 37, 62, 63]. Since they operate with individual function invocations, they cannot be compared with burst computing, but benefit from it to guarantee task parallelism and fast start-up time. Orchestration techniques may be applied atop burst computing, e.g., to coordinate multiple bursts, manage data dependencies between them, optimize task parallelism, and handle faults.

Other works explore a hybrid approach where traditional compute engines (e.g., Spark or Flink) offload computation spikes to serverless functions [14, 20, 51] to achieve faster adaptation to dynamic loads. This requires the deployment and management of the traditional compute engine, which is not ideal to achieve serverless execution of parallel jobs. Burst computing fully hides infrastructure: users only deploy their code and run jobs, while the cloud handles the rest.

Communication and state sharing in FaaS has been widely explored. Some works combine a data store and a FaaS platform into the same system to optimize data access by placing functions where the data they use is kept [52]. This is a fundamentally different kind of locality than in burst computing as it does not support any function grouping semantics and may present resource contention problems [45]. Other solutions [4, 6, 28, 40] target applications that require function coordination and communication, close to the objectives of burst computing. However, they employ a disaggregated storage solution to relay data between stateless functions and cannot exploit any form of locality. Boxer [58] explores direct communication, and FMI [10] builds a library of collectives between groups of FaaS functions (with NAT traversal). They only tackle current FaaS platforms and do not provide any locality optimizations (in contrast to burst computing). These solutions are orthogonal to our contributions. For instance, FMI may be used as a BCM remote backend to accelerate pack-to-pack transfers, but burst computing still contributes zero-copy communication between workers in the same pack.

Finally, we highlight a clear trend in FaaS that is aligned with burst computing: the emergence of "Big Lambdas" with multiple CPU cores (currently up to 6 vCPUs in AWS). Jobs may leverage function intra-parallelism and, similar to burst computing, worker locality becomes relevant and improves the execution of parallel applications. these high-capacity functions still lack group-aware mechanisms and parallel guarantees, requiring complex user-side handling.

8 Conclusion

In this paper, we have presented burst computing, a novel cloud computing model designed to address the growing demand to run sudden, variable, burst-parallel workloads without provisioning resources in advance. We have reviewed the challenges and shortcomings of current technologies (i.e., FaaS), and we have demonstrated the effectiveness and versatility of our proposed solution.

Burst computing offers several key advantages over existing FaaS technologies, primarily the addition of a group invocation primitive that allows the platform to manage jobs as a unit, instead of independent function invocations. This raises tenant isolation to the job level and allows to allocate resources en masse and apply worker packing, which in turn enables powerful locality between workers. Our experiments and performance evaluations have shown that our platform achieves significant improvements by exploiting this locality in job invocation latency, worker simultaneity, code and data loading, and worker-to-worker communication with group collectives. Further, we demonstrated speed-ups of 13×, and 2× in PageRank, and TeraSort, respectively, thereby validating efficacy in real-world scenarios.

In conclusion, burst computing represents a significant advancement for serverless data processing in the cloud, with potential to become a new paradigm of cloud services. It unlocks key limitations of FaaS, becoming the next step forward to support applications previously stymied by its restrictive model [18]. We believe that our contributions are just the substrate for further innovation such as new workflow definition tools and orchestration engines that leverage burst computing jobs and strive towards a simplified dynamic utilization of cloud resources.

Abstract

In this paper, we propose DEEPSERVE, a scalable and serverless AI platform designed to efficiently serve large language models (LLMs) at scale in cloud environments. DEEPSERVE addresses key challenges such as resource allocation, serving efficiency, and cold start latencies through four main design components. First, DEEPSERVE uses a simple serverless abstraction called the request-job-task model, which helps manage diverse AI workloads across post-training and model-serving tasks. Second, DEEPSERVE integrates an in-house serving engine named FLOWSERVE using a microkernel-inspired design, NPU-centric execution, and SPMD-based parallelism to optimize LLM serving. Third, DEEPSERVE includes novel scheduling policies tailored for a configuration with both PD-disaggregated and PD-colocated instances. Fourth, DEEPSERVE includes optimizations such as pre-warmed pods, DRAM pre-loading, and NPU-fork, which allow DEEPSERVE to scale up to 64 instances in seconds. DEEPSERVE has been in production for over a year, operating on a large Ascend NPU cluster and providing industry-standard APIs for fine-tuning, agent serving, and model serving to our customers.

1 Introduction

The rapid rise of generative AI, exemplified by the success of platforms such as ChatGPT, has transformed the landscape of AI and increased the demand for scalable systems capable of serving large language models (LLMs). Model-as-a-Service (MaaS) platforms, such as OpenAI's offerings, enable millions of users to access powerful AI capabilities through a simple API interface. Consequently, LLM serving has become one of the most crucial workloads in modern data centers.

Ensuring such services' performance, efficiency, and cost-effectiveness is complex, and we identify the following three challenges to achieve optimal performance and resource utilization while ensuring Service Level Objectives (SLOs) for multi-tenant users. First, AI workloads vary significantly in duration, from fine-tuning that can last hours or even days, to agent serving and LLM serving, which typically range from seconds to minutes. This variation makes it difficult to dynamically allocate shared resources without either underutilizing or overloading the system. Second, as LLM serving becomes increasingly distributed and stateful, managing resource allocation, synchronization, and fault tolerance across multiple instances is more complex. A single inference request may span multiple distributed instances and involve cached states, creating additional challenges in ensuring efficient operation. Third, the variability in LLM serving demands leads to fluctuating resource needs, further complicating resource optimization and the handling of cold-start latencies [10].

To address the preceding challenges, in this paper, we propose DEEPSERVE, Huawei Cloud's fully-hosted and serverless platform, offering industry-standard fine-tuning, agent serving, and model-serving APIs [31]. DEEPSERVE has been running for over a year atop a large Ascend NPU cluster [24]. We report how DEEPSERVE addresses the preceding challenges using four major design components: serverless abstraction and infrastructure, serving engine, scheduling algorithms, and scaling optimizations.

Serverless Infrastructure. DEEPSERVE introduces a developer-facing serverless abstraction called the request-job-task model. In this model, a *request* is an external trigger (e.g., a user-sent HTTP call). A *job* (or multiple *jobs*) matching the request type (e.g., chat, fine-tuning) handles the request. A task is a fine-grained operation within a job (e.g., prefill task, decode task). Users send HTTP *requests* that trigger internal *jobs*, which are broken down into smaller *tasks*. This request-job-task abstraction allows for the dynamic scaling of workloads and efficient resource sharing across post-training and model-serving tasks. DEEPSERVE's architecture, as shown in Figure 1, is built around this abstraction and consists of three core components: Job Executors (JEs), Task Executors (TEs), and a cluster manager. JEs handle incoming requests

*This work was completed during his internship at Huawei Cloud.
†Co-corresponding authors.

and decompose them into manageable tasks that are then distributed to TEs for execution. The cluster manager ensures the health and scaling of the job and task executors. DEEPSERVE deploys JEs and TEs dedicated to post-training and serving. We focus on serving in this paper.

Serving Engine. In DEEPSERVE, we design an efficient serving engine called FLOWSERVE, built on three fundamental principles. The first is a microkernel-inspired design, which divides system functionality into modular components that can scale independently. This separation ensures that different system parts can evolve and operate asynchronously. The second principle is NPU-centric execution, which aims to keep the NPU busy to minimize delays caused by other resources such as CPUs, DRAM, or storage. Finally, FLOWSERVE adopts a Single-Program-Multiple-Data (SPMD)-based design, enabling efficient parallel processing and scaling across multiple NPUs.

The FLOWSERVE engine has six core functionalities: tokenization, model execution, scheduler, memory management, caching management, and networking management. The tokenizer operates independently. Adhering to the SPMD design principle, FLOWSERVE follows a master-executor architecture: the master oversees scheduling, caching, and networking decisions, while per-NPU executors carry out these decisions on their respective NPUs. FLOWSERVE's scheduler is centralized at the master module, using both asynchronous KV cache prefetch and asynchronous execution to keep an NPU busy. FLOWSERVE has a Relational Tensor Cache (RTC) module to manage the relationship between tensors (primarily on the KV cache) and a distributed flow (DistFlow) module to transfer tensors across tiered storage within a single engine or across engines in a peer-to-peer manner.

Scheduling Algorithm. DEEPSERVE presents three designs to tackle the challenges introduced by prefix caching and disaggregation. First, we implement a locality-aware algorithm to maximize KV cache reuse, a design shared by previous work [11, 39, 50]. Second, we extensively compare PD-disaggregated and PD-colocated TEs in a controlled environment with varying configurations. Based on the profiling results, we develop a PD-aware scheduling policy that accounts for the dynamics of online serving and decode-length uncertainty. Finally, we propose a combined scheduling algorithm that integrates load-aware, locality-aware, and PD-aware strategies.

Scaling Optimization. DEEPSERVE achieves fast scaling by quickly adjusting to fluctuating workloads. It employs multiple key techniques, including reserving pre-warmed Pods and TEs, pre-loading models into DRAM, and leveraging high-speed NPU-to-NPU links for efficient model loading. Combined with optimizations such as parallel initialization and predictive model pre-loading, these techniques significantly reduce initialization time. DEEPSERVE can scale up to 64 instances in parallel within seconds.

This paper makes the following main contributions:

- Design of DEEPSERVE, a large-scale serverless AI platform for LLM serving (§3).
- Design of FLOWSERVE, an efficient and modular serving engine architecture (§4).
- Study of scheduling techniques for PD-disaggregated and PD-colocated setups (§5).
- Detailed description of optimization techniques for fast scaling in LLM serving (§6).

2 Background

We describe LLM and Ascend NPU chips in this section.

LLM. LLM inference consists of two main stages: the *prefill stage* and the *decode stage*. In the prefill stage, the model processes the full input prompt $(x_1, x_2, \ldots, x_n)$, computes Key-Value (KV) vectors for each token, and stores them in the KV cache [14, 15, 22]. The model then generates the next token x_{n+1} to initiate the decode stage. This stage is compute-bound and benefits from high parallelism. In the decode stage, the model iteratively generates one token at a time. For each step, it computes and appends the corresponding KV vectors to the KV cache. Token generation continues until a stopping condition is met. This stage is memory-bound, dominated by cache lookup and memory access rather than computation.

Ascend NPU and SuperPod. Our system runs on Huawei's Ascend Neural Processing Unit (NPU) AI chips [24]. The Ascend 910B provides 400 TFLOPS of FP16 compute and 64 GB of HBM. The newer Ascend 910C consists of two dies, each offering 400 TFLOPS and 64 GB of HBM. We currently support two generations of NPU clusters (see Figure 1). The first generation uses a scaled-out architecture. Each server contains 8 Ascend 910B chips, and servers are connected via a 200 Gbps RoCE network. The second generation adopts a scaled-up architecture, recently released as the CLOUDMATRIX384 SuperPod [37]. It comprises 48 servers and 384 Ascend 910C chips, all interconnected via a high-bandwidth network around 200 GB/s (unidirectional). All CPUs and NPUs in the SuperPod share a unified memory address space, enabling access to any chip's DRAM or HBM.

3 DEEPSERVE: A Serverless AI Platform

DEEPSERVE is Huawei Cloud's fully-hosted and serverless platform for running emerging generative AI workloads, offering industry-standard fine-tuning, agent serving, and model-serving APIs [31]. DEEPSERVE has been running for over a year atop a large Ascend NPU cluster. As a cloud platform, our goal is to maximize AI cluster *performance* and *utilization* while ensuring SLO guarantees for multi-tenant users. However, achieving this goal with emerging AI workloads faces the following three key challenges.

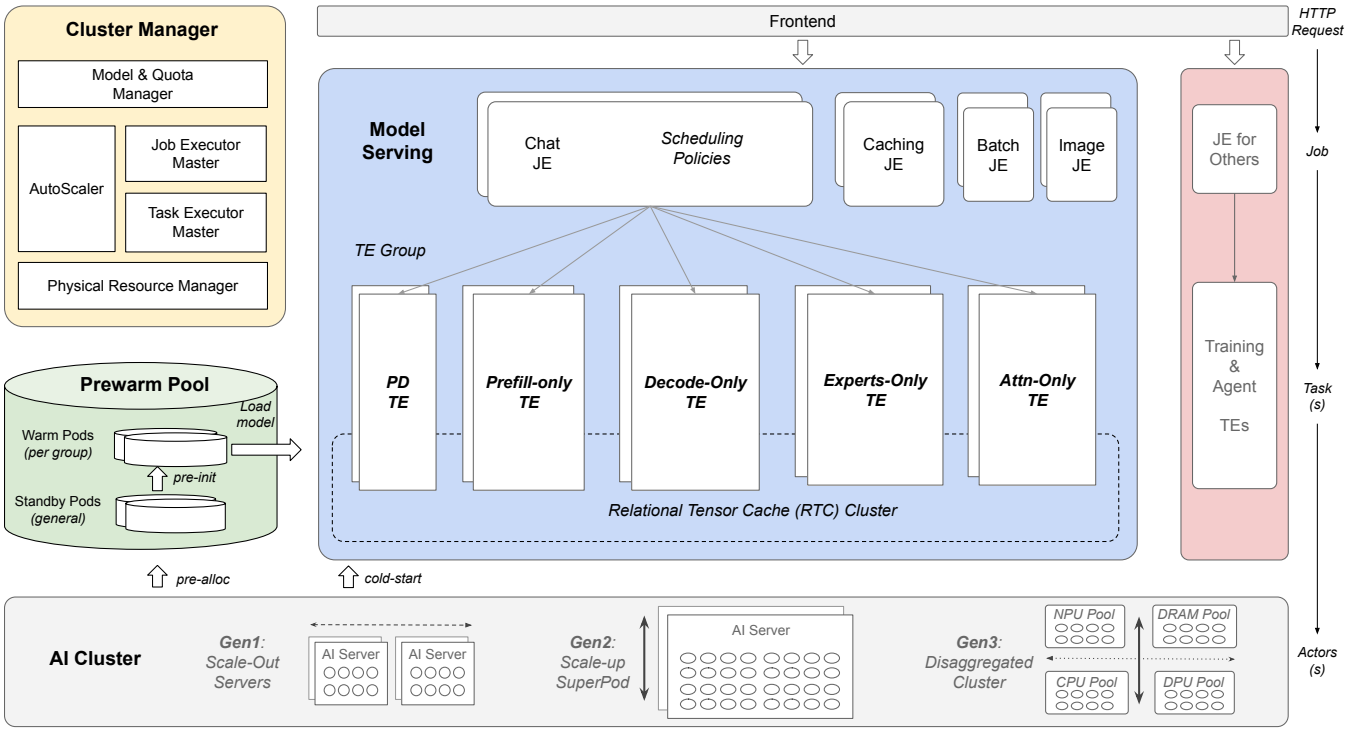

Figure 1: **DEEPSERVE Overall Architecture**. (a) User requests are routed through the frontend and dispatched to the appropriate JEs. (b) Model serving includes various types of JEs, such as those for chat completion and batch inference. (c) Each model-serving JE independently runs distributed scheduling algorithms. (d) Model-serving TEs in an RTC group can exchange tensors using DistFlow APIs (see §4.4). (e) The cluster manager is a centralized, high-availability module. (f) We omit post-training and agent serving for brevity. (g) We plan to run three generations of the NPU cluster. We currently support Gen1 and Gen2.

- Challenge 1: AI workloads have varying durations, posing challenges for efficient resource sharing. For example, fine-tuning can take hours to days, while agent serving and LLM serving typically take seconds to minutes. The challenge lies in dynamically allocating shared resources among these workloads without underutilizing or overloading the system.

- Challenge 2: LLM serving is becoming more distributed and stateful. A single inference request may span multiple distributed instances [12, 33, 51] and use cached states [11, 14, 50], making it challenging to efficiently manage resource allocation, synchronization, and fault tolerance across the system.

- Challenge 3: LLM serving is highly variable, leading to fluctuating resource demands [10, 49]. This fluctuation introduces challenges in optimizing resource utilization and handling cold-start latencies.

To address these challenges, DEEPSERVE (Figure 1) integrates the following four key designs.

Serverless Abstraction. DEEPSERVE introduces a developer-facing serverless abstraction called the request-job-task model. In this model, a *request* is an external trigger (e.g., a user-sent HTTP call). A *job* (or multiple *jobs*) matching the request type (e.g., chat, fine-tuning) handles the request. A task is a fine-grained operation within a job (e.g., prefill task, decode task). Users interact with DEEPSERVE by sending HTTP requests, each triggering one or more internal jobs. A job, in turn, may spawn multiple tasks. For example, a fine-tuning request triggers multiple jobs, such as preprocessing, training, and evaluation. A chat request triggers a single serving job. In the chat case, if executed on a PD-colocated engine [22], the job generates one task. If executed in a prefill-decode-disaggregated setup [33], the job generates two tasks: one for the prefill instance and the other for the decode instance. This abstraction allows DEEPSERVE to (i) scale AI workloads over shared infrastructure, (ii) consolidate post-training and serving on the same cluster, and (iii) simplify distributed LLM serving.

More specifically, DEEPSERVE's serverless abstraction consists of three core components: job executors, task executors, and a cluster manager. The Job Executor (JE) processes incoming requests, decomposes them into tasks, and assigns

tasks to available task executors for execution. The task executor (TE) is responsible for executing the tasks. DEEPSERVE deploys JEs and TEs dedicated to post-training, agent serving, and model serving. The cluster manager is a highly available system that oversees and scales all JEs and TEs. It includes centralized master modules for both JEs and TEs, each monitoring their health. Due to space limits, this paper focuses on the model-serving aspect.

Efficient LLM Serving. We design FLOWSERVE (§4) as an efficient serving engine used by each model-serving TE. To minimize interference between the prefill and decode stages of LLMs, FLOWSERVE adopts a PD-disaggregated serving paradigm for both dense and sparse models [11, 51].

Scheduling. To support increasingly stateful and disaggregated serving, we propose distributed scheduling algorithms (§5) that run on model-serving JEs. Model-serving TEs running the same model and serving mode (e.g., prefill-only, decode-only) are organized into a TE group. JEs dispatch requests to appropriate TEs within these groups based on our scheduling algorithms.

Fast Scaling. DEEPSERVE uses fast scaling (§6) to quickly adjust to changing online workloads. Key techniques include reserving pre-warmed Pods and TEs, pre-loading models into DRAM, and using high-speed NPU-to-NPU links for faster model loading. These techniques greatly reduce code-start time and allow DEEPSERVE to scale up to 64 instances in parallel within seconds.

In the rest of the paper, we discuss **serving** in §4, **scheduling** in §5, and **scaling** in §6.

4 FLOWSERVE: An Efficient Serving Engine

This section presents FLOWSERVE, our in-house serving engine for LLMs, Large Multimodal Models (LMM), and embedding models.

4.1 Overview

We build FLOWSERVE with the following three main goals[1]. First, we want to create a high-throughput serving engine that works as a single TE. Second, we aim for fast iteration, given that serving is a fast-moving field. Third, we want FLOWSERVE to be Ascend-NPU-native, able to work with different generations of the Ascend cluster—from regular scaled-out servers to scaled-up SuperPod, and eventually fully disaggregated data centers [38].

To achieve these goals, we build FLOWSERVE based on three guiding principles:

- **Microkernel-Inspired Design.** We apply the core principles of microkernel architecture by decoupling serving-engine functionalities into modular components. This modularity enables independent scaling, independent evolution, and asynchronous operations, thereby enhancing throughput.
- **NPU-Centric Execution.** We aim to keep NPUs busy all the time, reducing delays caused by waiting for other resources, such as CPU, DRAM, storage, and network.
- **SPMD-based Design.** We use the Single-Program-Multiple-Data (SPMD [5]) design to enable efficient parallel processing and scaling across multiple NPUs, a design shared by vLLM [22].

Figure 2 presents FLOWSERVE's overall architecture. Each model-serving TE has a *TE-shell* and a FLOWSERVE engine. The *TE-shell* is an infrastructure module consisting of predefined modules such as scaling, health reporting, and a few customized modules that serve as context caching handlers.

The FLOWSERVE engine has six core functionalities: tokenization (with a tokenizer), model execution, scheduler, memory management, caching management, and networking management. The tokenizer is an independent module that can scale on its own. Adhering to the SPMD design principle, FLOWSERVE follows a master-executor architecture: the master oversees scheduling, caching, networking decisions, while per-NPU executors carry out these decisions on their respective NPUs. We map the remaining functionalities, excluding the tokenization, onto this master-executor design as follows:

- **Scheduling and Model Execution (§4.2).** The master scheduler assigns the next batch, and each executor runs the model's forward pass on this batch. The master broadcasts requests to all executors when initiating a batch.
- **Caching and Memory Management (§4.3).** We build a Relational Tensor Cache (RTC) to unify the management of both caching and memory allocation. The master maintains indexing structures such as a prefix tree [50], while each executor handles memory allocation.
- **Networking Management (§4.4).** We build Distributed Flow (DistFlow) to transfer tensors between model-serving TEs. DistFlow runs on each executor, providing memory-transfer APIs for both the model generator and scheduler, supporting multiple transfer backends and Ascend cluster generations.

We implement FLOWSERVE primarily in Python, with RTC and DistFlow implemented in C++. Although having design principles is important, translating them into an efficient implementation is a significant challenge. Figure 3 shows the decoding performance of FLOWSERVE in three versions over a period of three months. From v1 to v2, we introduced asynchronous scheduling and IPC optimization, which resulted in more than 2x improvements when the TPOT SLO was set to 50ms. From v2 to v3, our optimizations focused on data structures, sampling, and so forth; these optimizations resulted in roughly 20% improvement.

[1] These goals were established in late 2023 and have guided the design ever since.

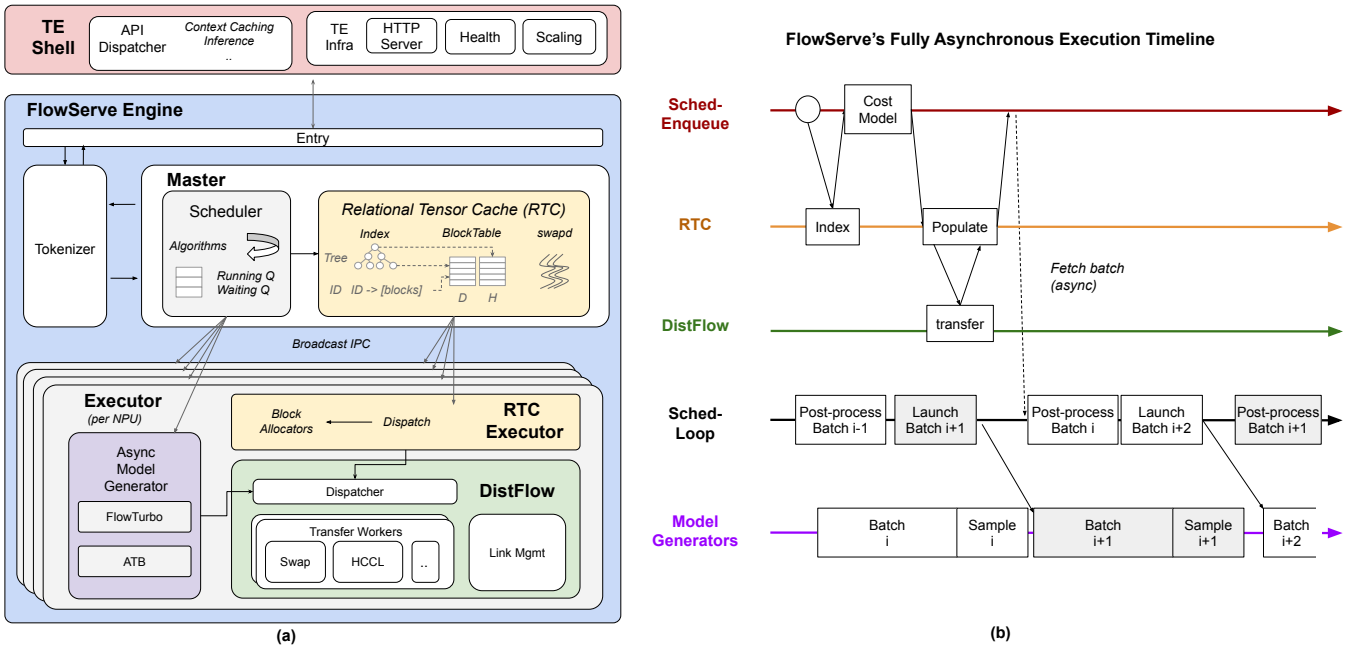

Figure 2: **FLOWSERVE Architecture and Asynchronous Execution Timeline.** (a) The FLOWSERVE engine can be deployed without the TE-shell. (b) The FLOWSERVE's model generator supports multiple backends. FlowTurbo is a torch-based dynamic graph. Ascend-Transformer-Boost (ATB) is a C++-based static graph [16].

4.2 Scheduling

The scheduler is centralized in the master module. We choose this approach over the distributed schedulers (used by SGLang [50]) due to its simplicity, albeit at the cost of frequent Inter-Process Communications (IPCs). The scheduler supports asynchronous KV cache prefetching enabled by RTC and DistFlow (described below) and asynchronous execution, a design shared by vLLM [22], SGLang [50], and NanoFlow [52]. We now describe the execution timeline in the right part of Figure 2.

Asynchronous KV Cache Prefetch. A sched-enqueue thread handles tokenized requests from the tokenizer with the following three steps. First, the thread calls the RTC `match` API to check for any preserved KV cache. The returned info tells whether a prompt prefix or ID has cached KV and the cached KV's location (e.g., in the NPU or swapped to tiered storage). Second, if there is cached KV but a portion of it is not in the NPU, the scheduler runs a cost model to decide whether reusing the cache is beneficial. If the cost model suggests that reusing the cache can improve performance, the scheduler calls the `populate` API to request RTC to fetch the cache into the NPU. This step is done asynchronously. RTC will call DistFlow to read KV from tiered storage or other TEs. Once RTC completes the cache population, it notifies the sched-enqueue thread, which marks the request as ready. The sched-loop will pick it up during the next scheduling cycle.

Asynchronous Execution. The asynchronous execution design aligns with our NPU-centric principle of fully utilizing the NPU. It is similar to the new zero-overhead scheduler introduced in SGLang-v0.4.0 [50]. The key observation behind this design is that scheduling decisions do not depend on the actual token IDs generated by the model, but rather on the number of tokens to be processed in each run. In typical decoding scenarios, where one token is generated per sequence per decoding step, the scheduler can predict the required resources for the next run before the current one completes. Doing so allows the scheduler to operate in a separate thread, preparing the necessary inputs for the model generator beforehand. By running the scheduler in parallel with the model execution, we eliminate unnecessary CPU wait time, ensuring that the NPU remains busy.

Pipeline Parallelism (PP). We optimize our scheduler for PP by running a centralized scheduler at the first stage of PP; other stages accept only requests from previous stages. This design enables FLOWSERVE to manage all micro-batches in a unified way. This approach has two main benefits. (1) Memory resources are managed in one place, making it easy to preempt sequences across micro-batches. (2) With chunked prefill enabled, the scheduler distributes chunks across consecutive micro-batches, rather than sticking to just one micro-batch [1]. Doing so helps reduce Time-To-First-Token (TTFT) by at least 20%.

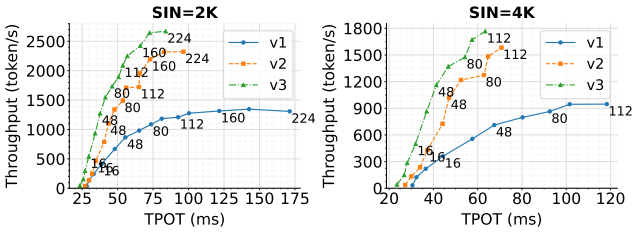

Figure 3: **FLOWSERVE Offline Serving Perf.** We run a 34B model with TP=4. The left has a prefill length of 2K, and the right is 4K. We run 256 decoding steps and report the average TPOT and decoding throughput.

Table 1: The Core APIs of Relational Tensor Cache.

API	Description
`MatchByPrefixToken`	Find preserved KV cache by tokens
`MatchByID`	Find preserved KV cache by ID
`Populate`	Fetch preserved KV cache into NPU
`QueryPopulate`	Check populate status
`AllocBlocks`	Alloc blocks for prefill
`AppendBlock`	Alloc block for decode
`Copy`	Copy blocks from NPU to DRAM
`Free`	Free blocks

4.3 Caching

We build a Relational Tensor Cache (RTC) to integrate prefix caching [50] and position-independent caching [14, 45] into FLOWSERVE. The core function of RTC is to manage the *relationship* between tensors, primarily the KV cache.

Abstraction. Table 1 lists the main APIs of RTC. RTC provides two main sets of APIs. The first set is for managing basic blocks, such as `AllocBlocks` and `AppendBlock`, which are used by prefill and decode requests, respectively. The second set is for managing KV caching. Notably, RTC includes various match APIs, each supporting different indexing mechanisms, such as prefix-token-based or explicit ID-based matching. FLOWSERVE's implicit caching uses the prefix-token-based mechanism, while the explicit ID-based mechanism is used by DEEPSERVE's explicit context caching endpoint. RTC also offers a novel `populate` API. When invoked, RTC fetches the specified KV cache in the given address range into local NPUs.

Design. RTC follows the master-executor architecture of FLOWSERVE. The master module manages the RTC module, making decisions about allocation and data movement, while each executor runs an RTC executor to perform these actions. Internally, RTC includes a traditional block table, originally proposed by vLLM [22], for managing data blocks. Additionally, RTC employs a hybrid indexing layer that combines radix-tree indexing [50] with ID-based indexing. In our current design, each index node can point to data stored either in the NPU or in local DRAM. We are also adapting RTC for SuperPod to leverage its global shared memory. Finally, the RTC master runs multiple background threads to handle tasks such as background swapping and prefetching.

4.4 Networking

Emerging distributed serving techniques—such as disaggregated prefill-and-decode [12, 33, 51] and disaggregated attention-and-experts [7, 32]—require new communication primitives that go beyond traditional collectives. `DistFlow` is designed to meet this demand. `DistFlow` specializes in peer-to-peer and many-to-many tensor transfers across heterogeneous memory. It supports transfers both within a single TE across tiered storage and between distributed TEs.

Abstraction. `DistFlow` provides a simple but expressive interface. Its control-plane APIs include `LinkCluster` for establishing peer groups, and its primary data-plane API is `transfer(srcInfo, dstInfo)`. Users are required to specify exact source and destination memory buffers; `DistFlow` operates on raw memory addresses rather than higher-level block abstractions. In FLOWSERVE, this API is used by the centralized scheduler, each executor's model generator, and the RTC executor.

Design. `DistFlow` follows key principles from high-performance RPC systems [19, 20, 29, 42]. It employs scalable threading models to avoid synchronization bottlenecks and supports multiple backends to adapt to heterogeneous network fabrics. In scaled-out Ascend clusters, `DistFlow` uses the Huawei Collective Communication Library (HCCL) peer-to-peer API as its transfer backend. In scaled-up Ascend SuperPods, where CPUs and NPUs share a unified memory space, it leverages NPU memory copy primitives for direct, high-bandwidth tensor transfers.

4.5 Disaggregated Serving

Serving is increasingly disaggregated. In DEEPSERVE, we define two levels of disaggregation:

- **Task-level**. This level refers to disaggregating prefill and decode into separate TEs. Our implementation is similar to previous work [12, 33, 51]: FLOWSERVE in the prefill TE sends prefilled KV cache to decoding TE either by-req or by-layer using DistFlow's transfer API. Figure 4 shows an online serving test comparing PD-disaggregated and PD-colocated using an internal trace. Disaggregation greatly improves throughput under certain SLOs and lowers TPOT with the same throughput.

- **Operator-level**. This level refers to disaggregating attention and experts into separate TEs. We take inspiration from pioneering work in this space [7, 32]. We are actively working toward deploying it over SuperPod.

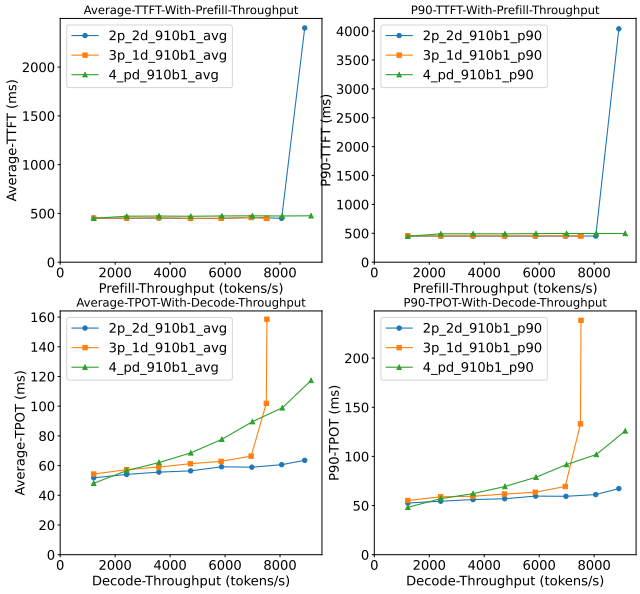

Figure 4: **FLOWSERVE Online Serving Perf.** We run a 34B model with TP=4 using an internal trace (roughly 2K input with 200 output). We test three setups: (1) PD-disaggregated with two prefill and two decode, (2) PD-disaggregated with two prefill and one decode, and (3) four PD-colocated. We vary RPS from 0.2 to 1.2 in a step of 0.2.

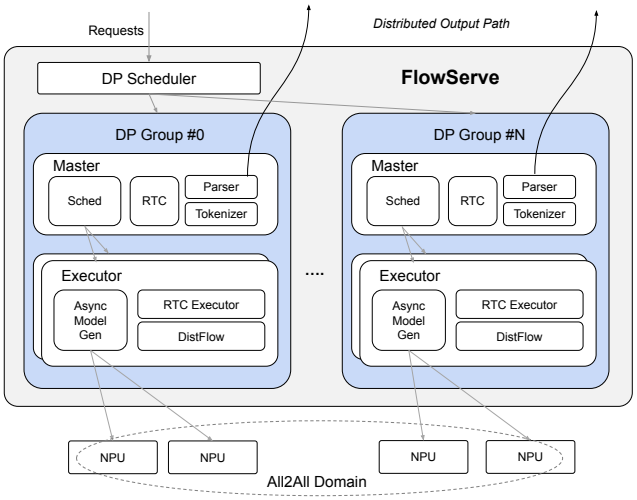

Figure 5: **Adapting FLOWSERVE for SuperPod.** A single FLOWSERVE TE can manage up to tens of servers and hundreds of NPU chips.

4.6 Serving at SuperPod-Scale

This section outlines the key changes (to FLOWSERVE) that enable it to run at SuperPod scale. We begin by examining the workload shift that motivates these changes, followed by a description of the corresponding architectural changes.

From a workload perspective, large Mixture-of-Experts (MoE) models—such as DeepSeek-V3/R1 [25] and Pangu-Ultra-MoE [41]—are a natural fit for SuperPod-scale infrastructure. First, MoE models require efficient all-to-all communication before and after the expert modules, benefiting significantly from a large-scaled-up domain with high-bandwidth interconnects. Second, MoE experts achieve high compute efficiency at only large batch sizes. Enabling such batches necessitates data parallelism in the attention layers (DP Attention) instead of traditional tensor parallelism. Under DP Attention, colocating the prefill and decode stages leads to severe interference [12,25]. As a result, effective deployment requires disaggregating prefill and decode (PD disaggregation), which further depends on fast, low-latency interconnects. The CLOUDMATRIX384 SuperPod provides a significantly larger scaled-up domain with a global shared memory address space and enables low-latency, high-bandwidth data transfers between any CPU or NPU in the system, making it ideally suited for serving large-scale MoE models.

Motivated by these requirements, we introduce two major architectural changes to scale FLOWSERVE to hundreds of NPU chips, as summarized in Figure 5. First, to avoid scheduling bottlenecks, we partition the system into multiple parallel DP groups. Each group includes a full set of components—its own scheduler, RTC, DistFlow, and executors. A centralized DP scheduler dispatches requests across DP groups using either a round-robin or greedy strategy. To eliminate bottlenecks on the return path, each DP group independently returns tokens to the frontends. Second, to support large-scale PD disaggregation, we extend `DistFlow` to support M:N connections. Specifically, we establish transfer channels between all prefill and decode DP groups.

5 Distributed Scheduling

This section discusses DEEPSERVE's distributed LLM request scheduling policies.

5.1 Overview

In DEEPSERVE, distributed scheduling for LLM requests faces three new challenges. The first challenge involves locality and states. Before prefix caching was introduced into FLOWSERVE, distributed scheduling was straightforward, as all TEs could be treated as stateless, and scheduling was based solely on load. However, with the introduction of prefix caching, TEs have become stateful, and the goal is to schedule requests where KV cache reuse is possible, leading to the need for locality-aware scheduling. Achieving locality-aware scheduling is non-trivial. Selecting the best TE for

a given request requires balancing KV cache reuse while avoiding overloading the TE that holds the most cache. The second challenge comes from disaggregated serving. Distributed scheduling was easier before PD-disaggregation was added to FLOWSERVE because all TEs were the same. However, with PD disaggregation, choosing the best TE for a request becomes more complex, as it is unclear whether PD-disaggregated TEs or a PD-colocated TE will perform better. The last challenge arises from the coexistence of both prefix caching and disaggregation in DEEPSERVE, requiring any practical algorithm to consider both factors.

DEEPSERVE uses the following designs in response to these challenges: a locality-aware scheduling algorithm (§5.2), a PD-aware scheduling algorithm (§5.3), and a combined scheduling algorithm (§5.4) as listed in Algorithm 1.

5.2 Locality-aware Scheduling

In this section, we aim to answer one question:

> Given a request and a set of TEs with associated KV cache residency information, how can we select the TE that maximizes KV cache reuse to efficiently serve the request?

To address this question, we implement a prompt-tree-based, locality-aware scheduling policy in the `select_tes_prefix_match` function, as shown in Algorithm 1. Similar to Preble [39], SGLang [50], and MemServe [11], the distributed scheduler in JE maintains a global prompt tree for each type of TE, while each TE also maintains a local prompt tree that shares an index with its corresponding global tree. When a request arrives at the JE, it matches the prompt tokens against the global prompt trees and selects the TE that has the longest common prefix, indicating the largest preserved historical KV cache.

5.3 PD-aware Scheduling

In this section, we aim to answer one question:

> Given a request and a set of TEs with both PD-disaggregated and PD-colocated instances, how can we select the most appropriate TE type that best aligns with the characteristics of the request?

We first study the performance comparison between PD-disaggregated and PD-colocated across various dimensions in a heatmap. We then discuss converting such a heatmap into a practical scheduling algorithm.

5.3.1 Study

We first run tests to compare PD-disaggregated and PD-colocated TEs (with chunked prefill). Figure 6 presents the results (see caption for detailed setup).

The heat map shows that PD-disaggregated and PD-colocated TEs divide the request space into distinct regions. We find three key observations. First, the PD-disaggregated setup performs better for requests with longer prompts and shorter decode. Additionally, as prefill length increases, its advantage becomes more pronounced for requests with longer decode lengths. Second, PD-disaggregated TEs provide a larger performance advantage over PD-colocated TEs (dark read) than the reverse (light blue), suggesting that a correct choice of PD-disaggregated TE leads to significant performance gains, while an incorrect choice results in minimal loss. Finally, the advantage of PD-disaggregated and PD-colocated TEs remains consistent across different RPS values.

5.3.2 Algorithm

The preceding study is conducted in a controlled environment, and applying it to a practical scheduling algorithm is challenging due to the dynamic nature of RPS and the uncertainty of decode length at the time of scheduling. There are multiple potential approaches to convert the study into an algorithm.

We propose a simple policy called `select-tes-PD-heatmap`, described in Algorithm 1. The policy works as follows. First, we combine the heat maps across all RPS values through element-wise addition. Given the stability of the heat map, over 80% of the squares consistently show either positive or negative values across all RPSs, while the remaining 20% are uncertain. Second, we predict the decode length for an incoming request using a predict model with 84.9% accuracy to balance prediction precision and overhead. For more details, please refer to the following discussion section. Third, we identify the corresponding square on the heat map based on the combined heat map, the prefill length, and the predicted decode length. If the value is positive, we select PD-disaggregated TEs; if negative, we select PD-colocated TEs.

We perform a microbenchmark study shown in Figure 7. We make three key observations. First, under certain RPS levels (e.g., 10 reqs/s), the PD-aware scheduling policy outperforms RR. Second, at low RPS levels, the performance of PD-aware matches that of RR. The reason is that under low RPS, interference between prefill and decode operations within PD-colocated TEs remains negligible, and PD-disaggregated TEs do not offer significant advantages. Third, at very high RPS levels, PD-aware performs worse than RR. The reason is that PD-disaggregated TEs, with the same resources (e.g., two cards), are more prone to overloading. However, even when overloaded, PD-aware scheduling does not exhibit significant performance degradation compared to RR.

5.3.3 Discussion of the Predict Model

Accurately predicting decode lengths with minimal overhead remains a challenging research problem. We adopt

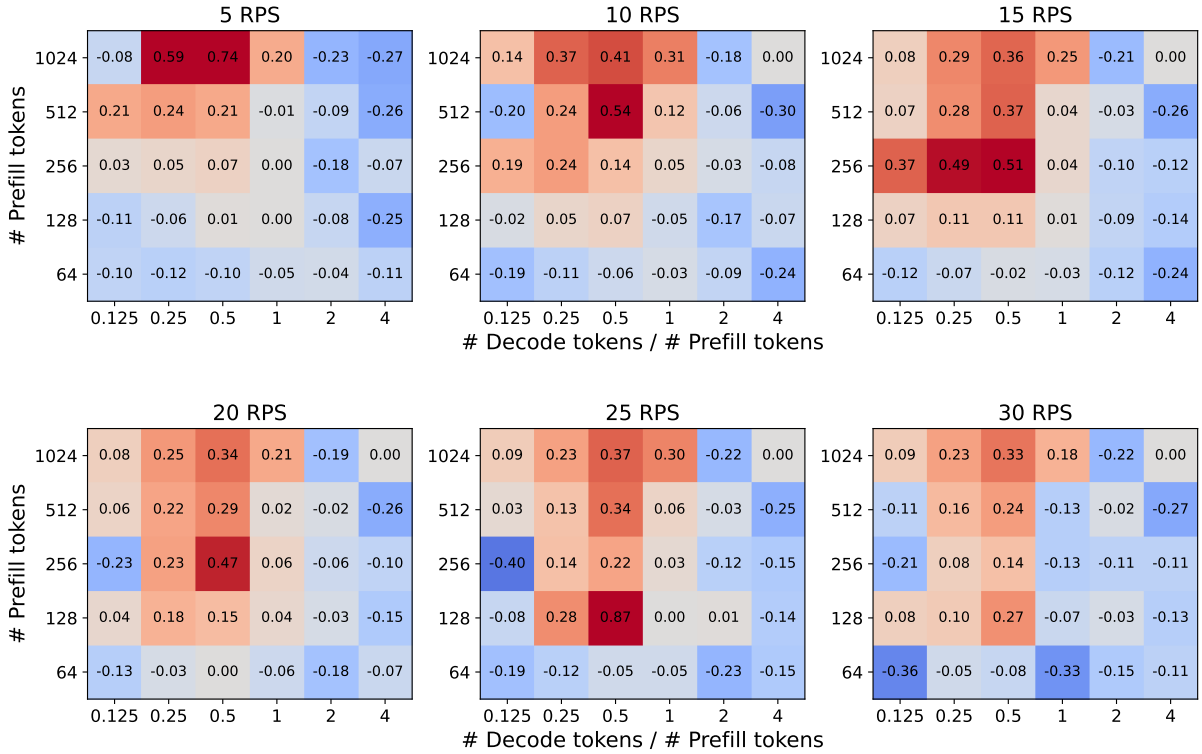

Figure 6: **Comparing the Performance of PD-disaggregated and PD-colocated (with chunked prefill) using Heatmap.** The y-axis represents the prefill length, and the x-axis shows the ratio of decode length to prefill length. For each combination of prefill and decode lengths, we execute a batch of identical requests at a fixed RPS on both PD-disaggregated and PD-colocated TEs. The heatmap cells display the difference in JCT between the two setups, computed as the ratio of JCT for the PD-colocated TE to the PD-disaggregated TE, minus one. A positive value indicates better performance of the PD-disaggregated TE, while a negative value suggests that the PD-colocated TE is more efficient. This figure uses a 34B model with TP=4.

the approach proposed in TetriServe [12], which employs a lightweight LLM-based classification model—referred to as the predict model—to classify decode lengths into fixed-size buckets, assuming execution by a specified target LLM.

We predict length ranges rather than exact token counts for two reasons. First, inference parameters such as temperature and top-p [3] introduce substantial variability in outputs, making accurate prediction difficult. Second, our goal is to support scheduling decisions, for which approximate length ranges are sufficient (Figure 6).

The training process for the predict model consists of the following three steps. First, we construct a prompt-only training dataset using public sources, a target model (e.g., LLaMA 70B), and a predict model (e.g., OPT 125M [17]). Second, we query the target model with the prompts to generate responses, which we discretize into fixed-size length buckets to serve as ground truth. Third, we split the dataset into training and evaluation sets, and train the predict model accordingly.

In our experiments, we use a bucket granularity of 128 tokens and achieve 84.9% accuracy. Since our focus lies in using prediction to inform scheduling, we leave further accuracy improvements to future work.

5.4 Combined Algorithm

We propose a combined algorithm that integrates load-aware, locality-aware, and PD-aware scheduling. The scheduling algorithm, outlined in Algorithm 1, relies on three core function calls: `locality_aware`, `PD_aware`, and `load_aware`. These functions progressively refine the TE group, narrowing it down from the entire set to a single TE based on the request's characteristics and the underlying TEs.

The scheduling process proceeds as follows. First, a subgroup of TEs is selected by choosing a specific type, such as PD-colocated or PD-disaggregated TEs, based on the request's length and the heatmap of the TE group (Section 5.3). Second, once a subgroup of TEs is identified, the selection is further refined. If the load is balanced across the remaining TEs, the algorithm prioritizes a TE with the most reusable KV cache, using tree-based prefix matching (Section 5.2). If

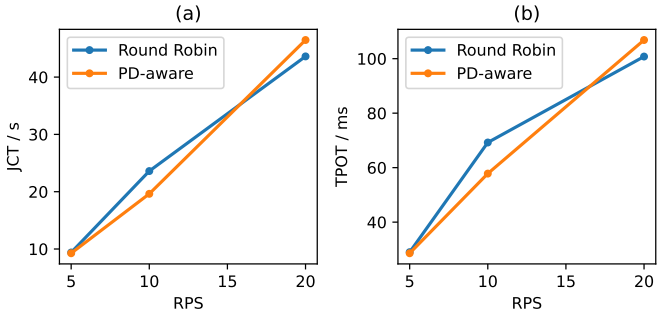

Figure 7: **Study of Distributed Scheduling Algorithm.** We run a 34B model with TP=4, and report JCT / TPOT. We run an internal trace sampled from a code-generation service. The cluster consists of four servers with two PD-colocated TEs and a pair of PD-disaggregated TEs (1P1D).

the load is unbalanced, the algorithm instead prioritizes a TE with the least load to achieve better load distribution.

Algorithm 1: Distributed Scheduling Policy

Input: A new request: req, a TE group: tes
Output: A TE to forward the request to

```
Function dist_sched(req, tes):
    tes ← PD_aware (req, tes);
    if tes.is_load_balanced() then
        tes ← locality_aware (req, tes);
    else
        tes ← load_aware (req, tes);
    return tes;
Function PD_aware(req, tes):
    p_l ← req.get_prefill_length ();
    d_l ← req.get_decode_length ();
    tes ← tes.select_tes_PD_heatmap (p_l, d_l);
    return tes;
Function locality_aware(req, tes):
    tes ← tes.select_tes_prefix_match (req);
    return tes;
```

6 Fast Scaling

In DEEPSERVE, the cluster manager's AUTOSCALER determines when to scale TEs and JEs based on metrics such as load or SLO-violation rates. Fast scaling is critical but particularly challenging for LLM-serving TEs, as it requires loading large model weights onto NPUs. This section describes our optimizations for fast scaling.

Figure 8 shows the autoscaling workflow, which involves five steps, with challenges and solutions summarized in Table 2 and performance breakdown in Figure 9. First, in the *Scaler-Pre* step, DEEPSERVE prepares resources and pod environments for the new TEs. For large models, a TE may span multiple pods on multiple machines. Second, the *TE-Pre-Load* step initializes the FLOWSERVE instance but does not load the model onto the NPU. Third, the *TE-Load* step covers loading model weights onto the NPU. We decouple the second and third steps to allow for pre-warmed TEs, facilitating faster scaling (see §6.1). Fourth, the *TE-Post-Load* step involves engine warm-up and CPU/NPU block allocation. Open-source inference engines such as vLLM [22] rely on warm-up to profile the allocable HBM size for KV caches. We find this step unnecessary in production, because we can offline profile this data and store it in configurations. To address the slowdown of the first request after removing warm-up, we add a dummy message post-startup. Finally, in the *Scaler-Post* step, the new TEs are announced to the cluster, and JEs direct requests to them.

6.1 Pre-warming Pods and TEs

DEEPSERVE maintains two levels of pre-warmed resources. First, at the pod level, DEEPSERVE reserves a small number of pre-warmed pods with basic environment setup. These workload-independent pods are usually managed by the infrastructure layer, such as Kubernetes, and can be shared across services to reduce overhead. Second, on these pre-warmed pods, DEEPSERVE maintains a small pool of pre-warmed TEs to minimize *TE-Pre-Load* time. The *TE-Pre-Load* step includes FLOWSERVE's startup time, which involves loading Python libraries, initializing NPU states, and setting up HCCL cross-NPU interconnections. We optimize this step by approximately 35% for most models using techniques such as late importing and parallel initialization. However, as shown in Figure 9, this step still accounts for the majority of startup time. To further reduce the startup time, we move the initialization out of the critical path by incorporating a TE pre-warming mechanism.

Our TE pre-warming design is carried out in two stages. First, we make the pre-warmed TEs model-agnostic. For example, a TP-8 pre-warmed TE can be adapted to run either a Llama3-70B or a Qwen2-72B model. This stage requires carefully distinguishing between model-specific and model-agnostic parameters. Second, we make the pre-warmed TEs agnostic to parallelism strategies by recognizing that, regardless of TP/PP/SP configurations, all TEs follow a master-SPMD architecture. This stage allows independent pools of pre-warmed SPMD-masters and SPMD-executors, and these pools can be packed on demand.

Table 2: **A Summary of DEEPSERVE's End-to-End Scaling Steps, Challenges, and Solutions.**

ID	Step	Definition	Major Issues	Our Solutions
1	Scaler-Pre	Creating pods to hold the TE.	1. Resource allocation is slow	1. Pre-warmed Pods
2	TE-Pre-Load	Launching the TE w/o model loading	1. Python startup is slow 2. NPU init is slow	1. Pre-warmed TEs
3	TE-Load	Loading the model onto the NPU	1. Model weight is large	1. DRAM pre-loading 2. NPU-fork
4	TE-Post-Load	Preparing TE to serve requests	1. Engine warmup is slow 2. Block alloc is slow	1. Offline profiling 2. Async allocation 3. Dummy req warmup
5	Scaler-Post	From TE ready to serve first request	1. The update of the global TE list is slow	1. Proactive pushing

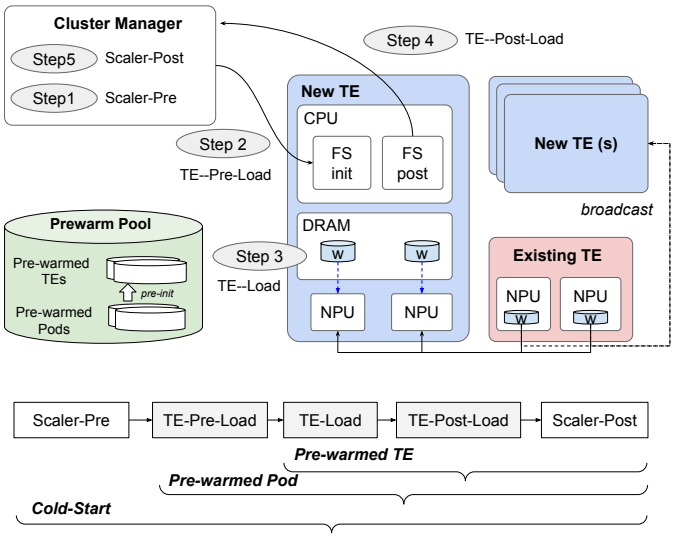

Figure 8: **DEEPSERVE's Scaling Design.** (a) We show TE-Load's two cases: loading from local DRAM (DRAM-hit) and loading from another TE's NPU (NPU-fork). NPU-fork can be either via scale-up or scale-out network link. (c) The bottom shows the timeline for three scaling cases.

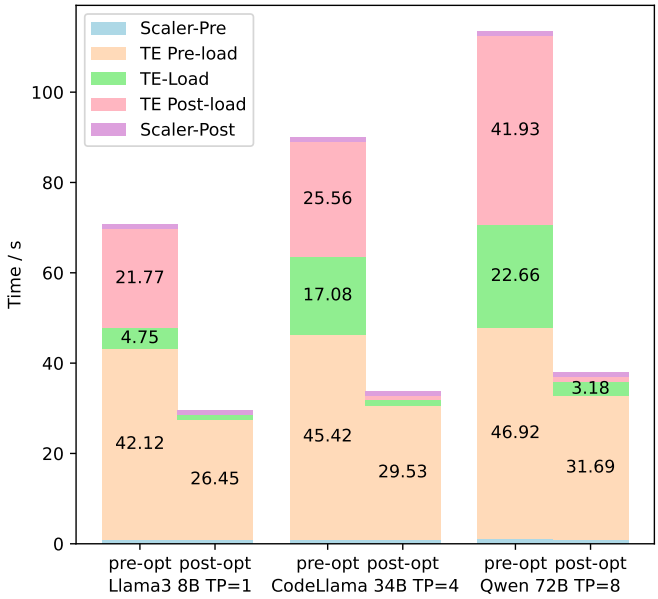

Figure 9: **Scaling E2E Breakdown**. We present the scaling latency both before and after optimizations. Even after optimization, the *TE-Pre-load* step still remains the dominant factor in scaling time, although this latency can be further reduced through pre-warming (§6.1).

6.2 Optimizing Model Loading

DEEPSERVE has two model-loading paths: *local loading* via PCIe from local DRAM or SSD, and *NPU-fork* using high-speed NPU-to-NPU links from a running TE. While NPU-fork is generally faster, it has higher hardware requirements and cannot be used during code start (scaling from 0 TE).

Local loading with pre-warming. We use the safetensors format [36] for model storage. Compared to the native binary format, safetensors reduce serialization costs by storing tensors in contiguous blocks that can be directly mapped into memory and trigger data reads only on page faults. Safetensors also simplify pre-loading into the page cache, reducing read amplification. Instead of loading the entire model file, each TP process loads only the required partition on demand.

To further optimize TE-load performance, we co-design it with our TE pre-warming mechanism. The cluster manager predicts models that are likely to scale and pre-loads them into DRAM page cache using pre-warmed TEs. When scaling is triggered, the master prioritizes selecting pre-warmed TEs with the required model already loaded. On our hardware, each machine has 1.5TB of DRAM, sufficient for pre-loading 10 70B models or 100 7B models.

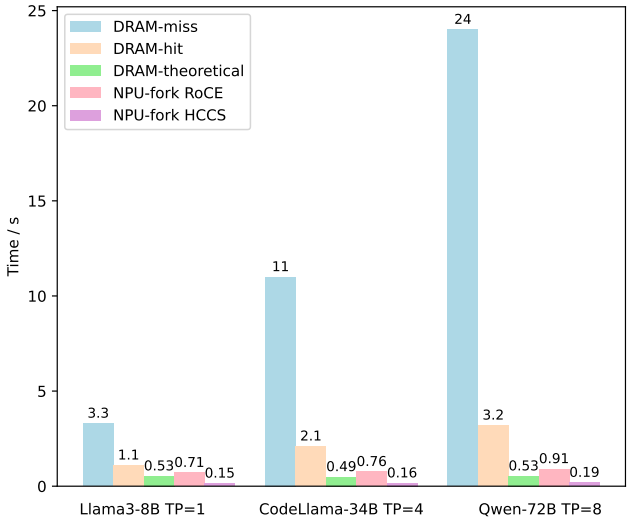

Figure 10: **TE-Load Study.** DRAM-hit means loading from pre-loaded weights in DRAM; DRAM-miss means pre-load miss, thus loading from SSD; DRAM-theoretical is calculated by model weights dividing PCIe bandwidth. NPU-fork has two different links—HCCS and RoCE (see the main text for the differences).

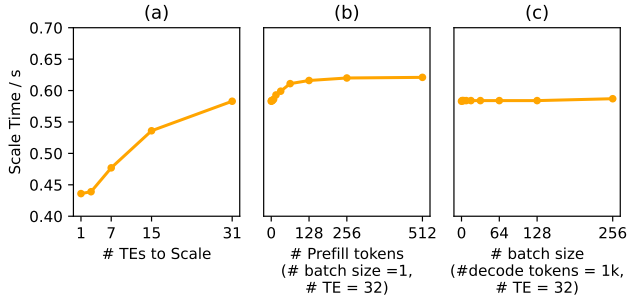

Figure 11: **Scalability and Sensitivity Study of NPU-fork**. We run NPU-fork over a scaled-up network (HCCS) using Llama3-8B-TP1. (a) Scaling multiple TEs in parallel from one running TE. (b) Time for scaling to 32 TEs when the source TE is prefilling sequences of different lengths. (c) Scaling time when the source TE is decoding different batches of sequences, each with a length of 1k tokens.

Figure 10 shows TE-load's performance under different cases (NPU-fork, DRAM-hit, and DRAM-miss). DRAM-hit occurs when the cluster manager correctly predicts the models to scale, while DRAM-miss reflects the opposite scenario. We also compute the theoretical model-loading time by dividing the model weights by the PCIe bandwidth. For DRAM-hit, the difference between measured and theoretical time arises from two factors: PyTorch-model tensor initialization (about 0.3s) and PCIe-bandwidth contention. The latter becomes more significant with larger TP ranks due to shared PCIe links. For the three models in Figure 10, the weights loaded by each NPU are roughly the same, but local loading time increases with larger TP ranks due to PCIe-link sharing among NPUs.

NPU-fork. NPU clusters typically feature high-speed NPU-to-NPU links designed for distributed training. In §4.3, we demonstrate how these links are used for efficient inference. We further exploit them in our NPU-fork technique to transfer model weights during fast scaling. When NPU-fork is triggered, the master notifies a running FLOWSERVE TE to connect to a pre-warmed TE, with model weights transferred using the DistFlow module (§4.4).

Figure 10 shows the performance of NPU-fork. On our Ascend hardware, there are two types of links: HCCS (higher bandwidth, smaller scale) and RoCE (lower bandwidth, scalable to thousands of nodes). All evaluations are conducted on cross-node setups. Overall, loading with HCCS is significantly faster than with RoCE, indicating that NPU-fork will benefit from the SuperPod architecture. The model-loading time is similar across the three models, as the weights to be loaded per NPU are roughly the same. NPU-fork experiences less bandwidth contention compared to local loading, as NPU-fork uses different physical links.

Figure 11 illustrates potential degradation when multiple expansions (up to 32) occur concurrently or when prefilling and decoding overlap the expansions. NPU-fork can scale to a large number of TEs by transmitting model weights simultaneously to multiple TEs using the `broadcast` API in the HCCL collective communication library. We also measure resource-contention sensitivity when the source TE handles prefill and decode requests. Since the NPU has dedicated AICPUs for data transfer, contention is limited.

7 Discussion

We now discuss the broader applicability of DEEPSERVE across hardware platforms and workloads.

NPU-agnostic vs. NPU-specific features. Although DEEPSERVE is built on Ascend NPU chips at Huawei Cloud, its high-level architecture and core design are largely hardware-agnostic. For example, the "NPU-fork" mechanism used for auto-scaling leverages Ascend's HCCS interconnect for rapid scaling. However, similar techniques can be applied to other hardware platforms with fast inter-chip links, such as NVIDIA GPUs with NVLink. Most NPU-specific features involve low-level computation and networking primitives. For instance, in the CloudMatrix384 SuperPod, memory across all NPUs is accessible, allowing data transfers between any two memory locations—a capability not available in regular scaled-out AI servers.

Generalization to non-LLMs. While the paper primarily focuses on LLMs, most components generalize to other model types, such as embedding models and multimodal-understanding models. In fact, all these models run within the FLOWSERVE engine similar to vLLM.

Fault-Recovery Mechanism. In the event of a TE or JE failure, DEEPSERVE reboots the affected component and redirects requests to redundant counterparts. The reboot process ensures recovery within 5 minutes. RTC maintains soft states, which can be recomputed if lost and are append-only. Therefore, we do not implement complex consistency protocols to avoid unnecessary performance overhead for RTC. However, in production, we have not observed a significant impact on service quality, primarily due to (1) system-level redundancy and (2) the SuperPod architecture, which ensures fast and uniform NPU-to-NPU communication regardless of physical location, enabling seamless substitution of failed NPUs.

8 Related Work

In this section, we review related work in four key areas: serverless infrastructure, serving engines, scheduling, and scaling for large language model (LLM) workloads.

Serverless Infrastructure. Extensive research has focused on optimizing LLM serving in serverless architectures [2, 8, 23, 35, 44, 47, 48]. Industry solutions, such as AWS SageMaker and Azure ML [28], deliver cloud-native solutions optimized for deploying, managing, and scaling model inference, tailored specifically to meet enterprise needs. Recent open-source systems, including KServe [21], AIBrix [6], NVIDIA Dynamo [30], and LeaderWorkerSet (LWS) [26], offer practical implementations with varying degrees of support for cloud deployment, auto-scaling, multi-model, multi-node execution, and so forth. DEEPSERVE offers similar functionality but differs in two key aspects. First, while existing systems primarily target GPU clusters, DEEPSERVE is designed for NPU-based clusters. Second, to the best of our knowledge, DEEPSERVE is the first publicly described platform that introduces request-job-task abstraction, integrating diverse AI workloads from post-training to serving.

Serving. Serving is a rapidly evolving field, with many open-source engines such as FLOWSERVE emerging. vLLM [22] pioneers PagedAttention for higher throughput. SGLang [50] uses RadixAttention for reusing cache. LightLLM [13] adopts asynchronous execution for improved throughput. We believe that all serving engines will eventually adopt similar architectures to optimize AI chip efficiency, with differences mainly in hardware support, features, and programming languages. Networking-wise, the Mooncake Transfer Engine (MTE) [34] is closest to FLOWSERVE's DistFlow. Both systems support multiple backends and efficient threading models, following seminal lines of work [19, 20, 42]. The key difference lies in backend implementation: MTE uses RDMA by default, while FLOWSERVE uses HCCL's peer-to-peer APIs on regular scaled-out servers and memory-copy primitives on the CLOUDMATRIX384 SuperPod.

Scheduling. Efficient scheduling is critical for improving the performance of serving systems [1, 9, 11, 22, 33, 34, 43, 46, 50, 51]. For example, at the local layer, Orca [46] proposes iterative-level scheduling to reduce bubbles. Sarathi [1] proposes chunked-prefill to overcome suboptimal prefill processing. FastServe [43] utilizes a multi-level priority feedback queue to minimize JCT. At the global layer, MuxServe [9] formulates a multiplexing problem and proposes a placement algorithm and adaptive batch scheduling strategy to identify optimal colocations in LLM serving. MemServe [11] prioritizes locality by directing requests to instances with the highest cache-hit rate. Our work introduces a novel PD-aware scheduling policy to determine whether a request should be processed by PD-disaggregated or PD-colocated TEs. Additionally, our approach integrates PD awareness with locality- and load-aware scheduling, providing a comprehensive solution for optimizing resource utilization and throughput across heterogeneous TE configurations.

Scaling Optimizations. Scaling serving instances dynamically is a major challenge, mainly because these instances are large and continue growing as modern LLMs' size increases. Recent work on model autoscaling [4, 18, 27, 49] has focused on improving resource use and reducing scaling delays. For example, SpotServe [27] and Llumnix [40] speed up scaling by making task migration between instances cheaper. BlitzScale [49] improves throughput when loading parameters, reduces delays in handling burst requests, and improves the overall service. Our NPU-fork mechanism is similar to BlitzScale [49] but differs in the underlying network fabrics.

9 Conclusion

We have presented DEEPSERVE, a serverless AI platform developed at Huawei Cloud. We have described its serverless abstraction and infrastructure, which enables efficient management of AI workloads. We have also outlined the architecture of FLOWSERVE, our in-house serving engine, detailing its design principles and core components. Additionally, we have explored distributed scheduling policies across a heterogeneous pool of serving instances. Finally, we have provided an end-to-end analysis of fast scaling, highlighting the techniques that allow DEEPSERVE to quickly adjust to fluctuating workloads.

Cosmic: Cost-Effective Support for Cloud-Assisted 3D Printing

Yuan Yao[1], Chuan He[2], Chinedum Okwudire[2], and Harsha V. Madhyastha[1]

[1]*University of Southern California* [2]*University of Michigan*

Abstract

In this paper, we consider a new workload for which serverless platforms are well-suited: the execution of a 3D printer controller in the cloud. This workload is qualitatively different from those considered in prior work due to the stringent timing requirements. Our measurements on popular serverless platforms reveal millisecond-level overheads that impair the timely execution of the example control algorithm we consider. To mitigate the impact of these overheads, we judiciously partition the execution of the algorithm across a set of serverless functions and exploit timely speculation. Our evaluations on AWS Lambda show that, for 30 diverse print jobs, *Cosmic* is able to ensure the timely execution of the controller while reducing cost by 2.8×–3.5× compared to other approaches.

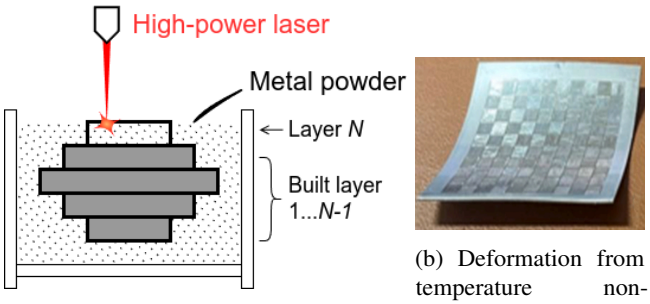
1 Introduction

Serverless computing platforms like AWS Lambda [2] and Azure Functions [3] have gained in popularity over the last few years. In these services, the customer registers their code – typically in the form of a container – with the cloud provider, who runs an instance of the code for every request received. Thus, the customer is freed from the onus of having to monitor load and correspondingly scale up or scale down their service deployment, and they do not pay for idle time.

The scalability and cost-effectiveness of serverless computing make it ideal for workloads with intermittent execution patterns, such as periodic data processing or event-driven workflows. However, when these workloads also demand high parallelization and millisecond-level latency guarantees, significant challenges arise. First, the overhead of cold starts and function invocations, while acceptable for many applications, becomes prohibitive for latency-critical tasks. Second, the management of large datasets across serverless instances introduces significant delays and coordination overhead, as network bandwidth and transfer times dominate.

In this paper, we study these challenges in serverless computing with a non-traditional workload: 3D printing. In particular, our interest is in the control algorithm that guides the operation of a printer by determining the sequence in which it should print the different portions of a product. What distinguishes the controller is the stringent constraint on the timeliness of its execution: before the printer is ready to execute the i^{th} step of a print job, the controller must have identified which portion of the product to print in that step.

Using a state-of-the-art control algorithm for a specific form of 3D printing as an example, we demonstrate that commodity 3D printers lack the hardware necessary to run complex control algorithms on-device. On the one hand, the CPU on the printer cannot execute the sequential control algorithm fast enough to keep up with the speed of printing. On the other hand, to ensure that I/O delays do not slow down the controller, the state needed by all steps of the algorithm must be preloaded into memory. But, the amount of on-board memory does not suffice to accommodate all the necessary state. Therefore, we consider the execution of the controller in a cloud region close to the 3D printer.

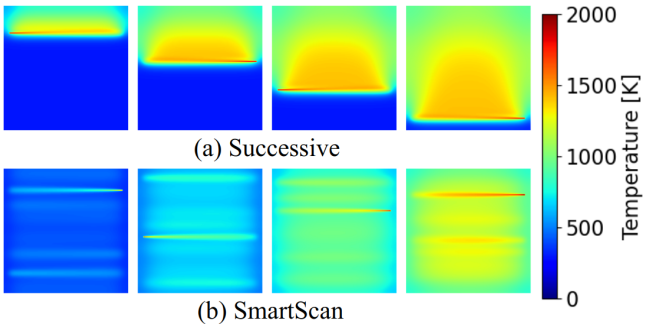


In contrast to running the control algorithm across a fleet of virtual machines, serverless offers two benefits.

- *No cost during idle time:* First, with serverless, the user incurs no cost during idle periods, such as when the printer pauses after each layer to spread metallic powder. These short idle periods of a few seconds make suspending and resuming a VM impractical.
- *No cost to keep state in memory:* Second, to handle requests at low overhead, cloud providers attempt to reuse serverless workers across requests [1]. These *warm starts* retain the state read into the memory of a serverless worker while printing one layer for subsequent layers, at no cost to the user.

Nevertheless, our measurements on AWS Lambda and Azure Functions show that exploiting these benefits while meeting the controller's timing constraints is nontrivial. Function invocation overheads, even on pre-warmed workers, remain too high to meet the stringent requirements of each step of the controller. While parallelizing each step across multiple workers reduces computation time, it introduces substantial delays due to the network overhead of transferring the relevant inputs to all workers.

To address these challenges, we have designed and implemented *Cosmic* (Cost-effective Serverless for Millisecond Computations), a system for cost-effective and timely execution of the low latency compute pipeline necessary to support high quality 3D printing. *Cosmic* distributes sequential algorithms across serverless workers, with three key strategies: intelligent workload partitioning to minimize coordination overhead and optimize function reuse, speculative execution to mask invocation delays, and an adaptive search for the configuration which balances performance and cost.



We use *Cosmic* to run the controller on Lambda for 30 print jobs: 10 diverse parts, each in 3 different sizes. We show that *Cosmic* satisfies the timing constraints on the controller's execution for all jobs; other approaches from prior work that have used serverless either fail in meeting these constraints for 23 of the 30 jobs, or do so at 3.2×–3.5× higher cost.

Figure 1: **Powder bed fusion.**

(a) Successive

(b) SmartScan

Figure 2: **Comparison of temperature distribution when scanning a layer's cells (a) in order versus (b) with SmartScan.**

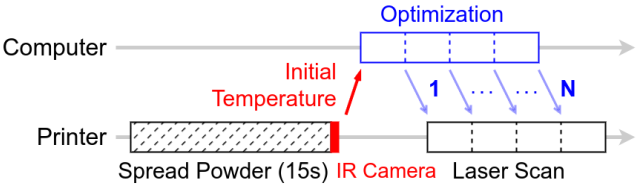

Figure 3: **Timeline of SmartScan execution.**

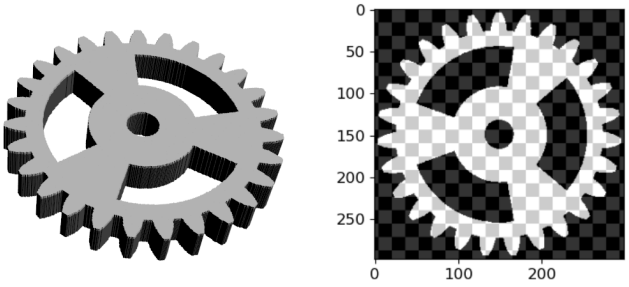
In summary, we make the following contributions:

- We consider a workload that has not been of much interest in the systems and networking research community – real-time control of 3D printers – and showcase the relevance of serverless computing for this workload.
- We present measurements of popular serverless platforms to highlight previously ignored overheads that make it challenging to satisfy the millisecond-level timing requirements of the control algorithm we consider.
- We introduce a new strategy for executing a sequential algorithm on serverless and demonstrate how to use it to cost-effectively satisfy the algorithm's timing constraints.
- Lastly, we demonstrate the utility of our system, *Cosmic*, by using it to run the controller for a variety of print jobs.

Though we focus in this paper on supporting the execution of a 3D printer's controller, many aspects of *Cosmic*'s design extend to other latency-sensitive compute pipelines. We discuss the broader applicability of our work in Section 7.

2 Background and Motivation

Powder bed fusion. There exist a variety of 3D printing technologies [12, 20, 26, 28]. In this paper, we focus specifically on laser powder bed fusion (LPBF), which is used to build three-dimensional parts by selectively fusing or melting metal powder using a laser, as shown in Figure 1(a).



In LPBF, three-dimensional parts are constructed layer by layer. Prior to scanning a layer, a thin layer of metal powder is spread across the platform. The high-power laser then scans this layer, selectively melting the powder to create a solid cross-section of the part. This procedure is repeated for each layer until the entire part is constructed.

One of the primary challenges in LPBF printing is in managing the distribution of temperature during the scanning process. For example, consider Figure 2(a), which shows the print of a square metal plate with the laser scanning each layer from the top edge to the bottom edge. By the time the laser starts scanning the end of the layer, the top half cools down, resulting in a non-uniform distribution of temperature across the layer. As shown in Figure 1(b), such non-uniformity in temperatures can lead to residual stresses and deformities in the final product.

SmartScan. To maximize temperature uniformity, the solution is to optimize the order in which an LPBF printer scans each layer. For this, we consider *SmartScan* [29], a feedforward control algorithm. SmartScan relies on a logical division of each layer into *cells*, e.g., a square metal plate can be partitioned either into a set of horizontal or vertical stripes, or a set of square islands. To determine the optimal sequence in which the cells in a layer must be scanned, SmartScan uses a physics-based thermal model to simulate temperature distribution and heat transfer.

As depicted in Figure 3, the print of a layer starts with the distribution of metal powder across the print platform, which takes a fixed duration of 15 seconds. The printer then employs an infrared camera to capture an initial map of how temperature varies across the layer. The SmartScan algorithm then iteratively computes the index of the next cell to print. Each iteration involves multiplying the current temperature map with a precomputed heat transfer matrix to produce an updated temperature map, which the controller analyzes to pick the next cell index. The process continues until the entire layer has been scanned. Figure 2(b) illustrates the improved temperature uniformity achieved with SmartScan.

Note that, though the cell-specific heat transfer matrices for a part can be reused across multiple prints of that part, the results of SmartScan's computations cannot be reused. The optimal sequence for printing a layer does not depend only on the layer's geometry. It also depends on the initial temperature distribution captured by the infrared camera before the scanning of a layer begins. The temperature distribution at the start of each layer is influenced by multiple dynamic factors which vary across layers, such as residual heat from

(a) A gear (b) One of the layers

Figure 4: **An example part printed using LPBF, and an example partitioning of one of its layers into cells.**

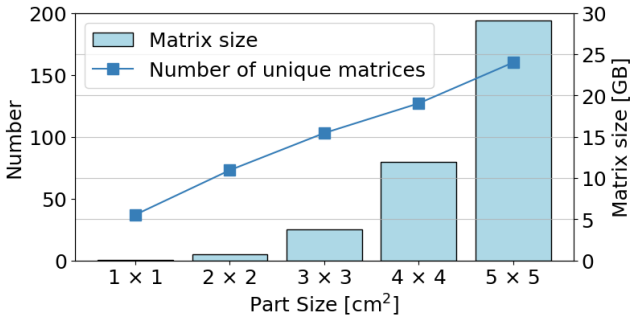


Figure 5: **For the gear in Figure 4, size of each heat transfer matrix, and number of unique matrices in relation to layer size.**

previously melted layers and the spreading of powder across the platform. Unlike the modeling of heat transfer across cells within a layer, these other heat transfer processes cannot be modeled efficiently; hence, real-time computation of the optimal scanning sequence is essential.

Challenges in local execution. Unfortunately, running SmartScan on an LPBF printer's on-board computer is infeasible for most print jobs. This is because, as shown in Figure 3, in order to maintain the accuracy of SmartScan's simulation of heat transfer, it is crucial that, by the time the printer is done scanning a cell, the cell that it should print next has already been computed and delivered to it. Given the typical speed of printing, the length of the time within which SmartScan's computation of the next cell to print must complete – which we refer to as a *time window* – is quite short. For example, at a speed of 600mm/s [29], printing a length of 3cm takes only 50ms. If SmartScan fails to finish computation within a time window, the printer will fall back to printing a random cell, thus degrading printing quality.

Due to this stringent timing constraint, the heat transfer matrices for *all* cells in a layer must be prefetched into memory; else, within any window, delays when reading the heat transfer matrix from disk for the cell currently being printed will leave little to no time to perform the computation necessary to select the next cell. This is a problem because, as shown in Figure 5 for the example gear shape in Figure 4, as the size of the printed part grows, so does the number of cells and the size of the matrix for each cell. For example, to print the gear with each layer of size 16cm^2, 1,514 GB of data – 127 matrices, each of size 11.92 GB – will need to be in memory, which greatly exceeds the amount of memory on-board an LPBF printer.

Moreover, the processor on a typical LPBF printer is incapable of executing SmartScan to keep up with the speed of printing. For example, it takes around 450ms to complete the matrix multiplication necessary to model the distribution of heat during the print of a single cell in the above-mentioned gear. This is significantly longer than the roughly 50ms time window within which this computation must complete.

3 SmartScan in the Cloud

One could potentially try to address the limitations of the computer on-board an LPBF printer by offloading control of the printer to a fleet of edge servers. But, given that SmartScan's memory and compute requirements increase with the size of the part being printed (Figure 5), an edge deployment sufficient to support the print of large parts would be significantly under-utilized when printing small parts.

To instead enable elasticity, we seek to run SmartScan at a cloud data center close to the printer. If the printer loses connectivity with its controller in the midst of a print job, it can revert to how it would operate without SmartScan, i.e., print all remaining cells in a random order. We focus on parts that are symmetric along the z-axis; for such parts, since the heat transfer matrices are identical for every layer, in-memory data can be reused across layers.

When running SmartScan in the cloud, precomputed matrices can be generated on a cloud VM and uploaded to cloud storage. Within a datacenter, cloud providers do not charge for data transmission between VMs and cloud storage, as well as between the storage and serverless workers. Moreover, since the heat distribution matrices need to be precomputed once per part, their generation has no impact on the delays involved in every job which prints that part.

3.1 Why serverless?

In every step of the SmartScan algorithm, the controller computes the temperature distribution expected after the printer scans and melts the cell chosen in the previous step. It does so by multiplying the temperature distribution vector computed in the previous step with the precomputed heat transfer matrix for the chosen cell. To ensure that the next cell to print is determined before the printer completes printing a cell, the multiplication can be parallelized across a set of virtual machines (VMs) or serverless workers; each VM/worker can multiply the vector with a partition of the matrix, and these results can be aggregated by a coordinator.

We argue that serverless workers are more well-suited for this workload than VMs for two reasons.

3.1.1 Cost overhead of VMs

Paying for in-memory data when not in use. First, SmartScan's timing constraints make it infeasible for a VM to dynamically read in the heat transfer matrix for the chosen cell on-demand from cloud storage. For instance, if we execute SmartScan for a 16cm^2 gear on a x2gd.xlarge VM on Amazon EC2, the computation can keep up with a printing speed of 600mm/s. But, the length of each time window at this speed is roughly 50ms, which is significantly shorter than the 350ms it takes for the VM to read in the 11.92 GB matrix for a cell from an EBS volume which uses a gp3 SSD configured with the maximum permitted limits on IOPS and throughput. Retrieving this data from Amazon S3 takes even longer: 8 seconds.

Therefore, to adhere to SmartScan's timing constraints, the heat transfer matrices for all cells must be readily available in memory throughout the algorithm's execution. This calls for the use of several expensive high-memory VMs. For example, the 249 cells in a 16cm^2 gear map to 127 unique heat transfer matrices, whose total size is 1,514 GB.

Paying for idle VMs. Second, as mentioned earlier, there is a 15-second period between layers when metallic powder is spread onto the printer bed. Though no computation is performed during this period, 15 seconds is too short to suspend and resume all the VMs that support SmartScan's execution. Thus, the user will need to pay to keep all data in-memory during this period.

Note that it is challenging to reduce idle time on VMs by multiplexing each VM across multiple print jobs. On the one hand, the 15-second idle period for one job is not long enough to read the data for another job into memory. On the other hand, if multiple jobs printing the same part share a set of VMs preloaded with the data for that part, the execution of SmartScan for these jobs will need to be carefully coordinated so that they do not interfere with each other's ability to use the CPUs on the VMs.

3.1.2 Advantages of serverless

In addition to enabling their customers to rent VMs, many cloud providers today also have function-as-a-service offerings; AWS Lambda and Azure Functions are popular examples. In these services, the user registers with the cloud provider a container which encapsulates the user's code. In response to a new request, the cloud provider spins up an instance of that container – which we refer to as a *worker* – and executes the request in that instance.

Two characteristics of serverless platforms help address the aforementioned cost overheads associated with using VMs to execute SmartScan.

Pay per use pricing. First, the pricing model for services such as AWS Lambda is structured such that users have to pay only for the duration when a worker is running the user's code. As a result, the user will not incur any cost during the 15-second idle period between layers when no computation is needed. Moreover, in each time window, the user need only pay for the workers that are computing the expected impact on temperature distribution due to the scanning of the cell chosen in the previous window.

Warm starts. Second, once a worker is initiated, the cloud provider keeps that worker's state in memory for a few minutes even after the worker's execution ends. As long as the gap between consecutive invocations of a function is less than a few minutes, the worker initiated for the first invocation is reused for the second invocation. Thus, the workers that are used to execute SmartScan when scanning one layer of a part will retain the heat transfer matrices in memory even when the scanning of the next layer is underway. Importantly, despite the cloud provider keeping the worker's state in memory between successive invocations of a function, the user incurs no cost during this period.

Though cloud platforms do not provide any guarantees on reusing worker state in this manner, our measurements on both AWS Lambda and Azure Functions reveal that warm starts are highly reliable. Over a 24-hour period, we conducted hourly trials where we issued sequences of function calls at fixed intervals. For shorter invocation intervals, ranging from 50 milliseconds to 1 second, cold starts were extremely rare, occurring in less than 0.1% of trials in a day. For longer idle periods, ranging from 5 seconds to 1 minute, memory eviction becomes slightly more likely, with cold starts increasing from 0.6% to 3.2% as the interval lengthened. To prevent cold starts across layers, which typically involve idle times of tens of seconds, users can periodically issue dummy requests to keep workers alive. The cost of sending such dummy requests is negligible, as they require only a few milliseconds of execution per second.

3.2 Challenges with serverless

Taking advantage of the characteristics of serverless platforms to support the cost-effective execution of SmartScan is, unfortunately, not easy. To see why, we now consider some of the approaches considered in prior work for other workloads and demonstrate their limitations via measurements. For simplicity, in this section and the next, we assume that each cell maps to a unique heat transfer matrix.

3.2.1 Even warm starts incur invocation overhead

The simplest approach to implement SmartScan on serverless, which we refer to as the *Invoke-on-demand* strategy, involves registering a separate function for each cell in the part being printed. At the start of the print, we concurrently invoke all functions once so that they can read in the matrix assigned to them from cloud storage into memory and exit; because of warm starts, this data remains in memory. Thereafter, to print each layer, a coordinator VM collects the temperature map from the printer, and then iteratively repeats the following steps (as shown in Figure 6): it invokes the function associated

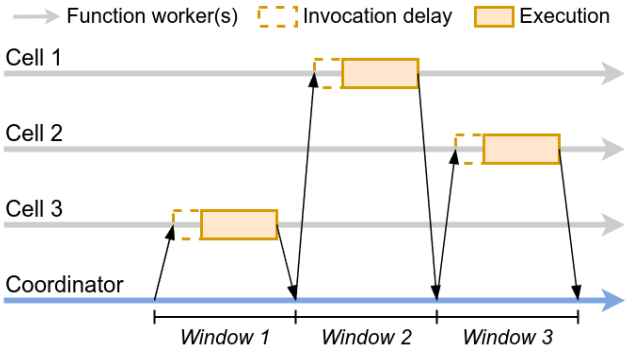

Figure 6: **Execution of SmartScan wherein a new function is invoked every time the algorithm picks a new cell to scan.**

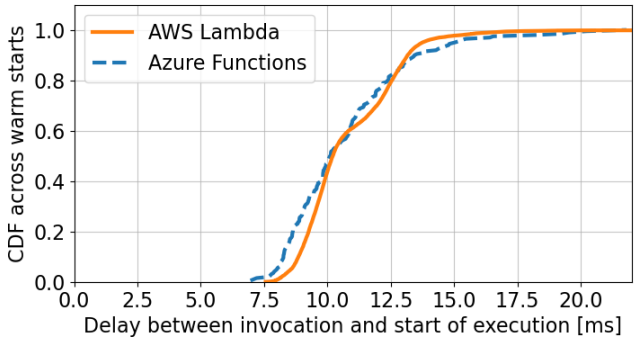

Figure 7: **Distribution of the overhead of invoking a serverless function when executed on a pre-warmed worker.**

with the cell chosen in the previous step, collects the result and identifies the next cell to scan, and relays this choice to the printer. In each step, the executed function multiplies the input temperature map with its in-memory heat transfer matrix to compute the estimated temperature map after the printer scans the chosen cell.

Like prior work which has aimed to take advantage of serverless computing's pay-for-use pricing model [34, 35], this simple implementation ensures that, at every step, the user incurs cost only for the computation associated with one cell. The user also does not incur any cost during the 15-second idle period between the scanning of successive layers. Thus, as long as the number of unique heat transfer matrices associated with a part is large, the cost for a SmartScan-optimized print of the part will be significantly smaller with this implementation than one which runs SmartScan on EC2 VMs; see Appendix A for a detailed analysis.

Invocation delays result in violation of timing constraint. However, we find that the *Invoke-on-demand* strategy for executing SmartScan on Lambda fails to keep up with the printing speed. For example, in our execution of SmartScan on Lambda for any one layer of a 4cm^2 gear, Lambda workers are actively executing code for only 1.30 seconds, which is less than the 3.33 seconds needed to print the layer. But, SmartScan's per-layer runtime includes an additional 2.98 seconds. When combined, these delays add up to 4.28 seconds per layer, exceeding the 3.33-second print time constraint. This additional delay averages 24.8ms for each of the 120 cells in a layer, encompassing not only the *invocation delay* (the time between when we invoke a function and when a worker begins executing the function's code), but also the time spent sending temperature maps to the workers and the cleanup overhead incurred by repeatedly invoking functions.

Invocation delays occur despite the fact that all of our function invocations are served by pre-warmed workers that already have the function state in memory. The underlying cause is overheads internal to Lambda associated with its routing of requests [7, 10] and context preparation.

To measure this overhead, we invoke a pre-warmed function instance from an EC2 VM. At the start of its execution, the function issues a HTTP request back to the VM. We measure the invocation delay by comparing the times at which the VM invokes the function and when it receives the HTTP request from the function. Note that the measured invocation delay includes a network round-trip between the VM and the worker, which is sub-millisecond within a datacenter.

Based on our measurements on AWS Lambda, Figure 7 shows that the invocation delay is 10.2ms at the median, and 13.2ms at the 90th percentile. Figure 7 also shows that these delays are similar with Azure Functions. For workloads that have previously been considered a good match for serverless, such as video processing [8, 16] and model training [18, 34], function invocation delays have been insignificant since the execution time of individual functions has been in the order of seconds or higher. In contrast, in our workload, overheads even in the order of 10ms end up resulting in violations of SmartScan's timing constraints.

3.2.2 High parallelism leads to coordination overheads

Eliminating invocation overhead inflates cost. To avoid the overheads associated with routing each function invocation to a worker, we can invoke the functions for all cells at the start of a new layer. Every function then waits for input from the coordinator to perform the appropriate matrix multiplication, akin to the strategy used in some prior systems [8, 16].

Executing SmartScan with this *All-persistent* strategy, however, significantly inflates costs. The user would not need to pay for any computation during the idle time between layers when metallic powder is being spread for the next layer. But, since the functions for all cells will be active throughout the duration that a layer is being scanned, we lose the benefit of warm starts; the user will have to pay for a function's state to be kept in memory even when the worker assigned to run that function is idle. Since serverless workers cost more per GB of memory per second than VMs, the net effect is that executing SmartScan with the *All-persistent* approach eliminates the benefits of using serverless.

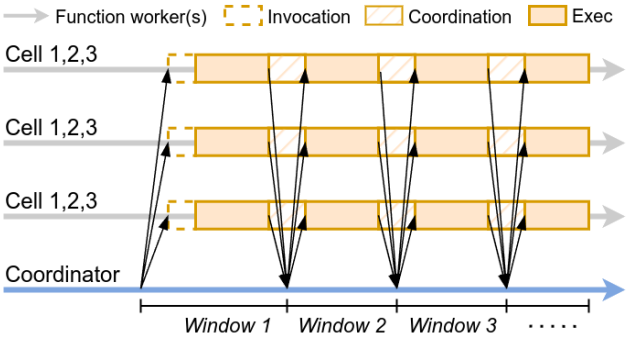

Figure 8: **Execution of SmartScan wherein the computation for every cell is parallelized across all workers.**

Keeping all workers active introduces coordination overheads. To lower cost, one might think: if the workers for all functions are active throughout the print of a layer, we might as well utilize the CPUs on all of them during that period? We can accomplish this by rethinking the assignment of cells to workers. Thus far, we have considered that each function is assigned to store and process the matrix for a unique cell. Instead, we can assign $\frac{1}{N}^{th}$ of every matrix to each function, where N is the number of workers needed to keep all the matrices in memory. As shown in Figure 8, in every step of SmartScan's execution, the coordinator VM sends the current temperature map to all workers, each of whom multiplies their slice of the matrix for the chosen cell. By aggregating results from all workers, the coordinator assembles the updated temperature map.

The high degree of parallelism with this *All-active* strategy, however, ends up inflating SmartScan's runtime. For example, we need 159 Lambda workers to accommodate all the matrices for the 16cm^2 gear. When we execute SmartScan across these many workers using the *All-active* strategy, it takes 16 seconds per layer, which greatly exceeds the constraint of 13.3 seconds imposed by the printing speed.

The primary source of delay here is the limited network bandwidth at the coordinator. For example, of the 16-second runtime per layer, only 270 ms involve any worker actively executing matrix multiplications. The remaining *coordination delays* stem from the overheads incurred in transferring the temperature map in each step from the coordinator to all workers. In our example job, each of the 249 steps involves the coordinator pushing a 312 KB map to 159 workers – up to 50 MB of data per step. Note that, though each worker computes the output temperature for only a subset of cells, every worker receives the entire input temperature map. This is because the heat transfer matrix models the distribution of heat from every cell to every other cell. This data is transmitted at a rate of roughly 5 Gbps, resulting in a delay – the *coordination delay* – which takes up almost all of the runtime.

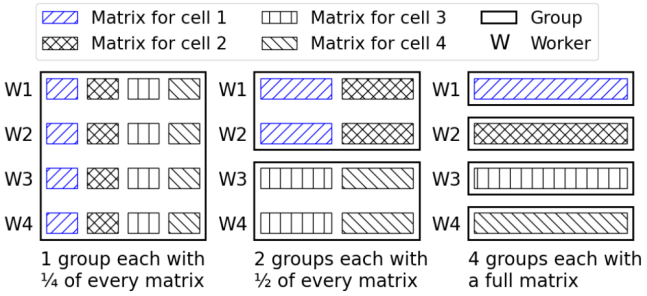

Figure 9: **Three ways of dividing the matrices for 4 cells into groups across 4 workers.**

4 Design

The takeaway from our measurements in the previous section is that simple approaches for executing SmartScan using serverless either fail to meet the algorithm's timing constraints or significantly inflate cost compared to using VMs. To address this problem, we present *Cosmic*, a new system for executing low-latency compute pipelines like SmartScan on serverless platforms.

Cosmic's design has three key components. First, in terms of how serverless is used to run SmartScan, we expand the configuration space beyond the point solutions discussed in the previous section. Second, we develop a model that can accurately estimate for each configuration, the execution time of SmartScan in that configuration and the cost the user would incur. Using this model, *Cosmic* is able to identify the lowest cost configuration that is expected to satisfy SmartScan's timing constraints. Third, we implement a runtime which can ensure that SmartScan is executed in accordance with the chosen configuration.

Though *Cosmic* is tailored to SmartScan's 3D-printing control loop, we believe its modular components are workload-agnostic and reusable across latency-sensitive cloud applications. We elaborate on this in Section 7.

4.1 Expanding configuration space

Any particular serverless configuration for running SmartScan specifies two properties: a) *which* set of functions are used to run the computation for any particular cell, and b) *when* those functions are invoked. In comparison to the approaches discussed in the previous section, we expand the space of configurations along two dimensions.

Grouping. First, we rethink the assignment of cells to functions. Existing approaches either assign each cell to a separate set of functions (*Invoke-on-demand* or *All-persistent*) or have a common set of functions execute the computations for all cells (*All-active*). In contrast, *Cosmic* allows for many more intermediate configurations as follows.

If N functions are registered in total across all cells – where N must at least be equal to the number of workers needed to store in memory the matrices for all cells – we divide these functions into G groups of $\frac{N}{G}$ workers each. Each group

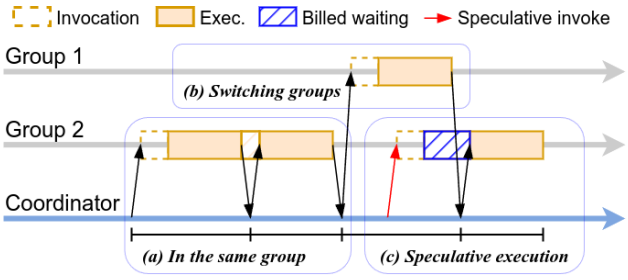

Figure 10: **Illustration of SmartScan execution with *Cosmic*.**

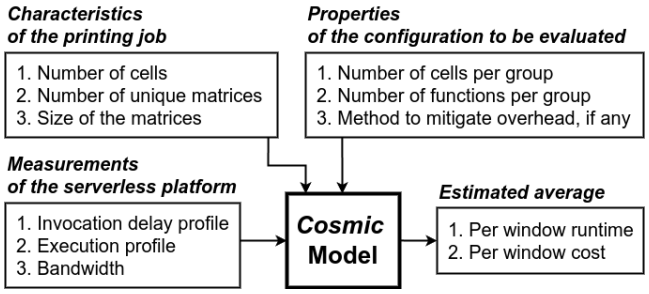

Figure 11: **Inputs and outputs of model used in *Cosmic*.**

of workers is responsible for performing the computations corresponding to $\frac{1}{G}^{th}$ of the part's cells.

For example, Figure 9 shows three groupings for a part which has four cells, each with a unique heat transfer matrix. The right and left show configurations realized by existing approaches: 4 groups with a unique function assigned to each cell (right), or the state for all cells is equally distributed across one group of 4 functions (left). In the middle is a new configuration enabled by our approach: 2 groups of 2 functions each, with 2 cells assigned to either group.

Speculation. Second, we observe that it is not necessary to incur the cost overhead of keeping the workers for all cells active throughout the printing of a layer. Instead, it suffices if every function is invoked prior to when it needs to start running. Thus, while any step of SmartScan is executing, we can *predict* the cell likely to be chosen in that step and preemptively invoke the functions assigned to that cell.

Benefits. Partitioning workers into groups and assigning multiple cells to each group combined with speculative execution offers multiple advantages.

- *New mechanisms for mitigating invocation overhead.* When the cells chosen in two successive windows belong to the same group, no function invocation overhead is incurred at the start of the second window. For example, in the first two windows in Figure 10, the workers that will execute the computation for the second cell will already be active after the first window. In addition, speculative invocation of functions enables *Cosmic* to reduce the impact of function invocation overheads without incurring the cost overhead of keeping all workers alive.
- *New tradeoffs between invocation and coordination overhead.* At one extreme, assigning all cells to a single group eliminates invocation overheads, but will result in high coordination overhead. At the other extreme, assigning each cell to its own small subset of functions ensures that the network on the coordinator VM does not prove to be a bottleneck; but, without incurring the cost overheads associated with speculation or keeping all workers alive, the start of every window will be delayed by function invocation overheads. By varying the number of cells per group, we can realize various intermediate points in the tradeoff between the two overheads.
- *Easier speculation.* The assignment of multiple cells to the same group of workers allows for easier use of speculation. As long as the predicted cell belongs to the same group as the cell chosen by SmartScan, invocation delays will not affect our ability to satisfy timing constraints.

4.2 Choosing most cost-effective configuration

Enumerating all configurations. Given a product to print, we use the combination of three attributes to represent every serverless configuration that *Cosmic* can use to execute SmartScan while the product is printed:

- The number of cells per group: varies from 1 to the total number of cells that the product has been partitioned into
- The number of functions per group: at least the number of workers needed to accommodate in memory the heat transfer matrices for all cells in a group
- Which, if any, method is employed to address function invocation overheads: workers for all functions are kept active throughout the printing of each layer, functions for the next window are invoked speculatively, or neither

The question at hand then is: among all configurations which will enable SmartScan's execution to keep up with the printing speed, which one minimizes cost? In our current implementation, *Cosmic* exhaustively enumerates all configurations; for the parts we have considered, this takes around 10 seconds at the start of a print job. Among those configurations where the estimated runtime is less than the time needed to print a layer, *Cosmic* picks the one with the lowest estimated cost. In extreme cases where the time constraint is too stringent (e.g., because of a high printing speed), *Cosmic* can determine when no feasible solution exists. In such cases, SmartScan must be run across a fleet of VMs.

Model to estimate runtime and cost. For every configuration that *Cosmic* considers during its search for the lowest cost configuration, it needs to estimate SmartScan's runtime per layer with this configuration and the corresponding dollar cost. Given the large number of configurations for even a simple part, it is impractical to determine these estimates by executing SmartScan in every configuration.

Instead, we need to estimate the runtime and cost associated with any configuration *without* running SmartScan in that

configuration. For this, as shown in Figure 11, we develop a model which takes three kinds of inputs: 1) characteristics of the product to be printed, 2) properties of the configuration being evaluated, and 3) measurements of the serverless platform. Since the SmartScan algorithm involves a linear sequence of steps, with each step lasting a window, the model's task is equivalent to computing the average runtime and cost per window. The duration of each window has two components:

- First, the coordinator VM requests the serverless platform to invoke the functions for the cell being scanned in the window. The workers which execute these functions request the function input from the coordinator. The delays involved depend on invocation overheads and the effectiveness of the speculation strategy.
- Then, the coordinator sends the input temperature map to all workers and receives the output from them. Delays include coordination and computation time.

We model each component of window duration separately.

In configurations where workers are kept alive throughout the printing of a layer, the first delay component is zero as no function invocation overhead is invoked. In configurations which employ speculation, this delay is zero for a fraction of the windows equal to the speculation accuracy; the expected speculation accuracy can be estimated from previously completed prints of the same product. The delay is also zero for windows in which the group is reused; we estimate the expected chance of reuse by simulating random selection of cells. For the other windows, or for all windows in the remaining configurations, we estimate the magnitude of the first component as equal to the overhead of invoking functions on warm workers. We rely on a one-time profiling of function invocation delays, using measurements akin to those used to generate Figure 7. Due to the heavy tailed distribution of these delays, instead of simply using the average or median value for all windows, we sample from the measured distribution independently for every window.

The second component of a window's duration, which is also the period for which the user is billed, includes 1) the time for the coordinator to disseminate the temperature map obtained at the end of the previous window as input to all the workers, and 2) the time taken by the workers to execute the matrix multiplication which models the distribution of heat during the printing. For the former, we observe that the bandwidth between the coordinator VM on EC2 and the Lambda workers is the bottleneck. We measure this bandwidth limit once using `iperf`. For every print job, we can then use the size of the temperature map for each layer and the number of functions per group to estimate the time it will take for the coordinator to finish sending the inputs to all workers. For the latter, we rely on a profile of the time to execute matrix multiplication on Lambda. We record the distribution of execution time for a range of matrix sizes, and interpolate from this data for any particular part.

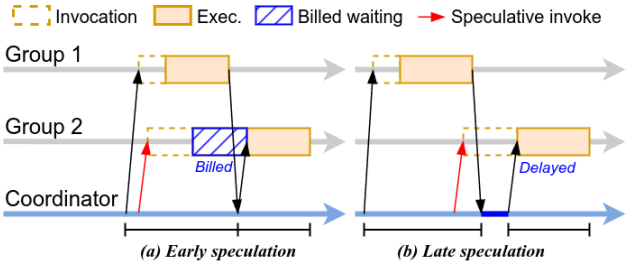

Figure 12: **Illustration of early and late speculation.**

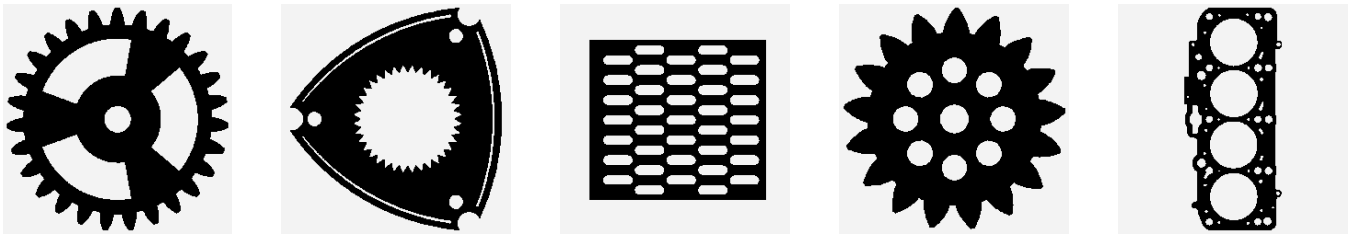
4.3 Executing chosen configuration



Once *Cosmic* uses its model to select the most cost-effective configuration, the coordinator VM oversees the execution. It invokes functions when necessary: all functions once at the start of the print job so that all workers can read their state into memory; then, the relevant functions at the start of each window. The primary complexity in the coordinator's role is in determining how and when it should speculate.

Speculation algorithm. While the SmartScan algorithm is running its computation in any particular window, we need a lightweight method to predict the cell that will be chosen for printing next. Our speculation strategy is inspired by approximation techniques commonly used in 3D printing algorithms to reduce computation at the expense of lower printing quality [29]. Instead of to avoid compute bottlenecks, we leverage approximation to quickly generate guesses with minimal additional execution time and cost.

In SmartScan, recall that the primary purpose of the computation is to model the diffusion of heat. SmartScan maintains a temperature map for a layer and simulates the scanning of each cell in two steps: 1) applying the input heat from the laser to the temperature map, and 2) updating the heat transfer across the layer during scanning. The compute bottleneck is the second step as it involves multiplying a matrix, which models the expected heat transfer, with the temperature map. In contrast, the first step simply involves adding a precomputed vector to the temperature map.

The approximation of this computation is rooted in the observation that scanning each cell with a laser typically takes only tens of milliseconds. Therefore, a good approximation of the updated temperature map can be obtained by considering only the laser input and ignoring the heat transfer over such a short period. This approximate temperature map, which can be computed by the coordinator using much less computation than the full algorithm executed concurrently by the serverless workers, can then be used to guess the next cell that will be selected.

Note that this approximation cannot replace the full algorithm. If we rely on the approximated temperature map in every window, the simulation gradually deviates from the real state of heat transfer, thus degrading SmartScan's ability to reduce the variance in temperature across the layer.

(6) Connecting rod (7) Mounting bracket (8) Ribbed bar (9) Holed L-bracket (10) Simple L-bracket

Figure 13: **Shapes of the printed parts.**

Speculation timing. In addition to identifying *which* functions to invoke speculatively, we need to determine *when* to invoke them. Launching the group of functions early can ensure that they are ready to begin executing when SmartScan's next window starts, but doing so can inflate cost. Deferring the speculative execution for as late as possible can reduce cost but also reduce the utility in overcoming function invocation overheads. Figure 12 illustrates these two scenarios.

To balance the two concerns, we rely on our profiling of invocation overheads (Figure 7). During any window in the execution of SmartScan, *Cosmic*'s coordinator estimates how long it expects the window to last. It speculatively invokes the functions for the predicted cell's group D ms prior to when it expects the current window to end, where D is the median of the measured distribution of function invocation delay.

5 Evaluation

We evaluate *Cosmic* from three perspectives: Is it able to satisfy the timing constraints associated with SmartScan's execution? What cost benefits does it offer? What contributions do each of *Cosmic*'s components make in enabling these benefits? We compare *Cosmic* to the three baselines from §3.2, which mimic the approaches used in prior work.

1) ***Invoke-on-demand***: The computation for every cell is distributed across a separate set of N functions, which are invoked on-demand.
2) ***All-persistent***: The computation for each cell is again spread across N functions. But, all functions are invoked at the start of a layer and return only once the computation for the entire layer ends. To minimize cost, we assign a group of cells to the same set of N functions if the workers for those functions can collectively store the state for all of these cells in memory.
3) ***All-active***: The data and computation for all cells are distributed across a common set of N functions. As a result, the workers for all functions are kept busy for the entire duration of the print job.

In addition, we also compare *Cosmic* to the traditional approach of using N VMs, with the data and computation for all cells equally split across the fleet. In all cases, we vary the value of N to identify the lowest cost solution which ensures that SmartScan keeps up with the printing speed.

5.1 Evaluation setup

We evaluate *Cosmic* and the baseline approaches by executing a real SmartScan controller in the cloud. We mimic a print job by having the controller relay its commands to a local desktop computer, which substitutes for an LPBF machine. This mirrors a realistic deployment because any industrial grade LPBF machine is itself driven by desktop software. On the desktop, we simulate the mechanical printing process using the printer's precise specifications, e.g., uploading randomly generated temperature maps and timing "laser movements" with corresponding delays. We host the controller in the AWS region closest to the desktop.

This setup enables us to examine the feasibility of real-time control, even though the current printer hardware does not yet support this capability; the current proprietary driver on our LPBF printer only accepts precomputed sequences. Importantly, it also provides two other major benefits: 1) enhanced data instrumentation, allowing fine-grained timing measurements, and 2) the ability to conduct large-scale, long-term evaluations without monopolizing physical resources.

Cloud hardware. We configure each AWS Lambda function to its maximum capacity: 10 GB of memory and 6 vCPUs. Using the largest worker size allows for fewer parallel workers or fewer groups for a given workload, reducing coordination delays and improving speculation accuracy. We choose Lambda functions equipped with ARM-based processors over x86 due to their lower cost, without sacrificing performance.

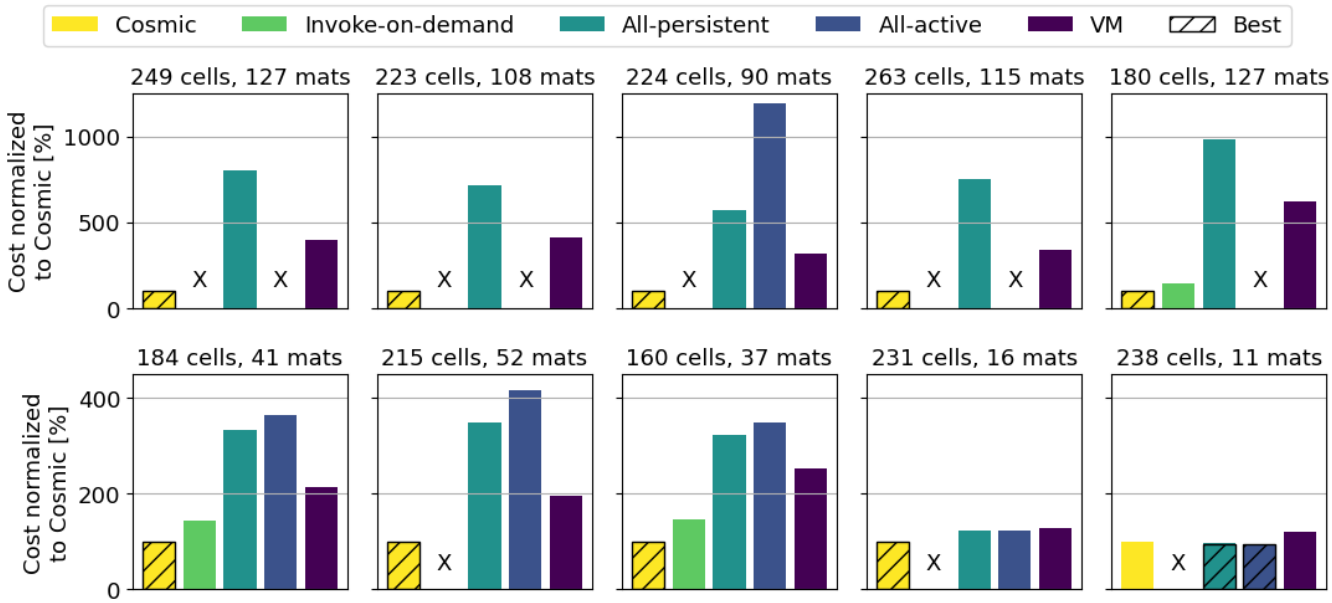

Figure 14: **Comparison of *Cosmic* with baseline approaches across 10 print jobs with layer size 16cm^2. The cost is normalized to that obtained with *Cosmic*. X indicates the timing constraints were not met. The bars filled with hatched marks show the cheapest solution for each job. The subplots are in the same order as in Figure 13.**

We set up the coordinator on a m6g.8xlarge instance with 32 vCPUs to efficiently handle concurrent requests. To minimize latency of communications between the coordinator and workers, we place all of them in the same VPC and disable TCP slow start on the coordinator.

For the VM-based baseline, we select instances from EC2's x2gd series, which are among the instance types with the highest memory-to-vCPU ratios, offering 16GB of memory per vCPU; a large memory-to-vCPU ratio helps avoid the cost inefficiency of over-provisioned cores.

Printing parameters. We consider a diverse set of 10 parts, shown in Figure 13, which are either derived from benchmarks used in PBF optimization studies [29,33] or designed to model real industrial parts. We consider each part in three layer sizes – 9cm^2, 16cm^2, and 25cm^2 – giving a total of 30 print jobs which vary widely with respect to 1) number of cells per layer, 2) number of unique heat transfer matrices, and 3) size of the matrices. For example, among the parts with a 16cm^2 size, the time constraint per window ranges from 38ms to 62ms, and the total memory requirement ranges from 131 GB to 1,514 GB.

We assume a printing speed of 800 mm/s, which falls within the range for optimal LPBF results on AISI 316L stainless steel, the material used in prior experiments [19, 22]. We selected this slightly higher speed than the more conservative 600 mm/s used in the original SmartScan paper [29], to evaluate *Cosmic* under more stringent conditions.

We assume the thickness of each layer to be 50 μm [29]. For example, a 1 cm thick part would comprise 200 layers.

We start each print job assuming temperature across the entire layer is uniformly at 293 Kelvin. Though the initial temperature map can vary in practice due to residual heat from previous prints, the computation performed when executing the SmartScan algorithm will be unchanged. Moreover, we show later that the accuracy of our speculation is largely the same as we vary the initial temperature map.

5.2 Satisfaction of timing constraints

In every print job, we measure the timing of the controller's commands received at the desktop. In all 30 print jobs, we find that *Cosmic*'s execution of SmartScan keeps up with the specified printing speed, i.e., prior to the start of every window, the desktop is expected to have received the next cell to be scanned. Though the *All-persistent* and VM-based approaches also manage to satisfy the timing constraints in all print jobs, they do so at the expense of over-provisioned compute resources and user-paid idle time. *All-active* satisfies the constraints in all 10 jobs with layer size 9cm^2, as few workers are needed to accommodate all the matrices in memory. However, *All-active* fails to finish running SmartScan in time for 11 of the remaining 20 jobs, as coordination overheads increase. *Invoke-on-demand* fares the worst, as it failed to meet the time constraints in 23 of the 30 jobs, irrespective of the amount of parallelism per cell. This is largely due to invocation delays associated with warm starts (§3.2.1).

5.3 Comparison of dollar costs

For printing the parts with layer size 16cm^2, Figure 14 shows the dollar cost for resources in the cloud with each of the approaches considered, normalized to the cost with *Cosmic*. Results are similar for prints of the other two sizes. For every approach, we consider the cost associated with the cheapest

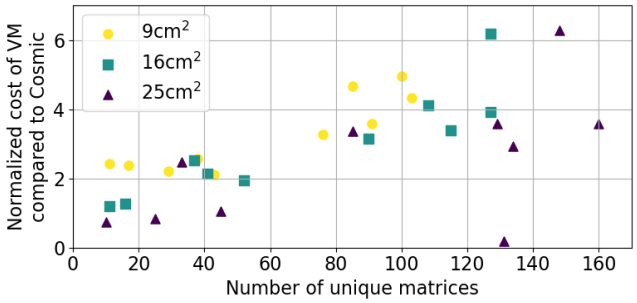

Figure 15: **Cost savings with *Cosmic* compared to VM-based approach as a function of number of heat transfer matrices.**

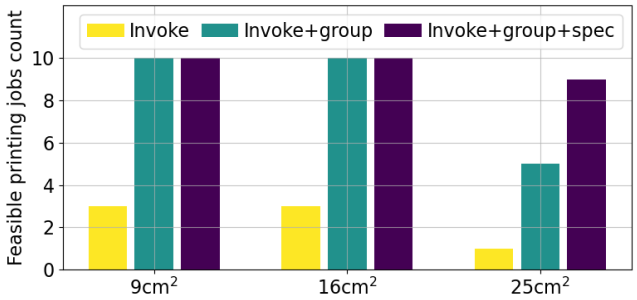

Figure 16: **Number of print jobs for which timing constraints are met first with *Invoke-on-demand*, and then by adding grouping and speculative invocation incrementally.**

configuration in which SmartScan's execution keeps up with the printing speed. We mark an 'X' if, for that job, that approach cannot meet the time constraints in any configuration.

We see that *Cosmic* outperforms all four baseline approaches in 26 of the 30 print jobs; it results in the lowest cost in all 10 prints of 9cm^2 layer size, in 9 of the 10 with layer size 16cm^2, and in 7 of the 10 with 25cm^2 layer size. In the 4 print jobs where *Cosmic* does not minimize cost, the cheapest solutions cost 0.94×, 0.83×, 0.75×, 0.17× lower, with the first achieved by *All-active* and the rest using VMs.

Cost-savings compared to VMs. Across all 30 print jobs, the cost overhead of VM-based solutions relative to *Cosmic* is 2.8× at the median, with a maximum of 6.3×. If the thickness of every part was 1cm, for example, these numbers translate to an average cost savings of $1.2, $4.5, and $18.7 per part for 9cm^2, 16cm^2, and 25cm^2 layer sizes, respectively. *Cosmic*'s cost savings relative to VMs increases with layer size due to the decreasing fraction of idle time in SmartScan's workflow (see Appendix A). Powder spreading between layers (§2) takes 15 seconds irrespective of layer size. Hence, this downtime takes up progressively less of SmartScan's total runtime as layer size increases: 73% for 9cm^2, 60% for 16cm^2, and 49% for 25cm^2.

As demonstrated in Figure 15, we also observe a correlation between *Cosmic*'s cost benefits relative to VMs and the number of unique heat transfer matrices needed for a specific print job. VMs are cost-effective for running SmartScan when the total size of precomputed data is relatively small (left end of the graph), as the data can be stored in a few instances which can all be kept busy without much coordination overhead. When the total data size is large, the number of VMs needed is dictated by the total memory size, resulting in most of the CPUs idling during runtime. In such cases, *Cosmic* benefits from Lambda's pricing policy, which charges customers only when workers are executing code, but not during idle periods in-between when worker state remains in memory.

Cost savings compared to other serverless approaches. In all but one of the 27 print jobs where using VMs is not the most cost-effective solution, *Cosmic* outperforms all other baseline approaches that use serverless. Again, if we consider all parts to be 1cm thick, the average cost savings enabled by *Cosmic* compared to the second-cheapest solution on serverless are $0.71, $8.3, and $78.4 per part for 9cm^2, 16cm^2, and 25cm^2 layer sizes, respectively.

Ideally, *Cosmic* is expected to outperform *Invoke-on-demand*, *All-persistent*, and *All-active* in all cases because *Cosmic*'s configuration space subsumes these approaches. However, in one of the print jobs – part 10 in layer size 16cm^2 – *All-active* provides a solution that costs 0.94× as much as *Cosmic*. Although this solution is within *Cosmic*'s search space, it is not chosen because *Cosmic*'s performance model incorrectly estimates it to be slightly more expensive than the selected alternative.

5.4 Utility of individual techniques

The fact that *Cosmic* combines many techniques to deliver cost savings is evident in the wide diversity of configurations that it chooses for the 30 print jobs we consider. The number of groups into which it partitions the serverless functions that it uses varies across jobs from 1 to 50. Whereas, the degree of parallelism per group ranges from 4 to 34. To mitigate the impact of function invocation delays, *Cosmic* chooses to keep all workers active throughout the print only in 3 jobs. It employs speculation in 21 of the 30 jobs. In the remaining cases – primarily when the number of groups is less than 10 – *Cosmic* relies on the property that no invocation overhead is incurred when the cells chosen in consecutive windows belong to the same group.

5.4.1 Ablation study

To further evaluate the utility of the two key techniques that *Cosmic* combines, we start with *Invoke-on-demand* and then incrementally add grouping of functions and speculative invocation. For each of the three approaches, Figure 16 shows the number of print jobs (grouped by layer size) for which they satisfied SmartScan's timing constraints. As seen earlier, *Invoke-on-demand* is capable of satisfying these constraints in only 7 of the 30 jobs. Adding grouping addresses this problem for all printing jobs with layer sizes 9cm^2 and 16cm^2, but falls short for larger parts. Adding speculative invocation

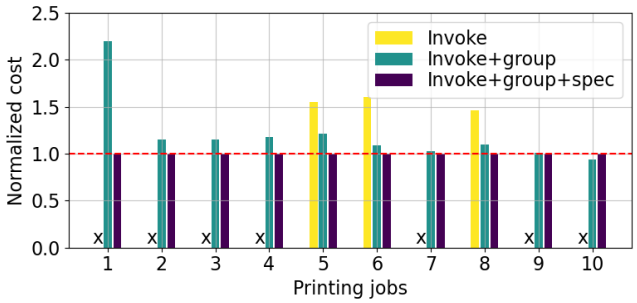

Figure 17: **For print jobs with layer size 16cm^2, cost with *Invoke-on-demand*, and with incremental addition of grouping and speculation; normalized to the cost with *Invoke-on-demand* plus grouping and speculation.**

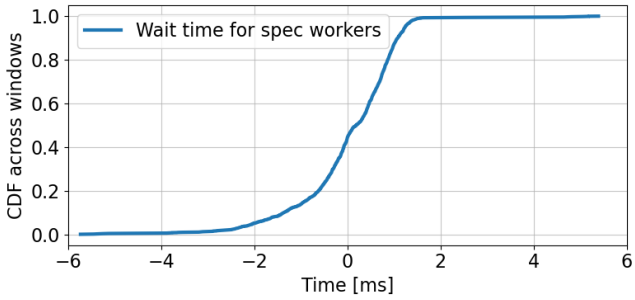

Figure 18: **For a specific print job, distribution across windows of the time from when the coordinator completes the current window until when the speculatively invoked workers are ready to start executing the next window.**

further improves the coverage to all but one job, for which all workers need to be kept persistently alive in order to ensure timely execution.

Beyond the ability to ensure timeliness, the techniques used in *Cosmic* also help reduce cost. Figure 17 demonstrates this for print jobs with 16cm^2 layer size; the results are similar for the other two layer sizes. In all 3 print jobs where *Invoke-on-demand* enables SmartScan to keep up with the printing speed, the addition of grouping lowers cost. We observe that grouping lowers runtime without increasing cost, as it increases the likelihood of reusing Lambda workers in consecutive windows, thereby avoiding invocation latency. In all but one of the printing jobs, adding speculation further reduces cost as it reduces the amount of parallelism needed to overcome the impact of invocation delays.

5.4.2 Speculative invocation

Next, we dive deeper into the efficacy of *Cosmic*'s speculative invocation of functions.

Speculation accuracy. First, across all 30 print jobs, we find that *Cosmic*'s algorithm for predicting the cell group whose functions need to be executed in the next window is 85% accurate on average. To examine the robustness of this accuracy to variance in the initial temperature map, we rerun *Cosmic*'s speculation for each part with 30 different initial temperature maps. We observed that the speculation accuracy is typically 85% $\pm$ 5%. This suggests that it is reasonable for our runtime/cost prediction model to take as input the speculation accuracy from previously completed prints of the same part.

Speculation timing. Next, we illustrate *Cosmic*'s effectiveness in using speculation to hide invocation delays at low cost. Figure 18 shows the distribution of speculative timing during the execution of SmartScan for a 16cm^2 gear shape. Specifically, we measure the gap from a) when the current window finishes, i.e., the coordinator has received outputs for the current window from all workers, until b) when the Lambda functions needed for the next window are ready to start execution, i.e., the coordinator has received a request for input from all the speculatively invoked functions. Negative values for this difference indicate early speculation, while positive values indicate late speculation. The data reveals a median value of 0.19ms, with the 5th and 95th percentiles at -2.00ms and 1.24ms, respectively. This implies that 95% of the speculation instances incur a billable idle time of no more than 2ms, and 95% of the speculation instances incur a latency overhead less than 1.24ms; both account for less than 5% of the duration of the average window in this case study. This efficiency demonstrates the balance achieved between cost and performance via accurate modeling.

6 Related Work

Applications on serverless. Prior work [8, 16] has utilized the massive parallelism enabled by serverless to significantly reduce the time needed to process videos. Other work [34] has taken advantage of serverless pricing policy to achieve time and cost savings in processing sparse graphs workloads. However, all of this work targets workloads in which each task takes tens of seconds, even minutes, to complete. To the best of our knowledge, we are the first to demonstrate the viability of serverless for workloads with latency targets in the order of tens of milliseconds.

Mitigating invocation latency. A significant body of prior work targets cold start latency in serverless computing. Some propose new optimizations that require changes to the serverless platform [14, 17, 32]. There has also been work [31] on reducing the platform's burden for keeping instances warm. Others try to avoid cold starts in the user space [8, 16, 23, 24, 30]. However, none of these prior efforts target eliminating warm start latency. We found that the latency associated with warm starts is a bottleneck in meeting millisecond-level time constraints, and we use a combination of strategies to mitigate this latency.

Performance modeling. Runtime optimization on serverless often requires accurate performance prediction. Previous efforts have modeled the combination of parallel and sequential function executions [24], used Monte Carlo simulations to predict the distribution of function costs [15], and modeled

cold start latency and execution time under different degrees of parallelism [9]. Our model accounts for a variety of delays, including function invocations and coordination overheads, and models the impact of techniques such as grouping of functions and speculative invocation.

Speculation. Speculative execution has been used to hide latency in a wide variety of networked systems, e.g., distributed file systems [27], distributed data processing [11], web browsing [25], and online gaming [21]. Speculative execution has also been employed to improve the performance of serverless applications. For example, SpecFaaS [32] pre-executes potential function calls before their control and data dependencies are resolved, and Xanadu [13] pre-invokes functions to mitigate cascading cold starts in function DAGs.

Our work developed a method for speculation specific to a 3D printing optimization algorithm, SmartScan [29]. Unlike prior work that uses speculation as a best-effort strategy to hide latency, our strategy for speculation is both time- and cost-sensitive. In addition, we use grouping of functions to improve the accuracy of speculation.

7 Discussion

Impact of changes in cloud pricing policies. *Cosmic* takes advantage of serverless computing's pay-as-you-go pricing model, which only charges for active execution time. In particular, *Cosmic* avoids the cost of retaining data in memory during the idle time between successive invocations of the same function. Presumably, serverless platforms already bake in the cost for supporting warm starts into their pricing policy, as they charge more per GB of memory than traditional VMs. These characteristics are not unique to AWS, but also exist in Azure [3], Google Cloud [5], and emerging serverless GPU inference services [4, 6], reflecting a deliberate design choice to enhance the utility of serverless, and one that is likely to persist in the near-term.

That said, if cloud providers alter their infrastructure – e.g., shortening warm start windows, or begin explicitly charging for idle memory – *Cosmic*'s design remains adaptable. To account for reduced persistence of warm workers, *Cosmic* can issue dummy requests to maintain warm containers at a negligible cost. *Cosmic* can also re-profile platform delays and pricing, adjusting invocation timing or the degree of parallelism. Though savings might decrease, many of our approach's benefits, such as minimizing the impact of invocation delays and reducing over-provisioning of resources, would still apply.

Printing larger parts. While our evaluation demonstrates *Cosmic*'s ability to meet timing constraints and reduce costs across a diverse set of print jobs, significantly larger printing jobs present additional challenges. With much greater parallelization, the overhead of communication between serverless functions and ensuring scalability without compromising timeliness are heavily constrained by the platform's specifications, and remains an area for future exploration.

Reusability of abstractions. Though we designed and evaluated *Cosmic* in the context of optimizing a specific form of 3D printing, its core abstractions and modular components are reusable in other domains: 1) *Cosmic*'s strategies for trading off invocation and coordination overheads – e.g., grouping parallelizable functions and optimizing invocation timing – apply to any latency-critical processing pipeline where each step is parallelizable. 2) *Cosmic*'s use of speculation to combat function invocation overheads is applicable in settings amenable to predictions. 3) *Cosmic*'s models for runtime and cost guided by measurement profiles and pricing policies can inform data partitioning and the degree of parallelization.

Generalizability to other workloads. *Cosmic*'s configuration framework and profiling tool, when supplied with other workload characteristics by users, can be adapted to a broad range of domains. For example, we believe *Cosmic* can be adapted for using serverless to support computations in scenarios where real-time spatial data is being analyzed, e.g., in AR/VR and online gaming. In these scenarios, models of the real/virtual world will need to be preloaded and data from user inputs or sensors must be processed quickly in order to render or make decisions in real-time. Processing of each input can be treated as similar to each window in SmartScan. Speculative execution could be used to predict inputs based on the user's trajectory, allowing for faster responses.

Another potential application of *Cosmic* could be autonomous vehicle fleet coordination, which requires real-time route planning and vehicle-to-vehicle coordination. Such systems rely on large preloaded datasets, including high-definition maps, traffic prediction models, and vehicle dynamics, to make decisions under tight timing constraints. At each step, the coordination algorithm processes these datasets to update vehicle paths dynamically, involving computation similar to SmartScan. *Cosmic* could enhance this process through speculative execution, precomputing likely scenarios – such as potential lane changes or congestion – to minimize delays.

8 Conclusion

In this paper, we demonstrated the utility of serverless computing for a new application workload: control of 3D printing from the cloud. While the pricing policy of serverless platforms make them a good match for this workload, our measurements highlighted the delays that make it challenging to meet millisecond-level time constraints. Our design of *Cosmic* combines a range of techniques with an accurate model that estimates runtime and costs. Our results showcased *Cosmic*'s utility across a diverse set of print jobs.

A Appendix

The cost for a VM per window is formulated as:

$$F_{vm} = (n \cdot m) \cdot (t + 15\ s) \cdot c_{vm}\ ,$$

where

- n = number of unique matrices,
- m = size of in-memory precomputed data per cell in GB,
- t = time constraint in seconds,
- c_{vm} = cost per GB of memory per unit of time for the VM.

It's important to note that VMs must stay operational between layers, hence the additional 15 seconds of billed time. This formula also assumes full utilization of the VM's memory capacity.

In contrast, the cost for Lambda per window is:

$$F_{\lambda} = M \cdot (t) \cdot c_{\lambda}\ ,$$

where M is the total memory capacity of Lambda workers running in parallel, and assuming Lambda functions are configured to complete computations precisely within the time constraint t. Unlike VMs, where the scale of operation is dictated by the total data size, the number of Lambda functions

running in parallel during each window is determined primarily by the need to meet stringent time constraints. Consequently, this total capacity M often exceeds what is necessary for storing the precomputed data per cell m. Given that we use the largest Lambda instances, we have $M = N_P \cdot 10\ GB$, where N_P is the number of parallelism in each window.

Solving $F_{vm} > F_{\lambda}$ simplifies to:

$$n \cdot m > \frac{t}{t+15} \cdot N_P \cdot 92\ GB\ . \tag{1}$$

Here, the left side represents the total size of precomputed data. Taking the example of the 16cm^2 gear shaped print job, this inequality holds true as $1514\ GB > 404.8\ GB$, with $n = 127$, $m = 11.9\ GB$, $t = 10\ s$, and $N_P = 11$. Qualitative interpretation of this inequality shows that Lambda is potentially more cost-effective than VM under certain conditions: 1) a higher total size of precomputed data, 2) a lower time constraint relative to powder spreading time, and 3) fewer parallel workers required in each window.

GMI-DRL: Empowering Multi-GPU DRL with Adaptive-Grained Parallelism

Abstract

With the increasing popularity of robotics in industrial control and autonomous driving, deep reinforcement learning (DRL) raises the attention of various fields. However, DRL computation on the modern powerful multi-GPU platform is still inefficient due to its heterogeneous tasks and complicated inter-task interactions. To this end, we propose **GMI-DRL**, the first systematic design for scaling multi-GPU DRL via adaptive-grained parallelism. To facilitate such a new parallelism scheme, GMI-DRL introduces a new concept – *GPU Multiplexing Instance* (GMI), a unified resource-adjustable sub-GPU design for heterogeneous tasks in DRL scaling. Besides, GMI-DRL introduces an adaptive *Coordinator* to effectively manage workloads and resources for better system performance. GMI-DRL also incorporates a specialized *Communicator* with highly efficient inter-GMI communication support to meet diverse communication demands. Extensive experiments demonstrate that GMI-DRL outperforms state-of-the-art DRL accelerating solution in training throughput (up to 2.34×) and GPU utilization (up to 40.8% improvement) on the DGX-A100 platform.

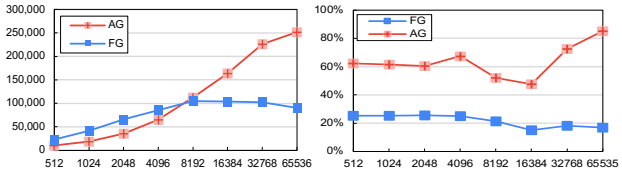
1 Introduction



Recently, deep reinforcement learning (DRL) has raised significant interest in research and industry fields. DRL combines the conventional RL algorithms [25, 39] with deep neural networks (DNNs) and has demonstrated superhuman performance in decision-making. DRL has been applied in many real-world applications across various domains, like robotics [12,18,33,44,50], industrial control [4,8,41,51], and autonomous driving [5,20,38,48]. The latest DRL application highlighted most is OpenAI ChatGPT [33], which is trained with DRL from human feedback. Due to the cost, efficiency, and safety concerns in the real world, DRL training is commonly conducted in simulated environments on computers. Then the pretrained DRL model (policy) is fine-tuned and deployed to the real-world environment [15, 24].

Unlike the conventional DL methods (e.g., DNNs) that learn from offline collected datasets, DRL learns from online collected data generated through model-environment interactions. DRL computation features heterogeneous workloads and multi-granularity communication patterns (Figure 1(a)). It interleaves the execution of three components: *Environment Simulator*, *Agent*, and *Trainer*. Agents will interact with environment simulators to collect enough experience (consisting of state, action, and reward). After a number of (e.g., 32) agent-environment interactions, the agent will communicate with a trainer to update the policy model. The above three components feature distinct computation patterns. The environment simulator relies on physics simulation (e.g., local motion and robotics control) while the agent and trainer depend on GEMM-based NN operations (e.g., policy model inference/training).

(a) (b)

Figure 2: (a) Throughput (samples/seconds) and (b) GPU utilization (via `nvidia-smi`) for DRL training scaling (increasing batch size) across three different DRL benchmarks.

(a) (b)

Figure 3: Training Comparison between fine- (FG) and adaptive-grained (AG) parallelism on (a) throughput and (b) GPU utilization on the Humanoid [46] (HM) benchmark.

To catch up with the increasingly intricate and dynamic real-world scenarios with high fidelity, modern DRL applications (e.g., power-grid control [4] and robotics [24]) tend to be more complex (enormous action and state space) and require millions/billions of interaction steps for the final convergence. This motivates the urgent demands for scaling up DRL training on more powerful multi-GPU platforms (e.g., NVIDIA DGX [29]), typically equipped with many (8 or 16) large-size high-end GPUs (e.g., A100 and H100). Such platforms are also the key AI computing building blocks (for more than 60% of machines on the latest Top500 list [42]) and the future trend of DL scaling.

However, existing DRL designs are still yet to maximize the computing benefits of those powerful platforms. For illustration, we profile the popular PPO [39] algorithm from the state-of-the-art Isaac Gym [24] on NVIDIA DGX-A100 (8 GPUs). Figure 1(b) gives the average utilization of GPUs on three representative DRL benchmarks over 10 training epochs. We can see that the multi-GPU training of DRL exhibits both *temporally low GPU utilization* (where a DRL training flow would only perform intermittent DNN model training/inference per epoch) and *spatially low GPU utilization* (where the computation/memory demands of DRL training flow could hardly occupy the entire GPU). This indicates that there is a large portion of the computing power of GPU platforms being throttled by the existing designs. DRL performance can potentially be improved by turning those "spare" GPU resources into full utilization.

The common practice to overcome such issues is to adapt computation to fit the underlying resources (i.e., scaling through fine-grained parallelism) [7, 24]. For example, we can increase the simulation batch size to promote DRL training throughput. Figure 2 shows that when first increasing the simulation/training batch size, the performance would increase proportionally w.r.t. the batch size. The overall throughput performance degrades when further increasing the batch size beyond a certain threshold (e.g., 16,384 for Anymal [16] (AY)). Such an increase-followed-by-decrease performance trend is similar across benchmarks and is also observed in GPU utilization. This is mainly because when increasing the batch size, individual DRL components will scale up their resource demands (e.g, SMs, memory/cache) for more task-level concurrency (e.g., DRL simulation). Different DRL components running in parallel would compete for a fixed amount of GPU resources. GPU utilization would suffer since different DRL components are busy waiting for some common resources to move forward. For instance, the GEMM-based DRL policy training/inference would wait for SMs occupied by DRL simulation. The performance penalty of such contention would offset the parallelism benefits after reaching a certain threshold.

Such an observation motivates us to think about whether it is a better option to tailor resources for computation demands, so that we can seek for optimal compute-resource efficiency instead of blindly increasing the batch size. Our key insight is to explore adaptive-grained parallelism (AGP) on GPUs. AGP opens a new way for flexible utilization of GPU resources, where a large GPU can be used as a set of size-adjustable sub-GPUs for different tasks. AGP also enlarges the existing design and optimization space for using individual GPUs. For instance, we can treat one GPU as a multi-sub-GPU system for computation and communication at the sub-GPU level. When scaling up to multiple GPUs, AGP is also an effective way for better resource management of different workloads. It can facilitate the creation of the best-fit GPU resource plans, given the specified number of GPUs and the GPU affinity demand (e.g., NVLinks).

However, AGP is not a low-hanging fruit. It is naturally hindered by the memory isolation among different sub-GPUs due to GPU spatial multiplexing. This would be the performance killer for DRL with heterogeneous tasks and substantial inter-task communication. Efficient communication at the sub-GPU level is still missing from existing high-performance GPU communication libraries (e.g., NCCL [28]). Such communication hurdles may offset computation gains of GPU spatial multiplexing. Besides, finding the right-fit parallelism granularity (sub-GPU size) for individual tasks is non-trivial. The mismatch between sub-GPUs and their assigned DRL workloads would easily degrade the overall performance while wasting valuable GPU resources (e.g., SM). Furthermore, identifying the optimal layout of sub-GPUs requires careful consideration of the specialties of workloads (e.g., communication) and hardware (e.g., GPU interconnections).

To this end, we introduce **GMI-DRL**, the first end-to-end system for scaling multi-GPU DRL via adaptive-grained parallelism (AGP), with significantly improved throughput and

GPU utilization compared to fine-grained parallelism (Figure 3). To facilitate AGP, GMI-DRL introduces a new concept – *GPU Multiplexing Instance* (GMI), a unified resource-adjustable sub-GPU design tailored for heterogeneous tasks. GMI-DRL also provides systematic support for communication, computation, and programming for GMIs. GMI-DRL automates DRL scaling while respecting the black-box nature of DRL simulation (which commonly takes months/years of effort for re-design and implementation).

In short, we make the following contributions

- We introduce a novel adaptive-grained parallelism scheme for DRL scaling and propose GPU Multiplexing Instance (GMI) to facilitate such a new scheme.
- We build a GMI-centric adaptive *Coordinator* (§3.1) and a specialized *Communicator* (§3.2) design to meet diverse communication demands among GMIs, to achieve better system performance and GPU utilization.
- We also provide GMI-centric programming support (§3.3) to ease the scaling of diverse DRL-like applications on multi-GPU platforms.
- Extensive experiments show that GMI-DRL outperforms the state-of-the-art DRL acceleration solution (Isaac Gym [24] + MSRL [52]) across various benchmarks.

2 Background

2.1 Deep Reinforcement Learning

Deep Reinforcement Learning (DRL) [25, 39, 49] features heterogeneous computational workloads and diverse communication patterns. Figure 1 exemplifies the workflow of a typical PPO [39] algorithm in DRL. It interleaves the execution of three components: *Environment Simulator*, *Agent*, and *Trainer*. The environment simulator is responsible for generating environment states and action rewards with the help of its internal physics simulation engine (e.g., local motion and robotics control). GPU-based simulators (e.g., Isaac Gym [24]) can hold hundreds or thousands of environments running concurrently. The agent is the key component to making action decisions based on the environment states. It depends on GEMM-based NNs (e.g., Multi-Layer Perceptron) for policy model inference (action prediction). DRL trainer updates the policy model based on experience (with states, actions, and rewards) from agents. There are two major computing modes of DRL in real-world settings.

DRL Serving: Agents interact with environment simulators by applying the pre-trained policy model. The interaction between simulators and agents demonstrates fine-grained state-action sharing. DRL serving is also essential for experience generation for the DRL training process on computers and the real-world evaluation of the DRL policy.

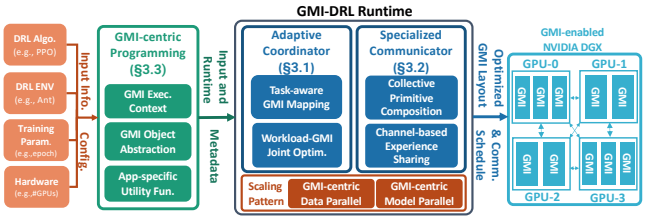


Figure 4: Overview of the GMI-DRL system.

DRL Training: Agents first interact with simulators to collect experience. After a number (e.g., 32) of interactions, agents will communicate with trainers via coarse-grained experience sharing for policy updates. DRL training aims to maximize the accumulated reward of agent actions by updating the policy iteratively. Depending on whether the policy model training happens sequentially or concurrently with each round of agent-simulator interaction, DRL training can be categorized into *synchronized* (e.g., PPO [39]) and *asynchronized* DRL training (e.g., A3C [25]).

2.2 Adaptive-grained Parallelism (AGP)

We propose AGP as a new type of parallel computing paradigm that can adjust the size or granularity of the parallel tasks to optimize performance. While the existing scaling schemes are commonly confined to a certain level of granularity for parallelism. For instance, existing data parallelism explores coarse-grained dataflow-level parallelization, model parallelism explores the middle-grained operator execution concurrence, and operator fusion/grouping explores fine-grained kernel-level parallelization. AGP is complementary to those existing schemes by adding parallelization hierarchies with "configurable" granularity.

AGP can be broadly categorized into two major types: 1) adjust the tasks' workloads (e.g., batch size in DNNs) to fit the hardware; 2) adjust the hardware resource size to fit the given workload. In DRL, the first one is hard to achieve (Figure 2) due to its intrinsically complicated simulator design and mixed workload. We thus advocate solution-2 for performance, resource efficiency, and design complexity. When targeting other workloads, solution-2 can be combined orthogonally with the existing solution-1 for a larger granularity space for diverse settings.

For AGP, *GPU Spatial Multiplexing* is the most potential candidate with adjustable resource granularity and minimized runtime interference. There are two major techniques: 1) Multi-processing Service (**MPS**) [31] can transparently enable cooperative multi-process CUDA applications to share a GPU. MPS provides concurrency among client processes to share a GPU via GPU SMs partitioning. 2) Multi-Instance GPU [30] is a new GPU spatial multiplexing solution introduced in NVIDIA Ampere GPUs (e.g., A100). Multi-Instance GPU offers higher isolation (SMs, memory space/bandwidth) compared to MPS. However, the existing practices of GPU

spatial multiplexing are limited to their initially targeted settings with *independent* and *homogeneous* tasks, like DNN serving [6, 22, 45], thus, unable to offer communication support and strategies for inter-dependent task mapping. Comparatively, we are the first to explore the potential of GPU spatial multiplexing for more challenging DRL applications with *heterogeneous* tasks and intricate *inter-task interactions*.

3 GMI-DRL Design

GMI-DRL (Figure 4) reshapes the existing GPU-based DRL scaling with a new notion of GMIs. To support such new scaling schemes, GMI-DRL introduces an adaptive *Coordinator* (§3.1) to manage the workload-resource mapping and configuration optimization and a specialized *Communicator* (§3.2) to handle diverse inter-task interactions.

3.1 Adaptive Coordinator

The key aspect of AGP is to generate a good mapping choice between DRL components and underlying computing resources. This motivates the GMI-DRL *Coordinator* to systematically combine coarse-grained mapping and fine-grained configuration tuning for maximized overall performance.

3.1.1 Task-aware GMI Mapping

The mapping of DRL tasks on GMIs demands careful consideration of the specialties of various DRL tasks and hardware, which requires the mapping that will not only benefit individual tasks but also complex inter-task interactions. For instance, using dedicated GMI instances for simulators can achieve high simulation task performance. However, it may lead to inferior inter-task performance due to the inefficient data communication between simulators and agents on other GMIs. We, therefore, introduce a *task-aware GMI mapping* strategy to explore the GMI-backed scaling design space.

DRL Serving DRL serving aims to collect enough experience by applying a trained policy model. DRL serving features continuous interaction between simulators and agents. Optimizing DRL serving aims to achieve *low latency* at each round of interaction between the simulator and agent so that experience can be collected quickly. The interaction between simulators and agents relies on *frequent and fine-grained* information exchange for high serving performance. With these observations, we explore the potential mappings with the synergy of data (DP) and model parallelism (MP).

1) *DP-MP Serving* (Figure 5a) uses DP as the backbone for running multiple copies of DRL serving and leverages MP to distribute individual components of each copy to different GMIs. This guarantees the performance of individual components but at a heavy penalty of inter-component performance,

Table 1: Definition of Terms.

Term	Meaning
R_s, R_a, R_t	the size of dominant resources for the simulator, agent, and trainer, respectively.
$\mathbb{I}$	the type of dominant resource: SM or Memory.
S, A, W	the size of a single state, action, and reward vector, respectively.
T_s, T_a, T_t	the execution time for the simulator, agent, and trainer in each DRL training/serving iteration.
BW	the bandwidth of inter-GMI communication.
M_p	the size of the policy model.
m	the number of simulation steps before a training.
n	the total number of GMIs in the current system.
α, β	the size ratio factor when multiple environment simulators are sharing agents or trainers.

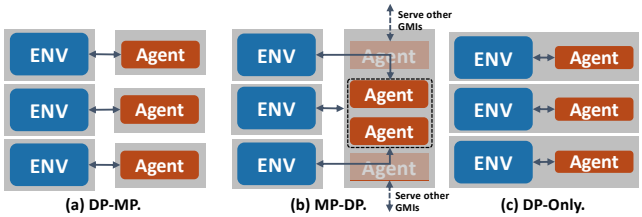

Figure 5: GMI mapping for DRL serving. Note that Grey shadows indicate GMIs.

since the fine-grained, frequent data movement between GMIs would incur high overhead.

2) *MP-DP Serving* (Figure 5b) leverages MP for inter-phase scaling for decoupled simulators and agents and utilizes DP for intra-phase scaling to run multiple copies of simulators and agents. The key insight is that the throughput of simulators and agents is naturally different, where an NN-based agent comes with high throughput and can thus be "shared" among different simulators which have relatively low throughput. With this insight, we can achieve higher resource efficiency by accommodating more simulators and agents to improve the theoretical performance. However, the communication between simulators and agents from different GMIs would still throttle the practical system performance.

3) *DP-only Serving* (Figure 5c) relies on DP for scaling. It runs multiple copies of DRL serving in parallel. In this design, simulators and agents are co-located within the same GMI. Compared with the prior two designs, the *state* data generated from the simulator can be easily shared with the subsequent agent for action prediction via low-cost intra-GMI memory access. However, it comes at the cost of additional resource consumption and potential resource underutilization. Since different GMIs have to maintain a full copy of the simulator and agent, each agent can only serve one simulator.

Serving Resource-Performance Analysis is to quantify the cost and benefits of different mapping solutions to guide our mapping selection. Terms are defined in Table 1. Here, we compare MP-DP and DP-only solutions for illustration. We first determine the dominated resources type ($\mathbb{I}$) based on

Table 2: Comparing MP-DP and DP-only in DRL serving.

Solution	Resource ($R^{\mathbb{I}}$)	Comm. (COM)
MP-DP	$(T_s \cdot R_s + T_a \cdot \alpha \cdot R_a)/(T_s + T_a)$	$2 \cdot S + A + W$
DP-only	$(T_s + T_a) \cdot \max\{R_s, R_a\}/(T_s + T_a)$	0

Equation 1 for R_e, R_a, and R_t, which can be either GPU SM or memory, depending on DRL benchmarks and GPUs.

$$\mathbb{I} = \begin{cases} SM & \frac{R_{SM}}{R_{SMperGPU}} \geq \frac{R_{Mem}}{R_{MemPerGPU}} \\ Memory & Otherwise. \end{cases} \quad (1)$$

R_{SM} and R_{Mem} are computing and memory resource consumption measured on a single DRL serving/training process running exclusively on a GPU. Take the DRL benchmarks from Isaac Gym on DGX-A100 as an example, our empirical study shows that α is around 0.2, $R_s \approx 10R_a$, and $T_s \approx 6T_a$. Thus, the overall serving throughput can be calculated as

$$TOP_{serving} = \frac{R^{\mathbb{I}}_{all}}{R^{\mathbb{I}}} \cdot \frac{1}{T_s + T_a + \frac{COM}{BW}} \quad (2)$$

With Table 2 and $\frac{COM}{BW} \approx 2 \cdot (T_s + T_a)$ based on our profiling, we can estimate that the overall serving throughput of DP-only serving would be higher (about 2.5×) compared with MP-DP serving. This is because the resource penalty (i.e., decrease in parallelism) of simulator-agent co-locating on throughput is minor ($(T_s + T_a) \cdot \max\{R_s, R_a\}/(T_s \cdot R_s + T_a \cdot \alpha \cdot R_a) - 1 \approx 0.16\times$) compared with the throughput benefits (around 3×) by saving inter-GMI data movements. We experimentally validate this in §4.3.

Synchronized DRL Training Synchronized DRL training has two stages, 1) simulator-agent interaction for experience collection and 2) agent-trainer interaction for policy training. These two stages happen sequentially at each iteration and the training performance is sensitive to both stages. The major goal of optimizing synchronized DRL training is to achieve higher model update frequency. Compared with DRL serving, synchronized DRL training is more complex in its components and inter-component interactions. This brings more tradeoffs for GMI mapping. We first discuss the ones that extend the existing DRL serving mapping principles and then introduce the new ones specific to DRL training.

1) *DP-MP and DP-only Training* (Figure 6a and 6b) follow similar scaling principles as the DRL serving. For DP-MP scaling, the size of communication would increase significantly compared with DRL serving due to the additional agent-trainer interaction for experience sharing and inter-trainer interaction for policy gradient synchronization. In DP-only scaling, it aligns the environment, agent, and trainer in the same GMI. Despite that it can enjoy the benefit of saving data movements, it would incur additional memory costs of duplicating both agents and trainers.

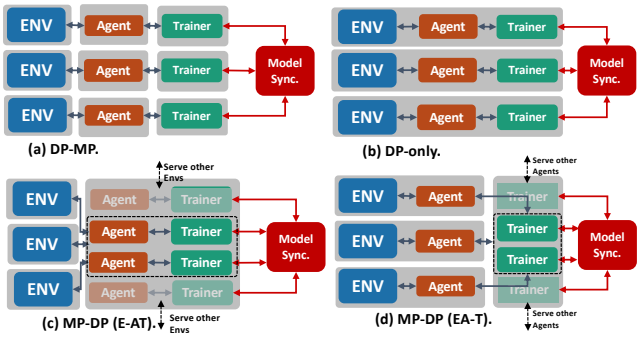

Figure 6: GMI mapping for Synchronized DRL Training scaling. Note that Grey shadows indicate GMIs.

Table 3: DP-MP (EA-T) and DP-only in Sync. DRL training.

Solution	Resource ($R^{\mathbb{I}}$)	Comm. (COM)
DP-MP (EA-T)	$(T_s \cdot R_s + T_a \cdot \alpha \cdot R_a + T_t \cdot \beta \cdot R_t)/(T_s + T_a + T_t)$	$m \cdot (S + A + W) + M_p + 2 \cdot (n-1) \cdot M_p/n$
DP-only	$(T_s + T_a + T_t) \cdot \max\{R_s, R_a, R_t\}/(T_s + T_a + T_t)$	$2 \cdot (n-1) \cdot M_p/n$

2) *DP-MP Training with Selective Pipeline Partitioning* (Figure 6c and 6d) enables the sharing of common resources like agents and trainers among different training instances. There are two major types of DP-MP training based on their training pipeline partitioning. The first one is E-AT, which partitions the DRL training pipeline between simulators (E) and agents (A). Such partitioning enables the sharing of agents and trainers among different simulators. The second type is EA-T, which partitions the DRL training pipeline between agents and trainers (T). It enables sharing of trainers among different training instances. With more component sharing, such as E-AT, the entire system could accommodate more training instances to achieve higher overall theoretical performance. While with less component sharing, such as EA-T, the communication critical path between the simulator and agent is no longer the bottleneck.

Training Resource-Performance Analysis on synchronized DRL training follows similar steps as DRL serving, except that we need to include the impact of the trainer on the pipeline. Here we compare DP-MP (EA-T) and DP-only training and take as an example the DRL benchmarks from Isaac Gym on DGX-A100. Our empirical study shows that α is around 0.2, β is around 0.3, $R_s \approx 10R_a \approx 5R_t$, and $T_s \approx 6T_a \approx 3T_t$, the overall throughput is calculated as

$$TOP_{train} = \frac{R^{\mathbb{I}}_{all}}{R^{\mathbb{I}}} \cdot \frac{1}{T_s + T_a + T_t + \frac{COM}{BW}} \quad (3)$$

With Table 3 and $\frac{COM}{BW} \approx 7 \cdot (T_s + T_a + T_t)$ based on our profiling, we can derive that the overall system throughput of DP-only training would increase evidently (about 5×) compared with DP-MP (EA-T). This is because the resource penalty on throughput ($(T_s + T_a + T_t) \cdot \max\{R_s, R_a, R_t\}/(T_s \cdot R_s + T_a \cdot \alpha \cdot R_a + T_t \cdot \beta \cdot R_t) - 1 \approx 0.5\times$) is offset by throughput benefits

(around 8×) via avoiding unnecessary inter-GMI experience movements. We provide experimental validation in §4.3. For other DRL benchmarks on different platforms, the lightweight profiling over several training rounds is sufficient to get the above parameters to analyze different training mappings.

Asynchronized DRL Training Asynchronized DRL training concurrently executes policy serving for experience collection and policy updates. However, it comes with the staleness of policy parameters that may impact the algorithmic efficiency (e.g., convergence rate). The common practice is to maximize throughput so that all DRL agents can get the model trained with the latest experience. We choose the mapping template from Figure 6d, with decoupled serving and training phase for the minimum communication bottleneck. We use designs in §3.2.1 for latency-optimized inter-trainer synchronization and §3.2.2 for throughput-optimized experience sharing between agents and trainers.

3.1.2 Workload-GMI Joint Optimization

After determining the efficient mapping templates, properly matching DRL workloads with right-size GMIs is also of great importance. However, there are two major challenges: *1) How to model the relation between the DRL training performance and GMI resources?* The performance of a single GMI depends on configurations of both the DRL algorithmic and the GMI resource, which creates a large design space for exploration. *2) How to balance the single-GMI performance and the overall system performance?* The high single-GMI performance does not always imply "optimal" system performance due to its excessive resource consumption and missing effective global planning to jointly optimize resources and performance. We introduce a *workload-GMI joint optimization* to co-optimize the configuration of the DRL tasks and the GMI resources for maximizing system throughput.

Configurations of DRL tasks and GMI resources. There are two key configurations that will impact the performance and resources of GMI-based DRL. i) *num_env* describes the number of concurrent environments running at each GMI. It is equivalent to the batch size in conventional DNN training. The common choices for *num_env* range from 128 to 32,768 considering the algorithmic (convergence) and system (runtime execution) efficiency [24]. Generally, a larger value of *num_env* would lead to higher throughput. However, when all the computation resources of a GMI are fully occupied, further increasing the *num_env* would only increase the memory consumption while being largely throttled by computation resources. This would lead to minor or even no throughput improvement. ii) *GMIperGPU* describes the quota of computation and memory resources assigned to each GMI. Computation resources determine the throughput performance of DRL computation, since the simulation and the training are computationally intensive and resource sensitive. Comparatively, memory resources mainly determine whether the DRL training can be successfully launched on GPUs, since DRL components have their own minimum memory requirements for basic execution without considering performance.

Algorithm 1: Profiling-based GMI Exploration.

```
   input  : DRL_bench, num_GPU
   output : num_env, GMIperGPU
1  best_config = tuple(); max_top = −inf;
2  for GMIperGPU in 10 ... 1 do
3      pre_top = 0; pre_mem = 0;
4      for num_env in [128, 256, 512, ..., 16384, 32768] do
5          ▷ Filter out the GMI OOM/crashing cases..
6          if num_env>=512 && projMem(num_env) >
             GPU_mem/GMIperGPU then
7              break;
8          end
9          ▷ Profile the performance of a GMI..
10         top, mem = profile(DRL_bench, GMIperGPU, num_env);
11         ▷ Initialize tracking variables..
12         if pre_top == pre_mem == 0 then
13             pre_top = top; pre_mem = mem;
14             continue;
15         end
16         ▷ Compute performance/resource changes..
17         R_top = (top − pre_top)/(pre_top);
18         R_mem = (mem − pre_mem)/(pre_mem);
19         Sat = R_top/R_mem;
20         pre_top = top; pre_mem = mem;
21         ▷ Check if the performance saturates..
22         if Sat < α then
23             break;
24         end
25         ▷ Project the overall system throughput..
26         acc_top = estimate(GMIperGPU, num_GPU, top);
27         if acc_top > max_top then
28             max_top = acc_top;
29             best_config = (num_env, GMIperGPU);
30         end
31     end
32 end
33 num_env, GMIperGPU = best_config[0], best_config[1];
```

Workflow of Joint Optimization. We will take the environment specification (e.g., name and type) and the *num_GPUs* as the input, and return *num_env* and *GMIperGPU* as the desired runtime configuration. As illustrated in Algorithm 1, we will iterate through the GMI resource space by adjusting *GMIperGPU* (Line 4). For instance, when *GMIperGPU* is 4, the resources of each GPU will be divided into 4 GMIs evenly. Another design dimension to be explored is the number of environments (*num_env*). These two dimensions will help us to pinpoint the design that can maximize the throughput given the GMI resource budget. To reduce unnecessary searches, we develop new metrics and heuristics for an early stop, as detailed in the following paragraphs.

We monitor memory at the first two steps of *num_env* (128 and 256 are unlikely to trigger out-of-GMI-memory based on our study). Then for all the following steps of *num_env*>= 512, we project its memory (m_p) based on the prior two steps of *num_env* (e_1, e_2) and memory (m_1, m_2), as shown in Equation 4. When m_p exceeds the GMI memory

limits, we avoid searching for even larger *num_env*.

$$m_p = \frac{(e - e_2)}{e_2 - e_1} \cdot (m_2 - m_1) + m_2 \quad (4)$$

The *profile* function will get the throughput (*top*) and memory cost (*mem*) of each configuration. We will then compare the change in computation throughput and the change in memory consumption between its current run and its last run (Line 17 to 18). Our empirical study (§4.3) shows that a GMI tends to saturate its computation capacity when we increase the *num_env* and observe (i) the large increase of memory consumption (ii) the minor improvement of *top*.

Algorithm 1 is currently running offline, given that real-world DRL training usually takes thousands of iterations (hours) for convergence. The major cost of profiling (several minutes) is minor compared to the entire training. We count down from 10 to 1 so as to prioritize (i.e., greedy search) the testing of the upper bound values of the number of GMIs, such that we can early terminate the search, which can make each of our experimental trials worthy and save efforts.

We also perform fine-grained measurement of GMI overhead across our evaluated datasets (§ 4) and policy NNs on the DGX-A100 platform. Specifically, the creation of the GMIs (1, 2, and 4) instance is low-cost (0.05s on average), which is largely minor compared to the typically hours of the DRL training process. Besides, the communication overhead is about 16% on average across GMIs. With the adaptive-grained sub-GPU design, we can better utilize those idle resources that can offset its communication cost brought by the memory isolation. Therefore, we can still achieve evident positive performance gains. per-GMI kernel launch is about 4.5% on average under different numbers of GMIs per GPU (1, 2, and 4), considering both the GPU-based simulation engine and neural network kernels, compared to the direct launch of a single kernel on the entire GPU.

3.2 Specialized Communicator

Scaling DRL via AGP demands handling diverse communication to connect DRL components. However, comprehensive communication support is absent from existing GPU multiplexing techniques [6, 45], communication libraries [28, 40], and schedulers [2, 26]. Such a gap drives the specialized design of GMI-DRL *Communicator*, which tackles two major types of DRL communication: the *inter-copy* communication in GMI-centric data-parallel scaling and the *inter-component* communication in GMI-centric model-parallel scaling.

3.2.1 Collective Primitive Composition

We introduce a novel *GMI-based collective primitive composition* strategy with two major primitives: *1) Inter-process primitive (**IP**).* This primitive treats inter-GMI communication as a pure inter-process synchronization. It firstly moves the policy model gradients from GMI to CPUs and then applies gradient reduction on the CPUs across different processes. *2) Ring primitive (**RP**).* This primitive works for GMI layouts with cross-GPU reduction demands. It counts on the existing inter-GPU communication infrastructure, like NCCL on NVLinks, to synchronize GMIs on different GPUs. Note that NCCL prohibits synchronization among GMIs on the same GPU. With the above primitives, we can generate diverse communication compositions given a GMI layout. There are three major types:

IP-only composition only leverages IPs for connecting GMIs. It can handle arbitrary GMI layouts regardless of their underlying placement on GPUs. As exemplified in Figure 7a, all GMIs are synchronized with each other through IPs in only one step. The theoretical cost of the IP-only solution is $\frac{2(m \cdot n - 1) \cdot S}{m \cdot n \cdot B_1}$, based on the standard allreduce operation [28], where B_1 is the bandwidth over PCIe, S is the policy model size, n and m are the number of GPUs and GMIs per GPU, respectively. However, our study shows that this composition can only show advantages in settings with fewer GMIs and small policy models due to the limited throughput of using IPs. In scale-up settings, IP-only composition would 1) incur an excessive amount of data traffic between CPUs and GPUs; 2) idle the high-performance GPU interconnects (e.g., NVLinks) that are available on most modern GPU-based platforms; 3) be throttled by slow CPU-based reduction.

RP-only composition only counts on the RPs for connecting different GMIs. It divides GMIs into separate communication groups that satisfy the NCCL constraints Figure 7b shows that GMIs on different GPUs form multiple non-intersect rings for RP communication (❶). We then use one additional RP to synchronize all partial results from the prior stage of reduction (❷). The theoretical cost of the RP-only solution is $2 * \frac{2(n-1) \cdot S}{n \cdot B_2}$, where B_2 is the bandwidth of NCCL on NVLink and synchronization on different rings of ❶ are parallelized. While this composition can enjoy high-speed inter-GPU communication, it is limited to settings where (#GMIs per GPU) $\leq$ (#GPUs) given the constraint of NCCL (connected GMIs must be on different GPUs). With more GMIs per GPU, there will be more NCCL rings and the communication contentions will also increase, potentially decreasing performance.

Hybrid IP + RP composition: This type of composition mixes IPs and RPs. It offers flexibility to fine-grained primitive combinations. One example of such composition is illustrated in Figure 7c, where we have k GMIs per GPU use RPs and $(m-k)$ GMIs per GPU use IPs for reduction. This composition example consists of two major steps: ❶ is gradient synchronization among GMIs on different GPUs through RPs. ❷ is gradient synchronization among GMIs on the same GPUs (and different GPUs, if possible) through IPs.

The theoretical cost of hybrid IP + RP solution is $\frac{2(n-1) \cdot S}{n \cdot B_2} + \frac{2(n \cdot (m-k) + k - 1) \cdot S}{(n \cdot (m-k) + k) \cdot B_1}$. The key to utilizing this hybrid composition is to properly adjust the ratio of IPs and RPs and apply

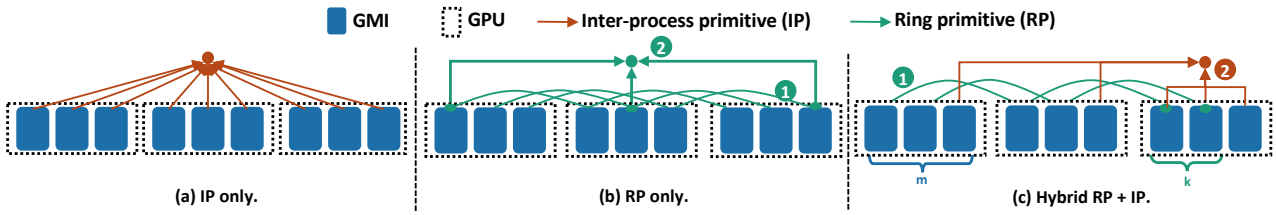

Figure 7: Exemplification of GMI Communication Primitive Composition. Note that the final broadcasting step is omitted for simplicity. n and m are the number of GPUs and GMIs per GPU, respectively. k is a configurable number of GMIs per GPU that uses RPs for communication. B_1 and B_2 are bandwidth by using IPs an RPs, respectively.

them in specific schedules. We next discuss the workflow of generating the effective composition given platform settings.

Overall Composition Workflow: Given an input GMI layout and DRL benchmark, we will generate a composition plan with optimized efficiency. We first analyze its characteristics (e.g., #GMIs per GPU and the GPU interconnects) and performs one-time profiling on basic composition. Based on the analyzed inputs, we will generate all candidate compositions. We then project performance based on profiling results to derive the latency cost of possible compositions. The costs of two basic compositions are IP-only ($Cost_{ip}$) and RP-only ($Cost_{rp}$) compositions measured on n GPUs with 1 GMI per GPU. This will determine the "unit" communication cost given the DRL benchmark and hardware platform. We measure $Cost_{ip}$ (i.e., $\frac{2(n-1)\cdot S}{n\cdot B_1}$) and $Cost_{rp}$ (i.e., $\frac{2(n-1)\cdot S}{n\cdot B_2}$) in raw latency (ms) by averaging 100 runs, where n is the number of GPUs, S is the policy model size, and B_1 and B_2 are the bandwidth of using IPs and RPs, respectively.

We then estimate the cost of (a) and (b) in n GPUs with m GMIs per GPU by scaling the $Cost_{ip}$ and $Cost_{rp}$ based on the ratio of measured and the target problem size. For example, in (a), we have $(n \cdot m)$ instance in the targeted problem size and n in the measured problem size, we then estimate $Cost(a) = \frac{2(n\cdot m-1)\cdot S/(n\cdot m\cdot B_1)}{2(n-1)\cdot S/(n\cdot B_1)} \cdot Cost_{ip} = \frac{(n\cdot m-1)}{m\cdot(n-1)} \cdot Cost_{ip}$. Similarly, we can get the $Cost(b) = 2 * Cost_{rp}$. Note that different RPs can be parallelized if there is no output dependency. For (c), given a parameter k (where $k \leq m$), we can derive $Cost^{(k)}(c) = (\frac{k}{n} + m - k) \cdot Cost_{ip} + Cost_{rp}$, Finally, we select the composition with the minimum projected latency. We provide an experimental demonstration in §4.3.

3.2.2 Channel-based Experience Sharing

The *model*-parallel scaling of DRL counts on connecting different DRL components effectively. Data movement of model-parallel DRL follows a point-to-point paradigm and is mixed with heterogeneous types of data under different granularities. For instance, the environment states of simulators are coarse-grained vectors, while the action/reward of agents is fine-grained scalars. Such heterogeneity and diverse granularity create a challenge to utilize existing GPU interconnections, which prefer fixed-sized coarse-grained data packages.

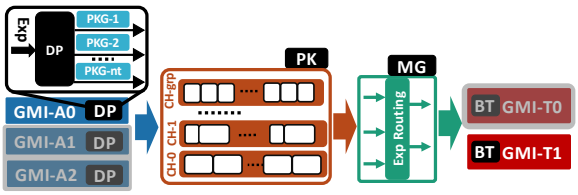

Figure 8: Exemplification of Channel (CH)-based Experience Sharing (A0 to T1). Note that "GMI-A*" is the GMI for DRL agents while "GMI-T*" is the GMI for DRL trainers; "PKG*" are packages decomposed from experiences.

One direct solution is to communicate with heterogeneous data packages. However, it would suffer from high startup costs and underutilized bandwidth for fine-grained transfers. Another direction is to tailor the communication strategies for different data so that we can manage the granularity and heterogeneity of data to maximize communication efficiency. Inspired by this insight and prior efforts on computer networks [17], we develop a *channel-based experience sharing* strategy for model-parallel DRL scaling. Each channel defines a customized way of communication that will manage inter-GMI communication for one type of data or a group of types of data that share similarities (e.g. shapes).

We build such a design with four components (Figure 8). Specifically, Experience *Dispenser* (***DP***) is to decompose the experience data into packages. Experience *Packer* (***PK***) is to group packages into channels and batch package groups in each channel for data movement among GMIs. Experience *Migrator* (***MG***) is to manage the routing of experience from agents to trainers. Experience *Batcher* (***BT***) is to conduct data preparation and model training.

Our initial empirical study shows that the overall performance mainly relies on whether PK can maximize inter-GMI data movement. With multi-channel design in PK, there are two major aspects that are critical to its performance: *1) Which types of packages should be grouped in the same channel?* and *2) How many such groups (i.e., batch size) should be transferred each time?* To address these questions, we define a proxy metric TOP_{mov} (Equation 5) for inter-GMI communication throughput given a package group ($\sum_{j=1}^{g_i} P_j^{(i)}$) and the batch size (*batch*) of package groups. TOP_{mov} will reward the higher bandwidth (due to package grouping) while

penalizing the extra-large packages (due to package concatenation overhead) and too many independent channels (due to inter-channel contention)

$$TOP_{mov} = \max\left\{\min_{i\in[1,grp]}\{\frac{B_i}{Cost_{cat}\cdot Cost_{ch}}\}\right\} \quad (5)$$

where B_i is the bandwidth given the current grouping and batching; g_i is the number of packages in a package group (G_i) and it can vary among groups; grp is the total number of package groups; $P_j^{(i)}$ is the package size (in Bytes) of the j-th package in G_i. Our empirical study shows that $B_i \propto (batch\cdot\sum_{j=1}^{g} P_j)$, $Cost_{cat} \propto (batch\cdot g)$, and $Cost_{ch} \propto grp$. Now, TOP_{mov} can be simplified as

$$TOP_{mov} = \max\left\{\min_{i\in[1,grp]}\{\frac{\sum_{j=1}^{g_i} P_j^{(i)}}{g_i\cdot grp}\}\right\} \quad (6)$$

$$s.t.(\sum_{i=1}^{grp} g_i = nt) \wedge (grp \in [1,nt]) \quad (7)$$

$$\prod_{i,j\in[1,nt]\wedge k\in[1,grp]}^{Constraints} (D_i \in G_k) \wedge (D_j \notin G_k) \quad (8)$$

where nt is the total types of original packages. Equation 8 describes the constraints that package D_i and D_j cannot be in the group/channel G_k due to their unaligned shape/dimension that complicates the concatenation. The maximization of TOP_{mov} will balance between the sizes of package groups and the number of package groups. Given $nt \leq 10$ and low evaluation cost per entry, we address this problem with enumerative combinatorics [11] with deduplication to find possible grouping combinations and backtrack search [47] with pruning to identify possible package concatenation in each group. We finally return the setting with maximum TOP_{mov}.

3.3 GMI-centric Programming Support

GMI-DRL follows a process-based design for performance guarantees and compatibility with GPU spatial multiplexing techniques. Processes offer better isolation with configurations (e.g., environmental variables) and memory address spaces. Listing 1 shows GMI-DRL example for synchronized DRL training. There are three major components: 1) *GMI Context* (Line 3) configures the basic GMI execution settings. For DRL training, MPS is used for communication efficiency. While for DRL serving, MIG is used for a better performance guarantee with minimized interference. 2) *GMI Runtime* (Line 5 to 28) manages the GMI-based DRL runtime. `init` function will set up the GMI based on its `GMI_id` and register a GMI to a global GMI manager. It also attaches GMIs to specific GPUs based on the GPU ids. The GMI will be assigned to a GMI group for collective communication if necessary. Users will implement the `GMI_run` for training.

Our GMI-based design, while demonstrated on A100, can be easily generalized toward other GPUs. This covers a wide spectrum of datacenter GPUs including 1) the older generations including Kepler (e.g., Tesla K40), Pascal (e.g., P100), and Volta (e.g., V100); 2) the newer generation of GPUs including Hopper (e.g., H100/H200), and Blackwell (B200). Our design can also work with desktop GPUs (e.g., RTX20/30/40 and Quadro series) seamlessly.

Listing 1: Illustration of GMI-based Programming.

```

```

4 Evaluation

Benchmarks: The DRL benchmark consists of the *simulation environment* and the *policy NN model*. We cover different types of environments, including locomotion simulation [16, 24, 46] (**L**), franka cube stacking [19] (**F**), and robotics hand control [34] (**R**). The details of our evaluated DRL benchmarks are listed in Table 4. "#Dim." is the dimension of environment state vectors. The policy NN models are expressed in "*in_dim:hidden_dim:...:out_dim*".

While there are many DRL algorithms, they can be broadly categorized into *on-* and *off-policy* DRL algorithms [52]. In this evaluation, we build our baseline based on the state-of-the-art MSRL [52] framework and Isaac Gym [24] simulator. Since the MSRL uses OpenAI Gym [3] by default for simulation workload, which is significantly (100×) lower in simulation throughput compared with Isaac Gym. We select the most representative PPO [39] for synchronized (Sync.) DRL training (*Isaac Gym + MSRL PPO as IG (PPO)*), which is the official implementation from Isaac Gym [24]. We also implement the most representative off-policy A3C [1] in Isaac

Gym for an asynchronized (Async.) DRL training study *Isaac Gym + MSRL A3C as IG (A3C)*.

Implementations: GMI-DRL is available[1]. For evaluation, we choose several baselines: *1) IG (PPO) in multi-GPU serving* is to directly scale the Isaac Gym serving to multi-GPU platforms with one serving process per GPU. *2) IG (PPO) + NCCL* is for Sync. DRL training in data parallelism and uses NCCL [28] as the communication backend and this is also the only distributed version officially supported by Issac Gym. *3) IG (PPO) + Horovod* is also for Sync. DRL training in data parallelism, and uses Horovod [40] as the communication backend. *4) IG (A3C)* is for study on Async. DRL training, where policy serving and policy training are running concurrently on different GPUs. *5) Ray* is the framework for DRL training. To compare with Ray [27], we select the officially optimized multi-GPU PPO training examples in RLLib [23] of Ray. For all baselines, we manually adjust the simulation batch size (i.e., *num_env*) of each DRL benchmark to reach its peak throughput by using each GPU exclusively. The configurations (*num_env* and *GMIperGPU*) are generated with Algorithm 1.

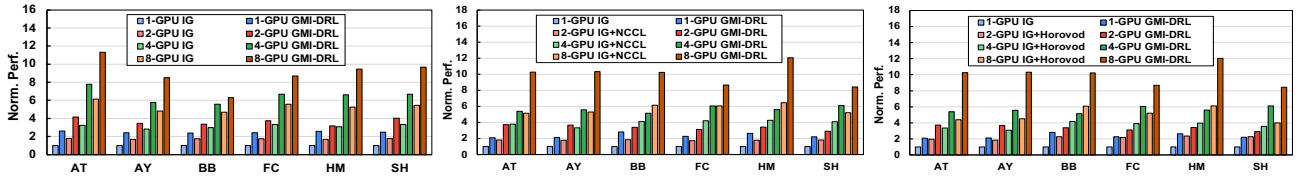
Platforms & Tools: We use a DGX-A100 [29] (including 8×NVIDIA A100 GPUs and Dual AMD Rome 7742 CPUs with a total of 128 cores@2.25 GHz). For environment simulation, we leverage NVIDIA Isaac Gym [24]. We use PyTorch (v3.8) [35] to build the policy model, and NCCL (v2.8.4) [28] and Gloo [10] (commit `a01540e`) to build the GMI-based communication layer. To measure the performance, we leverage the `nvidia-smi` tool and PyTorch runtime profiler. The throughput metric of DRL serving and Sync. DRL training is the training samples (simulation steps) per second [24].

4.1 Overall Performance

DRL Serving Figure 9a shows how with the help of our GMI-oriented design, the overall throughput of policy serving can be improved (up to 2.62×, averaged 2.08×) across settings with different numbers of GPUs. Based on our detailed profiling results, our GMI-based design can improve GPU utilization (up to 45.7%, averaged 27.9%) compared with the state-of-the-art Isaac Gym. This also demonstrates GMI-DRL to maximize GPU utilization and performance.

Sync. DRL Training We conducted two experiments. *Compared with IG (PPO) + NCCL:* Figure 9b demonstrates that GMI-DRL with the optimal GMI planning can achieve up to 2.07× (averaged 1.69×) throughput compared to Isaac Gym + MSRL with NCCL under the same number of GPUs. In the more complex DRL setting with a higher number of concurrent simulations and state/observation dimensions, GMI-DRL demonstrates more benefits. This is because of our effective resource planning to maximize the performance gains from available GPU resources, resource isolation to minimize execution interference and communication support to synchronize policy gradients among different training copies. In addition, our profiler shows that GMI-DRL improves GPU utilization by up to 40.8% (31.8% on average). Such an improvement can help users save evident cloud service costs under the same training throughput.

Compared with IG (PPO) + Horovod: Figure 9c shows that GMI-DRL outperforms Isaac Gym + MSRL with Horovod backend with up to 2.34× (averaged 1.72×) training performance throughput. We also notice that there are performance differences between NCCL and Horovod baselines. It can be attributed to the way of updating the policy model parameters. The NCCL-based designs rely on separate gradient reduction and PyTorch optimizer, while the Horovod-based designs manage their own distributed optimizer including both gradient reduction and the distributed model update. Besides, we notice the superlinear speedup number achieved by GMI-DRL in this experiment. This is mainly due to the combined effects of scaling up with multiple GMIs per GPU and scaling out with multiple GPUs. This implies that only focusing on optimizing communication is insufficient to exploit the full potential of multi-GPU platforms.



Async. DRL Training We compare GMI-DRL with IG (A3C) in Async. DRL training. We measure *predictions per second* (PPS) and the *training samples throughput* (TTOP) as [25]. Figure 10 shows that with the help of our GMI-based design and the throughput optimized experience transferring technique, GMI-DRL can achieve averaged 1.88× PPS and 1.65× TTOP over non-GMI baseline on 2 and 4 GPUs. This result shows the importance of collaboratively improving the performance of experience collection and experience sharing for Async. DRL training. Our additional study reveals that channel-based experience sharing (§3.2.2) with the searched optimal package grouping plan would contribute to 24% of overall performance improvement.

4.2 Comparison with Ray

We compare GMI-DRL with Ray RLLib (leveraging OpenAI Gym) on its expert-tuned multi-GPU PPO implementation [36]. Specifically, for our GMI-DRL design, we replace our Isaac Gym with OpenAI Gym [3] on several benchmarks (including Ant and Humanoid, which are from MuJoCo [46]).

Our result shows that GMI-DRL outperforms Ray evidently in training throughput (up to 62%). Despite that the Ray actor can leverage partial GPU (in percentage) for policy model

Figure 9: End-to-end computation throughput comparison for (a) *DRL serving*, (b) *Sync. DRL training with NCCL*, and (c) *Sync. DRL training with Horovod*. Note that computation throughput is normalized w.r.t. **Isaac Gym+MSRL** (*IG*) on a single GPU.

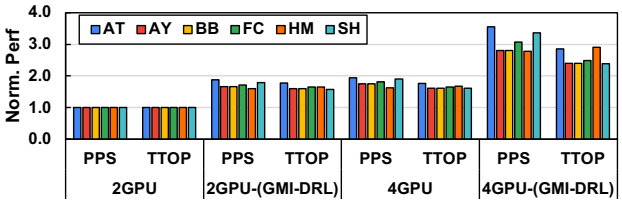

Figure 10: Async. DRL training throughput performance.

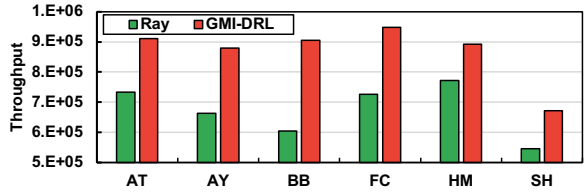

Figure 11: Training comparison with Ray on 8×A100.

inference (action prediction) to collect experience, for scaling policy training, Ray still has to follow the conventional one-to-one mapping between trainers and GPUs and leverage NCCL/Horovod for communication [37]. Therefore, Ray can only utilize GPUs in a fixed yet coarse-grained manner during the training, missing the opportunities to harness spare GPU resources. When we retarget our existing design to other simulators, we need to consider 1) placement of simulators on CPUs or GPUs depending on their property and computation efficiency, and 2) layout/topology of simulators based on their connected channels (e.g., NVLink and PCIe). Our design can flexibly accommodate such change by tailoring design parameters in our existing communicators and coordinators.

4.3 Additional Study

Multi-Node (Machine) Scaling As shown in Table 5, we compute the normalized throughput for *multi-node* w.r.t. *single-node* Sync. DRL training. We consider the settings of 1, 2, 4, and 8 nodes with (a) 1 GPU per node and (b) 2 GPUs per node. The throughput improvement from GMI-DRL remains consistent in the multi-node settings, which reaches an average of 83% of the ideal (linear) scaling performance. This demonstrates that our collective composition and its optimization technique can effectively adapt towards multi-node policy gradient synchronization by considering

Table 5: Multi-node scaling with (a) 1 GPU per Node and (b) 2 GPUs per Node on Sync. DRL training.

1 GPU/Node	**1-node**	**2-node**	**4-node**	**8-node**
BB	1.00×	1.84×	3.28×	7.16×
HM	1.00×	1.71×	2.87×	6.67×
2 GPUs/Node	**1-node**	**2-node**	**4-node**	**8-node**
BB	1.00×	1.83×	3.18×	7.04×
HM	1.00×	1.61×	2.72×	6.44×

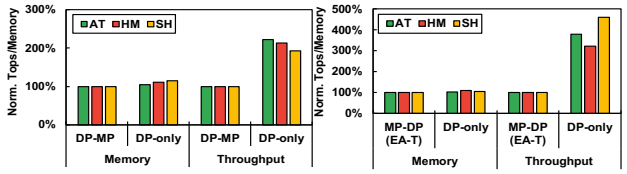

Table 6: Throughput on Collective Composition.

Benchmark	2G3T ($m=3$)			4G3T ($m=3$)		
	Baseline	GMI-DRL	k	Baseline	GMI-DRL	k
AT	319,699	**320,925**	2	529,081	**533,018**	2
HM	415,280	**425,641**	1	621,871	**636,339**	1

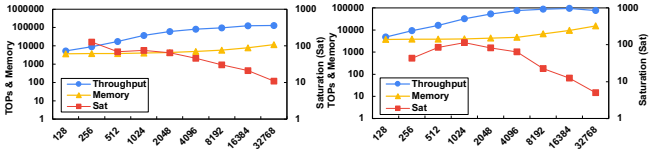
the intra- and inter-node GMI layout hierarchy and combining different inter-GMI communication options.



Collective Composition We also demonstrate the effectiveness of GMI-tailored Collective Composition. Our baseline is IP-only. We choose three settings, including (i) 2 GPUs with 3 Trainers per GPU (2G3T); (ii) 4 GPUs with 4 Trainers per GPU (4G4T). Table 6 indicates that our collective composition can bring evident throughput benefits for DRL training on different policy models. Our Algorithm 1 identifies the right choice for k to maximize communication efficiency. This indicates that our communication optimization can pinpoint the composition plan that will maximize the efficiency of different primitives on various types of interconnects.

Task-aware GMI Mapping We empirically demonstrate our mapping choice comparison for DRL serving (Table 2) and Sync. DRL training (Table 3). Results in Figure 12 show that 1) for DRL Serving, our DP-only design achieves significant throughput improvements (average 110%) with minor memory resource penalty (average 9.5%); 2) for Sync. DRL training, co-locating experience collection and trainer achieves significant throughput improvements (287.5% on average) with a minor memory resource penalty (averaged 6.5%) compared with DP-MP (EA-T). Note that for DRL benchmarks (other than Isaac Gym), our theoretical and experimental analysis methodology can still be applied but the mapping decisions could vary depending on the internal simulator implementation and policy model choices, which bring different performance-resource tradeoffs.

(a) (b)

Figure 12: Throughput performance and Memory consumption on (a) DRL serving and (b) Sync. DRL training.

(a) (b)

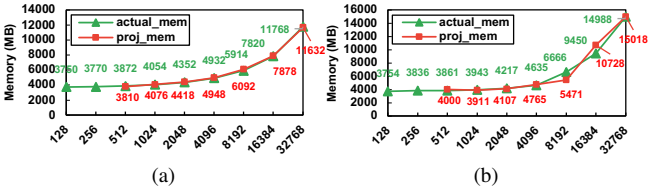


Figure 13: Saturation (*Sat*) Metric on (a) AT and (b) HM.

Saturation Metric & Memory Projection We analyze the Saturation (*Sat*) (Algorithm 1) metric in a single Sync. DRL training instance. Figure 13 shows that with the increasing *#environment* per training instance, the overall throughput will first increase, and then it will increase slowly or even show some decrease (e.g., HM at 32,768 environments). This is mainly due to the complex physics computation in the DRL simulator that cannot scale well to generate large-size data batches. This also justifies using such DRL-specific throughput increase-saturation property to determine an early stop of parameter search. We also evaluate our memory projection model (Equation 4). Figure 14 shows that our memory projection model can effectively predict memory cost given the *#environment* with minor deviation, indicating its usefulness in joint configuration optimization.

Individual DRL Libraries: Seed RL [9] introduces modern scalable RL agent. Acme [14] provides modularized libraries for building and scaling DRL applications. WarpDrive [21] is a lightweight and open-source library to accelerate single and multi-agent DRL simulation performance on GPUs. Isaac Gym [24] from NVIDIA Omniverse [32] represents the state-of-the-art GPU-based DRL acceleration design, which significantly outperforms its CPU-based counterparts [3] and GPU-based solutions [21] in terms of its simulation throughput. GMI-DRL focuses on adaptive-grained DRL tasks mapping and scheduling are orthogonal and complementary to these existing libraries for specific DRL tasks like simulation.

Holistic DRL Systems: Ray [27] is a distributed computing framework for emerging DL applications including DRL (RLLib). PodRecer [13] introduces a unified scaling architecture for DRL on TPU-based systems. TLeague [43] targets

(a) (b)

Figure 14: Memory Projection on (a) AT and (b) HM.

DRL scaling on hybrid CPU and GPU clusters for Multi-Agent Reinforcement Learning. MSRL [52] is the state-of-the-art DRL computing framework that features dataflow fragments for individual DRL functions on CPUs/GPUs. However, MSRL still relies on off-the-shelf communication infrastructures (e.g., NCCL) for scaling the DRL computation and it can only support very limited options of computation granularity in its DRL fragments on GPUs. For instance, the MSRL fragment plan can only allow one DRL simulator/learner on one GPU. Additionally, MSRL relies on hard-coded manual configuration and requires expert users to adapt to different DRL models/inputs. GMI-DRL opens up an all-new dimension by enabling adaptive-granular parallelism at the sub-GPU level that will enlarge the design space of those existing systems.

6 Discussion

Our work is the first one investigating the design choices of DRL training and serving for a multi-GPU system. We would like to highlight some key design insights and technical contributions.

Observations. Several observations are drawn through our initial investigation: (a) MIG (Multi-instance GPU) allows strict resource isolation through the full hierarchy (memory, cache, interconnect, SMs) to avoid potential resource competition, but has explicit limitations on communication, thus is more suitable for DRL serving; (b) MPS (Multi-Processing Service) does not enforce resource isolation among agents, but can be more flexible at communication, thus is a better choice for training, given the necessity to collect data from distributive GMI instances; (c) Overall, for single-node scaling-up, until the communication hurdle can be well-addressed by the vendor, MPS is more preferred for the implementation.

Architecture. Despite the use of spatial multiplexing in the prior CPU work, the GPU-based spatial multiplexing is relatively new (e.g., MIG). GPU spatial multiplexing is designed to support diverse and independent GPU applications while guaranteeing their quality of service. There is a trend to keep and consistently improve this feature in future hardware (e.g., H100/H200), and other GPU vendors also follow a similar trend (e.g., AMD MI200 GPU requires at least two MPI processes to fully utilize the GPU resources).

Software/Application. GPUs have now become a more generic accelerator, and many real-world applications (e.g.,

DNN inference) intrinsically cannot fully utilize GPUs. To maximize its utilization, existing work leverages MIG for scaling up simple applications, which just matches the initial design objective of MIG. However, we target complex DRL training with GPU underutilization and interaction/communication among different components. These challenges are outside the scope of MPS/MIG and demand careful resource/-workload planning and efficient communication support.

Performance. Our design evidently outperforms the state-of-the-art Isaac Gym and would facilitate the quick/wide deployment of DRL at scale. The performance regarding different DRL design choices, as well as these observations, are not reported by any existing works.

7 Conclusion

This paper introduces GMI-DRL, the first system to scale multi-GPU DRL with adaptive-grained parallelism. GMI-DRL includes a novel design of resource-efficient GPU multiplexing instances (GMIs), highly efficient communication support across GMIs, and an adaptive GMI management strategy to meet various demands of DRL training. Experiments demonstrate GMI-DRL advantages across various settings over the state-of-the-art DRL frameworks.

*m*Tuner: Accelerating Parameter-Efficient Fine-Tuning with Elastic Tensor

Kezhao Huang Siqi Zhu Mingshu Zhai Liyan Zheng Kinman Lei Jiaao He
Yuyang Jin Jidong Zhai
Tsinghua University

Abstract

With the growing importance of personalized large language models (LLMs) and fine-tuning techniques, parameter-efficient fine-tuning (PEFT) has emerged as a mainstream approach, offering reduced computational and storage demands compared to full-parameter fine-tuning. Compared to pre-training, we find memory efficiency more critical during fine-tuning. Although the overall memory capacity of fine-tuning hardware is typically limited, memory becomes more precious since most parameters are frozen and can be cached for performance optimization. To better utilize memory, we propose Elastic Tensor, an abstraction for dynamic tensor management, enabling flexible control over their availability, accumulation, and release in memory. Elastic tensor defines four key operations for static and runtime tensors with tunable ratios: *gather*, *discard*, *execute*, and *checkpoint*. With elastic tensors, a series of optimizations are enabled, such as improving temporal memory utilization, relaxing data dependence, and accumulating runtime tensors in a memory-adaptive way. We implement mTuner, an end-to-end fine-tuning system based on elastic tensors. Compared with state-of-the-art training and fine-tuning systems, mTuner achieves a throughput improvement of up to 51.2% and 24.8% (28.3% and 14.5% on average) on PCIe and NVLink servers respectively, for LLMs from 7B to 70B. *m*Tuner is publicly available at https://github.com/xxcclong/mTuner.

1 Introduction

Large language models (LLMs) [1,34,43,50] are becoming increasingly prevalent across various applications. Meanwhile, fine-tuning techniques for model personalization [9, 47, 52] have emerged as a critical topic in large-scale model training. Fine-tuning is typically conducted with limited data and modest hardware resources [10, 11, 59], while often requiring the rapid generation of multiple fine-tuned models [13, 17, 61]. However, the immense number of parameters in large language models poses significant challenges to performing full-parameter fine-tuning under these constraints [16, 44, 60].

To overcome this limitation, researchers have introduced parameter-efficient fine-tuning (PEFT). Unlike full-parameter fine-tuning, PEFT leverages pre-trained weights by updating only a small subset of parameters while keeping the majority of the model frozen [15, 22, 28, 37, 54]. This approach significantly reduces computational overhead and storage requirements, as only the updated parameters need to be saved, yet it maintains competitive performance. As a result, PEFT has become the predominant fine-tuning strategy [8, 16, 24].

Parallelization is essential for efficient fine-tuning of LLMs across multiple GPUs and servers, as it enables the distribution of computation and data to meet the high memory and computational demands. Various strategies, including data, tensor, and pipeline parallelism, have been proposed to improve distributed training performance [40, 45]. For better performance, previous work tried to search for the optimal parallel strategy [12, 51, 58] and improve communication efficiency [2, 3, 33, 62]. On the other hand, efficient parallel execution relies heavily on available memory, which not only stores weight parameters to reduce communication overhead but also supports larger batch sizes for increased parallelism. As shown in Figure 1a, fine-tuning throughput improves with higher memory utilization, making it critical to maximize memory usage while staying within hardware limits. Therefore, previous works optimize memory efficiency using swapping [3, 55], offloading [39, 41], and activation checkpointing [36, 42, 48]. However, memory efficiency still remains a key challenge, hindering the full potential of distributed fine-tuning.

The first challenge arises from low temporal memory utilization, which stems from the inherent first-in-last-out pattern of runtime tensor such as activations. This pattern creates *peaks and valleys in memory usage*, where memory is heavily occupied during peaks but is underutilized during valleys, resulting in inefficient usage of available memory resources (Figure 1c).

The second challenge comes from the data dependency between computation and communication. During fine-tuning, communication is often required for runtime tensors, such

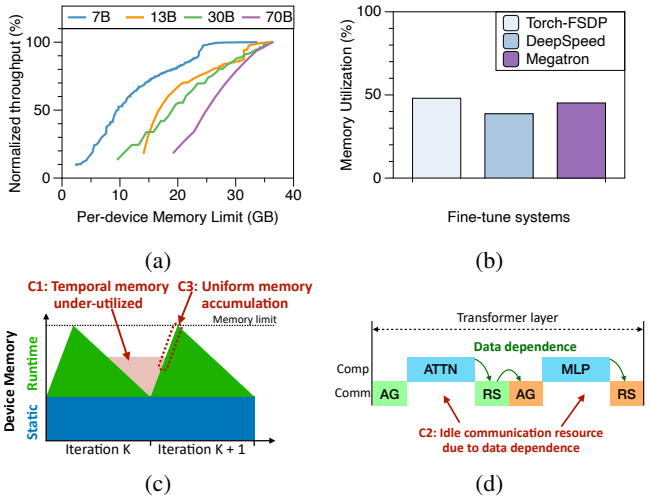

Figure 1: (a) The throughput of fine-tuning models is directly proportional to memory limit; (b) Existing fine-tuning systems have low time-average memory utilization; (c) Low temporal memory utilization and high peak memory caused by uniform memory accumulation; (d) Communication resource waste due to data dependence.

as performing all-gather for activations in tensor parallelism. However, communication can only begin after the relevant data is produced, leading to rigid data dependence. This dependence limits opportunities for overlapping communication with previous computation, causing inefficient utilization of communication resource (Figure 1d).

The third challenge is related to memory accumulation and peak memory consumption. Existing methods accumulate memory without considering the different phases of memory usage. As a result, memory accumulation strategies apply uniformly in both the peak and valley phases, leading to extremely high memory pressure during the peak phases, thus constraining other optimization space related to memory (Figure 1c).

As a result, existing frameworks have low time-average memory utilization as shown in Figure 1b. The underlying root cause of these challenges lies in the static deploying of memory adopted by current parallelization frameworks. Their static scheduling assumes a uniform and large-size pattern of memory, which fails to accommodate the highly dynamic nature of fine-tuning. This dynamism arises from several factors: the runtime tensor being generated and accumulated on-the-fly during computation, the dynamic availability of computational and communication resources, and the variable data dependence that must be resolved at runtime.

To address the above challenges, we propose *elastic tensor*, an abstraction for dynamic tensor management. By defining four core actions and allowing flexible control of memory through tunable ratios, elastic tensor provides a unified method for discovering memory optimizations.

With elastic tensor, a series of optimizations are enabled for fine-tuning. First, we introduce a temporal memory management strategy that leverages frozen parameters in PEFT to reuse idle memory during valley stages, significantly enhancing temporal memory utilization. Second, elastic tensor facilitates the interplay of communication between static and runtime tensors, thereby relaxing data dependencies and improving communication-computation overlap. Third, we propose an adaptive accumulation strategy that dynamically adapts how runtime tensors are stored and accumulated, effectively reducing peak memory pressure and improving overall memory efficiency.

Based on elastic tensor, we develop *m*Tuner, a fine-tuning system with high memory utilization for better PEFT efficiency. *m*Tuner leverages elastic tensor at runtime to maximize memory utilization and reduce communication workload. We evaluate *m*Tuner on transformer-based LLMs with sizes ranging from 7B to 70B parameters on an eight-GPU server. Results show that *m*Tuner improves fine-tuning performance by up to 1.51× (1.28× on average) compared to state-of-the-art training systems, including DeepSpeed [40], Megatron [21], and Flux [2].

In this paper, we have made the following contributions.

- We identify key memory efficiency challenges in LLM fine-tuning and analyze their impact on performance.
- We propose elastic tensor, an abstraction for dynamic tensor management. It supports four core actions with tunable ratios, providing fine-grained control to enable key optimizations in memory efficiency.
- We use elastic tensor to represent and apply three novel optimizations that improve performance by enhancing memory efficiency.
- We evaluate *m*Tuner on various models with parameter sizes ranging from 7B to 70B, achieving improvement of up to 51.2% and 24.8% (28.3% and 14.5% on average) on PCIe and NVLink servers.

2 Background

2.1 LLM Fine-tuning

LLM fine-tuning refers to the process of imparting domain-specific knowledge to a LLM based on a small amount of domain-specific data, building upon a pre-trained model. Fine-tuning holds significant importance in applying LLMs across various industries and domains.

Traditional fine-tuning is similar to pre-training, which updates all parameters. The example is shown in Figure 2(b), all weight parameters are trainable and need to be updated during backward propagation. To make fine-tuning more light-weighted, researchers propose Parameter-Efficient Fine-Tuning (PEFT), which also starts with a pre-trained model,

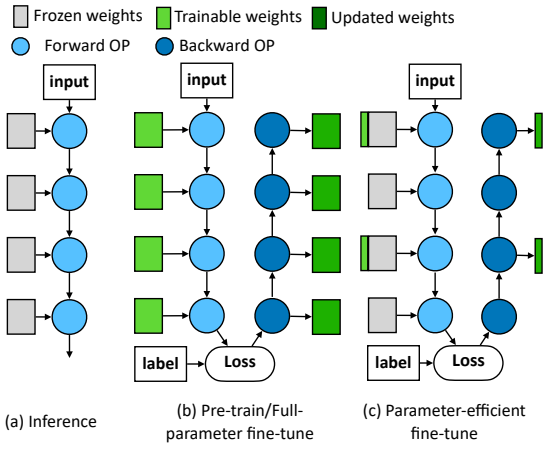

Figure 2: Illustration of (a) inference, (b) pre-training/full parameter fine-tuning, and (c) parameter-efficient fine-tuning (PEFT)

but does not update the whole parameters of the pre-trained model. Instead, it introduces a small number of trainable parameters called adapters into the model structure[1]. As shown in Figure 2(c), during training, the parameters of the pre-trained model (base model) are involved in computations but not updated (frozen); only the parameters of the adapters are updated based on the loss and optimizer state.

Compared with full-parameter fine-tuning, PEFT has the following advantages: 1). It significantly reduces the memory requirements for the optimizer state, needing only the adapter's optimizer state and not that of the base model; 2). As it does not compute gradients for the majority of parameters during backward propagation, it saves computational resources; 3) Since only the parameters of the adapter differ after tuning, saving only the adapter's parameters (along with the original base model's parameters) constitutes the tuned model, facilitating propagation and serving. Consequently, PEFT has become a commonly used method in current fine-tuning practices and is the main focus of this paper.

2.2 Data Communication

In distributed fine-tuning, data communication plays a crucial role in ensuring parallel efficiency across multiple GPUs. The data involved in fine-tuning can be broadly categorized into two types: static tensor and runtime tensor, each with distinct characteristics and communication requirements.

Static tensor primarily consists of model parameters, such as weights and biases, since these tensors persistently reside in memory. Distributed fine-tuning often employs techniques like data parallelism, where static tensor is either split across devices or replicated. For example, in fully-sharded data parallelism (FSDP), each device holds a partition of the parameters, and communication is required when executing a module to get all its weights locally available to perform computation on it.

Runtime tensor refers to intermediate activations, gradients, and other temporary data produced during the forward and backward passes. Unlike static tensor, runtime tensor is highly dynamic, with its communication pattern depending on the execution flow of the model. For instance, in tensor parallelism, runtime tensors such as activations needs to be gathered or scattered across devices during computation. Moreover, runtime tensor communication is constrained by data dependence, meaning communication can only occur after the relevant computation has been completed, which limits opportunities for overlapping communication with computation.

2.3 Memory Challenges in LLM fine-tuning

Fine-tuning involves dynamic memory patterns due to runtime tensors, such as intermediate activations and gradients. These runtime tensors often dominate memory consumption and directly affect the achievable batch size, sequence length, and ultimately the training throughput. On the other hand, memory can be used for caching static tensor to reduce communication overhead. To improve memory efficiency during fine-tuning, it is essential to address several challenges arising from the complex interplay of computation, communication, and memory accumulation. Specifically, we highlight three major challenges: inefficient utilization of idle memory during temporal valleys, waste of communication resources caused by data dependence, and high peak memory pressure due to inflexible accumulation strategies.

Ignoring valley memory: Low temporal memory utilization . One major challenge in LLM fine-tuning is the inefficient utilization of memory due to the fluctuating nature of temporal memory usage. During fine-tuning, runtime tensor follows a first-in-last-out pattern, which creates peaks and valleys in memory consumption. At peak moments, memory is highly occupied, while during valleys, a significant portion of memory remains idle. This inefficiency becomes even more pronounced when larger contexts or batch sizes are used, as runtime tensors occupy a larger fraction of the total memory. Without strategies to utilize idle memory during valleys, overall memory efficiency remains suboptimal.

Runtime tensor dependence: Waste of communication resources Another critical issue arises from the rigid data dependence during fine-tuning, which leads to underutilization of communication resources. Fine-tuning often requires communication for runtime tensor, such as gathering activations in tensor parallelism. However, communication resources are heavily constrained during these phases, as communication for runtime tensor can only occur after the corresponding tensor has been produced. In contrast, during other phases

[1]PEFT can also select some parameters from the pre-trained model and set as trainable. It has the same pattern with a large number of weights frozen and a small number of weights trainable

that involve only computation, communication resources are largely idle. This strict data dependence prevents preemptive communication, resulting in significant waste of available communication resources. Efficiently addressing this imbalance between computation and communication is key to improving fine-tuning performance.

Inflexible memory accumulation: High peak memory consumption . A third challenge is the rigid method used to accumulate runtime tensor under different memory status. Previous approaches do not account for the varying characteristics of peak and valley phases in memory usage. As a result, they apply the same memory accumulation strategy throughout, leading to excessively high memory pressure during peak phases. This accumulation method leaves little room for optimization at peaks, where memory is already a critical constraint. Consequently, peak memory usage becomes a major bottleneck, limiting the scalability of fine-tuning large models. Addressing this challenge requires flexible memory management strategies that adapt to the different phases of memory utilization.

3 Elastic Tensor

We propose the concept of elastic tensor, an abstraction for dynamic tensor management, where all tensors (e.g., weight parameters, activations, etc.) are treated as dynamic entities, of which real storage can be adjusted during execution. *m*Tuner enables elastic tensor management by providing the following four actions for tensors. These actions control all changes to tensor memory utilization during fine-tuning, thus affect the overhead (computation and communication) related to tensor memory changes.

1. *Gather*: For both static and runtime tensors, it makes remote data partitions locally available. It calls cross-device communication (all-gather) to fetch remote data and increases the ratio that represents how much data is locally available, which varies from $\frac{1}{D}$ (D is the number of devices, indicating tensors evenly partitioned) to 100% (tensors fully replicated on each device).

2. *Discard*: It drops gathered tensor to save memory and decreases the ratio of it with no overhead.

3. *Execute*: It performs model computation and generates runtime tensors. A ratio indicating the fraction of the input batch processed, ranging from 1/B (processing a single sample) to 100% (processing all samples).

4. *Checkpoint*: It saves generated runtime tensor for gradient computation. A ratio describes how many runtime tensors of the module is saved, ranging from 0% (no tensor is stored) to 100% (all runtime tensors in this module are stored).

For dynamic elasticity, *m*Tuner not only can perform these actions with various ratio, but also flexibly set the time for triggering. At the start and end of executing each operation, *m*Tuner can insert actions to change memory usage and utilize communication resource.

*m*Tuner performs operations such as partitioning and communicating tensors to achieve memory management for elastic tensor, just like the existing works such as distributed tensor representation, memory allocator, and different memory caching policies. However, elastic tensor enables conversions between operations that were previously unrelated. For example, trading off between storage and communication efficiency. This allows for a unified representation and transformation between memory, compute, and communication, which in turn optimizes memory planning and execution strategies under memory constraints.

4 Optimizations Enabled by Elastic Tensor

By leveraging elastic tensor, we can flexibly adjust the storage ratio and execution behavior of static and dynamic tensors. This enables further improvements in memory utilization under strict memory constraints and allows memory to be used for relaxing data dependence, thereby better utilizing communication resources and optimizing fine-tuning throughput.

4.1 Temporal Memory Adjustment

As discussed in Section 2.3, the first-in-last-out pattern of runtime tensors results in peaks and valleys in memory usage, which further leads to low temporary memory utilization. *m*Tuner uses elastic tensor to dynamically cache and reuse tensors at the memory valleys to solve this problem.

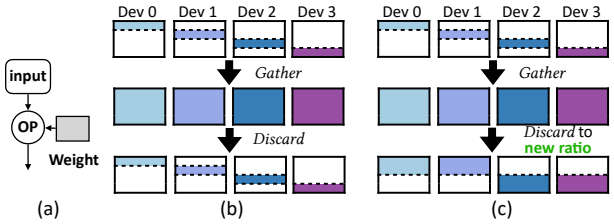

Figure 3: Illustration of *Gather* and *Discard* for weights. When performing computation on an operator (a), FSDP implementation will *Gather* all its weights, perform computation, and *Discard* them to the original ratio (b); In *m*Tuner, *Discard* can be adjusted to other ratio (c);

For fully-sharded data parallel, as shown in Figure 3(a) and (b), during the execution of an operator, each device acquires its complete weights by *gathering*, which is then used for computations. The *gathered* weights are *discarded* after that. As the device possesses complete weight during computation, *m*Tuner can re-adjust the ratio of the weight **without incurring additional communication overhead**. In the example

of Figure 3(c), prior to computation, each device only possess $\frac{1}{D}$ of the weight for the operator, which is then adjusted to $\frac{2}{D}$ after computation. Such dynamic adjustments can be made each time when the weight is used for computation.

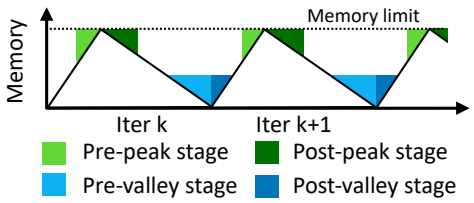

Figure 4: Memory stages resulted by generated runtime tensors

*m*Tuner schedules elastic tensors to improve temporary memory utilization by dynamic adjustment according to current and predicted memory usage trends. As illustrated in Figure 4, during the valley region, frozen weights from the pre-valley stage have a minimal reuse distance. Consequently, *m*Tuner *discards* less of these weights, thereby increasing the ratio of tensors retained in the pre-valley stage. This strategy facilitates the reuse of these weights and reduce the communication cost for *gathering* during forward computation in the post-valley stage. To restore memory efficiency before the pre-peak stage, *m*Tuner compensates by *discarding* more weights at this point, returning the memory state to its base level.

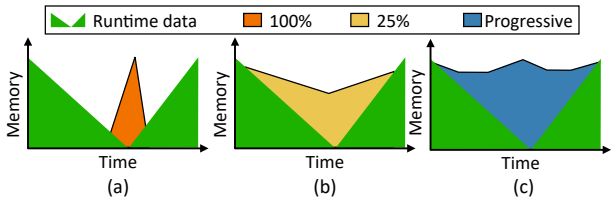

Figure 5: Filling memory valley with single size ((a) and (b)) and progressively changing ratio of elastic tensors (c)

As shown in Figure 5(a), caching frozen weights at a high ratio (e.g., 100%) during the valley can quickly exhaust the available memory, leaving insufficient space to cache other tensors. Conversely, caching frozen weights at a low ratio allows more tensors to be cached but fails to fully utilize the available memory during the valley (Figure 5(b)). Additionally, frequent memory allocation during the peak can lead to fragmentation, increasing the risk of out-of-memory (OOM) errors. To maximize the temporal utilization of available memory, elastic tensor gradually adjusts the discard ratio in the pre-valley region. As in Figure 5(c), closer to the valley, a higher ratio of tensors is cached, while nearer to the peak, the caching ratio is reduced to ensure efficient memory usage and minimize fragmentation risk.

4.2 Dependence-relaxed Communication

Another common parallel strategy in fine-tuning is tensor parallelism (TP). Unlike data parallelism, TP does not require *gathering* weight parameters; instead, it partitions and *gathers* activations for parallel execution, making activation communication a main performance bottleneck. Though communication resources are highly constrained during the TP communication phase, they remain underutilized during other phases dominated by computation.

This underutilization arises due to the data dependency of activations: communication can only begin after activations are generated, preventing it from being initiated in advance. Prior works [2,33] attempt to mitigate this issue by fusing activation communication with computation, breaking workloads into fine-grained tasks to enable partial overlap. However, data dependency still limits the full utilization of available communication resources.

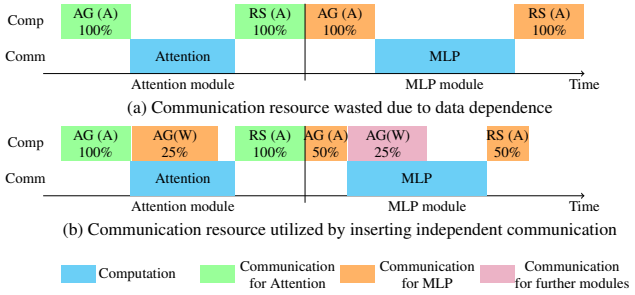

Figure 6: Timeline for attention and MLP module w/ and w/o dependence-relaxed communication

We find that, though data dependence for activation exists, static data, which is independent from execution, can be used to trade for activation communication. Therefore, *m*Tuner can relax the data dependence by elastically inserting communication for weight parameters. The enlarged weight parameter can reduce the communication workload for activation. Figure 6 is an example for an attention module followed by an MLP module in a Transformer layer. (a) shows the communication resource utilization constrained by data dependence of activations. However, in (b), *m*Tuner can insert the communication of weight while performing computation for attention module. With a larger portion of local weights, it can reduce the range and workload of communication for activation in MLP module, thus leads to faster all-gather and reduce-scatter. In MLP module, it can also insert communication for weights of further modules.

Here is a quantitative analysis of the communication savings achieved by dependence-relaxed method. We take input with batch size at B, sequence length at S, hidden size at H, and FFN hidden size F for example. At the start of the MLP module, original method performs a gather ranging from 8 GPUs to collect activations from $[B,S,\frac{H}{8}]$ into $[B,S,H]$, then performs MLP on devices each storing weight parameters

of $[H, \frac{F}{8}]$ and $[\frac{F}{8}, H]$, and performs reduce-scatter to reduce the tensor $[B,S,H]$ into $[B,S,\frac{H}{8}]$. However, with weight parameters prefetched into $[H, \frac{F}{4}]$ and $[\frac{F}{4}, H]$ (25% of the total number of parameters), the communication range is reduced from 8 GPUs to 4 GPUs. The communication at the start and end of TP is the all-gather and reduce-scatter for tensor size at $[\frac{B}{2}, S, \frac{H}{4}]$ and $[\frac{B}{2}, S, H]$, which is reduced by 50%. For scenarios that batch size is tightly constrained and cannot be split, *m*Tuner can split on the dimension of sequence for MLP module.

The percentage of weight prefetched to reduce activation communication is determined by the idleness of communication resource. The communication is fully overlapped and leads to low overhead. On the other hand, with communication of weight and activation interchanged, the efficiency of computation for TP module is improved: The reduction dimension for matrix multiplication gets larger, benefitting the parallelism and the use of TensorCore for GPU.

4.3 Adaptive Data Accumulation

Runtime tensors such as activations are generated and accumulated during the forward phase, and they are consumed and released during the backward phase. The accumulated tensors are part of the memory usage bottleneck. Some methods manipulate on the accumulated memory for better memory utilization. However, as the manipulation uniformly regards the memory at different stages (transformer layers), it causes high activation memory peak usage, therefore limits other optimizations related to memory. *m*Tuner uses elastic tensor to manage the generation and storage of tensors adaptively using the action of *execution* and *checkpoint*.

We observe that runtime tensors generated by different layers exhibit varying lifespans: deeper layers, which are closer to the loss computation, complete backward computations and discard runtime tensors earlier, without affecting computations in shallower layers. Consequently, initiating backward computations sooner for these deeper layers can shorten tensor lifetimes and enable earlier memory release, thereby reducing their residency time. To enable earlier backward execution, *m*Tuner adopts a non-uniform prioritization strategy for deeper layers: it can selectively prioritize partial execution on input tensors (by splitting along the batch dimension) and perform corresponding backward executions for those parts.

As shown in Figure 7(a), for training a 4-layer model on four input samples, the typical procedure involves processing them together, executing four forward computations followed by four backward computations. Shown in Figure 7(b), this process results in the accumulation of activations generated by the four samples across the four layers of forward computations in memory, peaking at the end of the forward stage. *m*Tuner's optimization is shown in Figure 7(c), it can divide execution along the batch dimension, splitting the four samples into two groups of two samples each. From the third

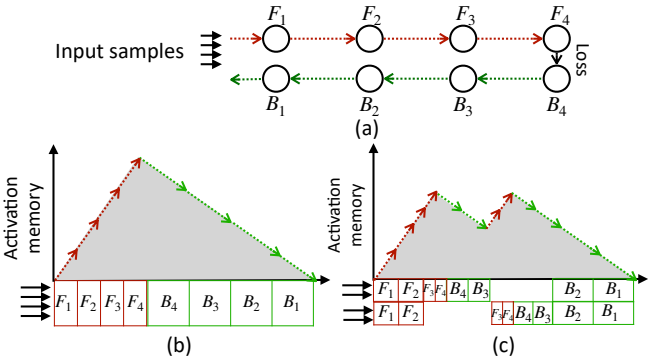

Figure 7: Increasing execution priority for samples to reduce peak activation memory usage; (a) Input samples and computation workflow; (b) Uniform execution priority for all layers; (c) Prioritizing execution priority for part of the samples

layer's forward execution (F_3), only a subset of samples firstly perform forward computation. After completing the forward computations for these samples, instead of executing the forward computations for the remaining samples, *m*Tuner prioritizes the corresponding backward computations for the completed samples, thereby reducing the duration for which these activations are stored in memory. We can observe that the height of the peak has been effectively reduced.

The peak memory usage can be arbitrarily adjusted using this method. Let the total batch size be B, the batch size after splitting be b, and the model consists of L layers. Among them, the l layers closer to the peak adjust the backward priority. Suppose the original peak height is H, then the new peak height is calculated as:

$$H_{new} = \frac{l}{L}\frac{b}{B}H + (1 - \frac{l}{L})H \quad (1)$$

This formula indicates that as the ratio of b to B decreases, the height of the portion with adjusted execution priority becomes lower. Additionally, as more layers are adjusted in terms of peak memory usage, the final peak memory usage will also be reduced. When $l = L$ and $b = 1$, it is equivalent to running the entire model with a batch size of 1, resulting in the lowest peak memory usage.

Moreover, this method enables fine-grained control over the execution batch size. In cases where the specified batch size cannot fully utilize available memory, it is possible to modify the execution priority and batch size of only certain layers, increasing the peak memory usage to fully exploit available memory and further enhance memory utilization.

In terms of performance, the fine-grained data accumulation impacts both computational efficiency and memory usage. From a computational perspective, larger batch sizes generally improve parallelism and enhance GPU utilization. However, in fine-tuning large models, the batch dimension of most operators is determined by the product of batch size and sequence length. Since the sequence length is already large (typically

at least 4K), GPU resources are already well-utilized, and increasing the batch size has limited additional benefit. On the memory side, fine-grained batch splitting allows for more efficient memory usage by better filling available memory and reducing communication overhead. As for accuracy, batch splitting has no impact on the final model performance. This is because gradients from different samples are accumulated before each optimization step. Whether gradients are computed using a single large batch or multiple smaller batches, the accumulation process remains mathematically equivalent.

5 Elastic Tensor Schedule Discovery

The elastic tensor significantly expands the optimization space for memory management during fine-tuning. However, identifying the optimal elastic configuration for a given hardware environment and model setup is challenging due to the large search space. To address this, *m*Tuner adopts a profiling-based approach to measure the time and memory overhead of each module under various partitioning strategies. Additionally, it introduces a search algorithm that simultaneously accounts for peak and valley memory constraints to determine the globally optimal strategy.

5.1 Elastic Tensor Representation

```
Forward:
  gather: 100% # get full MLP param from 50%
  discard: 12.5% # fully partition MLP param
  execute: 50% # execute half of a batch
  checkpoint: 0% # store none of activation
Backward:
  gather: 100% # get full param from 12.5%
  discard: 50% # discard half of param
  execute: 50% # execute half of a batch
# Forward_execute should equal to
    Backward_execute
# The input ratio for Forward_gather is the
    output ratio of Backward_discard (vice
    versa)
```

Listing 1: Example elastic tensor representation on an MLP module on an 8-GPU servers

*m*Tuner represents the schedule for elastic tensor by setting the actions and ratio for each module. To consider both peak and valley memory, we represent elastic tensor for forward and backward pass respectively.

Listing 1 demonstrates the elastic representation for an MLP module on an 8-GPU system. During the forward pass, the elastic tensor gathers the full MLP parameters from a partial partition at 50%, discards part of the parameters to 12.5% after computation, and processes half of the batch without storing any activations to minimize memory consumption. In the backward pass, it retrieves the full parameters from a highly partitioned state of 12.5%, but discards 50% of the parameters after computation, and processes the same batch fraction (50%) as in the forward pass. As it discards less data during backward pass, it has higher valley memory consumption and leads less gathering workloads at forward pass (50% $\rightarrow$ 100%).

5.2 Holistic Schedule Searching

To find an elastic schedule that minimizes the iteration time under memory constraints, the key challenge is that two kinds of memory, peak memory and valley memory, are utilized while constrained by memory limit. Peak memory is traditionally considered, as the runtime tensors are accumulated. Valley memory is the new problem in *m*Tuner, which indicates how *m*Tuner make use of idle memory as runtime tensors are consumed in backward phase.

In addition to memory constraints, there are interdependencies between transformer layers that complicate the scheduling process. Specifically, data required by later layers can be prefetched by earlier layers, meaning that a scheduling decision for one layer influences both memory availability and execution time of subsequent layers. Furthermore, two distinct types of resources—computation resources and communication resources—must be considered, and they can overlap. The interplay of these factors makes it challenging to fully utilize available memory and minimize execution time simultaneously.

To address these challenges, we propose a dual-memory dynamic programming (DP) approach that searches for the minimal execution time while respecting both peak and valley memory constraints. This DP algorithm evaluates different implementation options for each transformer layer and computes the optimal schedule by tracking memory usage at each step. We also improve resource utilization by overlapping communication with computation. By allowing communication to be brought forward, we hide communication latency behind computation.

Algorithm 1 shows the implementation of dual-memory DP. At each layer, multiple implementation choices are available, each with a unique combination of execution time, peak memory, and valley memory consumption. The dual-memory DP approach explores these options recursively, keeping track of both types of memory consumption at each step. For a given layer, the algorithm evaluates every possible implementation choice and updates the schedule only if it results in a lower execution time while respecting the memory limits. The implementation choices includes different parallel strategies and the ratio of stored weights and activations. It maintains a multidimensional state space where each state represents the cumulative execution time under specific peak and valley memory usage. The state transition involves updating execution time by adding the time of the selected implementation and adjusting memory consumption accordingly.

Algorithm 1 Elastic tensor schedule search

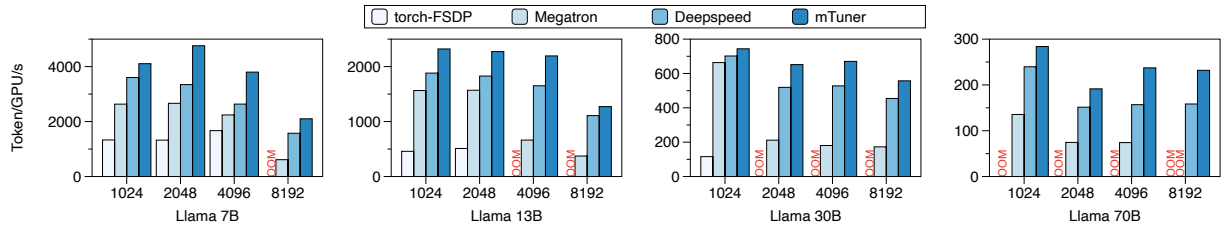
Input: Number of layers L, total GPU memory M_{total}, peak memory $M_p^i(j)$, valley memory $M_v^i(j)$, execution time $T^i(j)$ for each layer i and implementation j, number of implementations N_i for each layer i
$dp(i, m_p, m_v) \leftarrow \infty$, $\forall i \in \{1, \ldots, L\}, m_p, m_v \in \{0, \ldots, M_{total}\}$
$dp(0, m_p, m_v) \leftarrow 0, \forall m_p, m_v \in \{0, \ldots, M_{total}\}$ ▷ Initialize
for $i \in \{1, \ldots, L\}$ **do**
  for $m_p \in \{0, \ldots, M_{total}\}$ **do**
    for $m_v \in \{0, \ldots, M_{total}\}$ **do**
      for $j \in \{1, \ldots, N_i\}$ **do**
        if $M_p^i(j) \leq m_p$ **and** $M_v^i(j) \leq m_v$ **then**
          $m'_p \leftarrow m_p - M_p^i(j)$ ▷ remaining peak memory
          $m'_v \leftarrow m_v - M_v^i(j)$ ▷ remaining valley memory
          $dp(i, m_p, m_v) \leftarrow \min(dp(i, m_p, m_v), dp(i - 1, m'_p, m'_v) + T^i(j))$ ▷ Update DP state
$result \leftarrow \min_{m_p, m_v \in \{0, \ldots, M_{total}\}} dp(L, m_p, m_v)$
Backtrack to determine the selected implementation x_i for each layer
Output: Selected implementations $x_1, x_2, \ldots, x_L$ and total execution time

To reduce the search space of DP, we first prune the set of possible implementations for each layer, retaining only those that are likely to yield optimal efficiency. For example, when balancing between communication and storage, although *m*Tuner supports a continuous range of communication-to-storage ratios from 0% to 100%, we observe that significant changes in communication efficiency occur only when the number of involved devices changes. Thus, *m*Tuner only considers storage ratios of $\frac{1}{N}$, where N is an integer greater than or equal to 1. Furthermore, to further limit the number of states, *m*Tuner discretizes memory consumption by rounding it to integer values. This discretization strikes a balance between search efficiency and solution accuracy, significantly reducing the computational complexity of the DP search while maintaining efficiency.

*m*Tuner and its search method are applicable to models like Transformers, which execute sequentially and perform back-propagation of gradients. This applicability is independent of the specific operators used in the model (e.g., different types of attention mechanisms or operations like convolutions instead of MLPs). Moreover, applications like PEFT, which involve frozen parameters, provide *m*Tuner with more opportunities to cache parameters and reduce computation. In contrast, full-parameter fine-tuning, where parameters are distributed across multiple devices, introduces additional communication overhead, which diminishes the optimization benefits of the method.

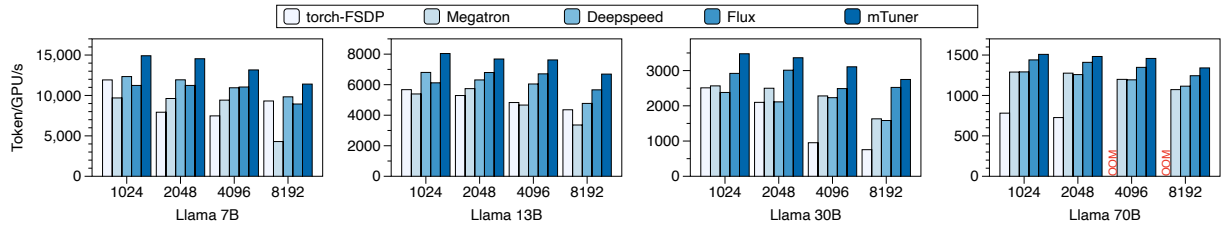
6 Evaluation

*m*Tuner is an end-to-end fine-tuning system based on PyTorch [35] and Torch-FSDP [57]. It statically and dynamically modifies the model's execution plan to transform a pre-trained model into a distributed, memory-adaptive PEFT model. Before running the model, *m*Tuner utilizes a wrapping method to partition the weights at the granularity of modules (embedding, MLP, and attention, etc.). It also adds trainable modules and parameters based on the user-defined PEFT scheme while freezing other parameters. During runtime, *m*Tuner employs hook methods using pre/post-forward/backward hooks of each module to perform actions. As a result, *m*Tuner can be applied to any LLM model structure without requiring additional modifications from the user.



We evaluate *m*Tuner to answer the following questions:

- Can *m*Tuner outperform existing fine-tune systems under various conditions, including model size, sequence length, and hardware settings?
- How elastic tensor influence the memory consumption and performance?
- How searched elastic tensor schedule improve the fine-tuning throughput, respectively for memory peaks and valleys?
- How is the overhead of runtime adjustment of elastic tensor?



6.1 Setup

Baselines and software configuration. We compare *m*Tuner with state-of-the-art training frameworks including Torch-FSDP@2.1.0 [57], DeepSpeed@0.15 [40], Megatron@0.9.0 [21], and Flux [2]. DeepSpeed employs various levels of ZeRO optimizations to reduce memory consumption and enhance performance. Torch-FSDP shares a similar core idea with DeepSpeed, and is implemented with torch-native components. Megatron is able to concurrently apply 3-D parallelization, including data parallel, tensor parallel, and pipeline parallel, to partition the model and reduce communication cost. Both systems are widely used and applied to pre-training and fine-tuning. Flux overlaps computation and communication by fine-grained partition, and is representative for state-of-the-art communication kernels. For a fair comparison, we run all baselines by setting the maximum batch size to saturate available device memory. They are all based on PyTorch@2.5, CUDA@12.1, FlashAttention@2.4.2 [5, 6], and NCCL@2.21.

Hardware configuration. We tested performance on two types of typical servers equipped with PCIe and NVLink respectively for cross-GPU communication. The PCIe server has eight NVIDIA A100-PCIe-40GB GPUs. They are connected via tree-like PCIe: Every four of them are connected

(a) Single PCIe-server with A100 GPUs

(b) Four NVLink-servers with H100 GPUs

Figure 8: Overall results on various sequence length; The higher throughput (Token/s) is better.

to the same NUMA, and cross NUMA communication goes through QPI between NUMAs. The NVLink server has eight NVIDIA H100-SXM-80GB GPUs connected via NVLink, four servers in total. Compared with PCIe, NVLink has much higher communication throughput.

LLMs and input data. We found that the scale of the LLM (number of parameters) has the most impact on performance, while other computational characteristics are similar across transformer-based models. Therefore, shown in Table 1, we tested different sizes of the Llama 2 model [50], with parameters of 7 billion, 13 billion, 33 billion, and 70 billion. For the input data, we tested samples with different sequence lengths ranging from 1024 to 8192. We use LoRA [15] as the PEFT config, which is commonly used [31] for PEFT.

Table 1: Information of tested models

	num_layer	hidden_size	intermediate_size
Llama 2 7B	32	4096	11008
Llama 2 13B	40	5120	13824
Llama 2 30B	64	6656	17920
Llama 2 70B	80	8192	28672

6.2 Overall Results

Figure 8 illustrates the overall performance of *m*Tuner across different models, input sequence length, and hardware configurations. Figure 8(a) shows the performance on PCIe-server, where the communication is the bottleneck. DeepSpeed is always the best among baselines due to its efficient computation-communication overlapping and communication operators. *m*Tuner can improve the throughput by 28.3% over DeepSpeed. On the other hand, *m*Tuner can achieve an average speedup of 4.15× over Torch-FSDP, on which *m*Tuner is built upon. In smaller models such as Llama 2 7B, where memory is more abundant, *m*Tuner can fully leverage the available memory, resulting in a speedup of 40% and the throughput exceeding 4000 tokens per second. Even in larger models like 30B and 70B, where the model parameters alone consume a significant portion of the memory, *m*Tuner still achieves a 27% speedup, demonstrating the effectiveness of our proposed method across various model sizes.

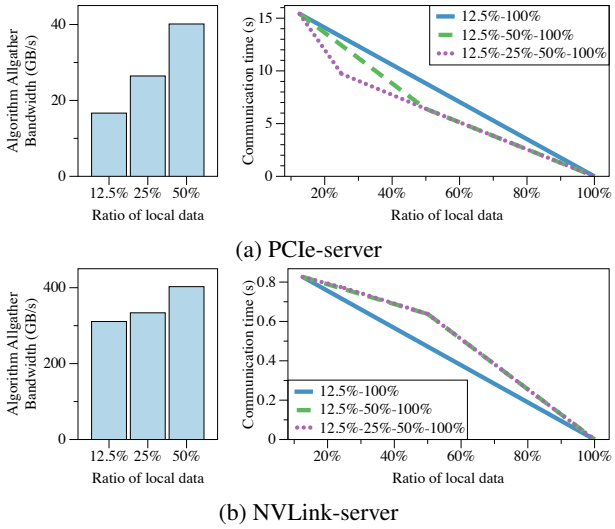


Figure 8(b) shows the performance on four NVLink-servers. Compared with the best baseline, *m*Tuner achieves 14.5% speedup. Flux is the best baseline on most scenarios due to its efficient communication kernel designed for NVLink. *m*Tuner gets improvement over it due to its implementation of better memory utilization and relaxed data dependence.

We find *m*Tuner more effective on inputs with larger sequence lengths. This is because they result in smaller batch sizes and larger activation memory consumption, which further leads to increased communication overhead for each sample with respect to weights. In the case of larger sequences ($\geq$4096), *m*Tuner achieves an average acceleration of 34%.

When comparing PCIe-server and NVLink-server, we find from Figure 8(b) that *m*Tuner achieves a higher speedup ratio in the PCIe-server configuration (28.3% vs. 14.5%). This can be attributed to the more severe communication bottleneck in the PCIe-server setup, while *m*Tuner primarily reduces communication overhead by increasing memory utilization.

6.3 Ablation Study

Ratio of local data influences communication efficiency. Figure 9 shows how varying ratio of local data affects the communication bandwidth of allgather operation. And it shows

(a) PCIe-server

(b) NVLink-server

Figure 9: The communication bandwidth and time with growing ratio of local data on PCIe and NVLink servers

how different schemes to increase the local data ratio influence the overall communication time. For instance, in the case of `12.5%-25%-50%-100%`, the process begins by increasing the local data ratio of elastic tensors in a module from 12.5% to 25%. Once all tensors reach 25% local data, the ratio is further increased to 50%, and so on. When all elastic tensors achieve 100% local data, the communication time effectively drops to zero.

As shown in Figure 9(a), communication bandwidth improves significantly when the elastic tensor has a low initial local data ratio (e.g., 12.5%). Increasing the local storage ratio from 12.5% to 25% yields a 59% bandwidth improvement, from 16GB/s to 26GB/s. However, further increasing the local ratio from 25% to 50%, despite consuming more memory, results in only a 54% speedup. Consequently, the schedule `12.5%-25%-50%-100%` achieves the shortest communication time by efficiently balancing memory usage and communication overhead. In contrast, for the NVLink server shown in Figure 9(b), increasing the local data ratio provides minimal improvement in communication bandwidth. Therefore, the schedule `12.5%-100%`, which directly minimizes communication by avoiding it for specific tensors, achieves the best memory-to-communication efficiency.

Larger batch size leads to less per-sample communication workload. Figure 10 shows how the memory of activation, adjusted with batch size, influences the efficiency of computation and communication. The bars shows under different batch sizes, the iteration time for communication and computation. We find that the communication time is invariant to the batch size, as it is only related to the model size. Therefore, the communication overhead averaged to each sample can be reduced when increasing the batch size. The computation, however, is proportional to batch size as the computational

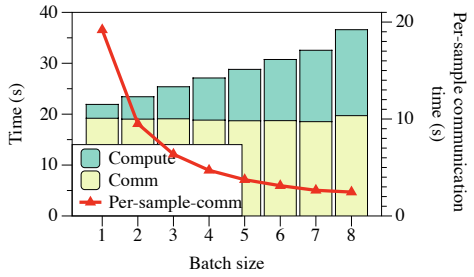

Figure 10: Computation and communication time with different batch sizes on PCIe-server for Llama 2 70B; Per-sample communication time decreases with batch size.

resource is saturated.

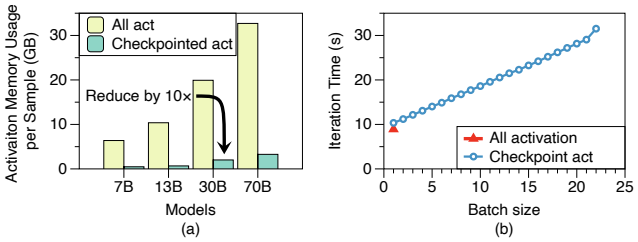

Figure 11: Memory usage of all and checkpointed activations for different models (a) and the execution time comparison (b) on PCIe server

Activation checkpointing saves memory and increases batch size. Figure 11 demonstrates the effect and overhead of activation checkpointing. Figure 11(a) illustrates the memory consumption of all generated activations and the checkpointed activations, with batch size of 1 and sequence length of 1024. For models of different scales, *m*Tuner can reduce the required memory for activations by a factor of 10. This reduction is particularly crucial for Llama 2 70B because preserving all activations would require over 30GB of device memory. Combined with the storage of weights on each device, this would lead to out-of-memory (OOM) errors, making it infeasible even with a batch size of 1.

Figure 11(b) presents the overhead introduced by activation checkpointing on 30B model. Both approaches can be executed with a batch size of 1. However, as the batch size increases, only the approach of checkpointing activations remains viable. By comparing the runtime, the recomputation overhead introduced by checkpointing activations is minimal. This is primarily because the execution time is dominated by communication. And *m*Tuner mitigates the additional communication introduced by activation checkpointing through reuse distance, reducing the runtime overhead associated with activation checkpointing.

Relaxed data dependence improves tensor parallel efficiency. Figure 12 illustrates the benefits of using elastic

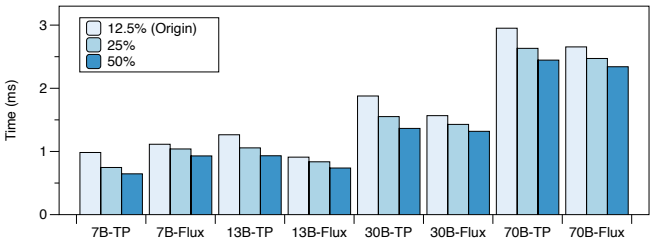

Figure 12: Execution time of an MLP module with tensor parallel size at 8. Data dependence is relaxed with weight parameters *gathered* to ratio of 25% and 50%

tensor to relax data dependence, improving TP efficiency. As shown, increasing the ratio of weights prefetched via early *gather* results in performance gains across various scenarios. Specifically, prefetching 25% and 50% of the weights reduces the overall execution time to 87.6% and 79.0%, respectively. Notably, even though Flux achieves overlapping of TP communication and computation through fine-grained splitting, relaxed data dependence further reduces execution time to 92.3% and 84.2% (corresponding to 25% and 50% prefetch weight, respectively).

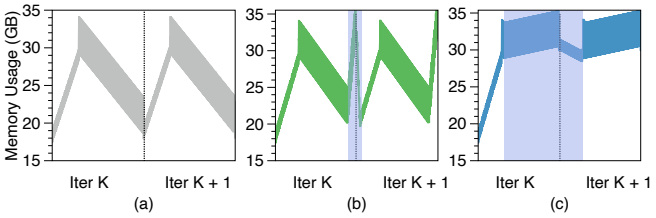

Figure 13: Memory-time curve; (a) No fill in valley area; (b) Filling valley area with 100% elastic tensors; (c) Progressively filling valley area; The colored are valley areas with elastic tensors filled

Temporal memory adjustment increases overall memory utilization. Figure 13 illustrates the changes in memory during the runtime process, with each subfigure representing two iterations. From Figure 13(a), we find that during the forward phase of each iteration, the memory usage keeps increasing because the activations used as checkpoints accumulate in memory. However, during the backward phase, the memory decreases in a zigzag manner. This is because when recomputing based on checkpoints, a significant number of activations that was discarded during the forward propagation is generated, and this memory is immediately consumed during the backward computation.

From Figure 13(b), if *m*Tuner caches and reuses the elastic tensors at the ratio of 100% at the valley area, the memory at the valley quickly fills up, resulting in only a small portion of the operators' weights being optimized, while a significant amount of time is underutilized in memory. Figure 13(c) demonstrates that by progressively filling the valley with elastic tensors, most of the weights can be increased in size for less communication while filling up the memory valley.

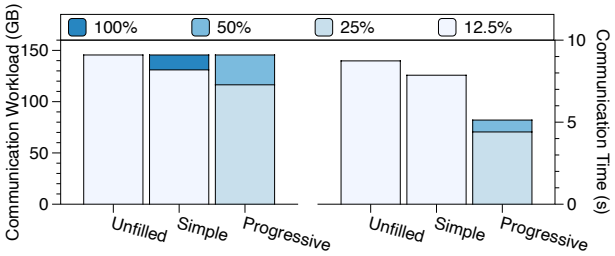

Figure 14: Distribution of elastic tensor ratio and resulted communication time

Temporal memory adjustment decreases communication overhead. Figure 14 illustrates the distribution of elastic tensor ratio and communication time during the forward phase for these three methods. Communication workload refers to the total weights collected, so different filling methods (including unfilling one) shows the same communication workload. We find that the non-progressive filling method only makes 10.3% of the workload to be communicated with elastic tensor at ratio of 100%, reducing the overall communication time by 10% through these locally available weights. However, by using the progressive method to fill the valleys, 80.2% of the weights can be optimized with 25% elastic tensor with 18.0% optimized with 50% elastic tensor, reducing the overall communication time by 41%.

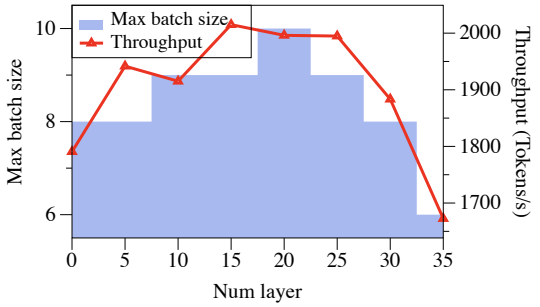

Figure 15: Max batch size and corresponding throughput change with the number of layers at pre-peak stage with high backward priority

Adaptive data accumulation can increase max batch size. Figure 15 illustrates the maximum batch size achievable with *m*Tuner for Llama 2 70B. By adjusting the backward priority of some layers in the pre-peak stage and reducing the peak height, *m*Tuner can increase the batch size per iteration. Additionally, to reduce the overhead of repeated computation for small batches in the flattened peak stage, *m*Tuner increases the elastic tensor of the flattened peak section. Consequently, when more layers are flattened, the memory overhead increases, resulting in a decrease in the maximum batch size.

Moreover, since the averaged communication workload is related to the batch size, the throughput reaches its maximum when the batch size is at its maximum, resulting in a 12% improvement in throughput compared to unflattened peaks.

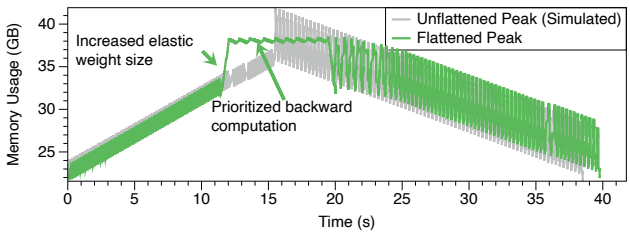

Figure 16: Memory to time curve for training Llama 2 70B at batch size of 10 with and without adaptive runtime tensor accumulation; The unflattened curve suffers from OOM (over 40GB memory usage), and is simulated using profile results.

Peak memory usage is reduced by adaptive data accumulation. As shown in Figure 16, the height of peak can be effectively reduced by adaptive data accumulation. To reduce the overhead of repeated execution at the peak, *m*Tuner increases the elastic tensor size at the pre-peak stage. Though compared to the simulated normal execution, non-uniform execution still introduces overhead and leads to larger execution time, the advantages, such as increased batch size and reduced per-sample communication overhead, still contribute positively to the overall performance.

Table 2: Schedule search time analysis

Time	7B	13B	30B	70B
Search (s)	20.3	25.3	34.5	147.9
Fine-tuning (h)	2.3	4.3	10.0	23.0

Schedule search overhead is acceptable compared with fine-tuning time. Table 2 presents the time required for schedule search. The search time scales with model size, but grows only moderately. We compare the search time with the overall fine-tuning time that tunes the model with one billion tokens on H100 server. The fine-tuning takes hours to finish, which makes the search overhead acceptable.

7 Related Work

Parameter-efficient fine-tuning. Parameter-efficient fine-tuning (PEFT) [8, 16, 24] encompasses three main approaches: adapter-based, prompt-based, and BitFit. Adapter-based methods [7, 14, 15, 25, 37] introduce a small set of trainable modules into the model architecture. A prominent example is low-rank adapters (LoRA) [7, 15], which inject low-rank matrix multiplications as bypasses to efficiently update the model. Prompt-based methods [22, 23, 28] insert trainable tokens into the input prompt, allowing fine-tuning by learning these tokens without manually modifying the prompt. BitFit [54] takes a minimalist approach by updating only the model's bias parameters during fine-tuning. PEFT has demonstrated remarkable effectiveness across various domains, including finance [53], healthcare [29], code [20], and mathematics [27], establishing itself as the leading approach for cost-efficient fine-tuning. QLoRA [7], AdaLoRA [56], and similar approaches [26, 49] differ in their specific definitions of trainable parameters, yet they all fall within the broader framework of PEFT, where only a subset of model parameters is updated. As such, our proposed method is compatible with and can be applied to optimize these techniques.

Systems for fine-tuning. To mitigate hardware limitations during fine-tuning, systems such as FTPipe [10], MPress [59], and Mobius [11] have proposed more efficient pipeline parallelism techniques tailored to the characteristics of PCIe. PetS [60] improves serving efficiency by sharing a single base model across multiple PEFT instances, while S-LoRA [44] offloads PEFT adapters to CPU memory, enabling the deployment of multiple PEFT models on a single GPU. Despite their advancements, these systems do not exploit the frozen weight property inherent to PEFT for optimizing parallel fine-tuning, nor do they provide fine-grained control over memory utilization.

Optimizing static tensors in parallel training. Existing approaches optimize static tensors, such as weight parameters and optimizer states, by leveraging parallel training techniques. DeepSpeed [39, 40, 46] introduces ZeRO, which enhances data parallelism by partitioning static tensors across devices or offloading to CPU memory. To mitigate communication overhead, subsequent works [3, 30] enhance overlapping mechanisms to hide latency effectively. Gpipe [18], Pipedream [32], and MPress [59] employ pipeline parallelism, dividing weights at the layer level across devices and enabling pipelined parallel execution with minimal communication overhead. However, this approach is prone to pipeline bubbles, leading to device idleness. Zero-bubble-pipeline [38] eliminates bubbles by adjusting the pipeline schedule, but accumulated activations still cause significant memory pressure. Tensor parallelism [2, 21, 33] takes a different approach by partitioning weights along an additional dimension, allowing multiple devices to collaboratively process the same sample. Systems like Megatron [21, 45] and Alpa [58, 62] combine data, pipeline, and tensor parallelism, either manually or through automated search, to identify optimal parallel strategies. Despite these efforts, existing methods focus primarily on static memory optimization through parallelism and largely overlook dynamic memory constraints and utilization caused by runtime tensors. Consequently, they lack mechanisms for adaptive, fine-grained memory optimization.

Optimizing runtime tensors with checkpointing and offloading. Checkpointing activation [42] is an important tech-

nique to optimize activation memory, which is also utilized in *m*Tuner for elastic tensor implementation. It is firstly proposed in [4], and widely used in training frameworks like Megatron [21] and MPress [59]. There are works [19] trying to find optimal checkpointing strategy considering model structure. However, these activation optimizations are independent with static tensor optimization, while *m*Tuner focuses on the interplay between them.

8 Conclusion

In this paper, we first observed that memory plays a crucial role in the performance of parameter-efficient fine-tuning. However, existing approaches have low memory utilization due to static scheduling of memory. To address this, we propose *elastic tensors* as an abstraction to dynamically adjust the memory sizes of tensors based on memory usage and the fine-tuning process. Based on elastic tensor, we developed *m*Tuner, a system that enables efficient fine-tuning of large models on multi-GPU servers. Compared to existing state-of-the-art systems, *m*Tuner achieves an improvement of up to 51.2% and 24.8% (28.3% and 14.5% on average) on PCIe and NVLink servers.

A Artifact Appendix

Abstract

This artifact includes the source codes and experiments for replicating the evaluations in this paper.

Description & Requirements

How to access

*m*Tuner is publicly available at https://github.com/xxcclong/mTuner.

Hardware dependencies

- NVIDIA Tesla H100/A100 GPU
- Memory > 400GB
- Disk space > 100GB

Software dependencies

We list the most important software we used:

- CUDA 12.1
- Torch==2.5.1+cu121
- triton==3.1.0

They can be installed by following the instructions.

Evaluation workflow

Using scripts here to run all experiments.

Major Claims

- *m*Tuner achieves throughput improvements on PCIe and NVLink servers for LLMs from 7B to 70B.
- Search overhead of *m*Tuner is kept to tens of seconds.

Please refer to the README to reproduce the results.

JENGA: Enhancing LLM Long-Context Fine-tuning with Contextual Token Sparsity

Abstract

The escalating demand for long-context applications has intensified the necessity of extending the LLM context windows. Despite recent fine-tuning approaches successfully expanding context lengths, their high memory footprints, especially for activations, present a critical practical limitation. Current parameter-efficient fine-tuning methods prioritize reducing parameter update overhead over addressing activation memory constraints. Similarly, existing sparsity mechanisms improve computational efficiency but overlook activation memory optimization due to the phenomenon of *Shadowy Activation*.

In this paper, we propose JENGA, the first LLM fine-tuning system that explores and exploits a new token-level sparsity mechanism inherent in long-context scenarios, termed *Contextual Token Sparsity*. JENGA minimizes redundant token involvement by assessing the informativeness of token embeddings while preserving model accuracy. Specifically, JENGA introduces three key techniques: (1) Token Elimination, dynamically identifying and excluding redundant tokens across varying inputs and layers. (2) Pattern Prediction, utilizing well-trained predictors to approximate token sparsity patterns with minimal overhead. (3) Kernel Optimization, employing permutation-free and segment-based strategies to boost system performance. We implement JENGA as an end-to-end fine-tuning system compatible with various LLM architectures and other optimization techniques[1]. Comprehensive evaluations demonstrate that JENGA reduces memory consumption by up to 1.93× and achieves up to 1.36× speedups, outperforming state-of-the-art fine-tuning systems.

1 Introduction

As the demand for comprehensive document analysis [13, 26], extended multi-turn dialogues [76], and intricate codebase handling [51, 54] grows, large language models (LLMs) with larger context windows are becoming integral to AI applications. Despite their utility, LLMs [1, 31, 52] are typically pre-trained with fixed context windows, such as the 4K token limit in Llama2 [67]. When these models encounter inputs exceeding this limit, their performance deteriorates markedly [18]. The discrepancy between the fixed context window during pre-training and the increasingly extended inputs during inference has emerged as a critical challenge in real-world deployments.

Table 1: Memory footprint (GB) comparison across different fine-tuning methods. LoRA and LongLoRA are representative of PEFT and sparsity-based methods, respectively ($S = 4K$).

Model	Llama2-7B	Llama3-8B	Mistral-7B	OPT-6.7B
Naive	67.9	78.4	73.4	63.8
LoRA	39.2	43.4	39.3	36.1
LongLoRA	41.3	43.9	39.3	38.1
JENGA	**31.3**	**34.5**	**31.4**	**30.0**

Recent studies [43, 53, 68, 73] show that the context window of pre-trained LLMs can be extended through fine-tuning on longer sequences. Unfortunately, managing these extended sequences imposes substantial resource challenges, particularly in terms of memory consumption. For instance, Position Interpolation [10] extends Llama models [66] from 2K to 32K but requires 128 A100 80GB GPUs, mainly due to memory limitations. Rather than model parameters, the primary memory bottleneck in long-context fine-tuning arises from *activations* [11, 35, 79], which include intermediate results and gradients that scale proportionally with sequence length.

Although various techniques have been proposed to improve the efficiency of fine-tuning, the substantial demands of activation memory remain largely unaddressed. By adapting only a minimal number of parameters, parameter-efficient fine-tuning (PEFT) methods [28, 29, 39, 78] reduce the memory requirement of parameter updates but leave activation memory unoptimized. Furthermore, recent works [12, 24, 50, 70] incorporate diverse sparse mechanisms to approximate standard dense attention. Despite achieving considerable compu-

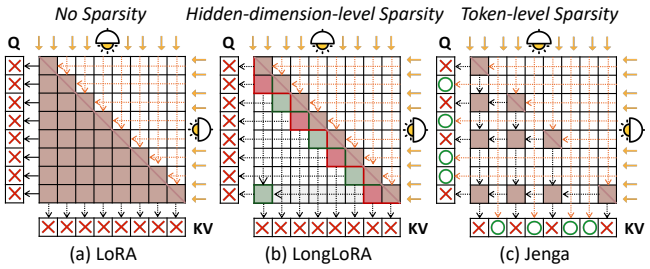

Figure 1: Illustration of shadowy activation. (a) LoRA performs full attention computation without incorporating sparsity. (b) LongLoRA adopts two shifted local attention patterns (colored in red and green) to approximate full attention, targeting sparsity at the hidden-dimension level. (c) JENGA employs token-level sparsity, minimizing token involvement and achieving activation savings compared to other methods.

tational savings, these methods fail to offer additional memory reduction, as highlighted in Table 1.

This limitation arises because existing sparsity mechanisms primarily focus on sparsity within the hidden dimension of individual tokens. As shown in Figure 1(b), while each token interacts with a reduced subset of tokens compared to dense attention, the entire token sequence remains involved. Crucially, once a token participates in the computation, regardless of the extent of usage, its activations are retained in memory—a phenomenon we term ***Shadowy Activation***. Given the large number of tokens involved in long-context fine-tuning, this observation prompts a critical question: Can we propose a novel LLM fine-tuning scheme with *minimal token involvement* that optimizes *both memory and computational efficiency*?

In this paper, we present **JENGA**, an efficient system for enhancing long-context fine-tuning of LLMs. The design of JENGA is rooted in an intuitive yet profound observation: natural language exhibits significant redundancy, particularly in long-context scenarios. This redundancy, proved to be ubiquitous in linguistic studies [60, 71], has been utilized across multiple LLM-related domains, including data engineering [22, 23], prompt compression [32, 40], and inference optimization [38, 61, 63, 82]. Most importantly, standard full attention can be effectively approximated by focusing on interactions among a small subset of the most informative tokens in a long text sequence. However, to our knowledge, no research has leveraged this approach to improve fine-tuning efficiency. Therefore, the key insight of JENGA is to *identify and retain only the most informative tokens, enabling long-context fine-tuning with minimized token involvement*.

However, this is not a long-hanging fruit, as this token-level sparsity exhibits unique characteristics in LLM long-context fine-tuning. Specifically, the token embeddings with the highest informativeness vary across different inputs and layers, a mechanism we term ***Contextual Token Sparsity***. Harnessing this mechanism effectively and efficiently demands heuristic designs that address both algorithmic and system-level considerations. Specifically, several challenges must be tackled:

Challenge 1: Identification. While long-context texts inherently exhibit significant redundancy, accurately identifying these redundant tokens is non-trivial. Eliminating informative tokens risks degrading model performance while retaining excessive tokens results in inefficient resource utilization.

Challenge 2: Detection. Given the dynamic nature of contextual token sparsity, the optimal sparsity patterns vary across different inputs and layers. This necessitates a selection mechanism capable of adapting to these variations at runtime while incurring minimal computational and memory overhead.

Challenge 3: Performance. The variability in token selection across layers incurs additional token movements, increasing memory access costs. Besides, naive gradient computation of model loss amplifies activation memory usage, resulting in inefficient memory peaks, especially in long-context scenarios.

JENGA consists of three fundamental techniques designed to address these emerging challenges, respectively:

Information-driven Token Elimination. JENGA evaluates token informativeness by analyzing its interactions with other tokens, selectively excluding less informative ones from computation. Moreover, JENGA exploits sparsity variations across layers by applying layer-specific thresholds, which maximizes resource efficiency while preserving model accuracy.

Context-aware Pattern Prediction. JENGA utilizes a neural-network-based approach for predicting optimal sparsity patterns that adapt to the context of the current input. Besides, JENGA introduces a technique that elastically transforms the predictor's parameter size, minimizing the memory and computational costs associated with the prediction process.

High-performance Kernel Optimization. JENGA adapts a permutation-free strategy to eliminate unnecessary global memory data movement during token selection and padding across different layers. Furthermore, JENGA develops a segmented-based gradient computation method, effectively alleviating activation memory peak in long-context scenarios.

We evaluate JENGA across two representative families of LLMs and on three distinct GPU architectures. The results demonstrate that JENGA achieves a memory reduction of 1.93× in end-to-end fine-tuning, compared to the state-of-the-art fine-tuning systems, while maintaining model accuracy.

To the best of our knowledge, JENGA is the first fine-tuning system that exploits the inherent token-level sparsity in long-context scenarios. This innovation allows JENGA to handle long-context sequences while demanding resources for fewer tokens. In summary, we make the following contributions:

- We identify a new sparsity mechanism, contextual token sparsity, inherent in long-context fine-tuning, enabling optimizing both memory and computational efficiency.

- We develop three key techniques that identify, detect, and perform contextual token sparsity, respectively. Our

design provides a heuristic fine-tuning scheme, encompassing both algorithmic and system-level optimizations.

- We implement these techniques as an end-to-end fine-tuning system compatible with various LLM architectures, enabling seamless integration with other optimization techniques to further enhance performance.
- We conduct comprehensive evaluations of JENGA across diverse LLM families and hardware platforms. The results show that JENGA achieves 1.93× memory savings and 1.36× speedups compared to the state-of-the-art.

2 Background and Motivation

2.1 Efficient LLM Fine-tuning

Fine-tuning, the process of adapting pre-trained LLMs to diverse downstream applications, is pivotal for their effective deployment. Particularly, fine-tuning a pre-trained LLM on longer text sequences is essential for extending its pre-defined context window size, enabling support for long-context scenarios. However, this process is typically resource-intensive, with the inclusion of long text sequences considerably amplifying both computational and memory requirements.

To improve fine-tuning efficiency, one promising direction is parameter-efficient fine-tuning (PEFT) methods [28, 29, 39, 78], which adapt pre-trained models by updating only a subset of parameters while maintaining model performance. A representative example is low-rank adaption (LoRA) [29], which freezes the pre-trained model weights and injects smaller, trainable low-rank matrices into each transformer block. By reducing the number of trainable parameters, LoRA markedly alleviates the memory demands of optimizer states, driving its widespread adoption in practical applications.

Another research direction [6, 24, 77, 83] focuses on exploiting the inherent sparsity [17] within attention mechanisms by employing various sparsity patterns to the standard dense attention. The central insight is that only a limited subset of interactions is critical, allowing the remainder to be safely disregarded with minimal impact on accuracy. More recent works [12, 70] integrate these two lines of research. Notably, LongLoRA [12] extends LoRA by incorporating a new shifted sparsity pattern, enabling efficient scaling of context length. By substituting global dense attention with two groups of shifted sparse local attention, LongLoRA achieves less training time compared to LoRA. However, subsequent analysis reveals that neither LoRA nor LongLoRA adequately addresses the memory bottleneck in long-context fine-tuning, as activations scale proportionally with sequence length.

2.2 Analysis: Fine-tuning Memory Breakdown

Here we provide a detailed analysis of memory consumption during LLM fine-tuning process. Beginning with vanilla fine-tuning, we extend our discussion to include two representative approaches: LoRA, a PEFT method, and LongLoRA, a sparsity-based technique. Our analysis demonstrates that current efficient fine-tuning techniques fall short of addressing memory limitations, particularly in long-context scenarios.

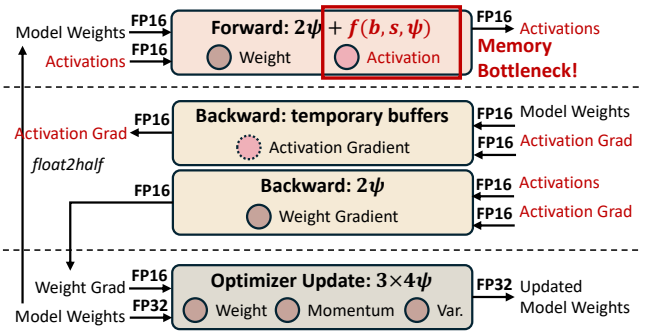

Figure 2: Memory breakdown during LLM mixed-precision fine-tuning. Compared to consistent model states, activations scale with both input batch size and sequence length, becoming the primary bottleneck in long-context scenarios.

Vanilla. The memory consumption of vanilla fine-tuning primarily consists of two parts: *model states* and *residual states*, as listed in Figure 2. The first part, *model states*, includes parameters, gradients, and optimizer states. In mixed-precision fine-tuning [47], parameters and gradients are stored in FP16, while optimizer states are stored in FP32. For modern optimizers like AdamW [46], the optimizer states include the parameters, momentum, and variance. Given model parameter size as ψ, the memory required for all model states is approximately 16ψ, which remains constant for a fixed model.

The second part of memory consumption comprises activations, temporary buffers, and fragmented memory. Among these, activations, which include the intermediate results and gradients stored during the forward pass, consume a considerable portion of memory. The memory required for activations is not only dependent on the model parameter size (ψ) but also scales with the input batch size (b) and sequence length (s). As detailed in Table 2, in long-context scenarios, the memory consumption of activations can easily exceed that of model states, emerging as the dominant memory bottleneck.

LoRA. Different from the vanilla, the pre-trained model parameters remain frozen in LoRA, and only the injected low-rank matrices are updated during fine-tuning. Consequently, the memory consumption for gradients and optimizer states

Table 2: Activation memory usage (compared to model states) of GPT-3 175B [8] across different sequence lengths.

Model States	$s = 4K$	$s = 8K$	$s = 16K$	$s = 32K$	$s = 64K$
$16 \times 175B = 2.8T$	937G	3.42T	13.0T	50.8T	201T
-	0.34×	1.22×	4.65×	18.14×	71.6×

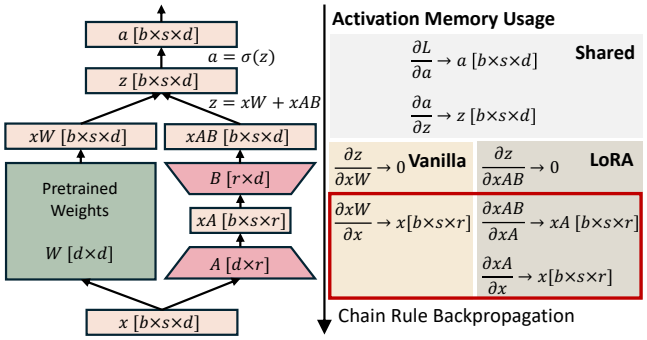

Figure 3: An illustrated example of LoRA for showcasing the activation memory usage of PEFT. Beyond the shared parts, LoRA requires storing more activations than vanilla.

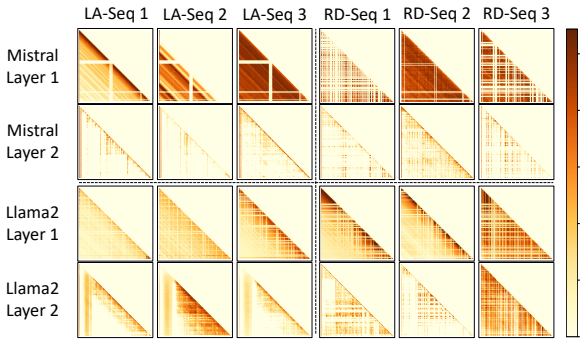

Figure 4: Visualization of attention scores across different models, datasets, layers, and sequences (darker is higher).

is significantly reduced. However, this reduction does not extend to activation memory, which emerges as the new memory bottleneck. As illustrated in Figure 3, LoRA not only fails to alleviate activation memory usage but increases it instead. This is because the trainable low-rank matrices are deeply embedded within the model structure. Gradient computation for these matrices requires a traversal nearly identical to the vanilla, following the chain rule in backpropagation. Similar issues also exist in other PEFT methods.

LongLoRA. Building upon LoRA, LongLoRA proposes a shifted sparse attention (S^2-Attn) mechanism for further efficiency. As depicted in Figure 1(b), S^2-Attn partitions the input tokens into two groups and performs attention individually in each group. For half of the attention heads, tokens are shifted by half group size to enable information exchange across groups. While LongLoRA achieves computational savings compared to LoRA, it fails to provide additional memory reduction. This limitation arises from the fact that the sparsity mechanism in LongLoRA, as well as other sparsity-based techniques, operates exclusively on the hidden dimensions of token embeddings. While such methods reduce the computational burden associated with individual tokens, they cannot entirely exclude tokens from the computation. However, once a token is involved in the computation, its activations are stored regardless of its usage. We refer to this phenomenon as ***Shadowy Activation***, analogous to how an object casts a shadow by blocking light. In this context, "blocking" refers to cases where a token is unnecessary for token 1 (meaning its activation could be discarded) but is needed by token 2 (requiring its activation to be preserved). The presence of shadowy activation leaves the activation bottleneck still unresolved.

3 Insight: Contextual Token Sparsity

To address the emerging challenges discussed in § 2.2, we introduce a fresh perspective that explores and exploits a token-level sparsity mechanism during LLM long-context fine-tuning. Our approach is grounded in the intuitive yet profound observation that natural language is inherently redundant [60, 71]. Specifically, as highlighted in several studies [38, 42, 61, 63, 72, 82], standard full attention can be effectively approximated by focusing on significant interactions among a limited set of query, key, and value values, involving only a subset of tokens in the sequence. Notably, this redundancy becomes even more pronounced in long-context scenarios. As presented in Table 3, the proportion of significant interactions in attention scores decreases as sequence length increases. These insights open up a compelling opportunity to optimize LLM long-context fine-tuning by identifying and retaining only the most informative tokens. Through directly reducing token involvement, shadowy activation constraints are naturally alleviated, enabling activation memory to achieve comparable benefits to computational savings.

We term this novel sparsity mechanism within LLM long-context fine-tuning as ***Contextual Token Sparsity***. Through comprehensive evaluations, we identify two key unique characteristics of this mechanism: (1) *Token-wise.* As depicted in Figure 4, a grid-like distribution of attention scores is observed across different models and datasets, confirming that token embeddings in the sequence exhibit varying levels of importance. This insight enables the exclusion of less valuable tokens, naturally leading to reductions in both memory usage and computational overhead. (2) *Contextual.* Figure 4 further demonstrates that the distribution of valuable tokens dynamically shifts based on input texts and varies across model layers, even for a given model and dataset. This dynamic nature underscores the need for a system capable of accurately

Table 3: Sparsity ratios (the proportion of values below 0.3 of the maximum) of attention scores across sequence lengths.

Seq len.	4K	6K	8K	10K	12K	14K	16K
Llama2	38.6%	48.8%	48.1%	65.3%	69.5%	62.2%	69.6%
Llama3	44.6%	46.0%	54.7%	52.3%	57.8%	50.2%	58.9%

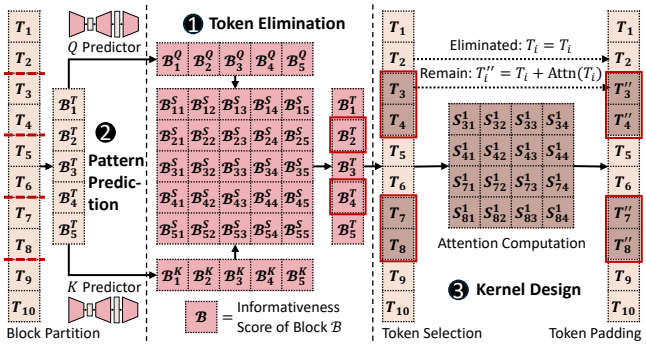

Figure 5: JENGA overview. At each layer, token embeddings are first partitioned into blocks and fed into the pattern predictors (❷). Using the predicted informativeness scores from these predictors, the token elimination algorithm (❶) effectively identifies and retains only the most informative tokens for processing. Optimized kernels (❸) then efficiently perform token selection, computation, residual addition, and padding.

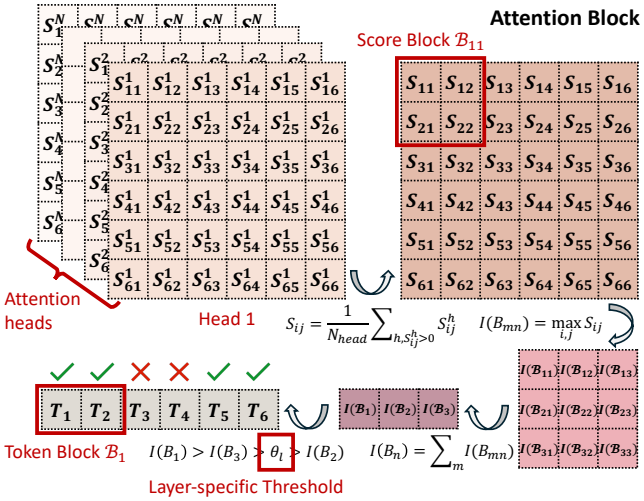

Figure 6: Token elimination algorithm. Attention scores are first aggregated across different heads and partitioned into multiple score blocks. The maximum value within each score block is defined as its informativeness score, which is then aggregated along the column. These resulting scores are compared against a layer-specific threshold to determine whether the corresponding tokens should be retained.

identifying and efficiently exploiting this sparsity in real-time during runtime. Serving as the cornerstone of our system, contextual token sparsity first introduces token-level sparsity into long-context fine-tuning, enabling LLMs to handle larger context windows while effectively involving fewer tokens.

4 System Design

4.1 Overview of JENGA

We propose JENGA, an efficient system designed to enhance LLM long-context fine-tuning by systematically exploring and exploiting contextual token sparsity. Figure 5 presents an overview of JENGA, which is built upon three key techniques:

Information-driven Token Elimination (§ 4.2). To determine whether a token is redundant, we first establish a formal definition for the informativeness of a given token. Building on this definition, JENGA utilizes a score-based algorithm that dynamically identifies and eliminates redundant tokens within the attention block. The algorithm performs in a block-wise manner and is further refined by adopting a layer-specific threshold, which ensures both effectiveness and efficiency. Additionally, we extend this approach to the MLP block, ensuring consistency across various components of the model.

Context-aware Pattern Prediction (§ 4.3). JENGA employs a neural-network-based approach to predict the token sparsity patterns, bypassing the need for costly full attention score computation. Once adequately trained, these predictors can accurately approximate the token informativeness based on contextual inputs. To minimize the overhead introduced by predictors, JENGA utilizes an elastic size transformation technique, optimizing both memory and computational efficiency.

High-performance Kernel Optimization (§ 4.4). JENGA delves into kernel-level optimizations to maximize system performance. To minimize unnecessary global memory movement, JENGA introduces a permutation-free strategy that fuses token selection, token padding, and residual addition directly into the computation pipeline. Moreover, JENGA incorporates a segment-based method to alleviate activation memory peaks, enabling efficient gradient computation for long sequences. By tightly coupling these kernel-level optimizations with algorithmic designs, JENGA fully exploits contextual token sparsity for enhancing LLM long-context fine-tuning.

4.2 Information-driven Token Elimination

To fully exploit contextual token sparsity, it is essential to accurately identify the redundant tokens across different inputs and layers. Discarding informative tokens may impact model accuracy while retaining excessive tokens leads to resource inefficiency. To tackle these challenges, JENGA proposes an information-driven algorithm that dynamically identifies and eliminates redundant tokens while preserving accuracy.

Token Informativeness. We begin by defining a token's informativeness based on its interactions with other tokens within the embedding space. In the attention mechanism, the attention score S_{attn} is commonly used to quantify the interaction between tokens [25, 42, 72]. Specifically, the attention score term S_{ij}, calculated as $Q_i K_j$, represents the interaction between token i and token j. Inspired by this, we define the informativeness of a token $I(T)$ by considering its interaction

with all other tokens in the long-context sequence:

$$I(T_j) = \sum_{i \neq j} S_{ij} = \sum_{i \neq j} Q_i K_j \tag{1}$$

where the sum aggregates the attention scores across all tokens i in the sequence, excluding the token j itself.

Block-wise Elimination. Building on the concept of token informativeness, the next step involves eliminating redundant tokens based on their informativeness scores. To optimize alignment with hardware characteristics, JENGA performs token elimination in a block-wise manner. As shown in Figure 6, JENGA partitions the attention scores along the token dimension into multiple *score blocks* $\mathcal{B}^S$. Following aggregation across attention heads, the maximum value within each block is selected as the informativeness score $I(\mathcal{B}^S)$. Notably, during aggregation, JENGA sums only the positive attention scores. Since attention scores undergo a softmax operation, negative values have a negligible impact on the final result but may offset the influence of positive values if included. By excluding negative scores, the aggregation process preserves the integrity of informativeness and ensures robust token elimination. The entire process can be formalized as:

$$I(\mathcal{B}^S_{mn}) = \max_{S_{ij} \in \mathcal{B}^S_{mn}} S_{ij} = \max_{S_{ij} \in \mathcal{B}^S_{mn}} \frac{\sum_{h, S^h_{ij} > 0} S^h_{ij}}{N_{\text{head}}} \tag{2}$$

where S^h_{ij} represents the attention score between token i and token j in attention head h, and N_{head} is the total number of attention heads, serving as the scaling factor. This block-wise token elimination preserves the original informativeness of long-context sequences for two main reasons. First, compared to long-context input sequences, the block size used in our approach is relatively small. Given the sparse distribution of important tokens across long-context sequences, most token blocks contain no important tokens and can be safely eliminated without compromising accuracy. Second, in cases where important tokens do fall within a block, our informativeness score for token blocks $I(\mathcal{B}^S)$ is designed to effectively identify and retain these blocks. This is because the difference in informativeness scores $I(T)$ for important versus unimportant tokens is large enough that important tokens cannot be averaged out by other unimportant tokens in the block. As a result, our method ensures that any block containing important tokens is preserved, regardless of how many such tokens it contains. We argue that maintaining fine-tuning accuracy is more critical than the negligible computational cost of retaining a few additional unimportant tokens.

Layer-specific Threshold. The informativeness scores of *token blocks* $\mathcal{B}^T$ are computed by aggregating the corresponding score blocks, i.e. $\mathcal{B}^T_n = \sum_m \mathcal{B}^S_{mn}$. These scores are then compared against a threshold to determine whether the tokens within the block should be eliminated. Particularly, JENGA further refines the token elimination algorithm by adopting a layer-specific threshold. The key insight is that different layers within LLMs exhibit varying sparsity patterns. As demonstrated in Figure 7, the average informativeness scores of token blocks vary greatly across different model layers, indicating that a universal threshold applied across all layers is suboptimal. Algorithm 1 outlines JENGA's approach, which initializes a default threshold for all layers based on score profiling and then fine-tunes these values to align with the unique sparsity characteristics of each layer.

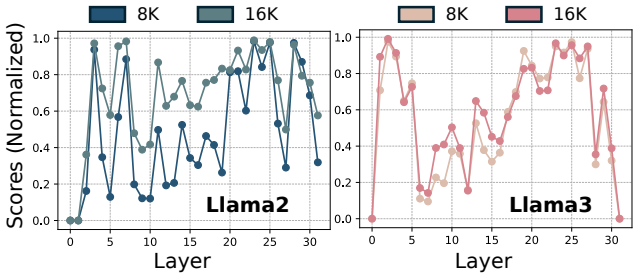

Figure 7: The average informativeness scores (normalized) of tokens blocks across different layers.

Extend to MLP Block. Additionally, we extend token elimination to the MLP block. Analogous to attention scores, JENGA utilizes intermediate activations within the MLP block to evaluate the informativeness of each token. This extension can be viewed as a variant of the widely studied neuron sparsity within MLP blocks [37, 41, 48], ensuring compatibility with various MLP block structures: for ReLU-based structure [2], the activations are the outputs of the ReLU layer, while for SiLU-based structure [20], the activations correspond to the element-wise multiplication of the gate projection (after SiLU) and the up projection. These techniques enable JENGA to adapt token elimination seamlessly across diverse model components and configurations.

Algorithm 1: Layer-Specific Threshold Optimization

Input : Model layers $\mathcal{L} = \{L_1, L_2, \ldots, L_n\}$
Output : Layer thresholds $\mathcal{T} = \{T_1, T_2, \ldots, T_n\}$

```
// Step 1: Threshold Initialization
```
foreach *layer* $L_i \in \mathcal{L}$ **do**
```
    // Average scores across token blocks
```
    $T_i \leftarrow \text{avg}\big(I(\mathcal{B}^T)\ \forall\ \mathcal{B}^T \in L_i\big)$;
```
// Step 2: Threshold Fine-Tuning
```
foreach *layer* $L_i \in \mathcal{L}$ **do**
```
    // Compute gradient with finite changes
```
    $G_i \leftarrow \big(\text{acc}(T_i + \varepsilon) - \text{acc}(T_i - \varepsilon)\big)/2\varepsilon$;
```
    // Update threshold based on gradient
```
    $T_i \leftarrow T_i + \eta \cdot G_i$;

return $\mathcal{T}$

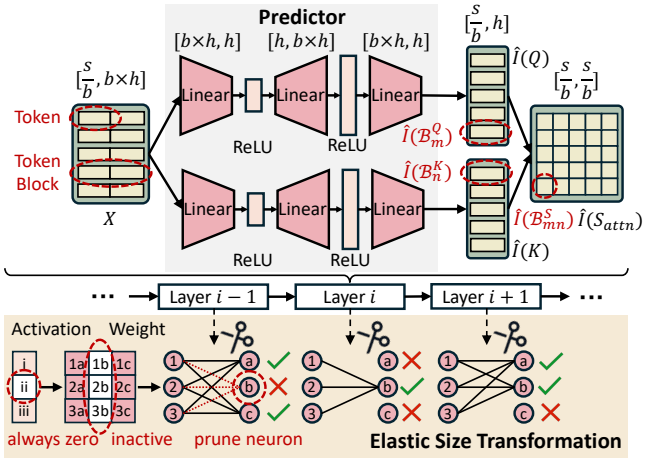

Figure 8: Pattern prediction process. Each layer is equipped with two predictors to approximate Q and K, respectively. Taking token embeddings as input (organized in token blocks), each predictor outputs the informative score, $\hat{I}(B_m^Q)$ and $\hat{I}(B_n^K)$, for each token blocks. These scores are then multiplied to compute the informative scores, $\hat{I}(B_{mn}^S)$, for blocked attention scores. Besides, elastic size transformation is employed to independently minimize the predictor size for each layer.

4.3 Context-aware Pattern Prediction

Although the exact sparsity patterns can be directly derived from the full attention scores, computing and storing these scores is prohibitively expensive, with complexity scaling quadratically with the sequence length. Furthermore, due to the dynamic nature of contextual token sparsity, the optimal sparsity patterns can only be determined at runtime, varying across different inputs and layers. To address these challenges, JENGA employs a set of lightweight neural networks as predictors. By taking contextual embeddings as inputs, these predictors infer sparsity patterns accurately and efficiently.

Neural-network-based Predictor. As illustrated in Figure 8, JENGA deploys a pair of predictors in each layer to approximate the informativeness scores of queries Q and keys K, respectively. Each predictor consists of three trainable low-rank matrices, with ReLU activation function applied between successive matrices. The inputs to the predictors are token embeddings X, which contain contextual information and are organized into blocks to align with the block-wise elimination. By extracting the representative embedding from each block, the predictors output the approximate informativeness scores, $\hat{I}(Q)$ and $\hat{I}(K)$. These scores are then multiplied to approximate the informativeness of attention scores $\hat{I}(S_{\text{attn}})$:

$$\hat{I}(S_{\text{attn}}) = \hat{I}(Q)\hat{I}(K)^T,\ \hat{I}(\mathcal{B}_{mn}^S) = \hat{I}(\mathcal{B}_m^Q)\hat{I}(\mathcal{B}_n^K)^T \qquad (3)$$

When Q and K predictors are well trained, $\hat{I}(S_{\text{attn}})$ can provide a close estimation of accurate informativeness scores $I(S_{\text{attn}})$.

With a limited training dataset, these predictors can quickly converge and perform well in prediction, as evidenced by prior studies [45, 62, 70]. Particularly, the predictor in JENGA first processes each token individually and then aggregates these individual predictions into a unified outcome. This strategy restricts the predictor's size to the dimension of a single token block rather than the full long-context sequence, thereby streamlining the design and mitigating prediction overhead.

Elastic Size Transformation. To further reduce the size of the predictors, JENGA utilizes an elastic size transformation technique that dynamically prunes neurons in the predictors based on their individual sparsity characteristics. Inspired by prior work on activation-based pruning studies [37, 41, 69], this design leverages the properties of the ReLU activation function, which introduces a large number of zero elements into the intermediate activation of the predictors. When an activation element is zero, its corresponding neurons (i.e., rows or columns of the model weights) become inactive and can be safely disregarded. Innovatively, JENGA integrates this mechanism into its custom-designed predictors. Specifically, JENGA tracks the zero frequency of intermediate activation elements during training and periodically prunes neurons associated with the highest zero frequencies. Without relying on any prior assumptions, elastic size transformation adaptively determines the optimal size for each predictor, effectively reducing both computational and memory overhead.

Comprehensive Overhead Analysis. We conclude with an analysis of the overhead introduced by predictors during both training and inference. In *offline training*, the primary bottleneck lies in obtaining the informativeness of attention scores $I(S_{\text{attn}})$. Thanks to the block-wise manner, we seamlessly integrate our custom training kernel into the state-of-the-art FlashAttention [15, 16]. This integration eliminates the need for explicit computation and storage of the full attention scores. Instead, $I(S_{\text{attn}})$ is derived online, leading to a memory complexity that grows linearly with sequence length.

In *online inference*, given sequence length s, head dimension h, and block size b, the computational overhead consists of two parts: (1) Prediction of $I(Q)$ or $I(K)$ with a complexity of $O(sh^2)$; (2) Prediction of $I(S_{\text{attn}})$ with a complexity of $O(s^2/b^2)$. In long-context scenarios, the second part becomes the dominant factor. However, this overhead can be effectively mitigated by increasing the block size b. On the memory side, the primary overhead arises from the linear weights within predictors, with a complexity of $O(bh^2)$. Importantly, this complexity remains constant relative to the model configurations. Finally, thanks to the elastic size transformation, both computational and memory complexities are reduced by a sparsity factor, leading to an average reduction of 50%.

4.4 High-performance Kernel Optimization

Focusing on token-level sparsity, JENGA introduces minimal modifications to the original fine-tuning dynamics, enabling seamless reuse of existing optimized computational flows.

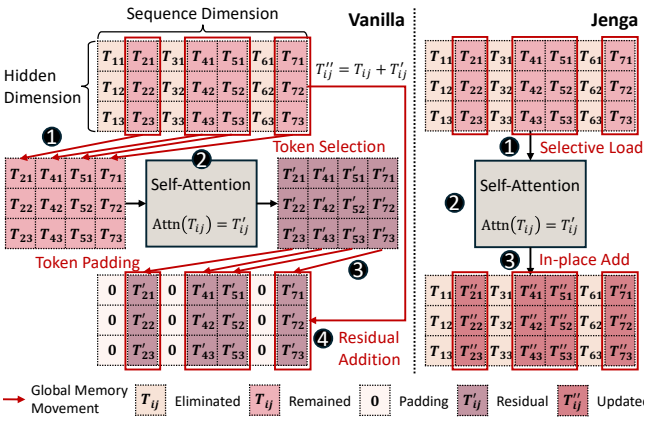

Figure 9: Comparison between naive token movement and JENGA. Highlighted by the red lines, the naive kernel incurs substantial global memory movement costs. JENGA develops a permutation-free strategy through kernel fusion.

However, two key challenges hidden in JENGA undermine its performance. First, the variability in sparsity patterns across layers necessitates iterative token selection and padding, leading to considerable costly global memory movement. Second, the extensive vocabulary size of LLMs necessitates substantial activation memory to compute the output loss gradient for each token, particularly in long-context scenarios. JENGA incorporates several hardware-efficient techniques at the kernel level, effectively mitigating these bottlenecks.

Permutation-free Token Movement. The dynamic nature of contextual token sparsity leads to varying sparsity patterns across different layers, involving distinct subsets of tokens. As illustrated in Figure 9, at each layer, a set of less informative tokens are eliminated and the remained tokens are re-permuted to serve as the attention block inputs. Then, the attention outputs are padded with zeros to maintain dimensional consistency and are finally residually added to the original inputs. The processes of token selection, token padding, and residual addition involve extensive data movement in global memory, which incurs high memory access latency.

JENGA develops a permutation-free strategy that fuses all unnecessary permutation operations with the attention computations. Instead of materializing re-permuted tokens, JENGA directly loads the selected tokens from original inputs. Furthermore, JENGA performs an in-place addition of attention outputs to the original inputs, simultaneously completing token padding and residual addition in a single step. During backpropagation, the original inputs are recomputed when calculating the gradient of the attention weights. Since the input embedding matrix can be recovered by subtracting the self-attention output from the output embedding matrix, the overhead is minimal. This streamlined approach eliminates unnecessary memory allocation and expensive global memory movement, significantly enhancing system performance.

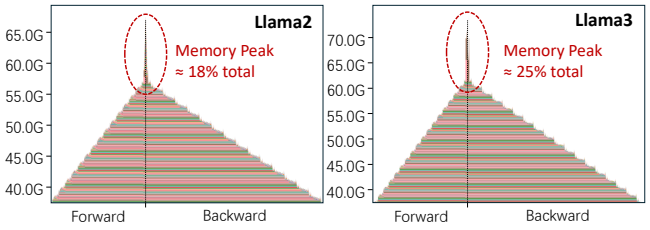

Figure 10: Memory peak during loss gradient computation, exacerbated by the large vocabulary size and long context. The x-axis represents the timeline of a fine-tuning epoch.

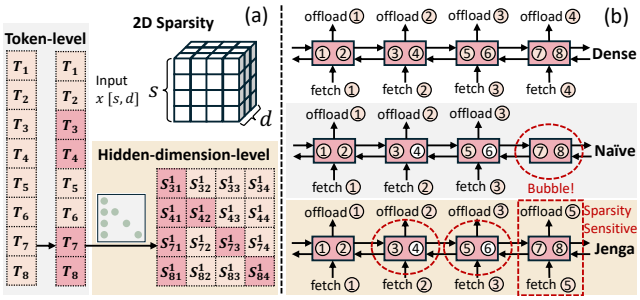

Figure 11: Two available extensions of JENGA: (a) Two-dimensional Sparsity and (b) Sparsity-sensitive Offload.

Segment-based Peak Cutting. LLMs are typically autoregressive, predicting the probability distribution of the next token given all preceding tokens. During fine-tuning, for each token in the input sequence, the model generates a probability distribution over the next token and computes the losses between predictions and ground truth. For LLMs with a large vocabulary size and long context window, this process imposes a significant surge in activation memory usage, as shown in Figure 10. While these activations are transient, the resulting memory peak elevates the upper bound of LLM fine-tuning, imposing stricter demands on GPU memory resources. Existing implementations [64, 65] commonly use column-wise parallelism to distribute the vocabulary across multiple GPUs. However, this optimization is only effective in multi-GPU configurations and provides no benefit for single-GPU setups.

To address this issue, JENGA adopts a segment-based peak-cutting strategy that partitions the token sequence into smaller, manageable segments during final loss computation. Instead of performing a forward pass over the entire sequence and retaining all intermediate activations, JENGA processes each segment independently and later aggregates their gradients. Activations for each segment are discarded immediately after the corresponding gradient computation is completed. Consequently, the activation memory peak is reduced to $1/N$ when the sequence is divided into N segments. This approach greatly alleviates memory pressure on individual GPUs and remains compatible with existing multi-GPU optimizations.

Table 4: Hardware platform configurations.

Platform	GPUs	Memory	FP32 TFLOPS	BF16 TFLOPS
Platform A	1× A800	80GB	19.5	312
Platform B	1× A40	48GB	37.4	150
Platform C	4× 4090	24GB	82.6	82.6

Table 5: Model configurations.

Model	# Params.	Def Len.	Seq Len.
OPT [81]	350M/1.3B/2.7B/6.7B	2K	2K-64K
Llama2 [67]	7B	4K	4K-64K
Llama3 [19]	8B	8K	4K-64K

5 Implementation and Extension

We implement JENGA with over 3000 lines of Python and C++ code. Given the minimal changes to the original fine-tuning dynamics, JENGA is compatible with a wide range of LLM architectures without requiring any code changes. Besides, JENGA can seamlessly integrate with other techniques:

Extension 1: Two-dimensional Sparsity. As illustrated in Figure 11(a), after applying token-level sparsity in JENGA, the remained tokens can further benefit from existing hidden-dimensional sparsity techniques. This natural combination of sparsity mechanisms across two dimensions, which we term *2D-Sparsity*, provides more granular control over the model's resource allocation, leading to a significant reduction in both activation memory and computational costs.

Extension 2: Sparsity-sensitive Offload. JENGA enhances existing offload-based techniques [27, 30, 55, 56] by incorporating contextual token sparsity into the optimization process. As depicted in Figure 11(b), we develop a sparsity-sensitive offloading strategy that adapts to the varying sparsity ratios across different layers. This approach enables the seamless transfer of larger data volumes between the CPU and GPU, effectively alleviating GPU memory constraints.

6 Evaluation

6.1 Experimental Setup

Hardware. We conduct experiments on three representative platforms, as listed in Table 4, covering both data-center workstations and desktop professional GPUs. Memory measurements are primarily evaluated on Platform A, as it offers the largest GPU memory capacity, with results being largely insensitive to GPU arithmetic performance. For speedup evaluations, we adhere to common practices by employing mixed-precision techniques [47], utilizing both BF16 and FP32.

Models. The models used for evaluation are detailed in Table 5. We choose models from two of the most popular LLM families: OPT and Llama. These models vary in architecture, parameter size, and default context window size. Evaluations on these models provide a robust demonstration of the scalability and versatility of JENGA's optimizations.

Dataset. We use the RedPajama [14] dataset for long-context fine-tuning, following the setup from LongLoRA. We evaluate the perplexity (PPL) of fine-tuned models on the book corpus dataset PG19 [57] and the cleaned Arxiv Math proof-pile dataset [3] to assess long-context modeling performance. Besides, we evaluate our method on LongBench [5] benchmark, following an instruction-tuning on dataset LongAlign-10k [4]. These tasks cover multiple critical long-text application areas, ensuring a comprehensive evaluation of our approach.

Baselines. We compare JENGA with two state-of-the-art fine-tuning methods, LoRA [29] and LongLoRA [12]. These methods represent the two dominant optimization directions: parameter-efficient fine-tuning and sparsity-based fine-tuning, respectively. For speedup analysis, we primarily compare with LoRA, leaving LongLoRA for reference. This distinction is because the two methods focus on orthogonal sparsity dimensions, making a direct and fair comparison challenging.

Metrics. Memory evaluations are conducted at the time step immediately following the forward pass, which generally corresponds to the memory peak. For execution time evaluation, we measure the time per fine-tuning step. To emphasize the effectiveness of JENGA, activation recomputation and offloading techniques are excluded unless explicitly stated. All metrics are averaged over 10 repeated trials to ensure reliability.

6.2 End-to-End Performance

Memory Footprint. We evaluate the memory efficiency of JENGA across various models and sequence lengths, as shown in Figure 12. The results reveal that JENGA achieves average memory savings of 38.2% and 50.5% compared to LoRA across six different models, with sequence lengths of 4K and 8K, respectively. Similar benefits are observed in comparison to LongLoRA, as the presence of shadowy activations renders its sparsity mechanism ineffective in benefiting memory usage (even slightly increased). Furthermore, the results reveal that for a fixed model, JENGA's memory efficiency improves as sequence length increases. This aligns with the observation that longer text sequences typically exhibit greater redundancy. The enhanced efficiency of JENGA largely extends the fine-tuning sequence length achievable under GPU memory constraints. Without activation recomputation and offloading, both LoRA and LongLoRA are limited to a sequence length of 16K (32K) when fine-tuning OPT 1.3B (350M). Instead, JENGA doubles this capacity, supporting sequence lengths of up to 32K (64K) on a single A800 GPU.

Execution Time. The minimized token involvement in JENGA also brings computational savings during long-context fine-tuning. Figure 13 presents the execution time and corresponding speedups of JENGA during fine-tuning different models at a sequence length of 4K. The results show that

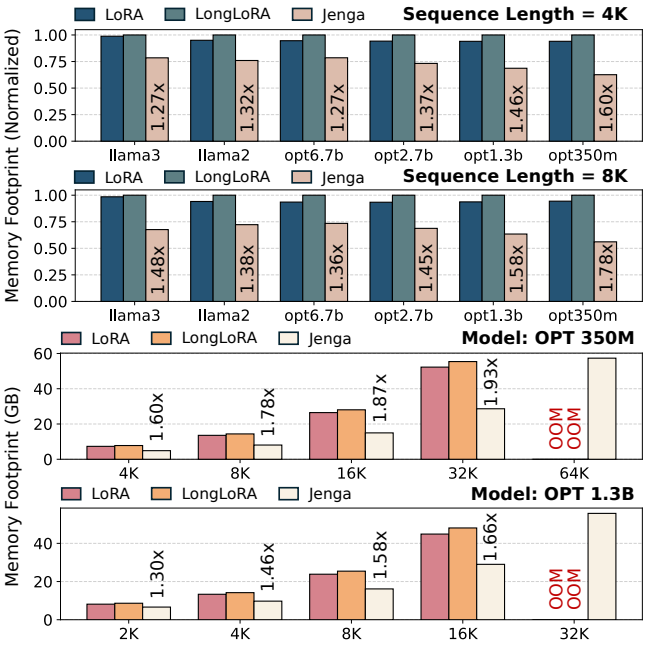

Figure 12: Memory footprints comparison on A800.

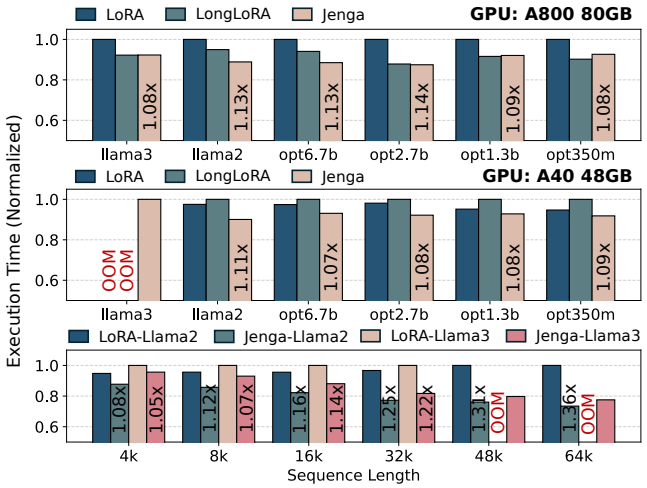

Figure 13: End-to-end speedup of JENGA on A800 and A40.

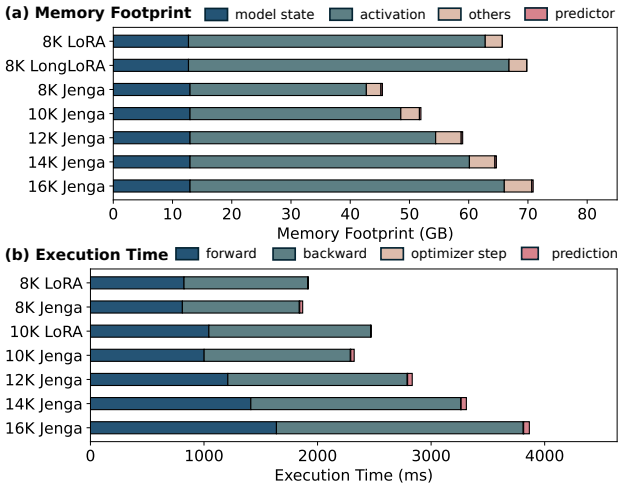

Figure 14: Performance breakdown of Llama2 fine-tuning: (a) Memory footprint and (b) Execution time.

JENGA achieves computational efficiency comparable to LongLoRA, achieving an average speedup over LoRA of 10.8% and 8.6% on two platforms, respectively. We also observe that LongLoRA may perform slower than LoRA in some cases. This is primarily due to the difficulty in fully utilizing hardware computational capacity for sparsity operations when the sequence length is insufficient. In contrast, JENGA introduces minimal modifications to the original computational flow, allowing it to effectively translate computational savings into practical speedups. Further evaluations of JENGA on longer sequence lengths (with recomputation) reveal additional performance gains, achieving up to 1.36× speedups.

Accuracy Evaluation. We test the impact of JENGA on model accuracy by comparing it with the original LoRA. First, we measure test perplexity of fine-tuned Llama2 7B on two representative long-context datasets, PG19 and Proof-Pile. As shown in Table 7, JENGA incurs only a minimal increase in perplexity scores compared to the original LoRA, across varying sequence lengths. Additionally, we evaluate JENGA on LongBench benchmark, which contains tasks from multiple key long-text application areas. Table 6 demonstrates that JENGA achieves accuracy comparable to the original LoRA. These evaluations collectively confirm that the inherent redundancy in long-context sequences can be effectively exploited for performance efficiency without compromising accuracy.

6.3 Ablation Study

Fine-grained Performance Breakdown Figure 14 presents a detailed performance breakdown of JENGA, covering both memory and computational aspects. For the memory aspect, the results show that JENGA effectively reduces activation memory consumption compared to both LoRA and LongLoRA. Although the predictors introduced incur additional memory usage, their overhead is minimal, ensuring that the overall memory reduction is preserved. Besides, this reduction is consistent across varying sequence lengths, with the decrease in activation memory scaling linearly with sequence length. For the computational aspect, JENGA also achieves computational gains over LoRA, as the reduced token involvement leads to decreased computation during both the forward and backward phases. Similarly, the computational overhead of predictors is negligible in the context of the overall process.

Technique 1: Token Elimination. We delve into the layer level to analyze the effectiveness of our information-driven

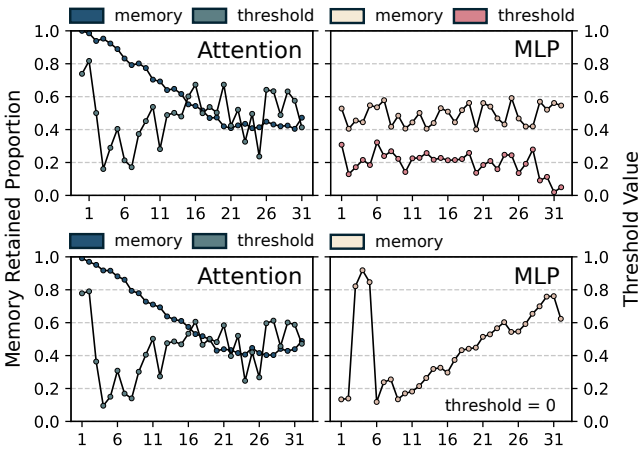

Figure 15: Memory footprint and corresponding threshold across layers on Llama2 7B (upper) and OPT 6.7B (lower).

token elimination algorithm. Figure 15 presents the memory consumption and corresponding threshold values across different layers in both self-attention and MLP blocks. Evaluations are conducted on both Llama2 and OPT models, considering their distinct MLP block architecture, which respectively uses SiLU and ReLU as activation functions. The results indicate that the token elimination algorithm achieves average memory savings of 38.3% (38.0%) on Attention block and 51.1% (54.8%) on MLP block for Llama2 (OPT) model. Besides, the application of layer-specific thresholds allows for varying degrees of reduction across layers, maximizing the exploitation of token-level sparsity while preserving model accuracy.

Additionally, we investigate the fundamental reason behind the effectiveness of our information-driven token elimination algorithm. Figure 16(a) illustrates the proportion of unimportant blocks across different layers. A block is considered

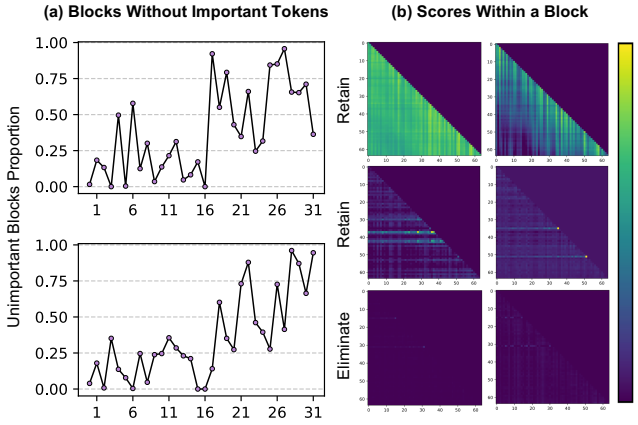

Figure 16: (a) Proportion of blocks without important tokens and (b) Distribution of attention scores within a token block.

unimportant if its informativeness score is less than 10% of the maximum (excluding outliers) within the same layer. The results reveal that a large proportion of token blocks do not contain any important tokens, especially in the deeper layers of the model. This can be attributed to the relatively small block size used (e.g., 64 in our evaluation settings), compared to the length of long-context input sequences. As the model depth increases, important tokens become more sparsely distributed, resulting in most token blocks containing no important tokens. These blocks can be safely eliminated without compromising model accuracy.

Moreover, we visualize the attention scores within individual blocks to analyze how the tokens within a token block affect its informativeness. Figure 16(b) presents three representative distributions of attention scores within token blocks. The results show that token blocks are generally classified as important when the majority of their tokens are informative, and as unimportant when none are. Particularly, even when only a few tokens in a block are important, the block is still considered as important. This is because the difference in informativeness scores for important versus unimportant tokens is large enough that important tokens cannot be averaged out under our block selection strategy.

Technique 2: Pattern Prediction. Figure 17(a) presents the training loss of predictors across two models and two datasets.

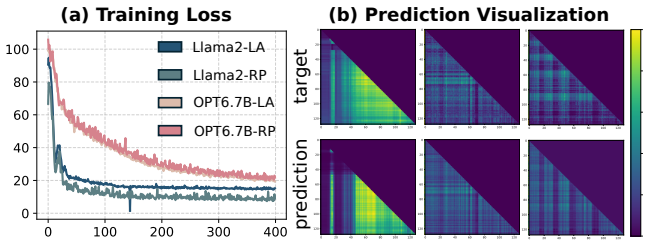

Figure 17: (a) Training loss curve on LongAlign (LA) / RedPajama (RP) and (b) Prediction visualizations of predictors.

The results show that the predictors converge quickly during offline training, requiring fewer than 400 epochs, an acceptable overhead given the following expensive LLM fine-tuning. We then calculate the recall metrics for evaluating the accuracy of predictors, achieving an impressive average of 95.13%. Particularly, we provide visual comparisons of the predictions against the ground truth. As depicted in Figure 17(b), the predicted attention scores closely approximate the ground truth, effectively identifying redundant tokens with high accuracy.

To assess the effectiveness of elastic size transformation, we measure the parameter sizes of predictors across various model layers. Table 8 details that by exploiting the inherent sparsity within predictors, their parameter sizes can be uniformly reduced across layers, on average 64.6%. This reduction in predictor size minimizes prediction overhead, aligning consistently with the findings in the performance breakdown.

Technique 3: Kernel Optimization. We benchmark the performance of kernels optimized with permutation-free token movement against their naive implementation under various sequence lengths, as depicted in Figure 18. The results reveal that both kernel fusion strategies, selective load and in-place addition, effectively enhance performance. The overall speedups increase with sequence length, ranging from 10× to over 50×. This improvement primarily stems from the reduction in global memory movement and temporary data allocation. These findings highlight the critical importance of high-performance kernel design, which serves as a robust foundation for the algorithmic framework of JENGA.

Meanwhile, Figure 19 illustrates the memory consumption during fine-tuning with and without the segment-based peak-cutting technique. In the naive implementation, gradient computation requires about 10GB of temporary activation memory, resulting in an inefficient memory peak. By partitioning the gradient computation into smaller segments, the sharp peak is divided into multiple, much smaller memory peaks, achieving an additional 15% of memory savings.

Table 8: Parameter size (in millions) of predictors across layers of Llama2, with or without elastic size transformation.

# Layer	1	5	10	15	20	25	30
Origin	12.58	12.58	12.58	12.58	12.58	12.58	12.58
Pruned	8.19	8.19	8.13	8.10	8.08	8.07	8.10
Pct.	65.1%	65.1%	64.6%	64.5%	64.2%	64.1%	64.5%

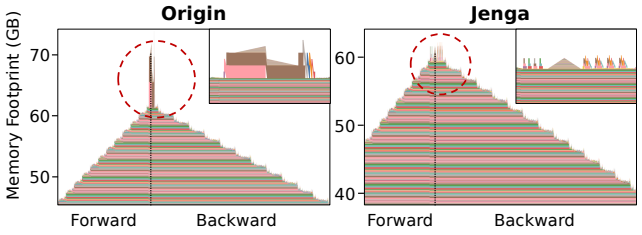

Figure 19: Memory usage peak in loss gradient computation. The x-axis represents the timeline of a fine-tuning epoch.

6.4 Extension Evaluation

Extension 1: Two-dimensional Sparsity. Building upon JENGA, we explore applying existing hidden-dimension-level sparsity techniques [70] to the remaining tokens during attention computation. Figure 20(a) shows that this two-dimensional sparsity further improves the computational efficiency of JENGA, achieving up to 2.04× speedups on Llama2.

Extension 2: Sparsity-sensitive Offload. We compare the performance of our sparsity-sensitive offloading against a naive uniform offloading strategy. Unlike the naive approach, JENGA considers the varying sparsity ratios across layers, allowing for the offloading of more activations or a reduction in data transfer latency. Figure 20(b) shows that this technique achieves an average speedup of 1.22× speedups on Llama2.

6.5 Scalability Analysis

We conclude by analyzing the strong scalability of JENGA on 4×4090 GPUs. Figure 21 shows that JENGA's performance scales proportionally with GPU number across different models and sequence lengths. The scalability is achieved because JENGA seamlessly minimizes token involvements and introduces no extra communication overhead. These results highlight JENGA's potential for deployment in large-scale systems.

7 Related Work

Optimizations for Activation Memory. As a primary memory bottleneck in LLM training or fine-tuning, activation memory consumption has been the focus of extensive research, which can be categorized into three main approaches: The first is *activation recomputation* [11,35,36], designed to avoid storing activations during the forward pass but recomputing them during the backward pass. The second is *activation offloading* [27,30,55,56], which asynchronously transfers activations from GPU to CPU and prefetches them back before required. The last is *activation compression* [9,21,44], which reduces the activation memory size through quantization or pruning. However, these methods primarily trade memory for additional computation or communication, rather than fundamentally reducing memory demands. In contrast, JENGA directly minimizes activation memory requirements and can be seamlessly combined with all these optimizations.

Optimizations for Long-context Fine-tuning. To effectively extend the context window to longer sequences, some methods [10,18,43] focus on optimizing the fine-tuning algorithm design. Besides, some methods [59,68,74] explore strategies for modifying the position embeddings of LLMs to handle longer context. All these efforts are complementary to JENGA.

Beyond effectiveness, some recent methods [80,84] are proposed to mitigate the substantial fine-tuning overheads for efficiency. Particularly, Parameter-efficient fine-tuning methods [28,29,39,78] first offer an effective solution by reducing the number of trainable parameters and memory usage while achieving comparable performance to full fine-tuning. Furthermore, a series of sparsity-based methods [12,70] are proposed to further reduce the computation costs by exploiting the inherent sparsity within attention mechanism [17]. However, while PEFT methods greatly cut down the memory consumption of optimizer states, the activation memory emerges as the primary bottleneck. Although existing sparsity mechanisms deliver notable computational gains, the presence of shadowy activation prevents comparable benefits for activation memory. Instead, JENGA achieves the best of both worlds by identifying and exploiting contextual token sparsity.

Optimizations for Token Utilization. Sharing the same high-level idea of JENGA, several studies also explore leveraging the inherent redundancy that existed in natural language, including data engineering [22,23], prompt compression [32,40], and inference optimization [38,61,63,82]. Notably, some works [7,25,33,34,49,58,75] propose eliminating tokens during inference to reduce model latency. Compared to existing token-elimination methods, JENGA offers two key innovations. First, prior works focus exclusively on small-model inference, where only a single request is processed at a time and there is no interference between the sparsity patterns of different tokens. JENGA is the first to extend attention-based token elimination to LLM long-context fine-tuning. Second, prior works typically prune tokens permanently throughout the computation of an entire epoch. While this strategy may be acceptable for inference with small models, it is not suitable for fine-tuning LLMs since the importance of a token can vary across different layers. To address this, JENGA proposes a novel sparsity mechanism-Contextual Token Sparsity.

8 Conclusion

We propose JENGA, an efficient system designed to optimize long-context fine-tuning for LLMs. Our approach introduces a novel sparsity mechanism within LLM long-context fine-tuning, termed contextual token sparsity. To systematically exploit this mechanism, we develop three key techniques that identify, predict, and exploit this sparsity, achieving both memory savings and performance speedups over state-of-the-art methods. Compression embodies intelligence, with sparsity serving as a potent form of compression. We envision JENGA inspiring broader exploration of sparsity for advancing LLMs.

A Artifact Appendix

Abstract

This artifact accompanies the ATC'25 paper titled JENGA*: Enhancing Long-Context Fine-tuning of LLMs with Contextual Token Sparsity*. It includes all necessary code, scripts, datasets, and pre-trained weights required to fully reproduce the experimental results, including figures and tables. The artifact also provides helper scripts for setup verification and quick result demonstration, and it supports both quick and full-scale experiment reproduction workflows.

Scope

This artifact allows users to validate all empirical claims made in the paper, including memory and runtime performance, prediction accuracy, and scalability of the proposed JENGA method on long-context fine-tuning tasks. It can be used to inspect all end-to-end results, perform ablation studies, and test generalization across models and datasets.

Contents

The artifact contains the following components:

- **Model and Predictor Weights (`checkpoints/`)**: Pre-trained model and predictor weights.
- **Dataset (`dataset/`)**: All datasets used in the experiments.
- **Log Files (`logs/`)**: Raw logs for generating paper figures.
- **Output Figures (`output_figures/`)**: Plots reproduced from logs.
- **Experiment Scripts (`scripts/`)**: Scripts to reproduce each figure/table in the paper.
- **Source Code (`src/`)**: Core implementation of JENGA.

Hosting

The artifact is hosted at a public Github repository. All resources, including models and datasets, can be obtained from:

- **Artifact Repository:** https://github.com/Pairshoe/Jenga-AE.
- **Model Weights:** Models Link (peft_model.zip and predictor.zip)
- **Hugging Face Models:** Detailed in Table 9.
- **Datasets:** Datasets Link (dataset.zip)

Table 9: Download links for required base models and their respective target directories.

Destination Path	Source URL
`checkpoints/llama3`	meta-llama/Meta-Llama-3-8B
`checkpoints/llama2`	meta-llama/Llama-2-7b-hf
`checkpoints/opt-6.7b`	facebook/opt-6.7b
`checkpoints/opt-2.7b`	facebook/opt-2.7b
`checkpoints/opt-1.3b`	facebook/opt-1.3b
`checkpoints/opt-350m`	facebook/opt-350m
`checkpoints/opt-125m`	facebook/opt-125m

Requirements

- **Software:** Python 3.10, PyTorch, Flash Attention (install separately).
- **Hardware (for full experiments):**
  - **Minimum:** 1 NVIDIA A800 or A40 GPU.
  - **For scalability experiments:** 4 NVIDIA 4090 GPUs.

A.1 Installation

1. Install dependencies:
   ```
   pip install -r requirements.txt
   ```
2. Install Flash Attention:
   ```
   pip install flash-attn -no-build-isolation
   ```
3. Install Jenga from source:
   ```
   pip install -e .
   ```

A.2 Experiment Workflow

1. Environment Setup Verification

Run the script to verify correct setup:
```
bash hello_world.sh
```

2. Quick Reproduction

Run the script to plot figures from raw data:
```
bash RUNME-a.sh
```

3. In-depth Reproduction

3.1 One-step Execution: Reproduce all results in a single run (runtime around 5 hours).
```
bash RUNME-b-a800.sh # for A800
bash RUNME-b-a40.sh # for A40
bash RUNME-b-4x4090.sh # for 4x4090
```

3.2 Separate Execution: For fine-grained control, individual scripts per experiment are summarized in Table 10.

Table 10: Generated output folders and corresponding scripts for reproducing results.

Generated Output Folder Name	Figure/Table	Script Path	Runtime
output_figures/end2end/memory	Figure 12	scripts/end2end-memory/run.sh	40 mins

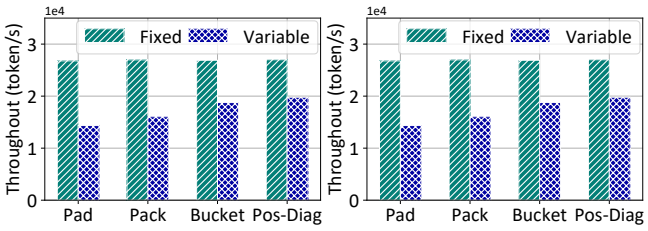
Abstract

Transformer achieves promising results among various deep learning architectures. Training transformer-based models (transformers) typically involves various parallelisms, such as data parallelism and pipeline parallelism (PP). Variable-length datasets have been adopted to facilitate multi-task training of transformers, which degrades training efficiency. Though many efforts have significantly improved the variable-length training, these efforts primarily focus on optimizations within a single iteration. However, substantial fluctuations of computation and memory requirements across iterations can also lead to inefficiency overall due to the static partitioning of distributed frameworks. Thus, this paper proposes FlexPipe from the perspective of a distributed system to enable high throughput variable-length training of transformers. To our knowledge, FlexPipe is the first flexible pipeline framework that dynamically adjusts PP by a live flexibility mechanism without training loss. We introduce a novel problem which aims at maximizing training throughput by adjusting the parallel configurations, along with an efficient heuristic algorithm to solve the problem. Extensive experiments show that FlexPipe achieves an average 1.25× training throughput compared to state-of-the-art methods.

1 Introduction

Recently, deep learning (DL) has shown tremendous success across a range of applications [22, 44, 52, 56]. Among various deep neural networks (DNNs), transformer-based models [43] (transformers) have emerged as the foundation for large language models (LLMs) due to their exceptional sequence modeling capabilities and scalability.



In pursuit of unprecedented accuracy, both data volume and model parameters of transformers are scaling rapidly, making it impossible to complete training on a single device. For example, GPT-4 [4], a 1.8 trillion parameters model, which required approximately 2 years to train on 1024 H100 GPUs. Thus, various parallelisms have been proposed, including data parallelism (DP) [25], tensor parallelism (TP) [17], pipeline parallelism (PP) [29, 41], and sequence parallelism (SP) [26].

Current training is mostly accommodated for traditional DNN models, presuming that they would have fixed-length inputs. However, it is not often the case for transformers, such as T5 [38], GPT [37] that are commonly trained on mixture datasets for effective multi-task learning [31, 40]. This inherently introduces variable-length inputs, e.g., the averaged 977.93 tokens per input for summarization [13], and 51.59 tokens for textual entailment [47]. The variable-length inputs significantly degrade the training efficiency of existing frameworks (i.e., padding) due to the considerable amount of wasted computations, which has attracted substantial attention [10, 16, 34, 38, 54]. Packing approach [8, 38] concatenates multiple shorter samples into a longer sample. Bucketing [34] sorts the dataset before constructing mini-batches. FlashAttention-2 [1] enables block diagonal attention by skipping irrelevant computations.

However, despite extensive efforts made by existing work, there still remains potential for further improving the variable-length training throughput. Fig. 1 shows the training throughput using different approaches, which highlights a significant performance reduction when training on a variable-length dataset compared to a fixed-length dataset. The main reason is that existing approaches focus on optimizing variable-length training within a single iteration. However, substantial fluctuations across iterations driven by variable-length inputs also lead to resource under-utilization of the overall system due to the static partitioning of existing distributed frameworks.

Existing distributed frameworks [14, 29, 32] typically launch a fixed number of devices with a static parallel strategy (i.e., combinations of different parallelism degrees) to maximize training throughput based on the memory requirements of the maximum sequence length. To alleviate resource under-utilization from fluctuations across iterations in variable-length training, the parallel strategy should be dynamically reconfigured based on sequence length. This enables

Figure 1: Throughput comparison between fixed-length and variable-length training.

the "redundant' devices (i.e., freed when handling shorter sequences) to be exploited for increasing the degree of DP, thereby improving overall efficiency.

Thus, this paper proposes FlexPipe from the perspective of a distributed system to enable high-throughput variable-length training of transformers. FlexPipe dynamically adjusts PP to meet both the computation and memory demands across iterations while maintaining the semantics of training. Then, FlexPipe utilizes "redundant" GPUs to enhance both resource utilization and training efficiency. Specifically, two main challenges are tackled when designing FlexPipe. The first challenge is how to achieve live (i.e., no termination) and efficient (i.e., minimize the GPU stalls) adjustment during the training. We introduce a live flexibility mechanism (LFM) in FlexPipe to minimize the overhead of the adjustment. The second challenge lies in determining when to perform the LFM and how to identify an appropriate new parallel strategy. We design a heuristic bound searching algorithm (HBSA) by efficiently balancing the trade-off between computational and memory usage by comprehensively considering the overhead of the LFM and other memory optimization approaches.

We make the following contributions in this paper:

- We first introduce a flexible PP framework, FlexPipe, that improves the efficiency of variable-length training by enabling the LFM of PP.
- We propose a novel flexible memory optimization problem aiming at maximizing the training efficiency by dynamically reconfiguring the parallel strategy and utilizing the "redundant" GPUs across different iterations.
- We design HBSA to solve the optimization problem while striking a good trade-off between computational efficiency and memory usage by comprehensively considering the overhead of the LFM and other memory optimization approaches.
- We implement FlexPipe [1] on Pytorch. Extensive experiments are conducted to evaluate the efficiency of FlexPipe. The results show that FlexPipe achieves an average 1.25× training throughput compared with state-of-the-art (SOTA) frameworks.

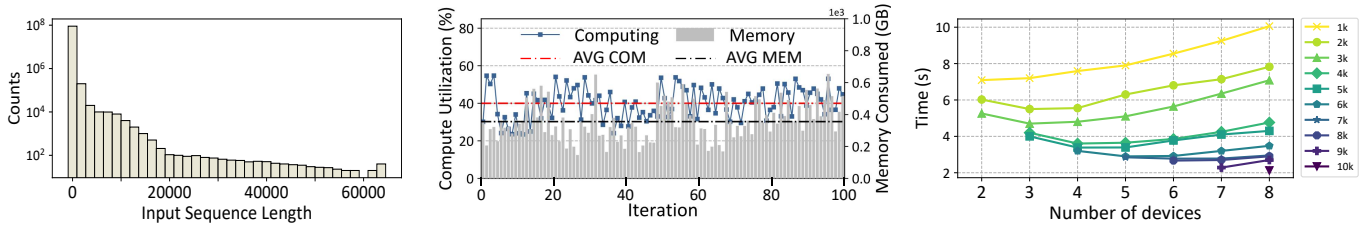
2 Background and Motivation

In this section, we first introduce the background of distributed transformer training, and then we illustrate this paper's motivation.

2.1 Background



Transformers have achieved impressive performance in a variety of deep learning applications. Their architecture is typically based on encoders and decoders, which consists of multiple homogeneous encoder and decoder layers, such as BERT [7] (encoder-only) and GPT-3 [37] (decoder-only), where each layer has similar training resource consumption. As reported [16, 31], to perform multiple tasks, transformers enable training on a mixture of datasets with variable-length inputs. Self-attention is responsible for focusing on different positions of variable-length inputs. Fig. 2(a) shows the high variation in sequence lengths of a mixed dataset FLANv2 [30], the difference of sample lengths can be up to 60000 across different iterations when random sampling. Note that FlexPipe can be generalized to models beyond transformers. This paper focuses on the challenges posed by variable-length sequences, for which transformers are the most representative.

With the exponential growth of computation and memory demands, distributed training of transformers has become indispensable. Transformer training generally involves a combination of various parallelisms, including DP, TP, PP, and SP. This paper mainly focuses on the elasticity of PP, which is widely adopted in both commercial and academic DL clusters due to its considerably lower communication [12, 16, 54]. With PP, model parameter of DNN is partitioned into multiple stages at layer level. In each iteration, a mini-batch is fed into the first stage for forward propagation (FP), and the intermediate activations are transferred to the next stages. Then, during the backward propagation, the gradients are computed based on the FP activations and passed following the reverse order of FP. To increase training concurrency, PP splits the mini-batch into multiple micro-batches [9, 14, 16] or injects multiple mini-batches [32]. Finally, the model parameters are updated by the gradients synchronously or asynchronously with an optimizer, e.g., adaptive moment estimation (Adam) [19]. Note that while our optimization targets variable-length sequence training through a dynamic PP framework and leverages DP to enhance throughput, the resources freed by short sequences can likewise be repurposed for TP or even 3D parallelism to further improve scalability.

2.2 Motivation

We conduct two experiments to analyze the observations that motivate this paper.

Observation 1: Variable-length training leads to under-utilization of both computational and memory resources

(a) The sequence length distribution in FLANv2 [30].

(b) The computation efficiency and memory usage when trained on 8 GPUs.

(c) The training time under different sequence lengths when trained on different number of GPUs.

Figure 2: The observations when training GPT (3.35B) with variable-length inputs.

across different iterations. To accommodate the variable-length inputs into the traditional training frameworks [3, 35], the inputs are typically zero-padded to a fixed-length. However, this introduces extra memory consumption and wastes computation on zero tokens [16, 54]. To improve the training efficiency, the packing approach [8, 38] concatenates multiple shorter samples into longer ones, aligning its length with the maximum sequence length of input. However, it introduces computational and memory overhead, as self-attention scales quadratically with sequence length [26]. It also introduces truncation and cross-contamination, putting the training accuracy at risk. Bucketing [34] constructs mini-batches with similar sequence lengths while it destroys randomness of sample batches. Block diagonal attention [20] addresses this with position IDs and masks, and some works leverage fusion [6, 54] reduce memory usage.

Despite the forward strides made by existing work, they still suffer from significant fluctuations in both computational and memory requirements across different iterations. Fig. 2(b) illustrates the training throughput and memory usage of training GPT (3.35B) on variable-length inputs under the packing method. Such high variance in sample lengths incurs under-utilization of most iterations, their average computation throughput and memory utilizations are below 55% and 39%, respectively. Because most iterations have shorter samples but are processed using the devices designed for handling the longest samples.

The fundamental reason can be attributed to the fact that existing methods typically focus on the operator-level optimizations within a single iteration (e.g., kernel fusion, non-matmul FLOPs reduction). However, the substantial fluctuations in both computational and memory requirements across iterations also lead to under-utilization. This opens up an inter-iteration opportunity from the distributed systems perspective.

Observation 2: Static partitioning of PP leads to inefficient variable-length training. Though PP is widely used in training large-scale transformers [18, 29, 36, 41, 57], variable-length training still poses challenges to existing methods. To maximize memory usage and throughput for traditional DNN, PP frameworks (PPs) typically initialize the PP configurations (e.g., batch size, number of stages) to maximize the occupation of device memory. These configurations will not be adjusted during the entire training process. While for variable-length training, current PPs still rely on static partitioning based on the longest sequence length in the dataset to avoid out-of-memory (OOM) errors, which degrades the system efficiency.

Fig. 2(c) shows the training time of GPT (3.35B) on datasets with different fixed lengths using different numbers of GPUs. We observe that the number of devices required for efficient training varies with sample length. For instance, when training a dataset with a sample length of 3k, using 3 GPUs achieves 4.7s per iteration, the shortest training time. However, when utilizing 8 GPUs, the throughput decreases, resulting in a training time as high as 7.08s/iteration. This is because smaller samples lead to significant communication overhead and poor utilization of GPU resources due to overly fine-grained partitioning [14]. Such static strategies (i.e., based on the maximum device requirement) significantly degrades the overall training throughput. Moreover, in variable-length training, the majority of iterations are typically composed of short data samples. For example, when random sampling in FLANv2, 95% of iterations have a maximum sample length under 4k, which exacerbates the performance degradation. This motivates us to explore dynamically reconfiguring the parallel strategy across different iterations and utilizing the "redundant" GPUs to accelerate variable-length training.

Besides efficient variable-length training, there is also a growing demand for flexible training in large-scale distributed frameworks. This includes optimizing cluster utilization through dynamic scheduling [42] and meeting job-specific service level objectives [45]. In addition, flexible frameworks are crucial for addressing the challenges of heterogeneous cloud environments with fluctuating resource availability. They can also provide lower-cost fault recovery mechanisms [15, 48–51].

2.3 Challenges

Though the flexibility of PP shows its potential when dealing with variable-length and dynamic training, two challenges must be tackled to design an efficient flexible PP framework.

Firstly, dynamically adjusting PP introduces a huge overhead during training. Existing distributed frameworks utilize

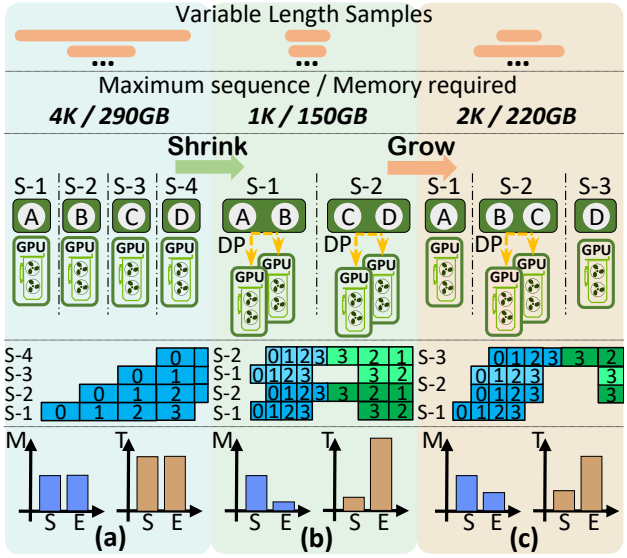


Figure 3: An example of FlexPipe when growing and shrinking. The bars (bottom of the figures) illustrate a comparison of memory usage (M) and training throughput (T). The label E represents training using FlexPipe, and S represents using the static partitioning based on a sequence length of 4K (i.e., Fig. 3(a)).

the suspend-resume or iteration stalling mechanism, which leads to a long stall due to initialization and communication overhead, usually longer than the duration of an iteration [57].

Although flexible PP could utilize "redundant" GPUs to improve the training throughput, frequent reconfiguration or an improper parallel strategy would still degrade its performance. This raises the second challenge about when to adjust PP and how to search for an appropriate parallel strategy to maximize throughput for variable-length training.

3 FlexPipe

3.1 Overview

The key insight of FlexPipe is to dynamically adjust the parallel strategy during training, adapting to the variable-length of transformers at each iteration. FlexPipe introduces a novel flexible PP framework, while previous PP frameworks rely on a fixed number of stages and static PP configurations during the whole training process, which misses opportunities to improve the variable-length training efficiency. Specifically, FlexPipe selects an appropriate number of devices used and configures PP, taking into account the computation and memory demands across iterations. Additionally, FlexPipe utilizes any idle GPUs to increase the degree of DP, enhancing both resource utilization and training efficiency.

Fig. 3 illustrates an example of flexible training with FlexPipe using four A100 GPUs to train GPT (3.35B) on a variable-length dataset with a maximum sample length of 4k. Fig. 3(a) shows that when processing a 4k sequence length mini-batch. To satisfy the memory requirement (290 GB), the model is partitioned into four stages, with each stage typically assigned to a single device (i.e., the middle of Fig. 3(a)). In this case, FlexPipe employs an identical parallel strategy and has a similar performance to the static partitioning (i.e., the bottom of Fig. 3(a), which shows the memory occupation and corresponding training throughput of GPipe and FlexPipe). This is because the maximum sequence length in the current mini-batch equals the dataset's overall maximum, leading to the same number of PP stages and configurations. In contrast, FlexPipe dynamically shrinks and grows PP stages as shown in Fig. 3(b) and (c) to improve throughput while meeting memory requirements. When training on a 1k sequence length mini-batch, FlexPipe adjusts the PP stages to 2 and leverages the remaining 2 GPUs for DP. For a 2k mini-batch, FlexPipe reconfigures the PP stages to 3 to satisfy the increased memory demands.

3.2 Design

FlexPipe is designed as an intermediary system between a typical training system (e.g., FlashAttention and Zero-Bubble) and its underlying execution engine (e.g., PyTorch [35]). FlexPipe dynamically adjusts the number of PP stages online and configurations for a given transformer-based model trained on a variable-length dataset. Fig. 4 shows the overview of FlexPipe architecture, which consists of three main modules.

Monitor profiles both the running system and devices to collect information, such as GPU states (e.g., TFlops and communication bandwidth), PP schemes (e.g., Zero-Bubble scheduler and partitioning), and DNN model states (e.g., hyperparameter and optimizer settings). Furthermore, it pre-fetches the future sequences from the data loader to minimize the profiling overhead. Based on the profiling results, it then estimates memory usage and throughput during training.

Planner leverages the collected data to decide whether to shrink or grow and generates the corresponding parallel strategy. Specifically, the Planner incorporates a trigger that first determines whether to apply a shrinking or growing algorithm to guarantee the memory requirements, based on the sequence length of the mini-batch in the next iteration. Then, the Planner calls the corresponding algorithm to evaluate the benefits of shrinking or growing (i.e., the trade-off between the throughput gains and the associated overhead) and makes a global decision, including a computation graph, adjustment decision, etc. As a way of alleviating memory pressure, PP may not always be the most cost-efficient approach. Other techniques such as recomputation [5, 14] or memory virtualization [39, 57], should also be considered. Further details on these algorithms are discussed in Section 5.

TwinLayer Manager receives global decisions from the Planner and refines them into detailed communication and computation operators. To enable an efficient and fast flexible PP mechanism, each server maintains a TwinLayer Manager.

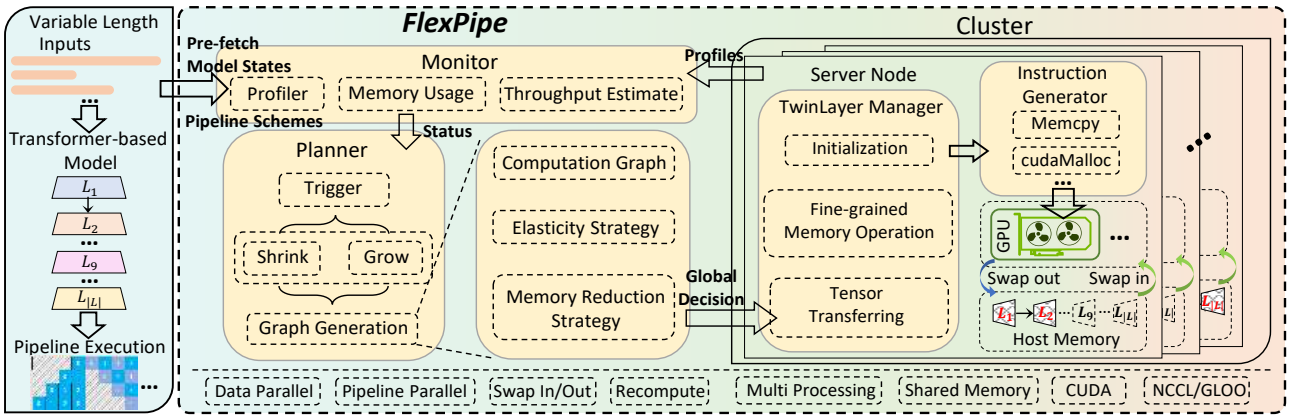

Figure 4: The overview of FlexPipe system architecture.

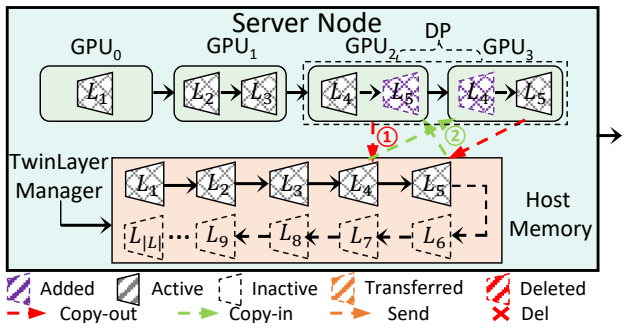
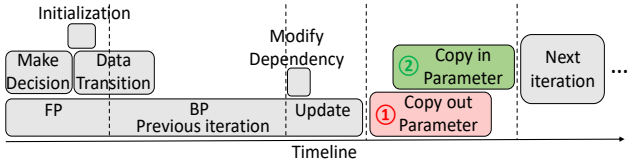
Additionally, all layers assigned to this node are duplicated and are stored in the host memory of each server. This design ensures flexibility and resilience and will be elaborated on in Section 4. The TwinLayer Manager is responsible for all operations (e.g., copying, swapping, and recomputation) related to the layers within each GPU, and the duplicated layers in the host memory. Then, the instruction generator converts the high-level operations from TwinLayer Manager into specific instructions, such as `cudaMalloc`, `cudaFree`, and communication primitives like `isend`.



4 Live Flexibility Mechanism

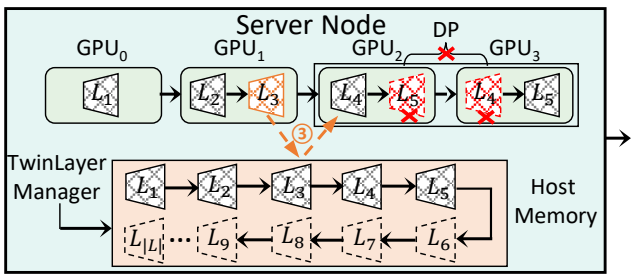
To achieve high throughput with FlexPipe, the key challenge lies in implementing a fast and live flexibility mechanism. Existing PP frameworks [9, 29, 36] typically do not support an adjustable number of PP stages and configurations during runtime. Thus, resource managers [28, 59] in DL clusters that rely on these PP frameworks reconfigure the resource allocation of PP through a non-live suspend-resume mechanism. However, this incurs heavy overhead, including checkpointing, bootstrapping, and data loading. To address this challenge, a basic way to maintain live training without requiring a full resume is to initialize the stages on devices, transfer parameters, and modify dependencies between the iterations. However, the overhead of initialization and communication during the training of large-scale transformers cannot be ignored, which still leads to a long stall across iterations. In summary, both approaches incur immense overhead, which can severely degrade the training throughput when the adjustment is frequently triggered.



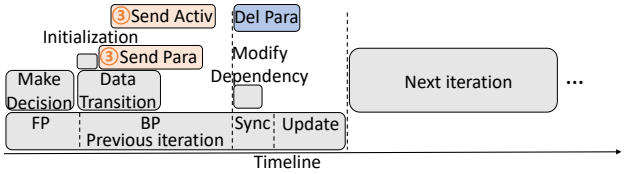
Thus, FlexPipe aims to design a *Live Flexibility Mechanism (LFM)* to transparently adjust the number of PP stages and configurations without stalling. The key idea behind this mechanism is to reduce the initialization overhead and overlap the communication and computation time. Specifically, FlexPipe introduces duplicated layers that are stored in the host memory of each node, containing all layers within that node and their corresponding optimizers, which brings two advantages. Firstly, TwinLayer supports a fine-grained layer granularity that reduces the overhead of initialization. Traditional PP frameworks operate at the stage of granularity during training, which prevents direct access to individual layers. When implementing flexibility, the parameters and optimizers of the stages must first be decomposed into individual layers, transmitted across devices, and then reassembled on the target devices. This process incurs significant overhead, e.g., 1.2s for GPT (3.35B). Secondly, by storing duplicated layers in the host memory, FlexPipe reduces the overhead of frequent memory allocations and deallocations.

Additionally, FlexPipe employs a TwinLayer Manager to efficiently orchestrate the communication and computation operations for each layer in the devices and host memory. To ease discussion, Figs. 5 and 6 illustrate examples of FlexPipe within a single node with four GPUs. Fig. 5(a) and Fig. 5(b) show the steps and their corresponding timeline when reducing a PP stage. The instructions are generated based on the global decision at the start of the previous iteration. To improve the training throughput, the freed GPUs will be utilized to increase the degree of DP. As shown in Fig. 5(a), a new DP instance is introduced between GPU_2 and GPU_3. Consequently, part of the data needs to be redistributed following the instructions for data transition. The initialization steps for PP and DP are executed following the decision-making step, which is overlapped with the data transition process (Fig. 5(b)). Then, the dependencies across different micro-batches (i.e., execution order) are modified after the BP step. Once the update of the previous iteration is complete, GPU_2 and GPU_3 send their updated parameters of layers L_4 and L_5 to the duplicated layers. Then, they respectively copy the parameters of layers L_5 and L_4 from the duplicated layers. Note that these copy steps are proceeded in a pipelined manner that copy-in process begins as soon as a portion of the parameters arrives. Then, the next iteration starts with a new configuration.

Conversely, to mitigate the memory pressure caused by training on temporary longer-length sequences, the degree of DP is decreased to add the PP stages. Fig. 6(a) and Fig. 6(b)



(a) Steps of adding a stage.



(b) Execution timeline of adding a stage.

Figure 5: Example of adding a stage with FlexPipe within a node with 4 GPUs.

(a) Steps of removing a stage.

(b) Execution timeline of removing a stage.

Figure 6: Example of removing a stage with FlexPipe within a node with 4 GPUs.

show the steps and their corresponding timeline when adding a PP stage. The same decision-making and initialization steps are first executed. Furthermore, the data redistribution and transition step is also needed to remove a worker of DP. Then, after the BP, the parameters of layers L_5 and L_4 can be directly deleted from devices GPU_2 and GPU_3, respectively. This is because all instances in DP maintain identical model parameters in each device. Once the gradients are computed during BP, the parameters can be updated after gradient synchronization without requiring the copies of parameters (Fig. 6(b)).

FlexPipe not only adjusts the number of stages but also enables flexible repartitioning by supporting layer migration between devices. As shown in Fig. 6, L_3 is migrated from GPU_1 to GPU_2 to satisfy memory requirements. By taking advantage of the characteristic of PP, where the activations generated by micro-batches in the FP are required during the BP, the transfer process can occur within the previous iteration when sufficient memory is available. After the decision-making step, the parameters are transferred immediately, and the activations of micro-batches already computed during the FP on GPU_1 are transferred to GPU_2. Then, the FP and BP for the remaining micro-batches will proceed on GPU_2.

In our evaluation, a non-live migration approach results in an average execution stall of 7.16s, while FlexPipe requires only 0.79s. The specific overhead will be discussed in Section 7. Due to space limitations, we omit the discussion of inter-server LFM, which is similar to the intra-server. The key difference lies in the overhead of transferring the TwinLayer across nodes due to lower inter-node bandwidth. This poses challenges for FlexPipe, particularly when migrating stages with large intermediate tensors. To address this, FlexPipe minimizes inter-node transfers by prioritizing intra-node remapping and pre-transferring critical data when necessary.

5 Efficient Variable-length Training

Although the LFM reduces the overhead of individual PP adjustments, frequent reconfigurations, and an improper parallel strategy can still degrade the training throughput. Therefore, an efficient algorithm is urgently needed to determine when to trigger the LFM and identify an appropriate parallel strategy. We formulate a new optimization problem, flexible memory optimization problem, which considers multiple memory optimization techniques and flexibility mechanisms to avoid unnecessary reconfigurations. To address this problem, we design a Heuristic Bound Search Algorithm (HBSA) that strikes a balance between flexibility and training efficiency.

5.1 Problem Formulation

We consider a transformer-based model trained on a mixture of datasets with variable-length samples. The model is deployed to a DL cluster and trained synchronously using PP across the device set.

System Model. With PP, the model that consists of $L = \{l_1, l_2, ..., l_{|L|}\}$ transformer layers is divided into multiple stages $S = \{s_1, s_2, ..., s_{|S|}\}$. Each stage consists of a consecutive set of layers (at least one layer, and $s_i \cap s_j \varnothing$), and the last layer of stage s_n is the predecessor of the first layer of stage s_{n+1}. For ease of formulation, homogeneous GPUs on several physical servers D are available for the training model, which is divided into multiple device groups $G = \{g_1, g_2, ..., g_{|G|}\}$ ($g_i \cap g_j = \varnothing$ and $||G|| = ||S||$). Note that $||S||$ does not necessarily have to be divisible by the number of total available GPUs $||D||$, i.e., $(||S||\%||D||) \in N$. Since "redundant" GPUs can be used to accelerate DP for part of the pipeline, as illustrated in Fig. 3(c) that has been widely adopted in hybrid

parallelisms [9].

Training Time Estimation. To estimate the training time of pipeline execution, we utilize an estimation function based on the existing work [36]. Given a mapping of stages to device groups ${}_S\Pi_G = \{s_1 \to g_1, ..., s_{|S|} \to g_{|G|}\}$, the training time $T({}_S\Pi_G, n_{micro})$ can be represented by,

$$T({}_S\Pi_G, n_{micro}) = \sum_{i=1}^{||S||} t_i + (n_{micro} - ||S|| + 1) \times \max_{1 \le j \le ||S||} t_j, \quad (1)$$

where n_{micro} is the number of micro-batches, t_i represents the time taken for a single operation of PP, including FP and BP computation, and the communication across devices (for PP and DP), which is proportional to μ.

Memory Usage. To efficiently leverage the "redundant" GPUs, we estimate the peak memory consumption of each iteration to calculate the maximum required device number for PP. Let B, μ, and M denote the global batch size, maximum sequence length, and memory capacity of a single GPU, respectively.

$$M_{peak}(L, B, \mu) = M_{p,g,o}(||L||, \mu) + M_{act}(||L||, B, \mu) + M_{buf}, \quad (2)$$

where $M_{p,g,o}$ represents the memory of parameters, gradients, and optimizer states, M_{act} and M_{buf} represent the memory of activation and other buffers.

The above runtime data (e.g., training time, communication time, batch size, and memory usage) is collected by FlexPipe's profiler during initial training iterations. Cost modeling for distributed training has been extensively studied in prior works [42], especially in DP [23] and PP [55]. Further modeling details were excluded for brevity.

Flexible Memory Optimization Problem. As a way of alleviating memory pressure, a flexibility mechanism may not always be the most cost-efficient approach. Other memory optimization approaches should also be comprehensively considered, such as recomputation [5, 14] or memory virtualization [39, 57]. Let O_{plan} represent the memory-optimized scheme utilized in the FlexPipe, including identifying layers for activation recomputation [41], portions of the optimizer to offload [27], and estimating memory savings for each action. $M_{Op}({}_S\Pi_G, O_{plan}, B, \mu)$ represents the memory consumption following optimized scheme O_{plan}. $T({}_{S'}\Pi_{G'} \to {}_S\Pi_G)$ represents the overhead of the LFM from ${}_{S'}\Pi_{G'}$ to ${}_S\Pi_G$. Let $T_{rc}(O_{plan})$ and $T_{swap}(O_{plan})$ represent the time of recomputing and offloading (swap-in, swap-out), respectively. Let M_G denote the total memory capacity of the current device groups G for PP and $M_G = M \times ||G||$, naively comparing the M_G and M_{peak} to decide whether to use the LFM may lead to inefficient adjustment, more details will be discussed in Sec. 5.2. Therefore, elaborate conditions are necessary to determine which mechanism to apply.

The memory of current ${}_{S'}\Pi_{G'}$ is less than or equal to the total memory capacity of the current device groups G', which is set as

$$condition\ \mathcal{A} : M_{peak}(L, B, \mu) \le M_{G'}. \quad (3)$$

The overhead of live flexibility from ${}_{S'}\Pi_{G'}$ to ${}_S\Pi_G$ and the computation time of ${}_S\Pi_G$ are greater than or equal the computation time of ${}_{S'}\Pi_{G'}$, which is set as

$$condition\ \mathcal{B} : T({}_S\Pi_G) + T({}_{S'}\Pi_{G'} \to {}_S\Pi_G) \ge T({}_{S'}\Pi_{G'}). \quad (4)$$

Under ${}_{S'}\Pi_{G'}$, the memory after using O_{plan} is less than or equal the total memory capacity of the current device groups G', which is set as

$$condition \quad \mathcal{C} : M_{Op}({}_{S'}\Pi_{G'}, O_{plan}, B, \mu) \le M_{G'}. \quad (5)$$

The overhead of the LFM from ${}_{S'}\Pi_{G'}$ to ${}_S\Pi_G$ and the computation time of ${}_S\Pi_G$ greater than or equal the sum of computation time of ${}_{S'}\Pi_{G'}$, the time of recomputing $T_{rc}(O_{plan})$ and the time of offloading $T_{swap}(O_{plan})$, which is set as

$$\begin{aligned} condition\ \mathcal{D} : T({}_S\Pi_G) + T({}_{S'}\Pi_{G'} \to {}_S\Pi_G) \ge T({}_{S'}\Pi_{G'}) \\ + T_{rc}(O_{plan}) + T_{swap}(O_{plan}). \end{aligned} \quad (6)$$

We use $\mathcal{T}$ to represent the iteration time of the model on the GPU cluster D,

$$\mathcal{T} = \begin{cases} T({}_{S'}\Pi_{G'}), & \mathcal{A} \wedge \mathcal{B} \\ T({}_{S'}\Pi_{G'}) + T_{rc}(O_{plan}) + T_{swap}(O_{plan}), & \neg\mathcal{A} \wedge \mathcal{C} \wedge \mathcal{D} \\ T({}_S\Pi_G) + T({}_{S'}\Pi_{G'} \to {}_S\Pi_G), & \mathcal{E} \end{cases} \quad (7)$$

where condition $\mathcal{E} = (\neg\mathcal{A} \wedge \neg\mathcal{D}) \vee (\mathcal{A} \wedge \neg\mathcal{B})$.

Definition1. Flexible Memory Optimization Problem (FMOP). *Given a transformer-base model L, a GPU cluster D, a current mapping of stages S' to device groups G' (${}_{S'}\Pi_{G'}$) and the maximum sequence length for the next iteration μ, FMOP seeks an appropriate the memory optimized scheme O_{plan} and mapping of stages to device groups ${}_S\Pi_G$ with minimum $\mathcal{T}$ considering variable-length data inputs, as:*

$$\begin{aligned} &\underset{O_{plan}, {}_S\Pi_G}{minimize}\ \mathcal{T} \\ &\text{s.t.} \quad (1), (2), (3), (4), (5), (6), (7) \end{aligned} \quad (8)$$

5.2 Algorithm

The FMOP can be formally shown as an NP-hard problem due to the extremely large search space. Moreover, frequent reconfiguration can still lead to significant performance degradation. To identify an appropriate parallel strategy and efficiently perform the LFM, we propose a Heuristic Bound Search Algorithm (HBSA), which consists of three parts: 1) computing the bounds of layer numbers in each stage and GPU numbers in each device group (Lines 3-11), 2) utilizing the bounds to navigate efficient mapping of stages and device

Algorithm 1 Heuristic Bound Search Algorithm (HBSA)

Input: Model L, GPU cluster D, time estimation functions. memory estimation functions, maximum sequence length μ. Current state: ${}_{S'}\Pi_{G'}, \mu'$.

Output: Memory optimization scheme O_{plan}, Mapping of stages to groups ${}_{S}\Pi_{G}$.

1: Initialize:$O_{plan} = \varnothing, S = \varnothing, G = \varnothing$.
2: // Exhaustive search.
3: **for** $i = 1$ *to* $||D||$ **do**
4: **if** $M_{peak}(B,\mu) < i \times M$ **then**
5: $N_{stage} = i$
6: *break*
7: // Computing the bounds.
8: **if** $N_{stage} \neq ||S'||$ **then**
9: $n^l_{low} = \lfloor ||L||/N_{stage} \rfloor, \quad n^g_{low} = \lfloor ||D||/N_{stage} \rfloor$
10: $n^l_{up} = min(\lfloor ||L||/N_{stage} \rfloor + (||L||\%N_{stage}), n^l_{max})$
11: $n^g_{up} = \lfloor ||D||/N_{stage} \rfloor + (||L||\%N_{stage})$
12: $Search(L, D, S, G, \nu)$
13: // Navigating efficient mapping.
14: **function** $Search(L, D, S_t, G_t, \nu)$
15: **for** $i = n^l_{low}$ *to* n^l_{up} **do**
16: **for** $j = n^g_{low}$ *to* n^g_{up} **do**
17: $s_t = Partition(L, i), \quad g_t = Partition(D, j)$
18: $L_t = L - s_t, \quad D_t = D - g_t$
19: **if** $||L_t|| > n^l_{up} \wedge ||D_t|| > n^g_{up}$ **then**
20: $Search(L_t, D_t, S_t \cup \{s_t\}, G_t \cup \{g_t\}, \nu)$
21: **if** $||L_t|| \in [n^l_{low}, n^l_{up}] \wedge ||D_t|| \in [n^g_{low}, n^g_{up}]$ **then**
22: $\hat{S} = S_t \cup \{s_t\} \cup \{L_t\}$
23: $\hat{G} = G_t \cup \{g_t\} \cup \{D_t\}$
24: **if** $T({}_{\hat{S}}\Pi_{\hat{G}}) + T({}_{S'}\Pi_{G'} \rightarrow {}_{\hat{S}}\Pi_{\hat{G}}) < \nu$ **then**
25: $S = \hat{S}, G = \hat{G}$
26: $\nu = T({}_{\hat{S}}\Pi_{\hat{G}}) + T({}_{S'}\Pi_{G'} \rightarrow {}_{\hat{S}}\Pi_{\hat{G}})$
27: // Determining the triggering timing.
28: **if** $\mathcal{A} \wedge \mathcal{B}$ **then**
29: **return** $O_{plan}, {}_{S'}\Pi_{G'}$ ▷①
30: **else if** $\mathcal{A} \wedge \neg\mathcal{B}$ **then**
31: **return** $O_{plan}, {}_{S}\Pi_{G}$ ▷④
32: **if** $\neg\mathcal{A} \wedge \neg\mathcal{B}$ **then**
33: $O_{plan} = init(L, {}_{S'}\Pi_{G'})$
34: **if** $\mathcal{C} \wedge \mathcal{D}$ **then**
35: **return** $O_{plan}, {}_{S'}\Pi_{G'}$ ▷②
36: **else if** $\neg\mathcal{D}$ **then**
37: **return** $O_{plan}, {}_{S}\Pi_{G}$ ▷③

groups (Lines 14-26), 3) exploiting the above conditions to determine when to trigger the LFM (Lines 28-37).

Bounds Computation. To complete the training of LLMs, it is crucial to ensure that PP can be executed without OOM errors. Therefore, the first step is to determine the minimum number of devices required to accommodate $M_{peak}(L,B,\mu)$, which corresponds to the number of stages. The HBSA can identify the minimum number of devices through an exhaustive search (Lines 3-6). To reduce the frequency and space of searching the mapping, we compare the number of stages in the next iteration N_{stage} with the current configuration $||S'||$. Based on this comparison, we compute the bounds for the number of layers in each stage (i.e., $||s_i||$ $(0 < i \leq ||S||)$) and the number of GPUs in each device group (i.e., $||g_i||$ $(0 < i \leq ||G||)$). HBSA leverages bounds to filter out a large number of invalid stage partitions and device combinations. The calculation of these bounds is based on the characteristics of transformer-based models and key observations.

The homogeneity of transformers allows us to easily predict the memory consumption of each layer, and stages with the same number of layers typically exhibit similar memory consumption. A key observation is that the variance in $||s_i||$ $(0 < i \leq ||S||)$ and $||g_i||$ $(0 < i \leq ||G||)$ is not significant in the optimal solution. Based on the heuristic, we should aim to keep the $||s_i||$ and the $||g_i||$ as consistent as possible. Therefore, we use $\lfloor ||L||/N_{stage} \rfloor$ and $\lfloor ||D||/N_{stage} \rfloor$ as the lower bounds for the $||s_i||$ and the $||g_i||$, respectively (Line 9).

Since the total number of model layers and GPUs cannot always be evenly divided by the number of stages N_{stage}, the upper bound for the $||g_i||$ is $n^g_{up} = \lfloor ||D||/N_{stage} \rfloor + (||L||\%N_{stage})$ (Line 11). Moreover, as the number of model layers per stage is also constrained by the GPU memory capacity M, where n^l_{max} represents the maximum number of layers that can be accommodated in a single GPU, the minimum value between $\lfloor ||L||/N_{stage} \rfloor + (||L||\%N_{stage})$ and n^l_{max} (Line 10) is the upper bound of layers.

Navigating mapping. To accelerate the search for efficient mapping of stages to device groups, HBSA uses the upper and lower bounds of layers and GPUs as the starting and stopping conditions for recursion. This effectively reduces the search cost by avoiding invalid and inefficient mappings caused by OOM or excessive overhead of the LFM.

In the *Search* function, we begin by using bounds to partition L and D (Lines 15-17). We then check if both remaining $||L_t||$ and $||D_t||$ exceed their upper bounds. If so, we recursively invoke the *Search* function with the remaining L_t and D_t (Lines 19-20). Conversely, if $||L_t||$ and $||D_t||$ are both within the defined bounds, we identify ${}_{\hat{S}}\Pi_{\hat{G}}$ as a valid mapping and assess whether it is the shortest in terms of time (Lines 21-26). Any other cases where $||L_t||$ and $||D_t||$ fall outside the bounds are deemed invalid mappings.

The introduction of the bound constraints effectively prevents extreme model-device partition (e.g., inefficient mappings with an excessively high degree of DP, causing communication overhead explosions). For candidate mappings within the bounds, we perform comprehensive cost modeling through Eq. 1 to estimate the training time, further searching for the most efficient mapping.

Determining triggering. Once an effective mapping is identified, it is essential to decide whether to trigger the LFM. Therefore, we use the conditions in Sec. 5 to guide this decision. As shown in Fig. 7, we summarize four types of so-

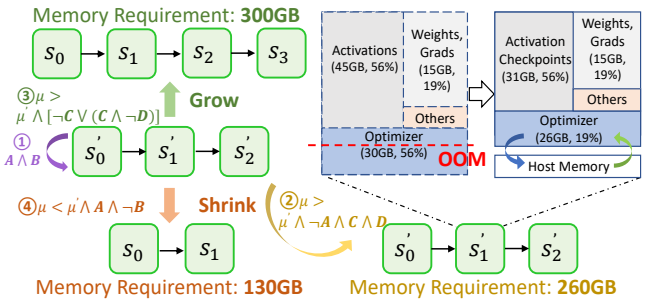


Figure 7: The trigger condition of flexibility by combining with recomputing and memory virtualization.

lutions in the HBSA, including ① maintaining the original mapping without memory optimization, ② applying current popular memory optimization techniques under the original mapping, ③ grow, which involves forming more stages and ④ shrink, which entails reducing the number of stages.

When both conditions $\mathcal{A}$ and $\mathcal{B}$ are satisfied, no action is necessary, meaning that neither memory optimization nor triggering flexibility is needed (①, Lines 28-29). If condition $\mathcal{A}$ is satisfied but condition $\mathcal{B}$ is not, then flexibility should be triggered (④, Lines30-31). When condition $\mathcal{A}$ is false, condition $\mathcal{B}$ must also be false. In such cases, it is necessary to employ memory optimization techniques (②, Lines 32-33). When both conditions $\mathcal{C}$ and $\mathcal{D}$ are true, triggering flexibility is unnecessary, and only memory optimization techniques should be utilized (Lines 34-35). If condition $\mathcal{D}$ is not met, flexibility should be activated (③, Lines 36-37). For example, as shown in Fig.7, increasing the maximum sequence length pushes GPU memory usage to 260GB, triggering an OOM error. Under condition $\mathcal{D}$, reconfiguration overhead exceeds that of memory optimization, thus FlexPipe prioritizes the memory optimization strategies (②). Specifically, in stage $S_1^{'}$, the recomputation reduces activation memory by 14GB, coupled with memory swapping that decreases optimizer memory by 4GB. Comprehensive reconfiguration details and examples are provided in Sec. 7, Tab. 2.

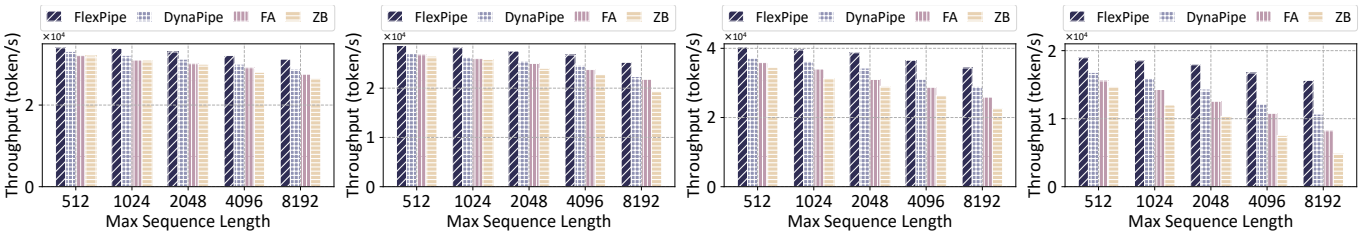
Here, reconfiguration is not required at every iteration during variable-length training. According to the input distribution, where the vast majority of sequences are short, only about 3% of the iterations contain long sequences. Thus, most training iterations fall within a relatively narrow resource range. Furthermore, HBSA provides a tolerant adjustment mechanism to avoid unnecessary reconfigurations by selectively combining reconfiguration with other lightweight memory optimization strategies. Empirical observations demonstrate that during training of the GPT-3.35B model on a 16-A100 GPU cluster, the system triggers grow (③) or shrink (④) at an average period of 37 iterations due to the symmetry. Memory optimization techniques (②) serve as the principal optimization methodology at an average period of 4 iterations.

6 System Implementation

FlexPipe is implemented using 8K LoC in Python and 2K LoC C++/CUDA code, a distributed DL runtime. Communication in PP and DP is implemented based on PyTorch's DDP with NCCL backend. We further describe the implementation of some of the unique aspects of FlexPipe.

Data preprocessing. To prevent delays between iterations and ensure efficient training, it is essential to preprocess the data before the training begins. Specifically, we implement a data prefetching strategy where the data loader not only fetches the current batch but also samples the next global batch in advance based on the training workflow feature. This advanced sampling process involves calculating the maximum sequence length, which ensures that the data is padded or truncated appropriately. The prepared data also prevents bottlenecks caused by input data stalls.

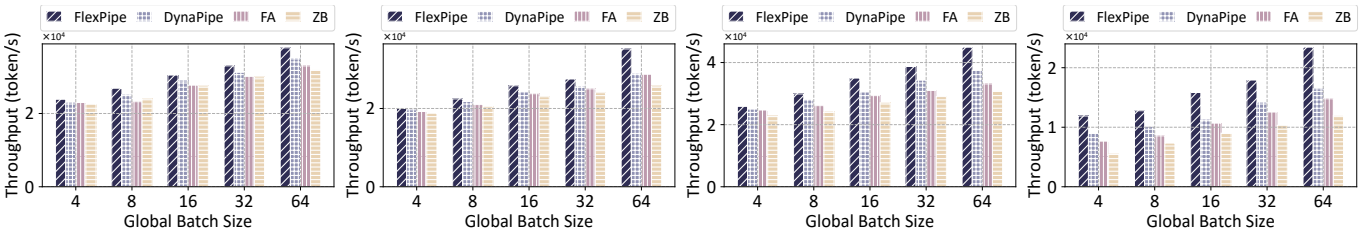
Model reconstruction. We designed a TwinLayer by reconstructing the original model layer. The TwinLayer minimizes the overhead of managing tensors by referencing their addresses directly rather than duplicating the tensors themselves, thereby reducing memory usage and improving computational efficiency. The TwinLayer Manager is implemented as an independent process on each server, where it runs multiple computational and communication threads using the C++ `thread` interface to avoid the Global Interpreter Lock limitations in Python's multithreading. Based on the timeline and current communication efficiency of the server, it generates effective orchestration strategies.



Communication transferring. We use DDP to transmit tensor between GPU-GPU and GPU-host. To leverage the duplicate channels between GPUs and the host, the weights and gradients are partitioned and transferred in a pipelined manner, which effectively reduces communication delays. To eliminate the potential disruption of training caused by live flexibility, we implemented asynchronous transfer operations using specific asynchronous interfaces, `cudaMemcpyAsync` and `isend`, which enable non-blocking data transmission.

7 Evaluation

We conduct comprehensive tests to evaluate the efficiency of FlexPipe. The results show that FlexPipe achieves 1.25× training throughput over SOTA methods on average.



7.1 Experimental Setup

Testbed. We evaluate FlexPipe in an environment consisting of 8 NVIDIA SXM4 servers. Each node is equipped with 4 NVIDIA A100 GPUs (Ampere architecture) with 80GB of on-chip memory and is connected to a 64-core AMD EPYC 7763 CPU. The GPUs are interconnected using NVLink, providing a communication bandwidth of 300GB/s. GPU-to-CPU communication uses PCIe 4.0, offering a bandwidth

Table 1: Transformer-based models for evaluation

Model	# Layers	# Heads	#Model Dim	# Params
BERT	24	16	1024	340M
BERT	96	16	1024	1.36B
GPT	16	32	4096	3.35B
GPT	40	40	5140	13B

of 64GB/s. These servers are connected by Infiniband with 50GB/s.The testbed runs on 64-bit SUSE Linux Enterprise Server 15 SP4 with CUDA 12.1 and PyTorch 2.1.1. As a middleware, FlexPipe is compatible with FlashAttention [6] and Zero-Bubble [36], which are incorporated to enhance the efficiency of the transformer-based model.

Baselines. FlexPipe is compared with three representative methods from different perspectives. (1) Zero-Bubble (ZB) [36] is currently the most effective PP training framework. We implement it by using padding to enable variable-length training. (2) FlashAttention (FA) [1] is widely used for optimizing LLMs from the kernel perspective, which reduces the computation time and memory footprint of attention. FlashAttention supports efficient variable-length training by packing methods and utilizes the default PP provided by PyTorch for distributed training. (3) DynaPipe [16] optimizes the variable-length training from the system perspective by supporting variable sizes of micro-batches to increase the padding efficiency.

Transformer-based models. Two transformer-based models are used in the experiments, including the variants of the GPT and BERT models. The details are shown in the Tab. 1. Both of them are trained on the FLANv2 dataset [30], one of the largest publicly available multi-task training datasets. The number of micro-batches for Zero-Bubble and FlashAttention is configured per model to maximize training throughput, while for FlexPipe and DynaPipe, it is dynamically adjusted.

Metrics. The average training throughput of actual tokens is used as the main metric, which is calculated by dividing the total number of tokens by the duration of one epoch. Moreover, we utilize the overhead of PP adjustment as a metric to evaluate the proposed flexibility mechanism.

7.2 Performance Comparison

7.2.1 Different Maximum Sequence Lengths

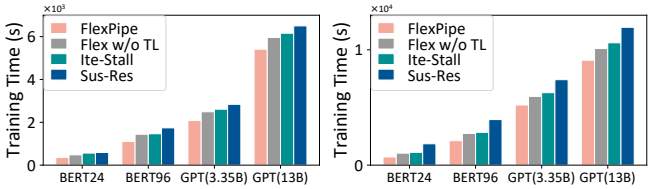
The average training throughput by using different methods under different maximum sequence lengths is shown in Fig. 8. We train BERT24, BERT96, GPT (3.35B), and GPT (13B) models with a global batch size of 4 on 1, 2, 4, and 8 nodes, respectively. The number of training devices is determined by the method with the highest peak memory requirement (i.e., ZA). For other methods with memory optimization techniques, the idle GPUs are utilized to accelerate training by launching DP, similar to FlexPipe. We could see that FlexPipe achieves 40.4% and 22.7% than Zero-Bubble and FlashAttention, respectively. Since Zero-Bubble and FlashAttention optimize variable-length training from a single perspective, either focusing solely on distributed systems or kernel optimization. In contrast, FlexPipe serves as a middleware system, enabling a holistic optimization approach to variable-length training. FlexPipe outperforms DynaPipe by 13.9%, as it takes accounts for fluctuations across iterations and utilizes "redundant" GPUs to further accelerate variable-length training, enhancing both performance and resource efficiency.

Moreover, as the maximum sequence length increases, throughput decreases due to a higher proportion of wasted tokens within each iteration. However, FlexPipe experiences a moderate decline in performance compared with other meth-

ods. This is because a larger maximum sequence length also amplifies the fluctuation between iterations, which FlexPipe is designed to handle more effectively.

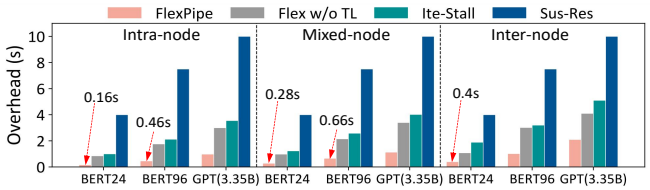
7.2.2 Different Global Batch Sizes

Fig. 9 illustrates the average training throughput under different global batch sizes, where the maximum sequence length is set to 2048. The performance of all methods improves with the global batch size, as larger global batch sizes enable efficient parallelism in computations and reduce per-batch overhead (e.g., gradient aggregation). FlexPipe and DynaPipe increase faster than other methods because they both support dynamic distributed training according to the variable lengths across multiple iterations. The overhead of such adjustments becomes relatively smaller as the duration of each iteration increases (i.e., larger global batch size).



Furthermore, we observe that FlexPipe exhibits better performance as the model size increases. For instance, it improves an average performance by 9% over other algorithms with BERT24 and 57% performance improvement with GPT (13B). This can be attributed to the following two reasons: (1) larger models exhibit larger fluctuations due to variable-length inputs, providing FlexPipe with greater optimization opportunities. (2) more devices are required for training larger models, which allows FlexPipe to explore stage-to-device mappings more comprehensively. On the other hand, the flexibility mechanism heavily relies on communication, which intuitively suggests a declined performance for larger models. While FlexPipe mitigates this by overlapping the computation and communication. This optimization leverages a higher computation-to-communication ratio, enabling FlexPipe to achieve better performance with larger models.

Based on the above analysis, FlexPipe achieves an average throughput of 1.25 × than SOTA methods across different maximum sequence lengths and global batch sizes. Additionally, FlexPipe demonstrates better performance in the context of large models and large-scale setups.



7.2.3 Overhead

We also evaluate the flexibility overhead of FlexPipe by comparing it against two common methods for adjusting PP: (1) Suspend-Resume is a non-live mechanism that suspends the training and saves the current status as a checkpoint, then restarts by loading the checkpoint with a new configuration. (2) Iteration Stalling supports live adjustment between iterations by transferring the model states without overlapping. Furthermore, to evaluate the effectiveness of TwinLayer, a degraded FlexPipe is implemented as Flex w/o TL by removing TwinLayer from the host memory.

Fig. 10(a) and 10(b) show the training time using different flexibility mechanisms under different maximum sequence lengths. We could see that FlexPipe significantly reduces

(a) Max_sequence length is 1024. (b) Max_sequence length is 4096.

(c) The detailed overhead under different envionments: intra-node consists of one node with 4 GPUs, inter-node consists of 4 nodes across 4 nodes, mixed-node consists of 2 nodes, each with 2 GPUs.

Figure 10: The flexibility overhead comparison with two common methods and a degraded FlexPipe.

35%, 23.1%, and 18.8% of the training time compared with Suspend-Resume, Iteration Stalling, and Flex w/o TL, respectively. This is because FlexPipe optimizes the initialization time required for dynamically adjusting pipelines by introducing the TwinLayer mechanism and designing elaborate fine-grained computation and communication overlap, enabling rapid flexibility and improving overall efficiency. As the maximum sequence length increases, FlexPipe demonstrates better performance compared to other methods, as discussed in Sec. 7.2.1 and 7.2.2, a larger maximum sequence length leads to more frequent fluctuations. Additionally, a larger maximum sequence length with a higher computation-to-communication ratio further reduces the flexibility overhead of FlexPipe.

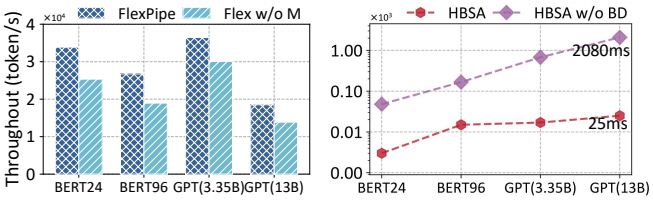
Fig 10(c) further presents the detailed overhead of a single flexibility operation under different environments, including intra-node, mixed-node, and inter-node. Suspend-Resume has a stable overhead under different environments. The other methods perform better within a single node, but experience degraded performance across nodes due to their dependency on communication bandwidth. Notably, FlexPipe maintains a minimal increase in overhead across nodes, attributed to its elaborate overlap of computation and communication.

For cases where new stages are added under the GPT (3.35B), we estimate the communication overhead per reconfiguration to be approximately 0.95s, measured as the interval between completing one iteration's update and beginning the next. The performance of FlexPipe comes with the overhead of each component, typically involving a trade-off between memory, computation, and communication. However, as discussed in Sec. 5.2, reconfiguration is infrequent during variable-length training, and each adjustment yields performance benefits that persist over multiple iterations. Furthermore, FlexPipe's profiling overhead is primarily confined to early iterations, where extensive sampling is required. There-

Model	μ	Parallel Strategy	M_{peak}	O_{plan}
BERT96	512	(4,4)	140	(0,0)
	1024	(4,4)	175	(10,5)
	2048	(3,3,2)	238	(0,0)
	4096	(2,2,2,2)	352	(20,12)
	8192	(1,1,2,1,1,1,1)	596	(18,18)
GPT (3.35B)	512	(8,8)	185	(15,10)
	2048	(4,4,4,4)	315	(0,0)
	2560	(4,4,4,4)	358	(25,13)
	3072	(3,3,3,4,3)	397	(0,0))
	2560	(3,3,3,4,3)	358	(0,0)

Table 2: The configuration and training details of BERT96 and GPT (3.35B) by using FlexPipe, where μ and M_{peak} denote the sequence length and peak memory usage, respectively. The parallel strategy denotes the DP degree of each stage of PP, e.g., BERT96 is divided into 7 stages, and the degree of the third stage is 2. O_{plan} (r, s) denotes r GB activations recomputed, and s GB tensors offloaded during the training.

fore, as demonstrated by the above experiments, the cost of a single adjustment is justified when amortized across the subsequent gains in throughput.



Furthermore, no significant performance degradation was observed from the compiler. According to our analysis, this is likely because FlexPipe's stage migration only remaps model stages across devices without altering the model structure or operator definitions, thus avoiding costly recompilation.

7.3 Discussion

7.3.1 Parallel Strategies of FlexPipe

To demonstrate how FlexPipe works, we train BERT96 and GPT (13B) on 2 and 8 nodes, respectively. Tab. 2 samples several representative iterations and illustrates their corresponding details. Unlike traditional training frameworks that rely on a fixed maximum number of GPUs (e.g., 16 GPUs for training GPT (3.35B)) to handle the variable sequence lengths across different iterations, FlexPipe dynamically adapts its parallel strategies according to the memory requirement to accommodate these fluctuations (e.g., 8 pipeline stages for a sequence length of 8192 and 4 stages for 512). Moreover, it effectively utilizes the "redundant" GPUs to boost the training throughput, leading to a significant performance improvement.

Note that the number of pipeline stages may vary even when the peak memory requirements are identical. For example, when training GPT (3.35B) with a sequence length of 2560, FlexPipe employed different parallel strategies across two iterations, which are influenced by the state of their previous iteration. This is because FlexPipe incorporates additional memory optimization techniques, such as recomputation and swapping, when adjusting its flexibility. FlexPipe balances the throughput improvements gained from these optimizations against their corresponding overheads.

(a) Throughput comparison. (b) Overhead comparision.

Figure 11: The ablation study of the algorithm.

Here, the number of iterations required for model convergence remains nearly identical with or without reconfiguration. FlexPipe is designed to accelerate each training iteration while maintaining strong training semantics. Therefore, even with long training runs, the reconfigurations in FlexPipe do not compromise training stability. With higher training throughput, the training tends to finish sooner. We omitted a detailed convergence analysis due to space constraints.

7.3.2 Effectiveness of Algorithm

To evaluate the effectiveness of HBSA, an ablation study is conducted by comparing FlexPipe with its modified versions. Fig. 11(a) shows the training throughput of different models using FlexPipe and Flex w/o M (only implements the flexibility mechanism, excluding recomputation and memory virtualization). We could see FlexPipe achieves an average 32.3% higher performance than Flex w/o M. When memory fluctuations are moderate, the overhead introduced by activation checkpointing and memory swapping is lower than the cost of flexibility adjustments. This mitigates the overhead caused by frequent adjustments. Furthermore, FlexPipe demonstrates even better performance advantages for larger models. This is because as the model size increases, FlexPipe w/o M requires more frequent PP adjustment, leading to greater overhead.

On the other hand, we compare the overhead of HBSA with HBSA w/o BD, which employs brute-force search based on the global solution space to determine the partitioning strategy. As shown in Fig. 11(b), HBSA achieves a significant reduction in overhead, with an average overhead of 15ms, compared to the 745ms for HBSA w/o BD. Although the overhead of HBSA increases with model size, the growth remains both reasonable and manageable.

As a heuristic algorithm, the computational overhead of HBSA is expected to grow linearly with the scale of the system. Compared to more complex methods, such as dynamic programming, HBSA remains relatively lightweight and incurs acceptable overhead. Moreover, FlexPipe's monitor performs sequence-length prefetching from the `dataloader`, allowing HBSA to be executed ahead of time and overlap with other computations. This further reduces the latency of reconfiguration decisions to the acceptable numbers of 15ms.

8 Related Work

Parallel Techniques. To deal with the explosive growth of both data volume and model complexity, a surge of studies have been proposed by researchers focused on various parallelisms [24,26,29,33,36]. With DP [24,25], multiple instances (i.e., worker) are launched by DL job, and each worker trains an identical DNN model with different parts of datasets. Thus, DP is commonly used to speed up large data training for the models that could fit on a single device. As the increasing of the model parameter, TP [17,46] splits individual layers (operation) into different devices to reduce the memory requirements. While each partition of operation requires two synchronous communication that slows down the training. Different from TP, PP [14,18,29,36] spits layers of the model into different stages, where each stage consists of a consecutive set of layers. Only transferring intermediate activations between the border layers of neighbor stages results in lower communication overhead. Recently, SP [26] aims at long sequence training by splitting the input into different devices and uses a ring-style communication, which is orthogonal to other parallelisms. This paper mainly focuses on the PP, which is indispensable in both commercial and academic DL clusters [29,33,53].

Pipeline Parallelism. Among the earliest PPs was GPipe [14], which reduces the bubble ratio by spitting a mini-batch into multiple micro-batches. Dapple [9] efficiently reduces this memory issue with a one-forward-one-backward scheduling policy, but it is not efficient enough. Hanayo [29] further improves the training throughput by utilizing a bidirectional pipeline without introducing additional memory copy. Zero-Bubble [36] nearly achieves zero bubbles by splitting the BP into two parts: computation for gradients and parameters. However, existing PPs either rely on static strategies (e.g., layer partitioning, micro-batch size) during training or reconfigure the parallel scheme based on suspend-resume [21, 42, 58] that brings huge overhead. vPipe [57] addresses the OOM issue when performing neural network search by dynamically partitioning layers. However, it cannot dynamically adjust the number of PP stages. PipeTransformer [12] improves the training efficiency of transformers by progressively freezing some layers during the training process while supporting elastic pipelines that dynamically allocate resources to the remaining active layers. However, PipeTransformer does not maintain the semantics of pipeline training, which is lossy. Though these works allow or support flexible pipelines, they do not take the variable-length training of transformers into account.

The optimizations of PPs often come at the expense of additional memory usage [18, 41, 57]. Therefore, they are typically combined with memory optimization techniques, which involve two widely used mechanisms. Memory virtualization [2,39] synchronously swaps in/out from GPU to host memory, which brings extra communication overhead. Chen et al. [5] propose recomputation that drops activations during the FP and later recomputes them when needed in BP, which reduces the memory footprint approximately to the square root of the total activations but incurs 33% extra computation.

Variable-length Training. The variable-length training of transformers has attracted lots of attention [8, 34, 38]. Traditionally, a straightforward solution is to pad all short samples with zeros to the length of the longest sequence. The naïve padding brings in redundant computations and wasted memory on padded tokens. Packing [8,38] can efficiently reduce the number of padding tokens by concatenating multiple short samples to form a long sample. However, packing is also memory inefficient because self-attention suffers from quadratic memory requirements with respect to the sequence length. Some libraries [34] sort the dataset so that each mini-batch contains samples with similar sequence lengths, which destroys the randomness and degrades the model performance (i.e., accuracy) [11].

Recently, a few DL frameworks have employed explicit designs for reducing the redundant computation caused by variable-length inputs [10,16,54]. ByteTransformer [54] proposes architecture-level optimization on multi-head attention and designs a padding-free algorithm for efficient variable-length training for transformers. DynaPipe [16] tackles the sequence length variation by advocating PP with variable-length micro-batches and optimizing micro-batch construction using dynamic programming. In contrast, FlexPipe mainly focuses on the trade-off between computational efficiency and memory usage.

9 Conclusion

This paper presents FlexPipe, a flexible PP framework that improves the efficiency of variable-length training by enabling the live flexibility mechanism (LFM) of PP. We propose a novel flexible memory optimization problem (FMOP) aiming at maximizing the training efficiency by dynamically reconfiguring parallel strategies and utilizing "redundant" GPUs across different iterations. We design an efficient heuristic bound searching algorithm to solve the optimization problem by comprehensively considering the overhead of the LFM and other memory optimization approaches. Experiments show that FlexPipe achieves an average 1.25× improvement in training throughput compared to existing SOTA frameworks.

Abstract

Multimodal large language models (MLLMs) have extended the success of large language models (LLMs) to multiple data types, such as image, text and audio, achieving significant performance in various domains, including multimodal translation, visual question answering and content generation. Nonetheless, existing systems are inefficient to train MLLMs due to substantial GPU bubbles caused by the heterogeneous modality models and complex data dependencies in 3D parallelism. This paper proposes Optimus, a distributed MLLM training system that reduces end-to-end MLLM training time. Optimus is based on our principled analysis that scheduling the encoder computation within the LLM bubbles can reduce bubbles in MLLM training. To enable scheduling encoder computation for all GPUs, Optimus searches for separate parallel plans for the encoder and LLM, and adopts a bubble scheduling algorithm to exploit LLM bubbles without breaking the original data dependencies in the MLLM model architecture. We further decompose the encoder layer computation into a series of kernels and analyze the common bubble pattern of 3D parallelism to carefully optimize the sub-millisecond bubble scheduling, minimizing the overall training time. Our experiments in a production cluster show that Optimus accelerates MLLM training by 20.5%-21.3% with ViT-22B and GPT-175B model over 3072 GPUs compared to baselines.

1 Introduction

Multimodal Large Language Models (MLLMs) build upon the advancements of Large Language Models (LLMs) by extending their capabilities to comprehend and generate content across multiple modalities, such as text, images, and audio. Notable MLLMs, including GPT-4V [21], Google Gemini [28], Grok-1.5 Vision [33] and LLava [18], have achieved remarkable progress in domains like visual question answering [2, 19], multimodal translation [27, 34], and content generation and understanding [21, 28, 40]. The substantial computational demands of MLLMs underscore the urgent need to enhance training performance to fully harness their capabilities.

Multimodal large language models (MLLMs) typically integrate multiple encoders, each specialized for processing a specific modality, alongside a substantial language model component. Multimodal data are input into their respective encoders, and the resulting outputs are combined to form the input for the language model.

The multimodal encoders and the language model exhibit significant differences in functionality, architecture, and input data sizes, leading to varied resource demands. However, existing distributed training systems are mainly designed for sequential unimodal (e.g., MegaScale [13], Megatron-LM [20], Chimera [16]), and fall short in training MLLMs. For example, when training a large MLLM containing several hundred billion parameters using Megatron-LM on over 3,000 GPUs, more than 40% of GPU cycles remain idle. Upon analyzing typical MLLM training tasks, we identified two critical issues: (1) Communication overhead in 3D parallelism is extensive and frequent, resulting in significant GPU idle times; (2) The pipeline stages of MLLM are imbalanced, and the data dependency between adjacent pipeline stages results in considerable data waiting time. Existing solutions can be categorized into two groups: (1) optimizing LLM, e.g.Megatron-LM and Zero-bubble pipeline [23]; (2) optimizing multimodal encoders, e.g.DistMM [12]. Nonetheless, none of the existing works consider LLM and encoders simultaneously. As demonstrated in Section 2.2, around 48% of GPU cycles are wasted in our internal large-scale MLLM training task.

In this paper, we introduce Optimus, a distributed MLLM training system that enables scheduling encoder computations within idle periods — referred to as "LLM bubbles" — to achieve efficient 3D parallelism. Scheduling encoder computations within these LLM bubbles using existing training frameworks is challenging for three reasons.

First, existing training frameworks, e.g., Megatron-LM [20],

*Work done during internship at Bytedance.

MegaScale [13], and zero-bubble pipeline [23], employ unified parallel strategies to MLLM models, distributing encoder and LLM layers across different GPUs. As a result, most GPUs contain only LLM model states and are incapable of performing encoder computations during LLM bubbles. In contrast, our approach utilizes separate parallelization plans for encoders and LLMs to colocate both encoder and LLM model states on each GPU. We systematically enumerate potential 3D parallelism plans for the encoder and eliminate those that violate GPU memory constraints.

Second, complex data dependencies inherent in MLLM constrain the scheduling of encoder computations within LLM bubbles. These dependencies include those related to synchronous training iterations and internal dependencies within the encoder itself, as discussed in Section 2.3. The most intricate dependency is the microbatch-level data dependency between the encoder and LLM, which requires that the encoder completes its forward pass before the LLM begins its forward pass for each microbatch, and that the encoder's backward pass commences only after the LLM has completed its backward pass for each microbatch. To manage these dependencies, we employ a two-stage dependency management strategy: local scheduling to address the first two types of dependencies and global ordering to handle the encoder-LLM microbatch-level dependencies.

Third, the LLM bubble duration varies significantly, ranging from sub-millisecond intervals to several hundred milliseconds, posing a considerable challenge for bubble reduction. Existing frameworks [16, 20, 23] schedule computations at the layer level, and sub-millisecond bubbles are too brief to complete even a single encoder layer forward or backward. To address this, we decompose encoder layer computations into sequences of kernels, enabling the effective utilization of these brief bubbles. Furthermore, we analyze common patterns in LLM bubbles and optimize the scheduling by interleaving encoder kernel computations with LLM computations, thereby minimizing the overall training time.

Optimus was implemented based on Megatron-LM, incorporating the aforementioned design principles. Comprehensive evaluations were conducted using several representative MLLM models. The results are promising - Optimus outperforms state-of-the-art baselines by 20.3% on average and Optimus also scales well with the size of models and GPUs. Our experiments in a production cluster show that Optimus accelerates MLLM training by 20.5%-21.3% with ViT-22B and GPT-175B models over 3072 GPUs compared to baselines.

2 Background

2.1 Multimodal LLM Characteristics

Multimodal LLMs are increasingly important. These models build upon the foundational principles of LLMs by integrating advanced natural language processing methodologies while extending their scope to encompass diverse data modalities. GPT-4 [21] exemplifies such an advancement, enhancing the capabilities of its predecessors to include multimodal understanding and generation. It demonstrates human-level performance across various benchmark tests involving both image and text inputs.

A multimodal large language model (MLLM) typically comprises three primary components: one or more modality encoders, input projectors, and a large language model backbone [36]. The Modality Encoders process inputs from non-textual modalities into their respective feature representations, while the input projector aligns these features with the text feature space. Subsequently, the LLM backbone utilizes the aligned multimodal and textual features as input. Figure 1 illustrates the architecture of the MLLM. The input projector is excluded from further discussion due to its relatively minimal computational demands compared to the encoder and the LLM backbone, as detailed in Llava [18]. For this analysis, the input projector is considered the final layer of the modality encoder.

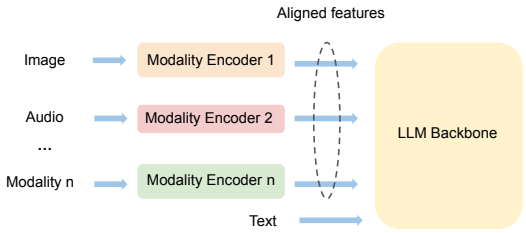

Figure 1: Multimodal model architecture.

Different from homogeneous LLM architecture, multimodal LLM has the following unique characteristics.

Dominant Model Size of LLM Backbone: In multimodal LLMs, the LLM backbone has a significantly larger number of parameters compared to other components such as encoders and projectors. For instance, Flamingo [3] boasts a total of 80 billion parameters, with its LLM backbone alone comprising 70 billion parameters.

Dependency between Encoders and LLM Backbone: In MLLM training, there are two types of data dependencies between encoders and LLM. During the forward pass, encoders must complete the generation of encoded features before the LLM backbone can proceed with forwarding. Conversely, in the backward pass, the LLM backbone calculates gradients before the encoders initiate the backward pass.

2.2 Bubbles in MLLM Training

Existing LLM pipeline optimizations lack model-agnostic properties and are inadequate for MLLM training tasks. In our internal large-scale MLLM training tasks with ViT encoder and GPT backbone (over 100B parameters), we employed

Megatron-LM across more than 3,000 NVIDIA GPUs and observed over 48% GPU cycle idleness despite utilizing multiple SOTA techniques, including MegaScale [13], Zero Bubble Pipeline [23], fine-grained communication-computation overlapping [32]. We analyzed the profiled timeline to identify and investigate the occurrences of GPU idleness (i.e., bubbles). Table 1 shows the total duration and percentage of average training step time (5.12s) occupied by different types of bubbles.

Bubble types	Percentage	Total time (s)
DP bubble (all-gather)	3.3%	0.167
DP bubble (reduce-scatter)	8.9%	0.458
PP bubbles (warmup)	5.0%	0.291
PP bubbles (cooldown)	9.2%	0.471
PP bubbles (other)	8.7%	0.445
TP bubble	11.2%	0.585

Table 1: Total time and percentage of average training step time (5.12s) occupied by different types of bubbles.

These bubbles can be classified into three categories based on their underlying causes.

(1) Communication in Data Parallelism (DP). Data parallelism requires communication to aggregate gradients, leading to GPU idle time during these communications. Specifically, MegaScale [13] and Megatron-LM [25] employ a distributed optimizer, similar to P_{os+g} in ZeRO [24], to save memory for large model training, which performs two collective communications: *all-gather* and *reduce-scatter*. At the start of each training step, an all-gather operation collects updated parameters from all DP ranks, resulting in a DP all-gather bubble that occupies 3.3% of the training time. At the end of the training step, reduce-scatter is performed to aggregate gradients, leading to a DP reduce-scatter bubble that consumes 8.9% of the training time[1]. It should be noted that overlapping optimization in data parallelism proposed in Megascale [13] has already been applied; however, the aforementioned DP communications for the first model chunk can not be hidden due to the nature of synchronous training [13]. Figure 2 illustrates DP bubbles arising from all-gather and reduce-scatter operations at the start and conclusion of each training step.

(2) Dependency in Pipeline Parallelism (PP). Despite applying pipeline send-receive overlap optimization from Megascale [13], pipeline bubbles persist due to the inherent data dependencies between stages during the forward and backward passes. Importantly, the Zero Bubble Pipeline method cannot eliminate pipeline bubbles in MLLM training, owing to the required changes in the optimizer [23] (see discussions in §7). Figure 2 illustrates the MLLM training pipeline schedule, comprising three phases: warm-up (forward only), steady (one forward and one backward), and cool-down (backward only). Throughout pipeline training, three types of bubbles arise:

- PP warm-up bubbles occur at all stages except the first one due to the forward dependency of the first forward pass, averaging 5.0% of the training time.
- PP cool-down bubbles occur at all stages except the first one due to the backward dependency of the final backward pass, averaging 9.2% of the training time.
- Other PP bubbles manifest in all stages except the last one due to dependencies of other forward and backward passes, occupying 8.7% of training time. For instance, PP bubbles emerge immediately after the PP warm-up phase due to the backward dependency of the initial backward pass. Additionally, in cases where pipeline stages are imbalanced due to the heterogeneity of MLLM models, extra pipeline bubbles not depicted in Figure 2 occur.

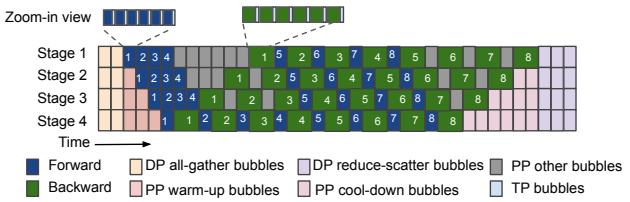

Figure 2: Timeline illustration of MLLM training showing different categories of bubbles (simplified based on the Megatron-LM 1F1B schedule [20]).

(3) Communications in Tensor Parallelism (TP). Tensor parallelism involves partitioning individual layers across multiple GPUs, necessitating communication during forward and backward passes to synchronize between GPUs. In Megatron-LM, each forward or backward pass of a transformer layer requires two all-gather and two reduce-scatter kernels [14]. Figure 3 provides a detailed view of CUDA computation and communication kernels during two GPT-175B [5] layer forward passes. Green kernels represent all-gather communications in the CUDA communication stream, while blue kernels denote reduce-scatter communications. The compute stream idles during these communications. Typically, these TP bubbles last for sub-millisecond durations, averaging around 300 μs. However, during MLLM training, there are thousands of TP bubbles, collectively accounting for 11.2% of the training time.

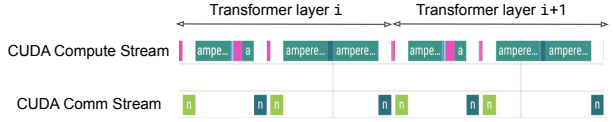

Figure 3: Zoom-in view of TP bubbles during two LLM layers forward.

[1]The reduce-scatter bubble is larger than the all-gather bubble because it involves higher communication volume (FP32 gradients vs. BF16 parameters) and suffers from synchronization delays due to straggling GPUs at the end of the training step.

2.3 Challenges

To minimize bubbles in MLLM training, we aim to exploit the distinct dual-component structure of MLLM, which consists of encoders and the LLM backbone. We make two key observations. First, the majority of bubbles during MLLM training occur during the forward and backward passes of the LLM backbone, with around 90% arising from LLM communication based on production data. Second, the encoders require fewer computational operations (FLOPs) than the LLM backbone due to their smaller parameter size [4, 7, 10, 17, 18].

Based on these insights, we propose **scheduling encoder computations in LLM bubbles** which occur during LLM communication to minimize bubbles throughout the MLLM training process. We identify three primary challenges of scheduling encoder computation to LLM bubbles.

Challenge 1: Only a limited number of GPUs have both encoder and LLM model states. Current training systems [20, 39] employ pipeline parallelism to distribute the MLLM as a single pipeline across multiple GPUs. Due to the dependency between the encoder and LLM, encoder layers are assigned to initial pipeline stages, while LLM layers are assigned to later pipeline stages. Consequently, only one pipeline stage typically contains both the encoder and LLM layers. To illustrate, Figure 4 demonstrates the use of 3D parallelism (DP=1, PP=4, TP=2) to parallelize MLLM across 8 GPUs, where only 2 GPUs in pipeline stage 1 hold both the encoder and LLM model states. The remaining 6 GPUs cannot execute encoder computations during LLM bubbles because they lack encoder model states.

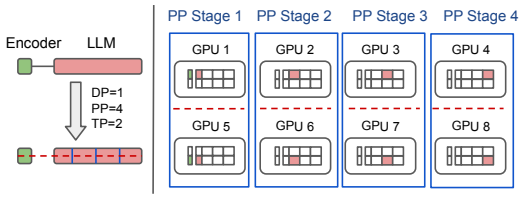

Figure 4: Only GPUs in pipeline stage 1 have both encoder and LLM model states.

Challenge 2: Complex Dependencies in MLLM Training. The complex dependencies inherent in MLLM training pose significant challenges when scheduling encoder computation within LLM bubbles. First, in synchronous training, the utilization of LLM bubbles is restricted to performing encoder computations solely within the current training iteration (*iteration dependency*). Second, dependencies within the encoder pipeline require that the forward computation of the current encoder pipeline stage i is scheduled only after the completion of the previous encoder stages, and the backward computation can be scheduled only after the subsequent encoder stage concludes. Lastly, the encoder-LLM dependency imposes microbatch-level constraints: the encoder must complete the forward pass of microbatch i before the LLM pipeline can initiate the forward pass of the same microbatch. Similarly, the encoder can begin the backward pass of microbatch i only after the LLM pipeline has completed its backward pass of microbatch i.

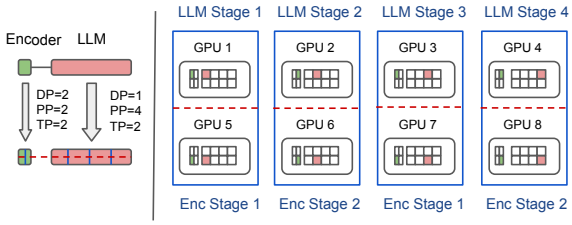

Figure 5: All GPUs both hold encoder and LLM model states when giving encoder and LLM separate parallel plans.

Challenge 3: Sub-millisecond LLM bubbles. Existing frameworks like MegaScale [13] and Megatron-LM [20] typically schedule at layer level. However, bubbles in the LLM exhibit a wide range of durations, spanning from sub-milliseconds (TP bubbles) to hundreds of milliseconds (DP bubbles). For instance, TP bubbles shown in Figure 3 average around 300μs across different LLM layers during forward and backward passes. This duration is insufficient to complete even a single encoder layer forward or backward. To illustrate, a single ViT-22B layer typically requires around 1.4 milliseconds to complete forward propagation and 2.0 milliseconds to complete backward propagation.

3 Design Decisions and System Overview

We discuss the core design decisions that drive Optimus design and provide an overview of Optimus. The next section discusses the detailed design.

3.1 Design Decisions

Design decision 1: Colocate encoders and LLM with separate parallelism. To ensure that each GPU possesses both encoder and LLM model states, we propose assigning separate parallel plans to encoders and LLMs across all GPUs. This strategy is illustrated in Figure 5, where using parallel plan (DP=2, PP=2, TP=2) for encoders and (DP=1, PP=4, TP=2) for LLM. Each GPU retains both encoder and LLM model states, and then it becomes feasible for all GPUs to execute encoder computations during LLM bubbles. Note that colocating both the encoder and LLM states may require more GPU memory, and we analyze the memory overhead in Section 4.5.

Design decision 2: Dual-Stage Dependency Management. We use two stages to handle complex dependencies in MLLM training: local scheduling and global ordering. Each encoder pipeline undergoes local scheduling, which schedules encoder computations with available LLM bubbles, adhering

to the iteration-dependency and encoder-internal dependencies. Global ordering ensures microbatch-level dependency between encoders and LLM by sequencing the encoder's ending times forward and the encoder's starting times backward across microbatches. This involves comparing timestamps to verify encoder-LLM dependency compliance. As shown in Figure 6, local scheduling is applied independently to two encoder pipelines, maintaining iteration dependency and encoder-internal dependency. In global ordering, timestamps across all microbatches (totaling 8) are checked to confirm that encoder-LLM dependencies are met.

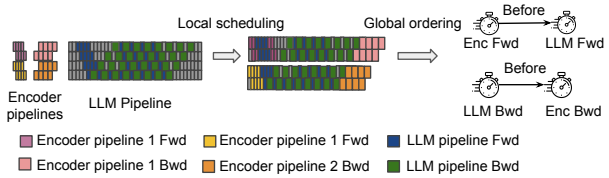

Figure 6: Solve complex dependencies in MLLM training through local scheduling and global ordering.

Design Decision 3: Schedule encoder computation at Kernel Level. Decomposing the encoder layer into kernels enables efficient utilization of sub-millisecond bubbles. However, TP communication kernels in the encoder layer compete for link bandwidth during LLM TP bubbles, causing longer time per iteration. To resolve this, we must additionally schedule encoder communication kernels during LLM compute (see Figure 7).

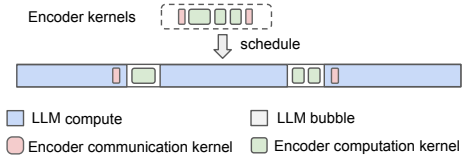

Figure 7: Schedule encoder computation kernels within LLM bubbles and encoder communication kernels within LLM compute.

3.2 Optimus Overview

Optimus is a distributed training system designed for MLLM, enabling the scheduling of encoder computation within LLM bubbles to improve end-to-end training latency. To tackle the challenges outlined in Section 3.1, Optimus comprises two components: the model planner, which addresses Challenge 1 by ensuring all GPUs hold both encoder and LLM model states, and the bubble scheduler, which addresses Challenge 2 (complex dependencies in MLLM training) and Challenge 3 (sub-millisecond LLM bubbles).

Model Planner. The model planner partitions encoders and the LLM backbone separately to all given GPUs (addressing Challenge 1 in §3.1). It selects a 3D parallelism plan for the LLM backbone and explores possible 3D parallelism plans for the encoders, considering the available GPU memory after the deployment of the LLM. With the model planner, each GPU holds both LLM and encoder model states, enabling encoder computation during LLM bubbles. The encoder and LLM model parallel plans are provided as input to the bubble scheduler, where Optimus selects parallel plans based on the output schedule with the shortest execution time.

Algorithm 1: Optimus workflow

```
1  Function Optimus(mllm):
2      encPlans, llmPlan = ModelPlanner(mllm)
3      bestLat, bestSchedule = +∞, None
4      for encPlan in encPlans do
5          schedule = BubbleScheduler(encPlan, llmPlan)
6          if schedule.lat < bestLat then
7              bestSchedule = schedule
8              bestLat = schedule.lat
9          end
10     end
11     return bestSchedule
```

Bubble Scheduler. Bubble scheduler is responsible for scheduling encoder computation into LLM bubbles. Given that the LLM training pipeline divides data into multiple microbatches, the scheduler schedules encoder computations on a per-microbatch basis and satisfies encoder-LLM data dependency at the microbatch level (addressing Challenge 2 in §3.1). In addition, the scheduler breaks down encoder computation into kernel granularity, to enable the utilization of sub-millisecond bubbles (TP bubbles) during LLM training (addressing Challenge 3 in §3.1). The current design is based on the 1F1B-interleaved pipeline schedule [20], but it is not tightly coupled to it and can be adapted to support other pipeline schedule strategies (as discussed in Section 6).

Optimus uses the model planner to devise parallel plans for encoders and LLMs. Subsequently, for each encoder parallel plan, Optimus utilizes the bubble scheduler to generate a schedule and estimate the latency. The latency estimation is based on offline profiling conducted during the model planner step, where we use the offline profiled encoder execution time and the LLM pipeline training timeline. Ultimately, Optimus selects the schedule with the shortest training time to schedule encoder computation into LLM bubbles. The workflow of Optimus is outlined in Algorithm 1.

4 Optimus Design

Section 4.1 describes how the model planner searches the parallel plans for the encoder, Section 4.2 details how the bubble scheduler exploits the coarse-grained and fine-grained bubbles through local scheduling, Section 4.3 discusses how

the bubble scheduler handles encoder-LLM data dependencies through global ordering, Section 4.4 designs the bubble scheduling in multi-branch encoder models, and Section 4.5 analyzes the memory consumption of the bubble scheduling algorithm.

4.1 Model Planner

The workflow of the model planner consists of searching encoders and LLM parallelism plans, colocating encoders and LLMs, ensuring memory constraints are met, and constructing separate microbatches for encoder and LLM pipelines.

Searching separate parallel plans. Initially, the planner determines the 3D parallelism plan $(DP_{llm}, PP_{llm}, TP_{llm})$ for the LLM backbone based on insights in Megatron-LM [20]. Subsequently, the planner enumerates potential 3D parallelism plans $(DP_{enc}, PP_{enc}, TP_{enc})$. To guarantee that multiple encoder models can be colocated with each LLM model, we enforce that PP_{enc} is a factor of PP_{llm} and TP_{enc} is a factor of TP_{llm}.

Colocating encoders and LLM. To guarantee that each GPU can perform encoder computations during LLM downtime, the model planner assigns encoder and LLM model states to every GPU. As illustrated in Figure 5, all GPUs contain model states for both the encoder (depicted in green) and the LLM (shown in red). Without such colocation, many GPUs would lack the necessary encoder model states to execute encoder computations.

Prune parallel plans based on memory constraint. Since the encoder and LLM stages are colocated on GPUs, we estimate the memory requirements for encoder and LLM model states, as well as LLM activations, based on the selected parallelism plan—drawing on the memory analysis in [14]. We omit encoder activations from the estimation due to their negligible memory footprint. Any plans that exceed GPU memory capacity are pruned early.

Constructing separate microbatches. Due to the different parallel plans for encoders and LLMs, there are $m = \frac{DPenc}{DPllm}$ times more encoder pipelines than LLM pipelines for a given set of GPUs (e.g. $m = 2$ in Figure 5). For GPUs belonging to the same LLM pipeline, there are m encoder pipelines colocated. Depending on the number of microbatches N_{mb} utilized in LLM pipeline training, the data from these N_{mb} microbatches needs to be distributed among these m encoder pipelines, where each encoder pipeline i handles forward and backward computations for N_{enc_i} microbatch data. The model planner enumerates possible ways to partition these N_{mb} microbatches among the m encoder pipelines. For instance, if there are 8 microbatches in the LLM training and $m = 2$ encoder pipelines, there are a total of 7 possible partitioning options, such as $[1,7]$, $[2,6]$, ..., $[7,1]$.

Algorithm 2: BubbleScheduler

```
1  Function BubbleScheduler(encPlan, llmPlan):
2      schedules = InitSchedule(encPlan, llmPlan)
3      dep = GetEncLLMDep(llmPlan)
4      bestLat, bestSchedule = +∞, None
5      for schedule in schedules do
6          schedule = OptimizeSchedule(schedule, dep,
             FWD)
7          schedule = OptimizeSchedule(schedule, dep,
             BWD)
8          if schedule.lat < bestLat then
9              bestSchedule = schedule
10             bestLat = schedule.lat
11         end
12     end
13     return bestSchedule
14 Function OptimizeSchedule(schedule, dep, mode):
15     while True do
16         encPPID = findCritical(schedule, mode)
17         newSchedule, success =
             ScheduleKernels(encPPID, schedule, mode)
18         if success and checkEncLLMDep(schedule, dep)
             then
19             schedule = newSchedule
20         else
21             return schedule
22         end
23     end
```

4.2 Bubble Scheduling

Although LLM bubbles in different GPUs have different start times and durations, there is one common pattern of LLM bubbles as shown in Figure 8. There is one single big bubble (the sum of DP all-gather bubble and PP-warm bubble) before any LLM computation starts, and one single big bubble (the sum of PP-cooldown bubble and reduce-scatter bubble) after all LLM computation finishes. And there are many small bubbles (PP bubbles and TP bubbles) [14, 20, 25] interleaved with LLM computation.

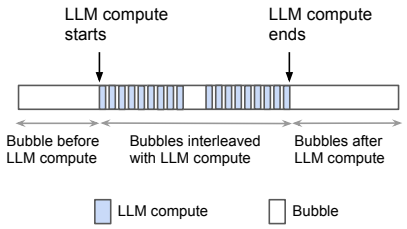

Figure 8: Bubble pattern of 3D parallelism.

The bubble scheduler, as described in Algorithm 2, initially engages in **coarse-grained bubble exploitation** by creating initial schedules that incorporate encoder computations within

the bubbles positioned before and after LLM computations (line 2). However, it's possible that these two bubbles may not allow sufficient time to complete all encoder computations, leading to some encoder computations being unscheduled within bubbles. To reduce the total training time, the bubble scheduler then executes **fine-grained bubble exploitation**. This involves refining the schedule by allocating encoder forward computations to the bubbles that alternate with LLM computations (line 7), followed by scheduling encoder backward computations to these same bubbles (line 8). The final output of the bubble scheduler is the schedule that achieves the shortest possible runtime.

Coarse-grained bubble exploitation. For each potential data partitioning approach, the bubble scheduler initializes the schedule by scheduling encoder forward operations to occur before LLM computations and encoder backward operations to occur after LLM computations. Figure 9 illustrates the initialized schedule when there are $m = 2$ encoder pipelines and the data partitioning approach is $[3,5]$, i.e., 3 microbatches are allocated to the first encoder pipeline and 5 to the second encoder pipeline.

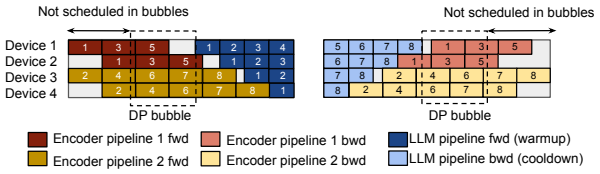

Figure 9: Bubble schedule initializes the schedule when the first encoder pipeline is allocated 3 microbatches and the second encoder pipeline is allocated 5 microbatches ($N_{mb} = 8$).

Fine-grained bubble exploitation. The `OptimizeSchedule` function (line 15 at Algorithm 2) refines the initial schedule through an iterative approach. Initially, the bubble scheduler employs `findCritical` to identify the encoder pipeline whose computation is on the critical path of the end-to-end MLLM training (line 17). Subsequently, it utilizes `ScheduleKernels` to allocate one microbatch of this encoder computation to bubbles interleaved with LLM computations (line 18). If enough bubbles are available to accommodate encoder computation and encoder-LLM data dependencies are satisfied (as discussed in §4.3), the bubble scheduler continues scheduling. Otherwise, it terminates and returns the best schedule found so far.

When optimizing the schedule for encoder forward computation (line 7 in Algorithm 2), `findCritical` identifies the encoder pipeline whose forward computation is critical. As shown in the left portion of Figure 10, encoder pipeline 2's forward computation (microbatch 8 forward) is initially on the critical path in the initial schedule. After successfully scheduling that microbatch forward to later bubbles, encoder pipeline 1 assumes the critical path position. This iterative process leads to a reduction in the end-to-end MLLM training time after each step. Similarly, encoder pipelines whose backward computation is critical are illustrated in the right portion of Figure 10. After each step, the bubble scheduler must verify if it still satisfies the encoder-LLM data dependency before proceeding with the next steps.

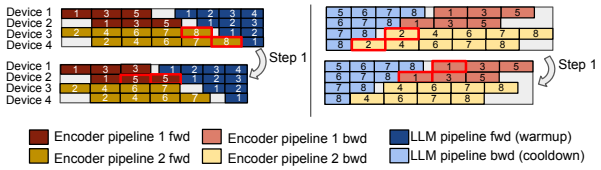

Figure 10: Find encoder pipeline that is on the critical path of end-to-end MLLM training (left: encoder forward on the critical path, right: encoder backward on the critical path).

When scheduling encoder computation to bubbles interleaved with LLM compute (`ScheduleKernels` at line 17), the bubble scheduler decomposes the encoder computation into kernel granularity and schedules these kernels based on the duration of the bubble. For each bubble, the bubble scheduler schedules multiple kernels while ensuring that the total execution time of these kernels is within the bubble duration. Additionally, the bubble scheduler must satisfy the encoder's internal data dependencies. As illustrated in Figure 11, device 1 holds the first two layers of the encoder, while device 2 holds the next two layers. When scheduling kernels during the forward pass, device 2 can only utilize bubbles that occur after device 1 completes its forward pass to execute encoder computation. For the forward computation, the bubble scheduler schedules encoder computation from upstream encoder pipeline stages to downstream encoder pipeline stages. Conversely, for backward computation, the bubble scheduler schedules encoder computation in the reverse order. While each encoder layer also includes communication kernels, the scheduler ensures that these kernels are not assigned to TP bubbles that occur during LLM communication. Instead, the scheduler identifies long-duration computation kernels within the LLM layers and overlaps them with encoder communication kernels. As the LLM and encoder layers alternately perform computation and communication tasks, they make efficient use of GPU bandwidth and Streaming Multiprocessors (SMs). This design strategy helps to minimize resource contention and improves overall GPU utilization [15].

Complexity. Our bubble scheduling algorithm has low complexity. Given n GPUs and the number of prime factors of n is n_p, the search space of parallel plans is $C^2_{n_p+1}$. The number of microbatch partitioning is $O(N_{mb}^{m-1})$. Hence, the complexity for scheduling bubbles is $O(C^2_{n_p+1} * N^m_{mb} * (F+B))$. In our experiments, it usually takes around several minutes to calculate the optimal schedule (see §5.3.2), which is also a one-time cost.

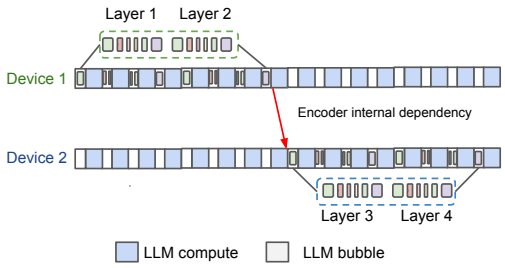

Figure 11: Scheduling encoder computation kernels needs to satisfy encoder internal dependencies.

4.3 Address Encoder-LLM dependency

Table 2: The list of symbols frequently used in the paper.

Symbol	Description
DP_{llm}	LLM Data Parallel Size
DP_{enc}	Encoder Data Parallel Size
N_{mb}	Number of microbatches in LLM training
MB_i	Encoder input data microbatch
A_i	LLM input activations for microbatch i
G_i	LLM output gradients for microbatch i
F_i	Forward dependency point for microbatch i
B_i	Backward dependency point for microbatch i

The model planner provides different parallel strategies for encoders and LLM backbone, including the number of microbatches, resulting in complex data dependencies both between and within the encoder and LLM. Also, the communication and computation of the encoder and LLM are executed by interleaving, and this may introduce additional pipeline bubbles, if not orchestrated effectively, intensifying the complexity of dependencies in the system.

The bubble scheduler addresses encoder-LLM dependencies at the microbatch level by examining the encoder-LLM forward and backward dependency points for each microbatch i. These dependency points, denoted as F_i and B_i respectively, represent the time when the LLM requires the corresponding activations A_i (output by the encoder) for forward propagation, and when the LLM generates the corresponding gradients G_i (input for the encoder) during backward propagation. To ensure the satisfaction of encoder-LLM dependencies, the bubble scheduler employs two functions: `GetEncLLMDep` (line 3 at Algorithm 2) and `CheckEncLLMDep` (line 19 at Algorithm 2), as described below.

`GetEncLLMDep` gets encoder-LLM forward and backward dependency points. Given that the interleaved 1F1B schedule [20] stands out as one of the most efficient pipeline schedules for LLM training, we delve into the specifics of the data dependency points F_i and B_i within this schedule. The top illustration in Figure 12 depicts an instance of the interleaved 1F1B schedule featuring two model chunks. Here, the forward dependency points denote the instances when the first pipeline stage (device 1) commences forward execution for the first model chunk (depicted in dark blue), while the backward dependency points signify the moments when the first pipeline stages (device 1) complete backward execution for the first model chunk (depicted in dark green).
We observe that deferring forward data dependency points for the last four microbatches ($F5$ through $F8$) is feasible without exerting any adverse effects on the overall pipeline latency. To accomplish this, we can adjust the number of warmup microbatches at each pipeline stage, as illustrated in the bottom portion of Figure 12. This adjustment enables the bubble scheduler to leverage bubbles during the phase transition from the warmup phase to the 1F1B-steady phase for scheduling encoder forward computation when optimizing initial schedules. `GetEncLLMDep` yields the adjusted forward and backward data dependency points for 1F1B interleave schedules.

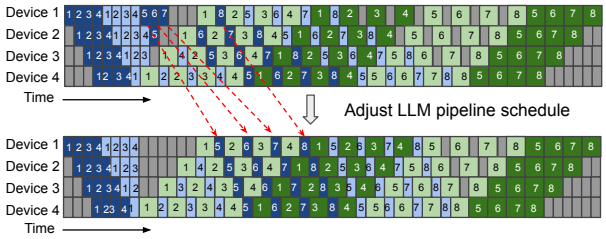

Figure 12: Interleaved 1F1B pipeline schedules before and after adjustment. The top figure shows the default interleaved 1F1B schedule in the Megatron-LM paper [20]. The bottom figure shows the interleaved 1F1B schedule after adjustment. In both schedules, each device is assigned 2 chunks. Dark colors show the first chunk, and light colors show the second chunk.

`CheckEncLLMDep` verifies the satisfaction of microbatch-level encoder-LLM dependencies. By considering the scheduled encoder computation into bubbles, the bubble scheduler estimates when the encoder finishes the forward pass for microbatches distributed over different encoder pipelines. The bubble scheduler sorts these finishing times in ascending order as EF_i (global ordering), representing when the encoder forward operation ends for microbatch i involved in LLM pipeline training. The forward dependency for encoder-LLM is considered met if the encoder completes its forward operation before the specified F_i timepoint ($EF_i \leq F_i$) for all microbatches ($i = 1...N_{mb}$). Similarly, the backward dependency is satisfied if the encoder's backward operation begins no earlier than the B_i timepoint ($EB_i \geq B_i$) for each microbatch ($i = 1...N_{mb}$). `CheckEncLLMDep` returns true when it confirms that both the forward and backward dependencies are successfully met. To illustrate this, Figure 13 provides an example of evaluating encoder-LLM dependency with two encoder pipelines, each handling four microbatches. The order in which the encoder completes its forward pass dictates

how the activations are used in the LLM pipeline: activations from encoder pipeline 1 are designated as the 1st, 3rd, 7th, and 8th microbatches, while activations from encoder pipeline 2 are used as the 2nd, 4th, 5th, and 6th microbatches. The bubble scheduler then verifies microbatch-level dependency by ensuring that each encoder's forward operation concludes before the start of the corresponding LLM forward pass and that each encoder's backward operation does not commence until after the LLM has ended, for each microbatch.

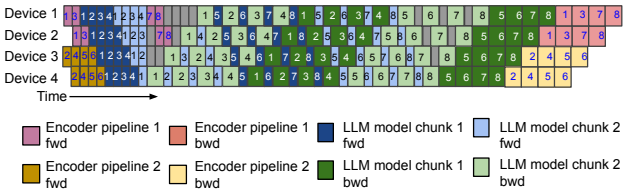

Figure 13: Illustration example of `checkEncLLMDep`.

When dependencies are satisfied, the bubble scheduler integrates necessary peer-to-peer (P2P) communications into the training schedule between the last stage of the encoder pipeline and the first stage of the LLM pipeline. For instance, if encoder pipeline j completes the forward pass for microbatch i, the scheduler will insert a P2P send (sending activations) at the last stage of encoder pipeline j and a P2P receive (receiving activations) at the first stage of the LLM pipeline. Similarly, when the LLM pipeline completes the backward pass for microbatch i, the scheduler adds a P2P send (sending gradients) at the first stage of the LLM pipeline and a P2P receive (receiving gradients) at the last stage of encoder pipeline j. In the scenario illustrated in Figure 13, where the training pipeline processes 8 microbatches, the scheduler inserts 8 pairs of P2P send-receive operations between devices 1 and 2 to manage the dependencies between encoder pipeline 1 and the LLM pipeline. These include 4 pairs for forward activation, send/receive, and 4 pairs for backward gradient send/receive. Similarly, another 8 pairs of P2P send-receive operations are inserted between devices 3 and 4 to handle the dependencies between encoder pipeline 2 and the LLM pipeline.

4.4 Multi-Branch Encoder Scheduling

To support MLLM with multiple encoders [6, 35], the model planner applies an encoder parallelism plan $(DP_{enc}, PP_{enc}, TP_{enc})$. Independently for each encoder. For pipeline parallelism, layers within each encoder are divided into PP_{enc} stages (as illustrated in Figure 14). Each layer of every encoder is then parallelized according to TP_{enc}. The bubble scheduler breaks down the layers of distinct encoders into kernel-level granularity and arranges their scheduling as if these kernels were part of a single encoder. This is because the encoders within MLLM operate independently, without any data dependencies between them.

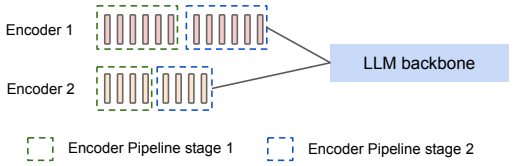

Figure 14: An example of model planner applying $PP_{enc} = 2$ to MLLM with two encoders.

4.5 Memory Analysis

When utilizing n_{gpu} GPUs for MLLM training, the model planner requires DP_{enc} replicated encoder model states and DP_{llm} replicated LLM model states based on parallel plans. Suppose the number of parameters in the encoder is ϕ_{enc} and the number of parameters in the LLM is ϕ_{llm}, with each parameter requiring k bytes of memory. The average GPU memory usage MEM_{model} for storing model states is calculated as follows:

$$MEM_{model} = \frac{k \cdot (DP_{enc}\phi_{enc} + DP_{llm}\phi_{llm})}{n_{gpu}}$$

In comparison to existing 3D parallel training solutions, where $DP_{enc} = DP_{llm}$, the estimated memory overhead $MEM_{overhead}$ can be expressed as:

$$MEM_{overhead} = \frac{k(DP_{enc} - DP_{llm})\phi_{enc}}{n_{gpu}}$$

With a larger value of DP_{enc}, there is a higher memory overhead due to more replicated encoder model states. However, this results in less complex encoder internal dependencies during scheduling (indicated by a smaller PP_{enc}). Model planner filters the encoder parallel plans based on the estimated memory usage MEM_{model}, ensuring adherence to GPU memory constraints. In practice, the memory overhead typically amounts to less than 12% in our evaluation (§5.3.1) because ϕ_{enc} is small (e.g., the largest vision encoder has 22 billion parameters [9]) and k is small (e.g., $k = 6$ when using $bf16$ parameters and $fp32$ gradients with distributed optimizer [1]).

5 Evaluation

We have developed Optimus based on the open-source Megatron-LM framework [1] and evaluated Optimus on training large-scale multimodal LLMs.

5.1 Methodology

Testbed. We conduct our experiments in a production training cluster with thousands of NVIDIA Hopper GPUs. Each GPU has 80GB of memory and 989 TFLOPS of computing performance. The intra-server connection is NVLink, and the inter-server connection is a high-bandwidth RDMA network.

MLLM models. We examine the performance of Optimus using various sizes of image encoders and LLM backbones.

The image encoders include three sizes: ViT-22B [9], ViT-11B, and ViT-5B, which are scaled-down versions of ViT-22B with smaller hidden sizes. For the language models, we employ two sizes: LLAMA-70B [31] and GPT-175B [5]. Appendix A includes detailed model configurations.

Baselines. We compare Optimus against three open-source MLLM training systems and one strawman baseline. DiffusionPipe [30] and DistTrain [37] are excluded from baseline comparison; the rationale is detailed in Section 6.

• PyTorch FSDP [38]: FSDP is a distributed data-parallel training module designed to scale PyTorch models across multiple GPUs with minimal code changes. It shards the model across GPUs, runs *All_Gather* to collect all shards from all ranks to recover the full parameter for forward and backward computation, and runs *Reduce_Scatter* to synchronize gradients.

• Alpa [39]: Alpa is a compiler system for distributed DL training that automatically generates parallel execution plans covering 3D parallelisms.

• Megatron-LM [20]: Megatron-LM is a state-of-the-art LLM training framework that integrates 3D parallelism techniques. Megatron-LM is designed for symmetric transformer models, and we place multimodal encoders in the pre-process in the first pipeline stage to adapt to MLLM training.

• Megatron-LM balanced: In this strawman method, we balance the layer partitioning among different pipeline stages with an interleaved 1F1B pipeline schedule. Considering the heterogeneity in MLLM submodules, we use a dynamic programming algorithm to assign different layers of submodules to pipeline stages and achieve approximately the same computation amount. The DP algorithm is a simplified version of Alpa's inter-operator DP algorithm and is included in Appendix B.

We use iteration time and Model Flops Utilization (MFU) [8] as the performance metrics. The reported performance numbers are averaged over 300 training iterations after a warm-up of 10 iterations. The detailed Megatron-LM configurations across experiments are included in Appendix D.

5.2 End-to-End Performance

5.2.1 Weak-Scaling Experiment

Experiment Setup. To study the ability to train large models, we follow common ML practice to scale the model size along with the number of GPUs. We evaluate the weak-scaling training performance of Optimus and baselines based on model configurations in Table 3.

Results. Figure 15 presents a comparison between Optimus and baseline methods across various sizes of MLLM. Optimus achieves a speedup of up to 1.22× compared to Megatron-LM and 1.18× compared to the Megatron-LM balanced. Alpa and FSDP face GPU out-of-memory (OOM) issues with these models.

Name	Encoder	LLM	#GPUs	Batch Size
Model A	ViT-11B	LLAMA-70B	64	32
Model B	ViT-22B	LLAMA-70B	128	64
Model C	ViT-11B	GPT-175B	256	128
Model D	ViT-22B	GPT-175B	512	256

Table 3: Weak-scaling MLLM configurations.

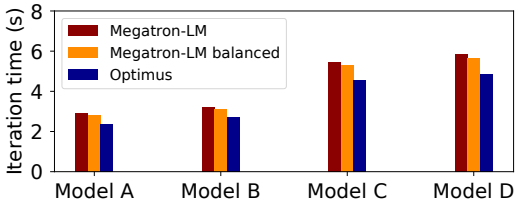

Figure 15: Weak-scaling experiment results (Alpa and FSDP are not shown in the figure because of OOM).

For our comparison with Alpa and FSDP, we crafted a modest MLLM that includes ViT-3B and GPT-11B, where Optimus demonstrates a 3.09× speedup compared to Alpa and a 15.1% improvement over FSDP, as detailed in Table 4. Further setup details can be found in Appendix C.

	Alpa	FSDP	Megatron-LM	Megatron-LM balanced	Optimus
Time (s)	8.61	3.20	3.42	3.04	**2.78**

Table 4: Training performance comparison with Alpa and FSDP.

5.2.2 Strong-Scaling Experiment

Experiment setup. We assess the strong-scaling training performance of Optimus and Megatron-based baselines using the ViT-22B+GPT-175B model. Following Megascale [13], we progressively increase the number of GPUs used (1536, 2048, and 3172) while keeping the batch size constant at 1536.

Results. Table 5 compares training performance between Optimus and Megatron-LM based baselines with an increasing number of GPUs. Optimus reduces iteration time by up to 21.3% compared to Megatron-LM, and by up to 20.5% compared to the Megatron-LM balanced. As the GPU count increases, Optimus demonstrates a greater speedup over baseline solutions. While Optimus maintains a stable MFU, baseline MFU drops at larger scales. This is expected—keeping the batch size constant while scaling up the GPU count increases the bubble ratio, allowing Optimus to schedule more encoder computation into LLM bubbles.

Batch Size	Method	GPUs	Iteration Time (s)	MFU	Aggregate PFlops/s
1536	Megatron-LM	1536	10.65	31.6%	480.7
		2048	8.26	30.6%	619.8
		3072	5.91	28.5%	866.3
	Megatron-LM balanced	1536	10.43	32.3%	490.9
		2048	8.06	31.3%	635.2
		3072	5.87	28.7%	872.2
	Optimus	1536	9.80	34.4%(**1.06**×)	522.4
		2048	7.29	34.6%(**1.11**×)	702.3
		3072	4.87	34.6%(**1.21**×)	1051.3

Table 5: Strong-scaling training performance of Optimus and baselines. The number in parentheses in the MFU column represents the speedup of Optimus compared to Megatron-LM balanced.

5.2.3 Multi-Encoder MLLM Experiment

Experiment setup. We assess the training performance of Optimus and Megatron-LM on multi-encoder MLLMs on 512 GPUs with batch size 256 (refer to Table 6). The Megatron-LM balanced baseline was excluded from this evaluation since its dynamic programming algorithm is designed to partition layers solely in MLLMs with a single encoder (linear model configuration).

Name	Encoder-1	Encoder-2	LLM
DualEnc(11B, 5B)	ViT-11B	ViT-5B	GPT-175B
DualEnc(22B, 5B)	ViT-22B	ViT-5B	GPT-175B
DualEnc(22B, 11B)	ViT-22B	ViT-11B	GPT-175B

Table 6: Multi-encoder MLLM configurations.

Results. Figure 16 illustrates the average iteration times of Optimus compared to the Megatron-LM. Optimus achieves a speedup of up to 1.25×, 1.26× and 1.27× on these MLLMs. This increased speedup by Optimus can be attributed to the Megatron-LM's approach of placing all encoders in the first pipeline stage, which leads to a more severe pipeline imbalance due to the larger total parameter count of the encoders.

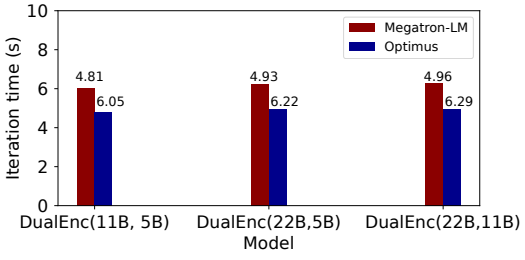

Figure 16: Training performance of Optimus and Megatron-LM on multi-encoder MLLMs.

5.3 Microbenchmarks

5.3.1 Optimus Memory

Experiment setup. We measure the GPU memory consumption of Optimus and baselines during the training of MLLMs of different sizes (listed in Table 3).

Results. As shown in Figure 17, Optimus presents a maximum GPU memory overhead of 12% when compared to the most memory-efficient baseline across various models. It is noted that Optimus uses less GPU memory than both baselines for model C and Megatron-LM balanced for model D. This discrepancy stems from the baseline's strategy of distributing computational loads across different pipeline stages, which can lead to memory imbalances due to varying hidden sizes in the encoder and LLM layers.

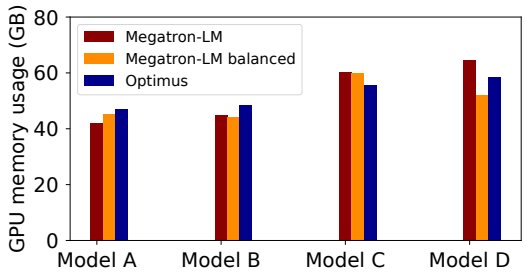

Figure 17: GPU memory usage of Optimus and Megatron-based baselines for MLLMs shown in Table 3.

5.3.2 Bubble Scheduler Algorithm

Experiment Setup. We executed the bubble scheduler algorithm on a single CPU core to compute the bubble schedule for training the ViT-22B+GPT-175B model with a global batch size of 1536 across an increasing number of GPUs (1536, 2048, and 3172), the same as the setting described in the strong-scaling experiment (Section 5.2.2). To evaluate the efficacy of the bubble scheduler algorithm, we developed a metric called *scheduling efficiency*, which quantifies the percentage of encoder computations that can be effectively scheduled within the LLM bubble. We report two efficiency metrics derived from simulations: Eff_{coarse}, observed when utilizing only coarse-grained bubble exploitation, and Eff_{fine}, observed when both coarse-grained and fine-grained bubble exploitations are activated (see §4.2). Additionally, we report

the runtime of the bubble scheduler algorithm.

Results. Table 7 illustrates that the bubble scheduler achieves higher scheduling efficiencies, Eff_{coarse} and Eff_{fine}, when operating with an increased number of GPUs for MLLM training. This improvement is attributed to the constant batch size of 1536, where the number of microbatches allocated to each LLM pipeline is reduced (32, 24, 16) as the number of GPUs increases (1536, 2048, 3172). Consequently, the LLM pipeline exhibits a higher bubble ratio due to the fixed durations of DP bubble and PP-warmup/PP-cooldown bubbles, while the total time for the end-to-end LLM pipeline decreases. Moreover, enabling fine-grained bubble exploitation can yield up to a 1.67× increase in efficiency compared to Eff_{coarse}. It is noted that the runtime of the bubble scheduler algorithm tends to decrease as the number of microbatches in the LLM pipeline reduces, due to fewer microbatch partitioning options (see algorithm complexity analysis in 4.2).

Settings	#Microbatch	Eff_{coarse}	Eff_{fine}	Runtime (s)
1536-GPU	32	34.3%	57.5%	322.2
2048-GPU	24	45.8%	69.3%	89.6
3172-GPU	16	68.7%	85.0%	15.1

Table 7: Scheduling efficiency and algorithm runtime of the bubble scheduler algorithm.

6 Discussion

MLLM training with frozen parameters. Optimus readily supports multi-stage training workflows commonly used in practice, such as those adopted by LLaVA [18]. While our paper focuses on the general setting where all parameters—including those of the encoder and LLM—are updated, Optimus can naturally adapt to stages where only adapters are trained. In such cases, Optimus schedules the encoder + adapter forward pass and the adapter's backward pass into the LLM pipeline bubbles, while skipping the encoder's backward computation due to frozen parameters. This maintains correct data dependencies and continues to utilize bubbles effectively.

Complex computation graph. Optimus focuses on the bubble scheduling on a typical MLLM model architecture, which consists of multimodal encoders followed by one LLM. We may further explore the bubble scheduling for complex MLLM computation graphs. A new partitioning algorithm is required to divide the computation graph into the backbone pipeline schedule and the bubble-filling workload. And the bubble scheduling algorithm of Optimus can be easily extended to the partitioned computation graph.

Other pipeline schedules. We use a widely used Megatron-LM interleaved 1F1B pipeline schedule for MLLM training. However, there exist other pipeline schedules (e.g., Chimera [16] and zero-bubble pipeline [23]) that may have superior performance in certain scenarios. The bubble scheduling of Optimus is orthogonal to these pipeline schedule optimizations, and Optimus can be applied to other pipeline schedules when the specific encoder-LLM dependency is analyzed and addressed.

Online scheduling. Our bubble scheduling algorithm simplifies execution by omitting the consideration of fluctuations in CUDA kernel runtime. We collect performance statistics, such as kernel execution time, to detect bubbles during a training step, assuming consistent behavior in future steps. However, deviations from predicted execution times can lead to suboptimal scheduling, with larger or altered pipeline bubbles. A possible solution is real-time performance monitoring to dynamically adjust the schedule.

Exclusion of DiffusionPipe and DistTrain as Baselines. We explicitly exclude DiffusionPipe [30] and DistTrain [37] from our set of baselines for the following reasons. DiffusionPipe is specifically designed for diffusion models and has been evaluated only on small-scale clusters ($\leq$64 GPUs). Its focus on a different model family and scale makes it ill-suited for comparison with Optimus, which targets large-scale multimodal LLM (MLLM) training across thousands of GPUs. DistTrain relies on a simplified model partitioning strategy that can result in significant pipeline imbalance when applied to the heterogeneous structures of MLLMs. Furthermore, DistTrain is not open source, preventing direct empirical comparisons.

7 Related works

Multi-modal training. Pytorch FSDP training [38] supports only data parallelism and is less efficient than hybrid parallel strategies. Alpa [39] automates parallelism for various models but falls short by not supporting state-of-the-art 1F1B-interleave pipeline parallelism [20] and requiring more memory than the optimized Megatron-LM framework [25], also missing opportunities in pipeline optimization due to its unified view of encoders and decoders. DistMM [12] provides solutions to orchestrating multiple parallel encoders, but it is designed for contrastive learning and overlooks the decoder, leaving a gap in comprehensive training efficiency. DiffusionPipe [30] and DistTrain [37] are two additional works on multi-modal training, each with limitations outlined in the previous section.

Bubble reducing. Previous efforts in reducing "bubbles" have approached the problem from various angles. The 1F1B-interleave pipeline [20] technique minimizes bubbles by chunking the model and alternating these chunks across different stages, whereas the Zero bubble pipeline [23] approach further granulates backward pass computations to eliminate bubbles. However, in practice, the Zero bubble pipeline schedule cannot completely remove all pipeline bubbles because it requires changes to the optimizer, which raises concerns about end-to-end model convergence. On the other hand, asynchronous tensor parallelism [26] and Google's overlapping

technique [32] aim to overlap tensor parallelism communication with computation, but are limited by specific hardware configurations and struggle to maintain full overlap as computing capabilities advance.

Bubble exploiting. Pipefisher [22] leverages pipeline bubbles across multiple training steps to complete the K-FAC, whereas our method operates within a single synchronized training step, focusing on immediate optimization. Hydro's Bubble Squeezer [11] utilizes GPT model bubbles for independent tasks like hyperparameter tuning, which can not enhance the performance of the training steps themselves. Bamboo [29] employs pipeline bubbles for redundant computations to mitigate the impact of preemption in training on volatile instances, based on the assumption that later pipeline stages host more layers, which often does not hold in large language model (LLM) training scenarios.

8 Conclusion

We present Optimus, a distributed MLLM training system that enables the scheduling of encoder computation within LLM bubbles to reduce end-to-end MLLM training time. To reduce GPU bubbles during MLLM training, Optimus partitions multimodal encoders and the LLM backbone, and schedules encoder computation in LLM bubbles. We search for the optimal parallelism plan for the encoders with the consideration of memory and computation resource constraints, which balances the encoder computation among GPUs for bubble filling. Optimus further employs a bubble scheduling algorithm to address encoder-LLM dependency and select the optimal schedule for filling kernel-level encoder computation into sub-millisecond LLM bubbles. Our extensive experiments demonstrate that Optimus can accelerate MLLM training by 20.5%-21.3% with ViT-22B and GPT-175B models over 3072 GPUs compared to baselines and significantly outperforms existing MLLM training systems by 20.3% on average.

A MLLM model configurations

Here we list all the the MLLM configurations used in the evaluation experiments of Optimus. ViT encoder configurations can be found in Table 8. LLM backbone configuration can be found in Table 9. In all experiments, we use sequence length 2048.

Table 8: Model configurations for ViT.

Models	Width	Depth	MLP dimension	Heads	Attention head dimension	Params
ViT-3B	2304	48	9216	18	128	3B
ViT-5B	3072	48	12288	24	128	5.5B
ViT-10B	4096	48	16384	32	128	10B
ViT-22B	6144	48	24576	48	128	22B

Table 9: Model configurations for LLM.

Models	Width	Depth	Heads	Attention-head dimension	Params
GPT-11B	3072	80	24	128	11B
LLAMA-70B	8192	80	64	128	70B
GPT-175B	12288	96	96	128	175B

B Megatron-LM balanced DP algorithm

We employ a dynamic programming (DP) algorithm to assign layers to different virtual stages for the Megatron 1F1B-interleaved schedule [20]. Following Alpa [39], the DP algorithm aims to minimize the latency of the slowest stage to reduce the end-to-end latency of the pipeline schedule. Given a pipeline parallel size of PP and V model chunks configured, the DP algorithm seeks to minimize the latency of the slowest virtual stage. It determines the optimal layer partition strategy that distributes layers across these $V \times PP$ virtual stages.

We define the function $F(l,m)$ to represent the maximum latency of a single virtual stage when the first m virtual stages. The computation begins with $F(l,1) = \sum_{i=1}^{i \le l} t_i$, where t_i denotes the execution time of the i-th layer (estimated based on FLOPs). The optimal structure of F is:

$$F(l,m) = \min_{j<l}(\max(F(j,m-1), \sum_{i=j+1}^{i \le l} t_i))$$

For a MLLM model with L layers, the layer partition strategy is determined by calculating $F(L, V \times PP)$ and recording the partitioning results to find the optimal solution. This ensures that the latency of the longest virtual stage, $F(L, V \times PP)$, is minimized across all virtual stages in a 1F1B-interleaved pipeline schedule. The dynamic programming algorithm described above is suitable for MLLM configurations with a single encoder, where encoder layers and LLM layers follow a linear structure. However, this DP algorithm does not apply to MLLM models that feature multiple encoders, as these encoders do not have data dependencies among each other.

C Comparison of Training Performance between Optimus, Alpa, and FSDP.

Experiment setup. To facilitate a comparison with Alpa and FSDP, we constructed a modest MLLM consisting of ViT-3B and GPT-11B, with specific configurations provided in Appendix A. We assessed the training performance using 8 NVIDIA A100 GPUs, as we encountered issues with the CUDA library when attempting to run Alpa on NVIDIA Hopper GPUs. The global batch size was set at 16, and the sequence length was 2048.

Results: According to Table 10, Optimus achieves a 3.09× speedup over Alpa and a 15.1% improvement over FSDP.

	Alpa	FSDP	Megatron-LM	Megatron-LM balanced	Optimus
Time (s)	8.61	3.20	3.42	3.04	**2.78**

Abstract

Rack-scale CPU scheduling has emerged as a promising direction to accommodate the increasing demands for microsecond-level services. However, prior work suffers from both inaccurate load balancing in the network and complex yet sub-optimal scheduling within each server due primarily to its application-agnosticism. This paper presents Pallas, an application-aware rack-scale CPU scheduling solution for microsecond-level services with near-optimal performance. At the heart of Pallas is an *in-network workload shaping* to partition the workload into different shards, each of them preserving high homogeneity regarding the CPU demands. With the shaped workloads, Pallas then performs simple yet near-optimal inter-server load balancing and intra-server scheduling. We have fully implemented Pallas and our extensive experiments across various synthetic workloads and real-world applications demonstrate that Pallas significantly outperforms the state-of-the-art solution RackSched by delivering stably low tail latency and high throughput, reducing tail latency by 8.5× at medium load and as much as two orders of magnitude at high load, while gracefully handling long-term workload shifts and short-term transient bursts.

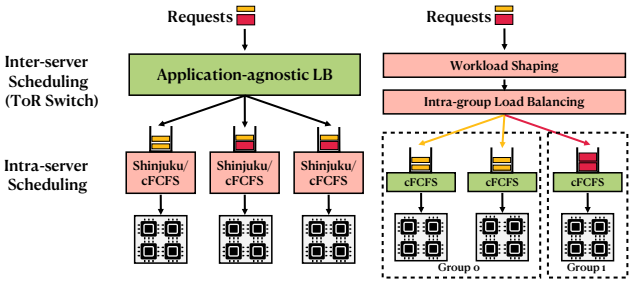
1 Introduction

Modern datacenters have deployed many user-facing applications for online services, such as key-value stores [9, 12, 13], interactive data analytics [55], search ranking & sorting [16], and function-as-a-service [19]. These services typically have strict service level objectives (SLOs) that require the applications to provide high throughput with *low tail latency* in the range of tens to hundreds of *microseconds* [15, 25]. To serve the increasing application demands, rack-scale CPU scheduling [53, 56, 85] have been proposed to scale beyond a single server to multiple servers within a rack. For example, as shown in Figure 1a, previous solution RackSched [85] leverages a programmable switch to perform inter-server load balancing and utilizes existing dataplane operating system, Shinjuku [45], for intra-server scheduling.

While RackSched enables cross-server scheduling, we find that it fails to provide consistently low tail latency for diverse workloads due to two key reasons. First, its Join-the-Shortest-Queue (JSQ) based inter-server load balancing method operates in an *application-agnostic* manner. Without the knowledge of the load each request generates at each server, it may cause *load imbalance* between servers. Second, this application-agnostic method also leads to assigning each server a mix of long and short requests, leaving the challenging *Head-of-line (HoL) blocking* problem to each intra-server scheduler. Unfortunately, our experiment in §2 shows that existing intra-server scheduling algorithms cannot provide near-optimal or even satisfactory low tail latency over heterogeneous workloads, resulting in ∼50× slowdown compared to the ideal.

This paper asks: *Can we design a rack-scale scheduler for microsecond-level services that can deliver consistently low tail latency and high throughput over diverse workloads?* To answer this question, we present Pallas, a novel approach for rack-scale CPU scheduling with near-optimal low tail latency and high throughput.

To design Pallas, we make an important observation: while it is challenging for each server to schedule mixed workloads, it is easier to schedule a *homogeneous* workload with near-optimal tail latency. Based on this observation, we propose to resolve both load imbalancing and HoL problem at network level through *workload shaping*. Our key idea is to proactively transform mixed workloads into groups of uniform ones, reducing the workload variance for servers. Then each server only needs to handle a shaped and uniform workload, which can be easily processed by simple scheduling algorithms to achieve optimal tail latency. Realizing this idea requires accurately estimating server load generated by each request and network devices capable of categorizing requests based on the estimation. Prior works have shown that existing data center application characteristics [29] and programmable switches [8] can achieve both requirements (§3). For instance, the service types can be inferred from the packet headers in key-value stores [9, 12] or in-memory databases [69, 75], and the CPU demands can be monitored and correlated with the



service types.

We fully explore *workload shaping*, aided by the above techniques, to design Pallas (Figure 1b), which decomposes the rack-scale scheduling into three levels : i) *workload-level shaping* runs at the ToR switch and partitions the entire workloads into different serving groups according to the estimated request CPU execution duration, with the goal to preserve group-level workload homogeneity; ii) group-level scheduling that also runs at the ToR switch and dispatches requests between servers within a group, ensuring equal load distribution among servers; and iii) server-level scheduling that runs at each server and steers uniform requests to CPU workers using the simple yet effective centralized First Come First Serve (cFCFS) policy. These three scheduling levels work in concert for Pallas to achieve the near-optimal tail latency (explained in §3).

Specifically, to translate the above 3-level architecture into a practical end-to-end system, Pallas addresses the following three challenges raised by real application characteristics and existing programmable switches:

- *Generating an effective scheduling policy that balances performance and server utilization* (§4.3): The scheduling policy, which decides how to divide workloads into groups, significantly impacts the ultimate performance. The key challenge lies in balancing workload homogeneity with server utilization: more groups might improve tail latency but lower server utilization, while fewer groups could optimize resource usage but potentially compromise tail latency. We address this challenge by designing a performance-oriented methodology to generate policy candidates with a tailored clustering algorithm and obtain the best performant workload shaping policy via micro-benchmarks.
- *Handling workload change gracefully via request bouncing* (§4.4): As the workload shifts over time, a static scheduling policy may become suboptimal. Simply replacing the policy is not sufficient and may result in temporal performance degradation during the transition. To provide consistently low tail latency, we dynamically adapt scheduling policies to runtime workloads and propose a request bouncing mechanism to resolve the temporal HoL blocking during the policy transition by prioritizing the precedence of short requests over long requests.
- *Mitigating transient workload burst via request cloning* (§4.5): To mitigate temporal server overload caused by bursty traffic, which happens in workload due to inherent variances, and avoid performance degradation, we propose a novel burst-aware request cloning which masks the tail latency inflation by cloning the overloaded requests to the under-utilized servers. Compared to the idea of traditional cycle stealing often used to mitigate intra-server burst [29], our approach offers a no-regret control and ensures the burst handling does not result in worse tail latency.

We have implemented the fully functional Pallas (§5) with commodity programmable switch, and evaluate it extensively

(a) Arch. of RackSched. (b) Arch. of Pallas.

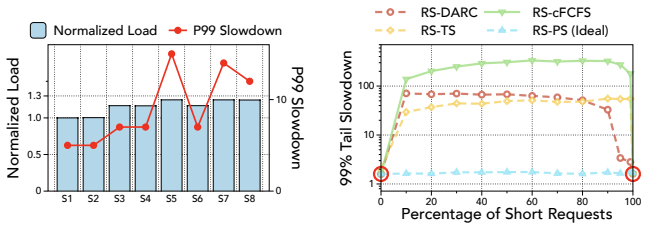


Figure 1: Rack-scale scheduling architectures: RackSched vs Pallas.

using a combination of synthetic workloads and real applications. Our results demonstrate that Pallas significantly outperforms RackSched [85] in terms of stably lower tail latency and higher throughput across various workloads (§6). For instance, compared to RackSched, Pallas reduces the tail latency by 8.5× and 5.5× in synthetic bimodal workload and real workload application RocksDB [13] at medium load, respectively. Besides, Pallas achieves 2.3× higher throughput than RackSched in the trimodal workload for the same tail latency objective, and reduces the tail latency by two orders of magnitude at high load in RocksDB. In addition, we show that Pallas can gracefully adapt to workload shifts and efficiently handle microsecond-level workload bursts. Our experiments further show that Pallas can preserve the performance superiority over other related solutions [56, 76, 82] (§6.5).

Similar to existing literature [53, 56, 76, 82, 85], Pallas focuses on stateless or replicated stateful services, including microservices, stream processing and replicated caches and storage. Supporting stateful services is beyond the scope of this paper. Besides, Pallas expects that the workloads' CPU demands can be statistically estimated based on historical data (see more details at §7).

Comparison with prior work. Compared to the DARC algorithm in Perséphone [29], which focus on intra-server isolation through CPU core partitioning, Pallas operates at rack scale, leveraging programmable switches to partition heterogeneous workloads before they reach servers. This architecture enables simplified and near-optimal scheduling both across and within servers. To the best of our knowledge, Pallas is the first to introduce application-aware workload shaping directly within the network switch, which differs from RackSched's application-agnostic load balancing, proactively preventing server-side HoL blocking rather than merely reacting to it after the damage is done. Moreover, while Pallas adopts request cloning to handle short-term workload bursts—a technique used by NetClone [53]—Pallas performs this selectively, within already-shaped workload groups, avoiding the excessive overhead of general-purpose cloning.

We open-source Pallas at `https://github.com/HKUST-SING/pallas`.

(a) Inter-server load imbalance. (b) Intra-server HoL blocking.

Figure 2: Existing rack-scale scheduler is inefficient.

2 Rack-scale Scheduling and Status Quo

Serving µs-level services at the rack scale requires the scheduler to provide both low-tail latency to serve requests and high throughput to utilize hundreds to thousands of cores in the rack. Recent work RackSched [85] is the representative rack-scale µs-level scheduler. As shown in Figure 1a, RackSched employs a two-level scheduling hierarchy: an inter-server scheduler in the top-of-rack (ToR) switch and an intra-server scheduler within each server. The inter-server scheduler tracks real-time server loads and selects a server for each request based on its current load. Then the intra-server scheduler assigns the request to its workers, leveraging an existing intra-server scheduling mechanism like Shinjuku [45] for high-dispersion workloads and centralized First-Come-First-Serve (cFCFS) for low-dispersion workloads.

Despite being promising, we have identified two main issues with RackSched that result in long tail latency: load imbalance between servers and head-of-line blocking at each server.

Load imbalance between servers. RackSched employs a Join-the-Shortest-Queue (JSQ)-based load balancing algorithm, directing requests to servers based solely on their queue lengths by having servers relay their load information to the inter-server scheduler. This *application-agnostic* method, lacking insight into the specific load each request imposes on servers, can inadvertently cause load imbalances between servers. This is particularly evident when different types of requests demand varying server resources. For instance, in Figure 1a, the first two servers have the same queue lengths. However, they manifest distinct loads due to the variability in the execution times of their respective requests.

Besides, it faces challenges in accurately capturing µs-level load dynamics. The inherent delay, approximately one RTT (around 10µs), required to obtain queue length data means that by the time the scheduler is updated, the server's actual load might have shifted. This results in the inter-server scheduler operating on potentially outdated and inaccurate load information. To understand this problem experimentally, we run RackSched to schedule requests among eight servers[1] and report their normalized perceived load and 99% tail slowdown in Figure 2a. We report the slowdown instead of latency as it better reflects the impact of long requests on shorter ones. The observation is that the load imbalance between servers can lead to a significant discrepancy in tail slowdown (∼3×).

Head-of-line blocking at each server. Given its application-agnostic load balancing strategy, the RachSched inter-server scheduler may distribute both long and short request types to each server. As a result, each server needs to address the challenges of head-of-line blocking, ensuring short requests are not blocked by longer ones. Unfortunately, even advanced intra-server schedulers [29, 45, 72] struggle to consistently offer near-optimal tail latency across diverse workloads.

To demonstrate this issue, we evaluated RackSched's performance using a Bimodal workload (short=1µs,long=100µs) with varying short-to-long request ratios. We integrated RackSched with four representative intra-sever scheduling solutions: i) Centralized first-come-first-serve (cFCFS) from ZygOS [72] and Shenango [68] which serves requests based on their arriving order; ii) Time Sharing (TS) from Shinjuku [45] which uses *preemption* to prioritize short requests [2]; iii) DARC from Perséphone [29] which reserves *dedicated cores* for short requests; and iv) Processor Sharing (PS) which is an *ideal yet impractical* one for comparison. We simulate it with 0.1µs preemption slice without *any* overhead. The simulation is based on ten servers, each equipped with twelve cores. All schemes are executed under a 95% load to highlight the performance discrepancy distinctly[3].

Figure 2b presents the results, with RS-X denoting RackSched combined with intra-server scheduling algorithm X. We find that all practical algorithms (cFCFS, TS, DARC) exhibit a notable performance gap compared to the *ideal yet impractical* algorithm RS-PS when the workload has a mix of short and long requests. This disparity becomes especially evident when the proportion of short requests ranges between 10% and 90%. By analyzing these solutions, we can see that cFCFS fails to address the HoL problem due to its inherent scheduling approach, processing earlier arriving long requests ahead of shorter ones. Despite TS and DARC using preemption or core reservation to mitigate the HoL problem, they also cannot fundamentally resolve it in practice and result in long tail latency.

To summarize, current rack-scale scheduling employs application-agnostic load balancing between servers, assigning a mix of short and long requests to each server. This approach essentially leaves the challenging HoL blocking problem to each intra-server scheduler, which unfortunately cannot be optimally resolved by any of the existing solutions.

[1] Refer to the `high` load case in §6.4.1 for the detailed experimental setting.

[2] RackSched uses Shinjuku (TS) with a 250µs preemption time slice by default. After adjustments, a 50µs time slice yielded satisfactory results for our setting. We simulate its context switching overhead as 1µs.

[3] Under light load, these schemes exhibit comparable performance, which is consistent with the results presented in [45].

3 Key Idea: In-Network Workload Shaping

Despite it is hard to optimally schedule mixed workloads within each server, we observed that it is easy to schedule *homogeneous* workloads. As shown in Figure 2b, when the proportion of short requests is 0% (purely long) or 100% (purely short), the three scheduling solutions—RS-cFCFS (theoretically optimal in these cases), RS-DARC, and RS-TS—achieve tail latencies comparable to the ideal RS-PS.

This observation led us to a novel approach: *in-network workload shaping*. By transforming mixed workloads into groups of homogeneous workloads at the network level, we can address the scheduling complexity within the network rather than leaving it to each server. This allows each server only needs to handle one type of request, either short or long, making it easy to achieve optimal performance.

There are two opportunities that support realizing the in-network shaping approach. i) As underscored by [29], cloud applications have the capability to transparently display request types within message headers. For example, Memcached [9] exposes request types at packet headers; Redis [12] specifies commands with a serialization protocol; Remote Procedure Calls (RPCs) with protobuf [2] can define message types. Notably, requests sharing the same type frequently demonstrate analogous processing behaviors and hence similar execution durations. Based on this observation, we can monitor the execution patterns of each type of request, enabling estimations of request execution durations based on these information. ii) Commodity datacenters are equipped with programmable switches, which provide programmable dataplane that can be leveraged to perform the workload estimation by extracting information from packet headers and hence implement advanced scheduling algorithms based on the estimated workload.

Our high-level architecture is shown Figure 1b. The programmable Top-of-Rack (ToR) switch stands central to this design, proactively partitioning mixed workloads into groups of uniform workloads based on their estimated running time. Each designated subset of servers then focuses on a specific workload group, with an intra-group load balancer ensuring even load distribution between servers. Then at each server, the intra-server scheduler handles requests using the simple and optimal cFCFS algorithm.

This architecture can effectively address the two limitations of existing rack-scale scheduling approaches to achieve near-optimal performance. i) *Accurate load balancing*: Within a given group, the actual load is proportional to the cumulative request numbers, enabling a more precise load balancing between servers. ii) *Eliminating HoL blocking*: After workload shaping, each server only needs to handle a specific type of request. This significantly eliminates HoL blocking problem for most servers. Only a few servers need to handle it when the workload cannot be entirely partitioned. By mitigating the HoL blocking, a simple cFCFS intra-server scheduler can be used to achieve optimal tail latencies.

Why this is theoretically near optimal. The CPU scheduling problem can be formalized as the classical `M/G/K` queuing problem [52]. While it can be theoretically resolved by JSQ/cFCFS and JSQ/PS for inter-server and intra-server scheduling, respectively, our findings in §2 have revealed that these approaches are impractical or inefficient for µs-level latency. Fortunately, `M/G/K` can be decomposed into multiple `M/D/K′` subproblems, each exhibiting deterministic workload. Wierman et al. [80] shows that FCFS is tail-optimal for deterministically light-tailed workload within each server, while round-robin is near-optimal for balancing the load between servers within each `M/D/K′` model. This convinces us that a near-optimal framework can be achieved through in-network workload shaping, which distributes homogeneous and deterministic workload for each server.

4 Pallas Design

In this section, we first discuss the design challenges of Pallas, then overview its workflow, and finally describe its design details for addressing these challenges.

4.1 Design Challenges

Realizing the idea of *in-network workload shaping* into a practical system presents three outstanding technical challenges:

- **How to generate an effective workload shaping policy?** Creating an effective scheduling policy requires i) accurately estimating the workload, ii) partitioning the mixed workload into groups based on estimated server loads, and iii) mapping these groups to available servers. The key challenge lies in balancing workload homogeneity with server utilization: more groups might improve tail latency but lower server utilization, while fewer groups could optimize resource usage but potentially compromise tail latency.
- **How to gracefully handle long-term workload changes?** A scheduling policy may become suboptimal as the workload distribution shifts over time. Simply replacing the scheduling policy to accommodate workload dynamics is not sufficient and may result in temporal tail latency degradation. For instance, new scheduling policy that transitions servers from groups serving long requests to the groups for short requests may incur HoL blocking.
- **How to efficiently handle short-term transient bursts?** Pallas encounters limitations in capturing microsecond-level dynamics due to the coarse-grained control granularity of long-term workload changes handling, especially in the face of transient partial workload surges due to its inherent variances. As a result, it is imperative for Pallas to incorporate a mechanism to mitigate the impact of these transient spikes.

4.2 Overview

Figure 3 shows the high-level workflow of Pallas. Pallas runs the inter-server scheduler as the ToR switch and the intra-

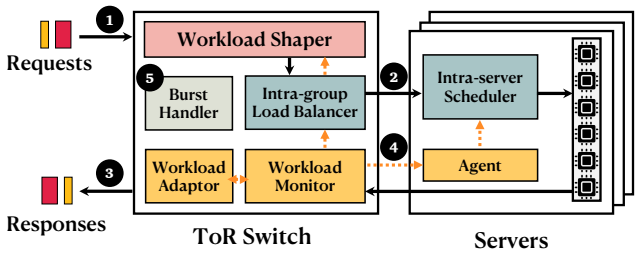

Figure 3: Pallas overview.

	Request Type	Time(μs)
RocksDB	GET(10)	12
	SCAN(5000)	650
TPC-C	Payment	5
	OrderStatus	6
	NewOrder	16
	Delivery	62
	StockLevel	74

Table 1: Workload examples of RocksDB and TPC-C with request types and corresponding execution times. GET(10) and SCAN(5000) denote retrievals of 10 values and scanning 5000 keys-value pairs, respectively.

server scheduler at each server. Central to the key workload shaper, Pallas composes two other components: intra-group load balancer and intra-server scheduler. Each component implements a portion of the scheduling policy, which is initially generated offline (§4.3).

Workload Shaper. The workload shaper proactively transforms mixed workloads into groups of homogeneous workloads at the ToR switch based on the request types shown in the packets (step ❶). This stems from the observation that the same type of requests have similar execution times on servers. For example, Table 1 shows the execution times of RocksDB and TPC-C workloads we profiled (details in §6.1), which are also used in [29, 45]. Clearly, the GET(10) and SCAN(5000) requests of RocksDB can be explicitly clustered into two groups. On the other hand, TPC-C necessitates a more nuanced grouping approach (e.g., NewOrder could be its own group or merged with Payment and OrderStatus requests).

Based on the well-shaped workloads, Pallas is able to perform *simple yet near-optimal* intra-group load balancing and intra-server scheduling according to the initially generated policies.

- **Intra-group load balancer.** After determining the group for each workload request, the load balancer is responsible for distributing the requests to servers within the group. To minimize the impact of load imbalance between servers, it leverages the weighted-round-robin (WRR) algorithm to distribute request to each server based on their provisioned computation capacity for the group (step ❷). WRR optimally weighted-balances the perceived number of requests for servers within a group, aligning with their provisioned computation capacity. We note that it is less practical for the intra-group load balancer to directly determine the CPU core for each request. The reason stems from the challenge of accurately tracking the states of hundreds to thousands of CPU cores within a rack at microsecond-scale [53, 85]. The core state requires one RTT to update in the ToR switch, which may introduce stale information and lead to inefficient scheduling decisions.
- **Intra-server scheduler.** After group-level load balancing, servers dispatch the well-shaped, load-balanced request streams to different CPU cores with optimal scheduling policy. Specifically, they use the simple and optimal cFCFS algorithm to serve the uniform workload. If the workload cannot be fully partitioned, a few servers that are allocated to handle multiple groups use the DARC algorithm [29]. Note that the workload monitoring and estimation in the Pallas framework are conducted at ToR switch. Therefore, the server employing the DARC algorithm is exempted from redundant workload estimations.

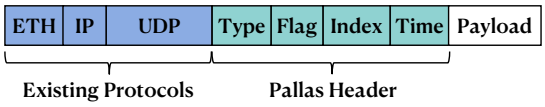

Figure 4: Packet format of Pallas.

Workload monitoring and change adaptation. To facilitate workload estimation, Pallas server embeds the actual execution duration of each request in the header of its corresponding response packet. The *workload monitor* extracts this information and updates the dataplane record registers when processing the response packets (step ❸). The control plane of the switch executes a *workload adaptor* to periodically read information from workload monitor, craft the appropriate scheduling policies (step ❹), and provision resources if it deduces significant long-term workload shifts (§4.4). When Pallas detects a bursty arrival of requests, the dataplane *burst handler* implements a no-regret burst reaction mechanism (step ❺) to mitigate the burst on time (§4.5).

Packet format. Figure 4 depicts the packet header format of Pallas's request and response. It consists of four major fields: 8-bit `Type`, 8-bit `Flag`, 32-bit `Index` and 32-bit `Time`, which are used for request grouping in workload shaping, request cloning in burst handling (§4.5), redundant replies filtering, and actual execution time of request recording in workload monitoring, respectively. Note that currently Pallas assumes each request is contained in one packet. Supporting requests with multiple packets is not the primary objective of this paper. However, this can be realized by incorporating RackSched's request affinity mechanism [85] into Pallas, which is feasible given Pallas's low hardware footprint as shown in §5.

4.3 Scheduling Policy Generation

In this subsection, we first describe how Pallas generates workload shaping policy, which is the core of Pallas to shape

uniform workload, and then elaborate how Pallas leverages it to provision resources and formalize the scheduling policies.

Balancing homogeneity and server utilization. Pallas should derive an effective request group mapping policy that preserves high group-level workload homogeneity with high system utilization. Drawing from the TPC-C workloads example[4] (Table 1), we observe that request types such as *Payment*, *OrderStatus*, and *NewOrder* exhibit comparable CPU demands. If one were to prioritize sheer request homogeneity, these types should be allocated to disjoint serving groups. However, such a configuration fragments system resources and may inadvertently result in more system idling, inducing system inefficiencies. Conversely, incorporating these request types within a single serving group could compromise group-level homogeneity, which may potentially result in a discernible performance deviation from the optimal. In summary, more groups improve homogeneity (potentially lowering latency) but risk lower utilization; fewer groups improve utilization but risk HoL blocking. Therefore, how to find a group mapping policy that achieves high intra-group homogeneity with high system efficiency remains a problem.

Since it is intractable to find the optimal policy analytically, we resort to a performance-oriented greedy mechanism to derive a solution inspired by [30]. This mechanism encompasses two primary stages: i) generation of group mapping and ii) selection of candidates. We describe each stage below by visualizing policy generation with TPC-C workload in Figure 5.

Group mapping candidates generation (step ⓐ). We employ a clustering algorithm to generate several group mapping candidates. With the monitored workload information, the algorithm derives group mapping policies by aggregating similar request types considering both the monitored CPU demands and their proportions across all requests with customized k-means algorithm.

Optimal candidate selection (step ⓑ). Upon obtaining all candidates from the preceding procedures, we aim to identify a policy that optimizes tail latency without compromising system utilization. To this end, we employ a performance-oriented strategy to obtain the most appropriate group mapping policy, with the focus on an empirical metric, i.e., 99th percentile latency, that matches our performance objective. Specifically, we compare the group mapping policies through offline simulations and evaluate their 99th percentile latencies. Consequently, the policy with the best objective value is selected (e.g., *Final Mapping* Table in Figure 5). We summarize these two steps in Algorithm 1 in Appendix §A.

Resource provisioning (step ⓒ). Upon determining the definitive request grouping policy, we compute the cumulative CPU demands for each group and allocate the requisite CPU resources to each serving group according to the reported computing capacity of each server (e.g., `server indices` in *Intra-group LB Policy* Table). We denote r as a class of requests with the same type, e.g., GET, E_r as the average execution time of r, ϕ_r as the ratio of r among all requests, $\mathcal{D}_r$ and $\mathcal{D}_g$ as the CPU demand of r and serving group g, respectively. We compute the CPU demand of each serving group and allocate resources as follows:

$$\begin{aligned} \mathcal{D}_r &= \frac{E_r \times \phi_r}{\sum_i E_i \times \phi_i} \\ \mathcal{D}_g &= \sum_{r \in g} \mathcal{D}_r \\ \mathcal{R}_g &= \frac{\mathcal{D}_g}{\sum_{g \in G} \mathcal{D}_g} \times \mathcal{R}_{total}, \end{aligned} \tag{1}$$

where G indicates total serving groups, $\mathcal{R}_g$ denotes the CPU resources allocated to serving group g, and $\mathcal{R}_{total}$ represents the total CPU resources provisioned to the application. It is noteworthy that Pallas allocates resources at fine-grained core-level. Hence, certain groups might be allocated with fractional server numbers, for instance, 12 cores in 1.2 servers for group 0 in the example. In such scenarios, a few servers will cater to multiple groups. To temper the scheduling intricacies throughout the system, our resource provisioning strategy guarantees that only a small number of servers serve multiple groups via gathering them to the same servers as much as possible.

Scheduling policy generation (step ⓒ and ⓓ). Upon finalizing the request grouping policy and resource allocation for each serving group, Pallas configures the policies in switch and each server, thereby establishing the system's request scheduling policy. When serving groups occupy multiple servers, the workload monitor formulates an intra-group load balancing policy and updates the load balancing table with weight values which correlate to the provisioned cores for each server within that group (e.g., `Round-Robin Weights` in *Intra-group LB Policy* Table). Concurrently, Pallas sends the intra-server scheduling policies (e.g., *Intra-server Sched. Policy* Table) to the agents located on each server. These transmitted policies encapsulate the scheduling algorithms and the relevant per-serving group CPU cores reservations, if any, especially in scenarios where a server accommodates multiple serving groups. In this way, the intra-server scheduler is able to conduct scheduling following the relayed scheduling policy from the agent.

Workload variance handling. We note that Pallas is resilient to the execution time dispersion as found in real workloads via the use of Exponential Weighted Moving Average (EWMA) for tracking execution times. EWMA inherently tolerates dispersion by capturing the central tendency, providing a stable average for grouping decisions even with variance in individual requests. As long as the EWMA-derived average execution times between different types of requests are sufficiently distinguishable, Pallas can effectively separate them into appropriate groups. Furthermore, the policy generation

[4] We use the TPC-C workload to examplify a workload with n-modal distribution.

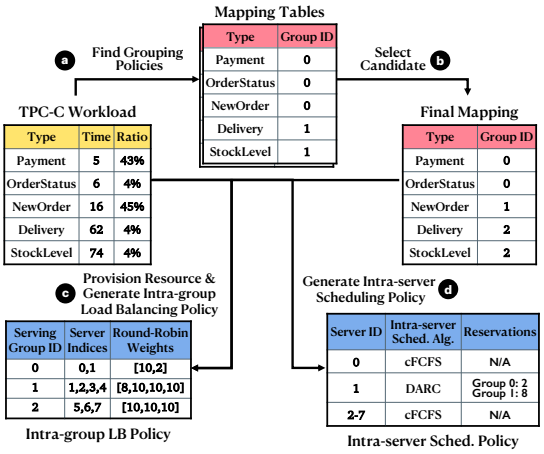

Figure 5: Example of generating a scheduling policy for the TPC-C workload across eight servers, each equipped with 10 cores.

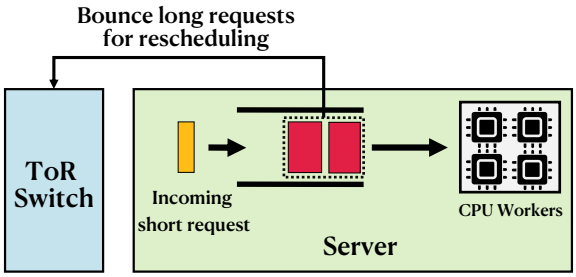
process itself evaluates grouping candidates based on overall empirical performance evaluated by simulation. This process selects groupings that perform well despite the expected level of intra-group variance inherent in the EWMA-based assignment.

4.4 Long-term Workload Change Adaptation

As workloads may vary over time, Pallas is tailored to accommodate workload changes and recalibrate its generated scheduling policies dynamically. It monitors real-time workload metrics in the switch control plane by accessing the state registers within the switch dataplane.

Workload change detection. Leveraging the detailed per-request metrics, i.e., average request execution time and total number of requests within a monitor interval, Pallas workload adaptor periodically assesses the new aggregated demand of each serving group in comparison to its allocated CPU resources. In particular, it examines the discrepancy between the allocated CPU resources and the real-time demand as inferred from the latest monitored workload data for each serving group, with the resource allocation methodology in §4.3. It then computes the cumulative demand discrepancy across all serving groups as the resource provision process in §4.3. If this discrepancy exceeds a predetermined threshold δ, Pallas activates a workload change reaction mechanism. Currently, the workload adaptor works at a 10ms granularity to capture relatively long-term workload changes. In our evaluation, we set δ to 10 and study its sensitivity in the Appendix §D.3.

Workload change reaction. In response to the detected workload changes, Pallas adapts its scheduling policies swiftly. Specifically, Pallas re-invokes the workload estimation methods outlined in §4.3 to formulate new policies for both inter-server and intra-server scheduling. Subsequent to this, the related tables within the switch dataplane are updated. It is



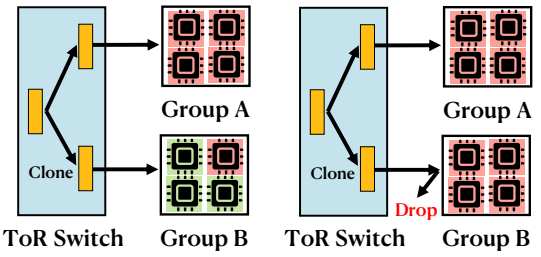


Figure 6: Pallas request bouncing.

worthy to highlight that, in order to temper potential disruptions during the policy reconfiguration phase which makes the system unstable and hence hurts the tail latency, Pallas adopts an *incremental update approach*. This includes caching the previously enforced scheduling policies in workload monitor and determines their deviation from the newly devised policies. Pallas then selectively updates only those segments of the policy tables that should be changed, thereby curtailing the reconfiguration duration. Additionally, Pallas restricts the number of servers impacted by the reconfiguration, via preserving the established roles of servers in relation to their serving groups and making adjustments only when necessary.

Request bouncing. Pallas aims to eliminate HoL blocking through in-network workload shaping. To accommodate workload dynamics, Pallas periodically revises its scheduling polices. This periodic adjustment leads to the reallocation of end-host servers across various serving groups. Consequently, during such reconfiguration phases, short requests within Pallas might experience temporary HoL blocking. This scenario arises especially when new servers, which previously catered to long requests, are allocated to serve short requests. As such, the HoL dilemma can resurface during switch reconfiguration phases. To address this, we introduce a novel *request bouncing* mechanism, ensuring Pallas navigates reconfiguration phases seamlessly. When a Pallas server receives new scheduling decisions, such as serving groups from long requests to short requests, we prioritize the processing of incoming short requests, thereby proactively emptying existing queues of long requests that might induce HoL blocking. To achieve this, the Pallas server compares its current serving groups against newly arriving ones. As shown in Figure 6, if the new request should take precedence by exhibiting relatively shorter CPU demands, Pallas purges the current queue, bouncing the requests back to the switch for re-scheduling. This approach stems from the rationale that the network transmission time introduces less slowdown penalty on long requests, especially when compared with the performance degradation by HoL blocking that would impose on shorter requests.

4.5 Short-term Transient Burst Handling

Although workload estimation captures long-term workload shifts, it faces challenges in handling sub-millisecond-level transient surges [60], as it might make the system temporarily

(a) Successful cloning. (b) Failed cloning.

Figure 7: Pallas request cloning. The yellow box represents the request of group A. The red core and green core represent the busy CPU and idle CPU, respectively.

overloaded and hence hurt tail latency. To remedy this, we introduce a mechanism that detects bursts and an innovative burst reaction method that mitigates such transient fluctuations. We note that Pallas specifically tailors this mechanism to manage bursts associated with particular request types or serving groups, attributing to their inherent variances[5].

Burst detection. Formally, we define a burst inspired by the Heavy Change Detection mechanisms [74, 81]. Consider a fixed time interval τ, we denote the number of requests for group g received by the switch during the one time interval τ_t to be $\mathbb{C}_{g,t}$. Pallas stipulates that a burst occurs when the real-time observed $\mathbb{C}_{g,t}$ exceeds a threshold $\mathbb{C}_{thres}$. Once a burst is detected, Pallas enters the *reaction mode* to react to the burst. The burst detection threshold $\mathbb{C}_{thres}$ represents the upper limit of requests from group g that can be processed by the entire allocated computational resources without inducing queuing. Let N denote the number of group g's requests a single core can process within the τ duration. The threshold $\mathbb{C}_{thres}$ can be formulated as $\sum_{i \in \mathcal{R}_g} N_i$. The value of N_i can either be determined through offline profiling or dynamically estimated by the *agent* resided within each server. To achieve prompt burst detection, we set the time interval τ at 20µs.

Why not server-level cycle stealing? While cycle stealing [37] proves effective for handling burst within an individual server in Perséphone [29], resulting from its ability to determine that the stolen cores are idle, this effectiveness diminishes at the rack-scale. The challenge emerges from the difficulties of accurately determining a server's idle state at scale for microservices [53]. In this case, the request that is redirected to other group servers via cycle stealing may even deliver worse tail latency when the destination server is busy. Consequently, we aim at a no-regret burst reaction mechanism. It should ensure that the ultimate performance never deteriorates compared to scenarios without any burst reaction, a guarantee that cycle stealing cannot provide.

Burst reaction. Upon detecting a burst at the serving group level in terms of request rates, Pallas employs a best-effort request cloning technique to handle transient spikes. Pallas assumes that a burst typically does not occur across the entire workload. Thus, when a specific serving group grapples with a burst, other groups temporarily experience underutilization. As a result, Pallas strategically clones [53] the incoming requests to idle groups for burst handling. The total cloning number hinges on the burst's intensity. Specifically, once Pallas enters the *clone mode*, it clones requests from the overloaded group to the underutilized ones, determining the total number of requests to be cloned as $\mathbb{C}_{clone} = \mathbb{C}_{g,t} - \mathbb{C}_{thres}$. When a request is selected for cloning, Pallas clones it and then dispatches the original request to its serving group and the cloned request to the group which exhibits the lowest degree of burst (Figure 7a). The `req.flag.clone` of the original request and the cloned one are set to 1 and 2, respectively. To avoid the potential HoL blocking caused by cloning long requests to short request groups, the server receiving the cloned request (`req.flag.clone` = 2) will directly drop it if it has no idle CPU cores (Figure 7b). To avoid redundant processing of multiple responses for the cloned requests, Pallas's switch dataplane filters out the slower responses with the globally unique request ID (`req.index`). Besides, experiments in §6.4.2 show that Pallas's cloning does not sacrifice sustainable throughput, as it only handles the bursty portion of requests. The overall request scheduling procedures are summarized in Algorithm 2 in Appendix §B for reference.

5 Implementation

We have implemented a fully functional Pallas prototype, including the inter-server scheduler in programmable switch, intra-server schedulers and paired agents in each server and request clients. 1) The inter-server scheduler within switch dataplane is written in P4 [18] and compiled to switch ASIC with P4 Studio [4]. Pallas uses 2.8% SRAM and 10.4% Stateful ALUs of Tofino ASIC resources. Pallas dataplane composes 763 lines of P4 code. The control plane was implemented with 1067 lines of python code, which uses the switch SDK to read aggregated statistics from data plane registers and update the policy tables if required. More details of dataplane implementation are presented in the Appendix §C. 2) The server is built atop Perséphone [29]. We have extended Perséphone to support the packet header and functionality of Pallas for measuring request actual execution time, and encode this time into Pallas responses for workload estimation. Besides, we have implemented the agent to relay intra-server scheduling policies, and request bouncing mechanism to protect system performance during switch reconfiguration of policy tables. 3) The client is open-loop, implemented in C, and utilizes DPDK for high-speed user-space networking. It can generate Pallas requests at high rate and measure the throughput and latency for each request accurately.

6 Evaluation

We evaluate Pallas to answer the following key questions:

- **How does Pallas compare against state-of-the-art sys-**

[5] Addressing the burst happening on the entire workload level usually requires techniques such as system overload control [20, 21] or resource auto-scaling [48, 65], which is beyond the scope of this paper.

	Synthetic Workloads												Real World Applications

Ratio	90%	10%	50%	50%	33.3%	33.3%	33.3%	43%	4%	45%	4%	4%	90%	10%	50%	50%

Table 2: Workloads with dispersion. In Bimodal and Trimodal workloads, S, M, L represent short, medium, and long request, respectively. In TPC-C workload, P, OS, NO, D, and SL represent Payment, OrderStatus, NewOrder, Delivery, and StockLevel, respectively.

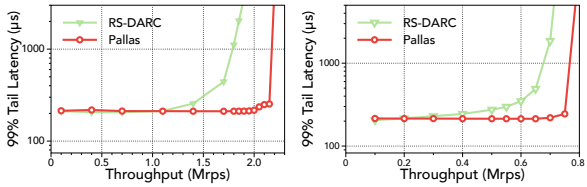
tems in static workloads? We show that Pallas achieves near-optimal tail latency in statically synthetic workloads (§6.2.1) and real-workload applications (§6.2.2), which significantly outperforms RackSched. For example, Pallas reduces the tail latency by 8.5× and 5.5× compared to RackSched in the Bimodal distribution and RocksDB experiments at medium load, respectively. Specifically, Pallas reduces the tail latency by two orders of magnitude compared to RackSched in the Port RocksDB experiment at high load. We also show that Pallas delivers low tail latency under light-tailed workloads (Appendix §D.1) and outperforms other solutions (§6.5), including R2P2 [56], Draconis [76] and Horus [82].

- **How does Pallas respond to workload changes?** We demonstrate that Pallas can agilely respond to workload changes and gracefully handle system reconfiguration (§6.3), maintaining the stable tail latency in both synthetic and real-world workloads.
- **How effective is Pallas in terms of its components and scalability?** First, we show that workload shaping significantly helps load balancing and intra-server scheduling (§6.4.1). Besides, we demonstrate that our request bouncing (§6.4.2) and burst handling mechanisms (§6.4.3) can both effectively mitigate the performance degradation under workload dynamics. We also show that Pallas can almost scale out linearly with more servers without compromising performance in Appendix §D.2.

6.1 Experimental Setup

Testbed. The experiments are performed on a testbed of ten machines connected by a Intel Tofino switch. Each machine is equipped with two 12-core CPU (Intel Xeon(R) CPU E5-2630 v2, 2.60GHz), 64GB memory, and one NVIDIA ConnectX-4 100G NIC. Each machine runs Ubuntu 18.04 with Linux kernel 5.4.100. We use eight machines as servers to process requests and two machines as clients to generate requests, which is the similar setting in RackSched. Both clients and servers runs DPDK 22.11.1 [5] for high-performance packet processing. All servers use 10 worker threads running on dedicated CPU cores. To improve system stability and reduce jitter, we disable TurboBoost, C-states, and CPU frequency scaling as recommended by [29, 68].

System compared. We compare the performance of Pallas against RackSched [85]. We note that RackSched leverages Shinjuku [45] as the default intra-server scheduler. However, as Shinjuku only supports Intel NICs [45, 63, 85], we replace it with Perséphone (DARC) within RackSched's framework for intra-server scheduling, since our motivation experiment (Figure 2b) has shown that DARC delivers comparable performance compared to TS (Shinjuku) for mixed workloads. We have extended Perséphone to support RackSched packet header and encode queue length in its response for JSQ-based load balancing. For ease of reference in the subsequent experiments, we name the system as *RS-DARC* or simply *RS*.



Workloads. We use a combination of synthetic and real world application workloads to evaluate Pallas, following the similar settings in recent works [29, 45, 72, 85]. By default, both request and response contain one packet. In the context of synthetic workloads, servers conduct the fake work by spinning the CPU for the specified number of cycles. For the real world application workloads, we harness RocksDB [13], an in-memory key-value store, as the experimental platform. We summarize the workloads in Table 2. Notably, we profile *TPC-C* [11] transactions with silo [75], an in-memory database, and evaluate it as a synthetic workload to showcase how Pallas performs on the n-modal workload. Additionally, we craft dynamic workloads characterized by fluctuating request distributions. This setting aims to elucidate Pallas's adaptive capacities and response mechanisms when confronted with variations in workload patterns. Note that Pallas targets stateless or replicated stateful services. The profiled TPC-C transactions are used primarily as a source of realistic, multi-modal execution times for synthetic load generation to test shaping effectiveness. In addition, the evaluation on RocksDB uses an in-memory setup with read-only GET/SCAN requests.

Evaluated metrics. We adjust the request rates (request per second (rps)) from the clients to modulate the system load, and report the 99% tail latency, measured in microseconds, corresponding to each specific rps adjustment.

6.2 Static Workloads

6.2.1 Synthetic Workloads

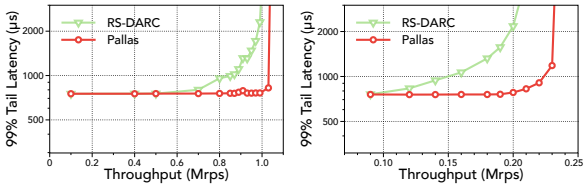


Figure 8 compares Pallas to RS-DARC for three service time distributions. Note that the y-axis is log-scaled for good visibility. Overall Pallas achieves significantly better tail latency than RS-DARC. For example, as shown in Figure 8a, the tail latency of RS-DARC starts to increase when system load is above 1.5Mrps, and its tail latency reaches 1112µs when

(a) Normal Bimodal (b) Port Bimodal

(c) Trimodal (d) TPC-C

Figure 8: Experimental results for synthetic workloads.

(a) Normal RocksDB (low) (b) Port RocksDB (high)

(c) GET Latency (high) (d) SCAN Latency (high)

Figure 9: Experimental results for RocksDB.

the load reaches 1.8Mrps, which is 5.2× higher than Pallas (211µs) at the same load. In contrast, Pallas maintains a stably low tail latency (∼200µs) before the load reaches 2.15Mrps. In specific, Pallas reduces the latency by 16× when the system load is 1.9Mrps. For the 250µs tail latency objective, Pallas achieves 1.5× higher throughput. The reason of Pallas's significant performance improvement is twofold. First, by employing the workload shaping, Pallas adeptly steers short and long requests to different subsets of servers for intra-group scheduling. Therefore, under this workload configuration, seven servers exclusively process a singular type of requests (either short or long), where the simple yet efficient cFCFS scheduler is utilized to achieve optimal tail latency. This entirely addresses the HoL blocking problem. Only one residual server works in the hybrid mode, accommodating both short and long requests. Second, the approach to load balancing also undergoes refinement through workload shaping. In Pallas, intra-group scheduling only requires a weighted balancing of request numbers among servers. This mechanism demonstrates better load balancing than the queue-length based solution adopted in RackSched.

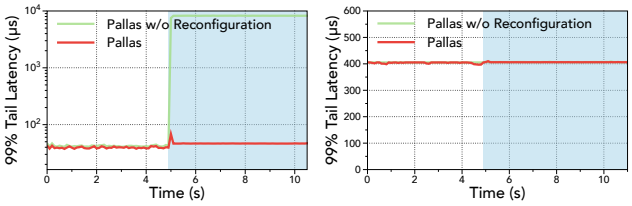

Figure 8b depicts the results for a more challenging Port Bimodal workloads, which represents the workloads characterized by an even split between short and long requests. We find that Pallas maintains a consistently low tail latency until the system reaches its saturation point. In specific, Pallas reduces the tail latency by 8.5× compared to RS-DARC at a load of 0.7Mrps. For the 300µs tail latency objective, Pallas achieves 1.4× higher throughput. Figure 8c illustrates the performance of Pallas under a trimodal workload. The results show that Pallas delivers 2.0× higher throughput than RS-DARC when targeting a tail latency objective of 1200µs. Furthermore, at a system load of 0.18Mrps, Pallas manages to reduce the tail latency by a factor of 2.3× compared to RS-DARC.

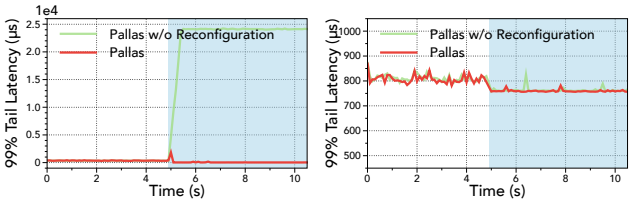
Finally, we evaluate Pallas with the profiled TPC-C workload. In this context, the best performant grouping policy is: the Payment and OrderStatus transactions are cohesive in one group, the Delivery and StockLevel transactions form another group, and the NewOrder transaction represents solely the third group. The results are shown in Figure 8d. Notably, when targeting a tail latency objective of 200µs, Pallas delivers as much as 2.5Mrps high throughput, which is 1.7× superior to that of RS-DARC.

6.2.2 Real Application: RocksDB



In this section, we showcase the performance gain of Pallas when applied to real-world applications RocksDB [13]. Adopting the configuration presented in [45, 85], we configure the database to operate on an in-memory file (/tmpfs/) for processing database transactions. Our evaluation incorporates two distinct request types: the GET request, which retrieves 10 key-value pairs with a median service time of 12µs, and the SCAN request, designed to scan 5000 key-value pairs with a median service time of 650µs. Figure 9a shows the performance under a workload mix of 90% GET and 10% SCAN requests. We observe that Pallas adeptly handles system loads up to 1Mrps without increasing tail latency.

Figure 9b presents the performance results for RocksDB workloads with an equal mix (50-50) of GET and SCAN requests. We find that Pallas maintains stable tail latency until the system load reaches 0.21Mrps, achieving a 5.5× latency reduction when compared to RS-DARC. Notably, Pallas achieves as much as two orders of magnitude lower latency at the 0.22Mrps and 0.23Mrps load. For a more granular analysis, we break down the results of GET and SCAN requests under the port RocksDB workload, respectively, as depicted in Figure 9c and Figure 9d. Owing to the application-agnostic nature of inter-server scheduling in RS-DARC, each server continues to handle heterogeneous workloads. This necessitates the reservation of at least one CPU core for short requests exclusively, resulting in an over-provisioning of GET requests and an under-provisioning of SCAN requests. This imbalance results in a rapid surge in the tail latency of SCAN requests under RS-DARC as the system load escalates. In contrast, Pallas optimizes resource provisioning for each request

(a) Short requests (b) Long requests

Figure 10: Results on the changing synthetic workload.

(a) GET requests (b) SCAN requests

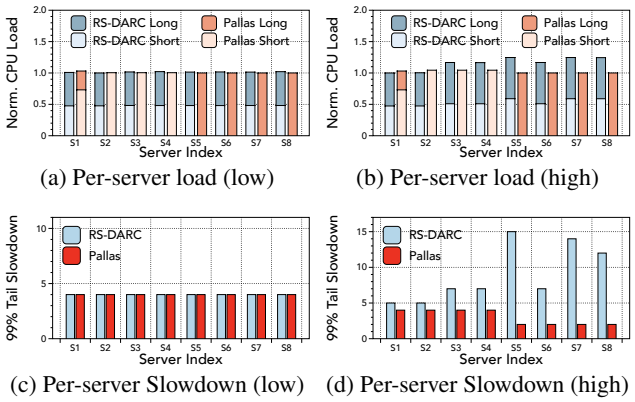


Figure 11: Results on the changing RocksDB workload.

type at rack-scale, yielding a far more efficient and effective allocation. Consequently, Pallas significantly curtails the tail latency of SCAN requests compared to RS-DARC, and yet without compromising the tail latency performance of GET requests.

6.3 Dynamic Workloads

Synthetic workloads. We initiate by dispatching requests that follow the Port Bimodal (50%-10µs, 50%-100µs) distribution to the system, subsequently transitioning the workload distribution to Normal Bimodal (90%-10µs, 10%-100µs). Throughout this experiment, we maintain the system load at approximately 80%. The results are shown in Figure 10, where the shaded region signifies the period of new workload. The performances of long requests under these two schemes remain relatively stable due to their decreasing resource demands (Figure 10b). For short requests, we observe that Pallas without policies reconfiguration cannot adapt to workload shifts and hence results in explicit tail latency inflation (Figure 10a). On the other hand, during this transition phase, the Pallas workload estimator discerns the workload pattern and promptly updates both the inter-server scheduling policies and intra-server scheduling policies. Further, as the workload changes, the proportion of short requests surges. Consequently, there is a noticeable spike in the 99% tail latency for Pallas's short requests, which is attributed to system reconfiguration and transient overloads. Nevertheless, the temporal overload can be mitigated by the burst handling mechanism, which takes effect before the control plane detects the workload change by cloning increasing short requests to the group for long requests to reduce its latency. Besides, our dedicated request bouncing strategy reconciles this latency elevation. These two mechanisms work in concert to ensure that Pallas accommodates the changing workload gracefully.

RocksDB. We adopt a similar setting to assess Pallas's performance on dynamic RocksDB workloads. The request distribution transitions from Port RocksDB (50% GET, 50% SCAN) to Normal RocksDB (90% GET, 10% SCAN). The results are depicted in Figure 11. We observe that Pallas swiftly adapts to the workload changes, ensuring consistent tail latency. Its counterpart of Pallas without workload adaptation delivers a significant worse performance, as current scheduling policies are largely inefficient for GET requests. During the workload transition phase, there is also a slight surge. However, the tail latency inflation is effectively bounded by the mechanisms of burst handling and request bouncing.

(a) Per-server load (low) (b) Per-server load (high)

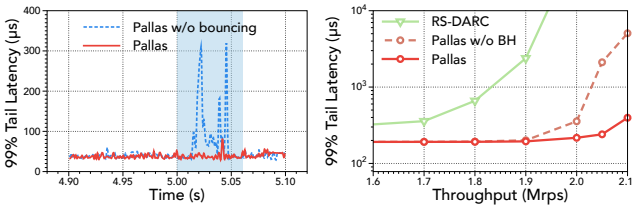

Figure 12: Comparison of per-server perceived load and performance between Pallas and RS-DARC.

6.4 Pallas Deep Dive

6.4.1 Effectiveness of Workload Shaper

To delve deeper into why Pallas significantly outperforms RackSched in terms of tail latency, we analyze the perceived request load and resultant performance slowdown for each server during the experiments under Normal Bimodal workload in §6.2.1. This analysis is conducted at two distinct system loads: 0.05Mrps (referred to as 'low') and 1.8Mrps (referred to as 'high').

In the low load scenario (first column), it is evident from Figure 12a that both RackSched and Pallas manage to achieve commendable inter-server load balancing. Consequently, their overall slowdowns are comparable, as seen in Figure 12c. However, when we examine RS-DARC at high load, a clear disparity in server load balance emerges. As Figure 12b shows, servers S1 and S2 in RS-DARC handle noticeably fewer requests than their counterparts, while S5 is scheduled to handle more requests. This imbalance is attributed to the application-agnostic nature and outdated load information used by the JSQ-based load balancer in RackSched, resulting in the divergent slowdown performance. Additionally, each server in RackSched continues to process a mixture of short and long requests, necessitating the use of complex algorithm (DARC) for ongoing workload monitoring and core allocation adjustments for different type of requests. This dynamic adjustment, however, still culminates in suboptimal performance. In con-

(a) Request bouncing (b) Burst handling

Figure 13: Effectiveness of Pallas's components.

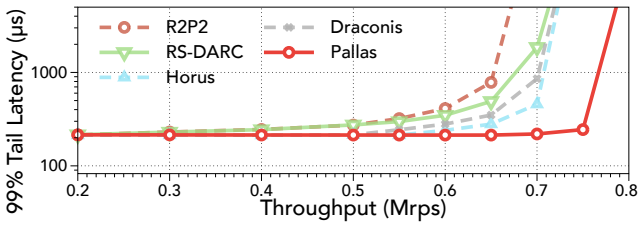

Figure 14: Comparison with other solutions.

trast, Pallas showcases impressive load balance across servers, even at high load, as the results shown in Figure 12b. This balance is achieved through in-network workload shaping and nearly optimal intra-group scheduling. Consequently, servers S2-S8 in Pallas exclusively handle a single request type, allowing them to employ cFCFS to optimize tail latency and slowdown. For instance, when examining server S5, we find that Pallas reduces the slowdown by 7× compared to RS-DARC, as highlighted in Figure 12d.

6.4.2 Request Bouncing

We offer a granular breakdown of the experiments under dynamic Bimodal workloads in §6.3, with results presented in Figure 13a. We observe that the bouncing policy adeptly facilitates Pallas's management of workload shifts, particularly in curtailing the tail latency of short requests. For instance, the fluctuations of tail latency for short requests in Pallas are effectively tempered in comparison to the system without bouncing mechanism.

6.4.3 Burst Reaction

To showcase the efficacy of Pallas's burst handling mechanism, we evaluate it under a challenging bursty workload comprised of 90% short requests of 10µs and 10% long requests of 90µs. The arrival pattern for short requests adheres to the bursty gamma distribution with a standard deviation of 5, whereas the long requests conform to a standard Poisson arrival pattern. In this scenario, both short and long requests are allocated to two distinct serving groups, with each group being provisioned with 4 servers, offering 40 cores cumulatively. After profiling the maximum throughput under this configuration, we configure the burst detection threshold C_{thresh} as 42 for the group of short requests. The tail latency under varying system loads is illustrated in Figure 13b. Our results reveal that both Pallas and its variant, i.e., with the Burst Handling (BH) disabled, significantly outperform RS-DARC in terms of reduced latency. Furthermore, Pallas reduces the tail latency by an average factor of 6.1× compared to its variant when the load surpasses 1.9Mrps. This is because Pallas clones the bursty short requests to the group for long ones, which effectively masks the latency inflation and hence mitigates the performance degradation of short requests.

6.5 Comparison with Other Solutions

Several other solutions aim to improve rack-scale scheduling by leveraging in-network support. R2P2 [56] introduces a join-bounded-shortest-queue (JBSQ) policy for dynamically distributing requests across servers. Horus [82] enhances scheduling accuracy by proactively monitoring server states and loads via network switches. Draconis [76] is the latest proposal for optimizing latency for µs-level services, which implements centralized first-come-first-served (cFCFS) scheduling directly within the switches. Figure 14 compares Pallas with them under a port bimodal workload. We find that Pallas achieves superior performance, delivering lower tail latency and greater sustainable throughput. The reason is that they distribute mixed workloads to each server, where HoL blocking may still occur. However, Pallas eliminates it through its efficient in-network workload shaping and thus delivers the near-optimal performance.

7 Discussion

Target workloads and applications. Pallas can support CPU-intensive stateless or replicated stateful services, which is consistent with recent proposals [53, 56, 76, 82, 85]. Example applications comprise in-memory databases, replicated caches and storages, function-as-a-service and replicated inference services for machine learning. Pallas currently does not support stateful services, as it is less likely to replicate them within a rack and scheduling may not be required. Pallas may be extended to support stateful applications by implementing a *sticky* policy, similar to [56], which distributes stateful operations to determined master nodes to maintain consistency.

Workload practicality. Pallas assumes that the workloads can expose statistical characteristic in terms of the CPU demands, which is practical in many workloads [11, 14, 22]. This characteristic helps Pallas to generate effective workload shaping policies. As a result, Pallas's performance gain may diminish if the workloads are highly dynamic and unpredictable. We acknowledge that it is Pallas's limitation to rely on the correlation between request types and execution time, which is a simplified assumption. For more complex workloads whose request execution time cannot be related to their types alone, such as Lucene [1], we environ Pallas with a more intelligent workload monitoring mechanism, e.g., using a machine learning model, to estimate the request execution time based on the necessary information at packet headers

exposed by the programmers.

Scaling to multiple racks. Currently, Pallas is designed within a single rack, as a modern rack can already provide hundreds of cores and is expected to pack thousands of cores [3, 7], which is sufficient for many services [85]. We further note that *in-network workload shaping* of Pallas can naturally be extended to multiple racks or even the entire datacenter in a hierarchical manner, e.g., leveraging both core switches and ToR switches. Realizing this requires efficient collaboration between core switches and ToR switches to enforce a holistic workload shaping policy across racks. Meanwhile, managing heterogeneous servers across racks and handling more frequent workload changes and spikes may also present challenges. We leave it as future work.

Optimization of intra-server scheduling. By design, the majority of servers in Pallas are expected to employ the simple and efficient cFCFS scheduling algorithm. A natural enhancement would be to transition this scheduling algorithm to hardware [6, 10, 63], which promises to curtail scheduling overheads substantially and improve intra-server scalability.

Resource multiplexing and placement constraints. In the context of CPU scheduling, Pallas's workload shaping strategy may not be efficient regarding the resource multiplexing of other resources, e.g., memory and disks. Extending Pallas to schedule microsecond-level services with multi-resource multiplexing is an interesting future direction. Moreover, Pallas's workload shaping strategy essentially implies the placement constraints of requests. Therefore, system operators and designers may utilize the outcome of Pallas's workload shaping to guide specific optimizations for different types of requests [58, 79].

Deployment considerations. Pallas is incrementally deployable. Its major components are implemented in the programmable switch, without requiring complex modifications to end hosts, and may even simplify server-side designs. Pallas uses reserved UDP ports to trigger its logic, allowing it to co-exist with other applications. Practical deployment of Pallas requires access to programmable switches with sufficient dataplane and control plane resources. As shown in the implementation (§5), Pallas consumes modest hardware resources, suggesting the feasibility on modern switch hardware. Integrating Pallas into production environments may also require coordination with existing dataplane programs [33] and control plane infrastructure, particularly to support multiple concurrent applications. We leave it as future work.

8 Related work

Rack-scale scheduling for µs-level services. There exist some solutions to optimize the tail latency for rack-scale µs-level services [53, 56, 76, 82, 85]. However, all of them may still suffer from the load imbalance and the HoL blocking under workloads with highly diverse execution times. Pallas optimizes the tail latency through an entirely different way: instead of scheduling requests, Pallas poses the concepts of workload shaping and schedules the workload to each server, which significantly reduces the complexities of both load balancing and intra-server scheduling and improves the scheduling quality. NetClone [53] employs general request cloning as a primary mechanism for tail latency optimization. Pallas utilizes cloning differently and more strategically: as a conditional mechanism (§4.5) integrated within its shaping framework, and triggered only for detected bursts within specific and pre-shaped workload groups. This makes Pallas's cloning a precise tool to maintain stability for already optimized workloads and maintains resource efficiency.

Intra-server optimizations. Several intra-server designs have been proposed to reduce latency and improve throughput by introducing optimized network stacks [5, 24, 42, 49, 67], designing dataplane operating systems [17, 23, 29, 31, 32, 39, 41, 45, 46, 50, 62, 66, 71, 72, 84] and performing hardware-based optimizations [38, 40, 51, 63, 78]. For example, Perséphone [29] focus on mitigating HoL blocking within a single server by isolating requests with different execution times to separate CPU cores. These optimizations are orthogonal to Pallas and can be integrated in it to further reduce latency and improve throughput.

Job scheduling. There is a long line of research on the job scheduling at cluster-level [26, 27, 28, 34, 35, 36, 47, 70, 77]. These systems target second-level jobs and therefore allow for complex scheduling algorithms to achieve good performance. However, Pallas is designed for microsecond-level services which requires the scheduler to make simple and effective scheduling decisions at line speed.

Programmable networks. Programmable switches enable the network to perform more complex operations to improve datacenter applications [43, 44, 54, 57, 59, 61, 64, 73, 83]. To the best of our knowledge, Pallas is the first to design application-aware in-network scheduling for microsecond-level services with significant performance improvements.

9 Conclusion

This paper presented Pallas, a new solution to schedule µs-level services at rack-scale. Pallas leverages the core idea of workload shaping by proactively transforming mixed workloads into uniform ones within the network and performs simple yet near-optimal inter-server load balancing and intra-server CPU scheduling. Our evaluation demonstrates that Pallas significantly outperforms the state-of-the-art solution in terms of both throughput and tail latency.

8  |   latencies.append(latency)
9  opt_mapping ← argmin_{m∈mappings}{latencies}
10 return opt_mapping
```

Appendix

A Algorithm of Workload Mapping Generation

We summarize the algorithm for generating Pallas workload shaping policy in Algorithm 1. It consists of two stages. First, Pallas generates several group mapping candidates with a tailored k-means algorithm (Lines 3-5). Then, Pallas determines the best performant mapping policy through offline simulations (Lines 6-8).

B Overall Request Scheduling

We summarize the scheduling workflow in Algorithm 2. Initially, Pallas identifies the serving group corresponding to each request (Line 4), and ascertains whether the group has encountered a burst (Line 5). Upon detecting a burst, Pallas clones the request and recalibrate it with a proper serving group ID (Lines 6-12). Pallas then sends the request to a server within the determined serving group, ensuring load balancing (Line 13). Once the server receives the request, it leverages its intra-server scheduling algorithm to allocate the request to a CPU core (Lines 16-20). In the concluding step, the server generates a response and sends it back to the client.

C Switch Dataplane Implementation

Weighted round-robin. Pallas employs a weighted round-robin (WRR) algorithm for the intra-group scheduling. In this approach, Pallas assigns a unique counter for each group to determine the destination servers for incoming requests. This counter is incremented sequentially with each request and is programmed to reset to zero upon reaching the aggregate limit, defined by the WRR parameters of the group. The request finds its destination by aligning the counter's current value with the predetermined weight range of servers. The counter is implemented with the register in P4, and updated with the ALU operation.

Algorithm 2: Pallas Request Scheduling

```
1  Event: On request arrival at switch:
2  Init the metadata (meta) for each request
3  if req.flag.clone = 0 then
4      meta.group ← GroupMapping(req.type)
5      burst ← BurstDetection(meta.group)
6      if burst = True then
7          Event: On burst detected:
8          cloned_req, cloned_meta ←
             CloneRequests(req, meta)
9          req.flag.clone ← 1
10         cloned_req.flag.clone ← 2
           /* Assign group for the cloned
              request                          */
11         cloned_meta.group ← FindCloneGroup(req)
12         resubmit(cloned_req, cloned_meta)
13 server ← WeightedRoundRobin(meta.group)
14 send(req, server)
15 Event: On request arrival at server:
16 if server.policy = cFCFS then
17     FCFSSchedule(req)
18 else
19     cores ← core_reservation(req)
20     DARCSchedule(req, cores)
21 send_response(req)
```

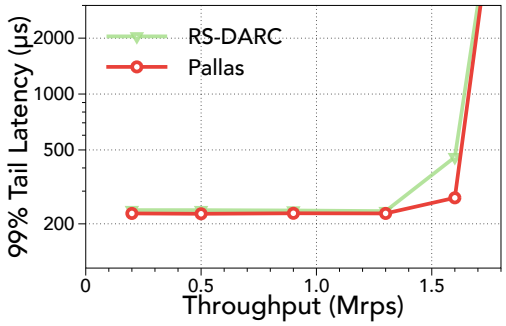

Figure 15: Exponential

Workload recording. Pallas records the workload information of each type of request with two registers in P4. The first register is tasked with recording the cumulative count of monitored requests, while the second is dedicated to computing the Exponentially Weighted Moving Average (EWMA) of the execution times of these requests. The EWMA factor is set to 0.125 in our current prototype, which helps compute the division by bit-shifting operations in P4. The register responsible for counting request numbers is programmed to reset periodically by the regular workload monitoring schedule.

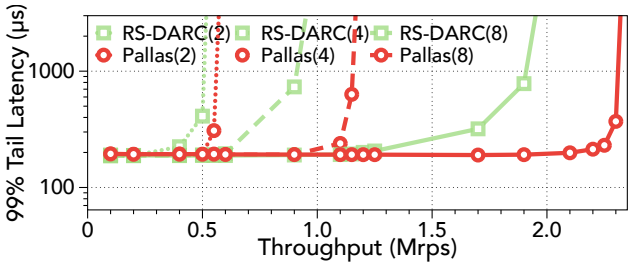

Figure 16: Scalability results of Pallas.

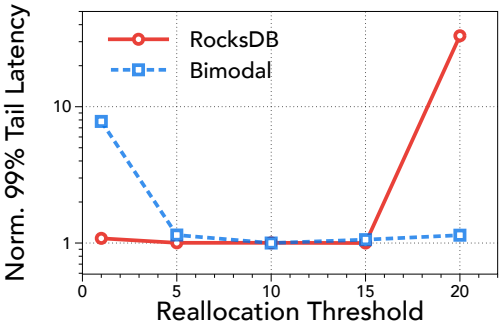

Figure 17: Sensitivity analysis of the reallocation threshold δ.

D Supplementary Experiments

D.1 Performance under Light-tailed Workload

Figure 15 compares Pallas and RackSched under a light-tailed exponential workload with an average request execution time of 25µs. As suggested in RackSched paper, its intra-server scheduler is configured to use cFCFS. We find that RackSched exhibits very close performance to Pallas. This is attributed to the uniformity of request execution times characteristic of the exponential workload. Consequently, both JSQ and Pallas's intra-group load balancer can effectively distribute the load across servers, in which the optimal intra-server cFCFS scheduling is utilized.

D.2 Scalability

We show the scalability of Pallas with two, four and eight servers. We use the Bimodal workload comprised of 90% short requests of 10µs and 10% long requests of 90µs. Figure 16 shows the results of 99% tail latency. We observe that the sustainable throughput of Pallas almost scales linearly with the number of servers, exhibiting much better scalability than RS-DARC. This is because RackSched's application-agnostic inter-server load balancing incurs more variability when facing high request rates and hence results in load imbalance and degrades tail latency. The linear scalability of Pallas can attribute to the near-optimal load balancing and intra-server scheduling with in-network workload shaping, demonstrating that Pallas is able to scale out with more servers without compromising performance.

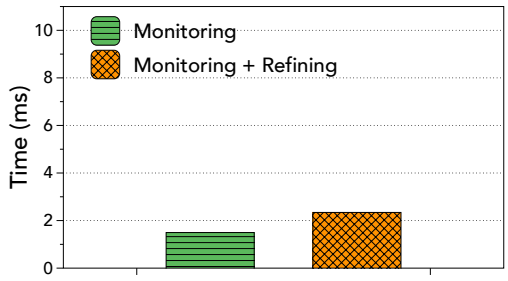

Figure 18: Monitoring overhead of Pallas.

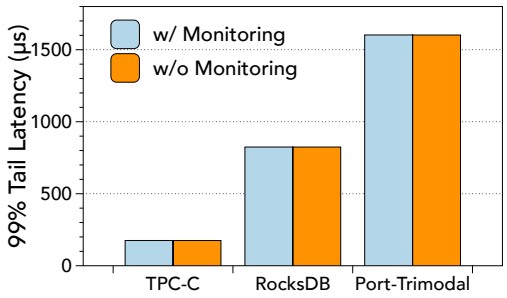

Figure 19: Impact of workload monitoring under static workloads.

D.3 Parameter Sensitivity

Sensitivity to realloaction threshold. We vary the reallocation threshold δ from 1 to 20 and investigate the performance of Pallas with different thresholds. We use both the synthetic workload in Figure 10 and real application RocksDB in Figure 11 to evaluate the sensitivity of Pallas to the reallocation threshold. Figure 17 shows the overall normalized 99% tail latency.

From our observations, Pallas exhibits relative insensitivity to the reallocation threshold within the range of 5-15. This can be attributed to the fact that this threshold range effectively captures workload fluctuations while simultaneously ensuring system stability by avoiding excessive resource reallocations and switch reconfigurations. Specifically, in the context of the synthetically changing bimodal workload, a threshold set at 1 renders the system over-responsive to minor workload variations, thereby substantially impairing system performance. On the other hand, in the scenario of the varying RocksDB workload, a threshold of 20 makes the system oblivious to workload shifts, consequently deteriorating the tail latency.

D.4 Monitoring Overhead

We evaluate the overhead introduced by workload monitoring in Pallas's switch control plane. Figure 18 reports the execution time of two key control plane operations: periodic register reading (workload monitoring only) and infrequent register updates (monitoring together with refining) upon workload shift. Results show that both operations is lightweight relative to the 10 ms monitoring interval, confirming the practicality of our design. We also note that the 10 ms interval targets long-term workload changes and represents a configurable trade-off. If needed, Pallas can scale to support more workload groups by operating at longer monitoring intervals.

D.5 Impact of Workload Monitoring

We further examine the impact of workload monitoring under static workloads. Specifically, we evaluate three static workloads at their respective maximum sustainable request rates in Pallas. As shown in Figure 19, enabling monitoring has no observable effect on system performance, since policy updates are not triggered when no workload shift is detected. This confirms that the monitoring logic is lightweight and non-intrusive.

TGW: Operating an Efficient and Resilient Cloud Gateway at Scale

Abstract

Large-scale cloud data centers have become a critical Internet infrastructure. As the cloud entrance, today's cloud gateways have integrated multiple functions such as elastic public access and load balancing to cope with the rapid growth of services and requirements. To meet the demands of large-scale clouds for efficient packet forwarding, scalable state management, and high resilience, we design, deploy, and operate Tencent Gateway (TGW), an efficient and resilient cloud gateway at scale. Compared to other large cloud providers that primarily offer services like search, e-commerce, or short-form video, the "killer services" of Tencent Cloud are online gaming and live streaming, which come with much stricter requirements for latency, jitter, and packet loss. From a technological perspective, TGW is highly decoupled and modular, with core components focused on efficient forwarding planes, a scalable state migration mechanism, a resilient failure recovery mechanism, and a failure detection and localization system. In terms of engineering, TGW has been operating in large-scale, real-world industrial environments for eight years, during which we have gained extensive insights and experience. We evaluate TGW both in testbed and real-world scenarios. In our testbed, TGW's single node achieves 2.9× the forwarding capacity of prior systems. Between clusters, states and traffic can be migrated in 4s without packet loss. In our real-world environment, TGW handles tens of Tbps of traffic, with a worst-case packet drop rate ranging from 10^{-7} to 10^{-4}, while balancing traffic across clusters. Additionally, TGW can quickly migrate states and traffic and recover from failures without tenant awareness, guided by our failure localization system, achieving 100% availability for years.

1 Introduction

Large-scale public clouds have increasingly become an essential Internet infrastructure, providing services to millions of clients [2, 4, 12, 17, 32, 35]. We, Tencent Cloud [52], as one of the largest cloud service providers, have been facing rapid growth in traffic volume, service type, and service demand. Our service number and gateway traffic have grown at an average rate of over 100% and 60% per year, respectively, in the past few years. To meet the service level agreements (SLAs) for the high volume and uptime [42] of inter- and intra-data center traffic, efficient and resilient services must be provided in a large-scale cloud carrying tens of Tbps traffic.

As the primary component of the cloud, the cloud gateway plays a vital role in ensuring high-performance and high-availability networking. With the rapid advancement of virtualization technologies and the increasing performance demands of backend services, cloud gateways have evolved beyond merely providing connectivity between external and internal networks. They now also integrate additional complex functions such as load balancing, network intrusion detection, and stateful firewalls. These functions are crucial for maintaining the robustness and security of cloud services.

However, operating such a large-scale networked system is challenging. Traditional gateways, consisting of commodity hardware routers and switches, can provide high throughput, but their fixed functionality does not adapt to the changing scheduling dynamics and proprietary protocols in the cloud. The slow iteration cycle of fixed-function hardware also becomes a bottleneck for the cloud's rapid growth [40]. While there have been efforts in cloud gateway design and implementation using software solutions [3, 31, 47, 58], most of them have been evaluated in small-scale laboratory environments and cannot meet the large-scale cloud requirements for efficiency, scalability, and resilience. Some hybrid solutions [40] utilize programmable hardware to improve performance, but they suffer from vendor dependency and supply chain challenges [10], due to the uncertain outlook of programmable switches.

To bridge the gap, we propose Tencent Gateway (TGW), the gateway system of Tencent Cloud with efficient packet forwarding, scalable state management, and high resilience. TGW has been in operation for eight years and deployed in more than 30 regions. In our largest region, TGW scales to

*Both authors contributed equally to this work.

hundreds of clusters and thousands of machines, handling tens of Tbps of traffic.

TGW's main functions are elastic public access [5, 51] and cloud-level load balancing [50] (§2.1). Compared to other large cloud providers that primarily offer services like search [6, 23], e-commerce [2, 4], or short-form video [8], the "killer services" of Tencent Cloud are online gaming and live streaming, which have much more stringent requirements for latency, jitter, and loss [33]. Based on these requirements and after weighing various alternatives in performance and cost, TGW leverages DPDK-based [27] software server clusters to ensure the efficiency, scalability, and resilience of the gateway system with sequentially increasing priorities (§2.2 and §2.3).

Architecturally, we decouple and modularize TGW's functions at different levels (§3). For the forwarding plane, we decouple public access and load balancing by designing the corresponding TGW instances separately in a hierarchical manner. We design TGW-EIP for stateless elastic public access in regional data centers and TGW-CLB for stateful cloud load balancing in each available zone (AZ) of the region. The tenant traffic will be processed by different forwarding instances and load-balanced. In addition to tenant traffic, the TGW also hosts and manages its internal traffic, including state migration, state synchronizing, and running logs.

TGW mainly consists of efficient forwarding planes, a scalable state migration mechanism, a failure resilience mechanism, and a failure detection and localization system. First, we unleash the forwarding capacity of DPDK by utilizing and optimizing different forwarding models based on the specific functions of TGW-EIP and TGW-CLB (§4). We implement a scalable run-to-completion (RTC) model for TGW-EIP and a two-stage pipeline model for more complex TGW-CLB with empirical tuning and optimization. Second, we design an efficient, lockless, and lossless connection state migration mechanism for fast cluster scaling (§5). In case of overload or failure, TGW can quickly scale the cluster and steer the traffic at runtime. Third, we develop different recovery mechanisms for various levels of failures (§6). TGW uses an empirical multi-cycle synchronization mechanism for stateful backup and establishes failure recovery plans at all levels. TGW can react to failures as soon as they are discovered to minimize their impact, without knowing the cause. Fourth, we design a taint-based telemetry system to detect and localize failures (§7). By distributed analyzing collected logs from active probers and forwarding planes, TGW can automatically detect failures and make decisions within 1 minute.

In addition to technical details, in contrast to most existing work, which is only evaluated in the laboratory, TGW is a mature system that has been commercially operated for years. We summarize our insights and experiences during years of operating TGW, from network topology and hardware setup, to cluster construction and management (§8). We believe that these experiences are helpful for both academia and industry.

We prove TGW's efficiency by listing the evaluation data of TGW running both in a testbed and a real-world environment (§9). In our testbed environment, TGW's single node achieves 2.9× forwarding capacity than in prior work. Between two clusters, states, and traffic can be migrated in 4s without packet loss. In our real-world environment, TGW carries tens of Tbps of traffic with the worst-case packet drop rate of 10^{-7} to 10^{-4} and divides traffic among clusters in balance. TGW can also quickly migrate states and traffic and recover from failures without tenant awareness, achieving 100% availability for multiple years.

2 Background and Motivation

This section describes the background and motivation for building TGW. We commence by providing some foundational background on cloud gateways. Subsequently, we analyze and contrast the alternatives that we have contemplated. Finally, we illustrate our motivation for building TGW under the requirements of our cloud services. For clarity and to make the paper more self-contained, we provide explanations for technical acronyms whose full names do not appear in the main text in Table 1 in the Appendix.

2.1 Background

Today's cloud gateway has evolved far beyond its traditional role as a simple network address translation (NAT) device. It now functions as a traffic scheduler, offering flexible flow distribution with high scalability and availability to meet the demands of modern data centers [40]. The cloud gateway serves as a critical bridge between the public network and the data center network, facilitating seamless communication between users and applications. Services such as online gaming or video streaming often deploy application instances beneath the cloud gateway, which are accessed by users worldwide. Modern cloud gateways, including TGW, support two primary traffic scheduling services:

Elastic public access. Elastic access [5, 51] has become a fundamental service in modern cloud data centers. It allows the assignment of a static public IP address to one or more cloud virtual machines (VMs) or network functions (NFs), such as L4 load balancers. Each VM is typically assigned a private IP address called a direct IP address (DIP). A service exposed to the public is given a public IP address called a virtual IP address (VIP). A cloud gateway distributes traffic destined for the VIP to enable connectivity while ensuring tenant isolation. A client's external public IP address is called a client IP address (CIP). TGW's elastic access service is particularly noteworthy for its transparency, scalability, and high availability. Firstly, TGW ensures seamless access to internal resources and services for public users across various Internet service providers (ISPs) worldwide. Secondly, TGW associates an anycast public IP address with service instances deployed across multiple regions globally. This allows incoming traffic

to be routed to the nearest cloud gateway entrance. Thirdly, by steering traffic through the data center's backbone infrastructure and dynamically selecting the nearest gateway via multiple ISPs, TGW minimizes latency for users worldwide.

Cloud-scale load balancing. Load balancing is one of the most essential services in modern cloud data centers [34, 42], enabling efficient distribution of traffic across a pool of resources. Taking the L4 load balancing as an example, the cloud load balancer maps a single (*VIP, VPort*) tuple to a pool of (*DIP, DPort*) tuples. When the first packet of a new flow arrives, the load balancer selects one (*DIP, DPort*) tuple from the backend pool based on a predefined load-balancing algorithm. This mapping rule is applied to all subsequent packets of the same flow. The load balancer ensures traffic is evenly distributed across instances in the pool while maintaining service performance and reliability. With the rapid growth of the cloud, the traffic scale in data centers has increased significantly, including both north-south and east-west traffic [40]. Besides inter-cloud traffic from public access, there is also tremendous traffic from tenant data centers, on-premise cloud VMs, and other public clouds [45]. In our cloud, the number of data center instances accounts for more than 45%, and the intra-cloud traffic accounts for about 80%. For both inter- and intra-cloud traffic, TGW provides multi-granularity cloud load balancing services with the awareness of real-time workload distribution and link health.

2.2 Alternatives

Due to the variability of services and proprietary protocols in cloud data centers, fixed-function switches are usually not suitable for cloud gateways. Over the years, many advanced schemes, both software-based and hardware-based, have been proposed or matured during TGW's evolution. Despite these advancements, completely replacing TGW's DPDK-based infrastructure with these emerging solutions is extremely challenging in terms of CapEx and OpEx. Nonetheless, we have experimented with these alternatives and even deployed them at a small scale in our cloud. The details are as follows:

XDP [55]. In terms of performance, we find that the XDP-based forwarding plane is not suitable for complex network functions that process large traffic volumes. However, it is simple to develop and deploy as it runs in the kernel without external dependencies. As a result, we deploy XDP-based network functions only at the edge of the data center rather than at its entrance. For example, we deploy XDP on the edge hosts of our cloud CDN, where it achieves load balancing and anti-DDoS functions at 10 Mpps per host, utilizing just 5% of CPU resources.

VPP [54]. VPP offers rich routing features and good performance. However, in a cloud gateway, the functions of elastic access and load balancing are logically simple yet highly coupled. Decoupling these functions into multiple graph nodes does not yield any performance improvement. Instead, it increases OpEx due to the need to manage an additional overlay on top of DPDK. Furthermore, VPP distributes packets to different CPU cores using the NIC's receive side scaling (RSS), which fails to meet the requirements of cloud-scale load balancing in our infrastructure (see §4).

DPUs, FPGAs, and smartNICs. DPUs, FPGAs, and smartNICs offer full or partial programmability and are effective for accelerating NFs [36, 57]. However, their relatively high cost and power consumption [40] make them less appealing for large-scale deployment within cloud gateway infrastructures.

Programmable switches. Programmable switches have proven beneficial in large-scale productive environments [40], offering line-rate throughput of ∼Tbps with minimal CapEx and power costs. For example, Tofino [28] achieves around 3 Tbps throughput at a cost of less than 10$ per Gbps and 1 Watt per Gbps [59]. Consequently, we have introduced programmable switches to accelerate gateway functions within our data center. We directly replace LDs and their upstream and downstream access routers with programmable switches. These switches are directly connected to regional core routers. Each cluster consists of two switches, which serve as backups for each other. To maximize throughput and optimize memory usage, we identify the largest elephant IP flows and distribute them across multiple programmable switches. Each switch manages O(50K) IP addresses and contains O(200K) rules, including GRE [15] encapsulation, rate limiting, and statistics. This setup provides up to 2 Tbps throughput. However, two significant challenges prevent the large-scale deployment of programmable switches: 1) Current programmable ASICs are highly resource-constrained, with tightly coupled network functions that are challenging to manage. 2) The programmable switch ecosystem and community remain underdeveloped and fragmented. Existing programmable chips and associated programming languages lack a unified standard. The programming community has yet to mature, and the software toolchain is still incomplete and evolving. Prematurely committing to a specific type of programmable ASIC risks vendor dependence and potential supply chain issues, such as the discontinuation of Tofino chips [10].

Hyper-converged gateway. As discussed above, the significant advantages of deploying programmable hardware are highly appealing. Combining high performance with extensive flexibility, the hyper-converged gateway [39] integrates the entire cloud infrastructure using CPUs, ASICs, and DPUs. We believe that the hyper-converged solution will be a key area of exploration for the next generation of TGW, although it lies beyond the scope of this paper.

2.3 Motivation

Before discussing our motivation for building TGW, it is important to highlight that its design principles are rooted in the stringent requirements for low latency, jitter, and packet loss demanded by our cloud services. Unlike other major

cloud providers that focus primarily on search [6, 23], e-commerce [2, 4], or short-form video [8], Tencent Cloud's killer services—online gaming and live streaming—demand much stricter latency, jitter, and loss thresholds. For users of online gaming and live streaming services, high round-trip time (RTT) or reconnections caused by network latency, jitter, or packet loss can drastically degrade the QoS (quality of service) [7, 11, 33]. In particular, online gaming users require latency to remain below 100 ms [18,33,41], which means TGW must deliver µs-level latency to compensate for the delays introduced by the Internet and backend servers. With these foundational requirements in mind, we outline our motivation for building TGW, with increasing priorities:

Efficient packet processing. The rapid growth of the cloud has significantly elevated the performance demands of cloud services. The deployment of more and larger services has resulted in a rapid surge in bandwidth requirements. To meet these demands, our cloud gateways must deliver tens of Tbps throughput with µs-level latency. Among the alternatives discussed in §2.2, DPDK stands out as the preferred choice due to its robust performance, flexible development environment, rich community support, and long-term stability, backed by consistent version updates and a reliable compilation toolchain. However, while DPDK offers numerous advantages, scaling it for large-scale environments presents challenges. Simply adding more servers horizontally leads to substantial CapEx and OpEx increases. Therefore, TGW leverages specialized DPDK-based forwarding models tailored to specific forwarding functions, optimizing performance while maintaining scalability and efficiency.

Scalable state management. Data centers handle immense traffic volumes, expansive address spaces, and a vast number of concurrent flows [21, 34, 42, 58], resulting in the need to manage a significant number of states. Additionally, the variety of services requires flexible and fine-grained connection state maintenance. Frequent occurrences of microbursts and software or hardware failures further complicate operations, leading to state loss, flow interruptions, load imbalances, or collateral damage to other tenants, ultimately disrupting performance isolation. These challenges impose stringent requirements on precise state management and scheduling. Traditional cold migration, which causes reconnections, fails to meet the demands for low latency, jitter, and loss. Therefore, TGW needs a scalable connection state management mechanism that ensures seamless, lossless runtime state migration without impacting service continuity.

Fast failure recovery. Large-scale data centers frequently encounter machine and link failures [22, 24, 53]. These failures in the cloud gateway can lead to significant performance degradation or even downtime. In commercial environments, the consequences of such frequent failures include customer losses and reduced revenue. As a result, ensuring the reliability of TGW has become our top priority. TGW must exhibit high resilience to network failures to maintain high availability.

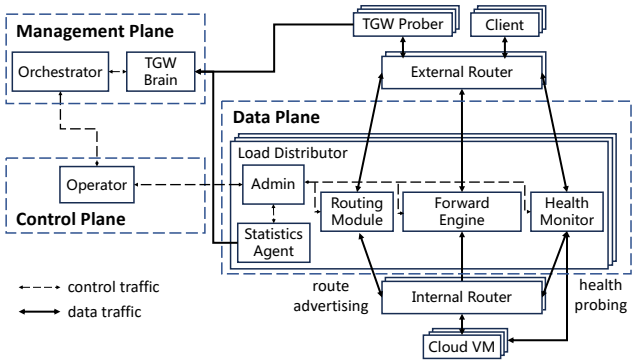

Figure 1: The architecture of a TGW instance. All components are loosely coupled to isolate failures and allow independent scaling.

When network failures of varying severity are detected, TGW should react quickly and recover swiftly without significantly affecting tenant traffic.

3 TGW Overview

In this section, we first illustrate the architecture of TGW by listing its components across different levels. We then present the workflow of TGW's packet processing.

3.1 Architecture

TGW instances are mainly deployed in both the regional entrances, i.e., TGW-EIP, and each AZ of every data center, i.e., TGW-CLB. Each TGW instance is a loosely coupled, disaggregated system composed of multiple components. As illustrated in Fig. 1, a TGW instance spans different operational planes, including a global management plane, cluster-local control planes, and distributed data planes. Besides, TGW has routers located upstream and downstream of the data planes and probers located on the Internet. The details are as follows:

Routers. Commodity external and internal routers are employed between upstream devices, TGW instances, and backend servers. These routers establish BGP [43] connections with the data-plane routing modules and distribute incoming traffic using the ECMP protocol [26].

Load distributors. We refer to the data plane of a TGW instance as a load distributor (LD). The LD is the core component of TGW and comprises several modules. The routing module advertises BGP routes to neighboring routers. The forwarding engine is responsible for handling workload traffic. The admin is a control process within the LD, tasked with interacting with the controller, updating data plane rules, and maintaining network status, such as link connectivity and backend server workload. The health monitor continuously sends probes to detect the activity of routers and servers. It alerts the admin process to adjust scheduling policies based on network health, e.g., by adjusting the weight of servers in load balancing. The statistics agent aggregates LD usage metrics (e.g., CPU, memory, and disk usage), collects data

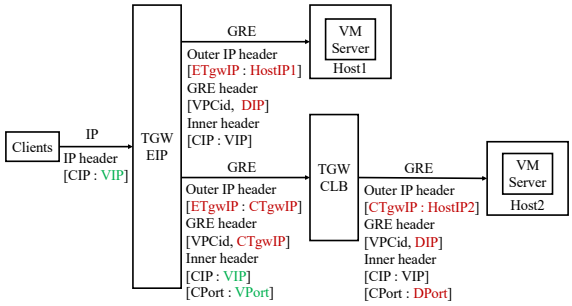

Figure 2: TGW's inbound packet processing flow. Green fields are checked by downstream LDs, and red ones are set by upstream LDs.

from the health monitor, and records the abnormal packet loss information in the forwarding engine. It periodically reports to TGW brains.

Operator. The operator serves as the local controller for an LD cluster and provides northbound APIs to the management plane for resource management tasks, such as managing hardware clusters and network addresses. The operator translates abstract resource configurations defined in the management plane into low-level, concrete rules (e.g., VIP-DIP mappings and rate-limit rules). It then installs these rules into the LDs through their respective admin modules.

Orchestrator. The orchestrator is a global controller, offering comprehensive observability across the entire cloud data center. It evaluates multiple metrics, such as workload, available capacity, and the health status of network links and devices in each cluster. Using a multi-dimensional scheduling algorithm, the orchestrator makes decisions on traffic scheduling and state migration to ensure balanced workload distribution.

TGW probers. TGW probers are active monitoring tools that periodically send probing packets to backend servers and get the probing result from the response packet.

TGW brains. TGW brains are distributed log analyzers that gather runtime telemetry and health data from TGW probers and LDs' statistics agents. They analyze the logs within seconds and report the results to the orchestrator.

3.2 Workflow

The TGW-EIP at the regional entrances primarily handles elastic access, while the TGW-CLB in each AZ manages cloud load balancing for traffic involving cloud VMs or other resources within the zone. In a TGW instance, LDs are configured with rules that map VIPs to DIPs in the cloud data center. A DIP can represent a cloud VM or other successive NF instances, such as a TGW-CLB. Additionally, a VIP can integrate multiple services identified by different VPorts, allowing for more granular mapping rules. Fig. 2 shows the inbound traffic processing flow in TGW. When traffic arrives, external routers initially distribute it based on L3 information via ECMP. The LD clusters then distribute the load at different granularities based on the rules. TGW-EIP and TGW-CLB configure different functions in the LDs and are adapted to distinct forwarding models (§4). TGW-EIP looks up backend cloud VMs or NFs based on the rules and encapsulates the traffic in a GRE tunnel. The DIP and additional critical information, such as the identifier of the VPC (i.e., VPCid), are encoded into the GRE header. These packets are then forwarded as standard IP packets. TGW-CLB distributes traffic based on the 5-tuple and supports other scheduling methods, such as load balancing for QUIC [29]. It selects DIPs and cloud VMs using load-balancing algorithms and pre-configured rules. It then encapsulates the traffic into GRE tunnels, similar to TGW-EIP, but establishes and maintains connection states within the LDs. Subsequent traffic for the same connection is directed to the same DIP and DPort to ensure flow affinity. Internal routers forward these packets as standard IP packets to the corresponding backend servers. Virtual switches in the VPCs, where the cloud VMs are deployed, decapsulate the tunnel, rewrite the destination IP address to the DIP, and add a new Ethernet header for forwarding to the host cloud server. This process uses the VPCid and VM DIP encoded in the header and the routing table maintained by the switch. Outbound traffic processing is the inverse of the inbound packet processing flow. Additionally, there is also traffic between TGW components, such as state migration traffic for cluster scaling (§5), state synchronization traffic for failure recovery (§6), and log aggregation traffic for failure detection and localization (§7). This internal traffic primarily consists of UDP packets with an IP header specifying the source and destination TGW components.

4 Packet Forwarding

This section outlines our optimization of the DPDK-based forwarding plane for efficient packet forwarding. We first unleash DPDK's potential for efficient and scalable forwarding by decoupling the forwarding behaviors of TGW. Specifically, we employ different DPDK forwarding models tailored for TGW-EIP and TGW-CLB. In addition, we enhance the performance of these models by leveraging the traffic characteristics in our cloud and drawing from years of operational experience.

RTC model. As a regional gateway for elastic IP access, TGW-EIP employs an RTC model where packets in a single connection are processed in a single core. This approach minimizes latency and achieves better scalability as cores can operate in parallel for stateless packet forwarding. To further accelerate the forwarding process, we optimize the forwarding table lookup. The forwarding table is implemented as a hash table that maps packet features to the memory address of a forwarding entry. This entry includes the DIP and additional flow control information, such as the flow rate limit or maximum connection limit. However, frequent hash lookups often lead to CPU cache misses, accounting for up to 20% of CPU usage and causing a performance bottleneck in our practice. To mitigate this issue, we utilize a batch-based hash lookup approach. First, we calculate the hash values for packets sequentially in a batch and prefetch them into the cache. The maximum

batch size is set to 64, and the actual packet number in a batch depends on the throughput. We use a separate-chaining-based hash table and extend each list node to store up to four forwarding rule indexes. Storing multiple indexes reduces the overhead of chain expansion when multiple entries share the same hash. We limit each node to four indexes to constrain the node size to 64 bytes, which aligns with the CPU cache line size and maximizes cache utilization. Second, to handle hash collisions—when more than four forwarding rules correspond to entries with the same hash—we prefetch only the first node of the corresponding slot into the CPU cache. Thanks to the CPU's sufficiently large RAM space for hash buckets and the extended linked list nodes, the first node is highly likely to be the one we need. Prefetching it greatly reduces cache misses. This optimization improves L2 and L3 cache hit rates by 8% each and reduces CPU usage for hash lookups from 20% to 5%.

Pipeline model. Although the RTC model has good scalability and performance in stateless packet processing, it cannot be directly applied to `TGW-CLB`. `TGW-CLB` requires more complex and fine-grained L4 flow scheduling than `TGW-EIP`, leading to more intricate connection states indexed by various combinations of flow identifiers. For example, in latency-sensitive services like online gaming, TCP and UDP flows originating from the same client IP must be processed on a single core to minimize delay jitter. This means that the IP-pair-based flow scheduling is more suitable than the traditional 5-tuple approach. Another case is QUIC-aware load balancing, where it is more efficient to distribute and maintain connection states at the granularity of (*srcIP, connectionID*). Additionally, the backend server associated with a VIP may dynamically change based on load distribution algorithms, meaning that only the core processing the flow's first packet has knowledge of the required state. To maintain flow affinity across various service scenarios, the dispatcher must flexibly allocate packets using service-specific identifiers, which are not supported by the NIC's RSS mechanism. Therefore, we implement the forwarding plane of `TGW-CLB` as a two-stage pipeline model. The model consists of 1) the dispatching stage, which maps packets to the appropriate packet processing cores using the service-specific identifiers defined by the rules, and 2) the processing stage, which performs rule and state table lookups, encapsulates packets into a tunnel, and transmits them. Based on our operational experience, a typical proportional relationship between dispatcher cores and processing cores is 1:2, reflecting the flow distribution patterns in our cloud environment. To further enhance performance, each dispatcher core is equipped with its own dedicated ring buffer to avoid locking operations.

5 Live Migration of Connection States

In data centers, core routers commonly employ ECMP to distribute traffic to the cloud gateway. One huge challenge we have faced when building `TGW` is the well-known but tricky "80/20 rule" [40]. In LD, each flow—identified by a unique 5-tuple—is processed by a single forwarding core. However, elephant flows can consume excessive resources on one core, resulting in core overload and rapid performance degradation. Sailfish [40] mitigates this issue by using programmable switches to absorb most of the traffic. However, the remaining responsive traffic is still processed by x86 nodes, creating performance bottlenecks. To address the issue, we design a scalable state migration mechanism. This mechanism enables the seamless migration of network states and traffic from an overloaded cluster to a more capable standby cluster or even multiple standby clusters during runtime. Importantly, this migration is carried out without any packet loss or awareness on the part of the tenant, ensuring uninterrupted service and maintaining the overall performance of the gateway.

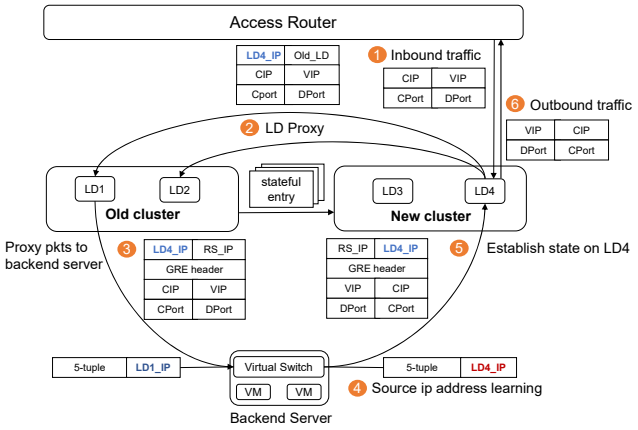

Figure 3: The process of LD proxy for new connections when we migrate connection states during runtime.

Live migration and cold migration. `TGW` supports both live and cold migration of traffic. The key distinction between live migration and cold migration lies in whether the connection information stored in the old cluster is transferred to the new cluster before redirecting traffic. For the critical services hosted in our data centers, such as video gaming and live streaming, the latency overhead caused by reconnections in cold migration is unacceptable. Consequently, we primarily rely on live migration during runtime, enabling traffic redirection without tenant awareness or service disruption. Cold migration, on the other hand, is utilized in scenarios where the original cluster has failed, rendering the connection information invalid, or when the data center faces an urgent fault that requires immediate traffic redirection to maintain availability.

Major state migration. In the live migration process, to migrate the existing states from the old cluster when the migration process begins, the operator module first replicates the stateless configurations to the new cluster. Subsequently, the states are then transferred to this new cluster. `TGW` realizes the migration through a customized application-layer protocol under UDP. This is more engineering work, so we omit this part from this paper. To prevent traffic bursts dur-

ing this process, we employ a time-slice-based mechanism to control the number of states synchronized per slice. Once the majority of connection states—typically over 90%—have been successfully migrated, the operator module directs the routing module in the LD to send BGP advertisements for the migrated VIPs, thereby steering the inbound traffic to the new cluster.

LD proxy for new connections. To avoid dropping new incoming flows during migration, the old cluster remains unlocked during the major state migration, allowing new states to be established. This introduces a consistency issue, as new connections are continuously created in the old cluster. As a result, the new cluster may lack the connection states for subsequent packets of these flows after the routing update. To address this, the LDs in the new cluster will act as proxies, forwarding packets from unseen flows to all LDs in the old cluster during the migration process (② in Fig. 3). Specifically, the proxy LD will forward these packets to every LD in the old cluster. To prevent duplicate responses, a flag is set in the connection state to identify the LD where the state was initially created (i.e., the LD that processed the first packet of the flow). Only the correct LD will process the proxied packets and forward them to the VMs.

Fast convergence. While the LD proxy method helps prevent packet loss during migration, it will amplify traffic, leading to increased latency and potential security risks. To minimize these impacts on tenant traffic, we accelerate the migration process by leveraging the source IP address learning capabilities of the backend server's virtual switch. As shown in Fig. 3, the new cluster initially forwards packets to the old cluster via GRE tunnels, using the source IP in the outer header as its own *LD_IP* (②). The old cluster then forwards the packets to the VM without modifying the outer source IP (③). This action updates the learning table of the virtual switch, causing outbound traffic for these flows to be directed to the new cluster (④). The new cluster will then establish the connection state based on the outbound traffic, completing the migration for this flow (⑤). The amplification is significantly reduced since each new flow is proxied only for the brief period required to receive the outbound traffic from the first packet.

State aggregation. In our forwarding cores, we typically use hash tables to maintain connection states, indexed by the 5-tuple. However, in practice, we often migrate packets at the granularity of the VIP, as a VIP generally corresponds to one or more specific types of services. Within a single LD of our data center, there can be up to 240M states distributed across the cores. Aggregating these states across forwarding cores by VIP would introduce an unacceptable overhead if we were to directly use the connection state tables for migration. Therefore, we decouple the migration from packet processing by introducing an independent thread called the migration agent. This agent manages migration states using reorganized logic and data structures. Specifically, the migration agent reorganizes the states by VIPs as the key, storing only the state addresses of these states. It also maintains additional information, such as the connection ID, to ensure consistency throughout the migration process.

6 Failure Resilience

Failures in cloud data centers occur at different levels, including links, devices, clusters, and regions. These failures can stem from diverse causes such as human errors (e.g., misconfiguration), hardware malfunctions, and software bugs [22, 24, 53]. In this section, we illustrate our multi-cycle connection synchronization scheme for state backup, a fault tolerance model designed to address issues across different levels, and a dispersal migration scheme for blast radius isolation and attack defense. With the continuous evolution of `TGW`'s failure resilience strategies, the unavailability time has been reduced to zero by the first half of 2021.

6.1 Multi-cycle State Synchronization

Naively replicating and broadcasting new states to other LDs would impose significant overhead on link bandwidth and CPU usage. Therefore, based on three practical observations, we design a multi-cycle synchronization mechanism to back up states efficiently and consistently at runtime.

First, to reduce the number of replicated states, we set a timer for each new flow and only replicate those that have been active for at least 3 seconds. The 3-second time limit is an empirical value that reduces the number of replicated flows by 70% to 80% in practice. This is based on the observation that most connections in our cloud, such as HTTP requests and Radius database queries, last only a short time. Their states do not need to be replicated, as they are typically terminated before replication is completed.

Second, we find that exporting all states for replication simultaneously can lead to traffic bursts, while keeping separate export cycles for each state generates a large number of short packets, which decreases throughput. To reduce the replication frequency, we create a batch to cache the states to be exported, with a size of MTU (e.g., 1500 B in `TGW`). Each state identified for replication is inserted into the batch every 4 minutes. The batch is then exported to other LDs via UDP packets every 2 seconds. If the batch becomes full in less than 2 seconds, it is exported immediately. These processing time cycles are empirically defined based on the observation that long-lived connections do not modify their states frequently.

Third, for connections that are being established or closed, the LD will not replicate their states to further reduce overhead. This is because we observe that there is no need to synchronize the states of inactive connections, as they do not compromise failure resilience. We preserve consistency through the timeout recycling mechanism of peer LDs. Each synchronization event refreshes the timer of a connection state, and the state will be recycled if it times out. We do not

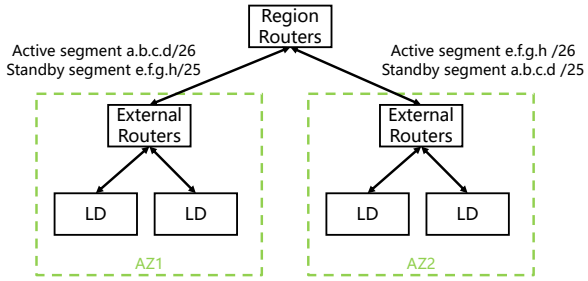

Figure 4: TGW's inter-AZ Active-Standby model. AZ1 and AZ2 operate on different IP segments but back up each other's states.

use dirty flags to enable incremental state updates, as every active state's timer needs to be refreshed by synchronization.

6.2 Fault Tolerance Model

In TGW's fault tolerance model, we combine both the Active-Active model and the Active-Standby model. Given synchronization cost and service requirements, we employ different fault tolerance models under different levels.

Intra-AZ Active-Active model. The failure of one LD within an AZ is common but typically has minimal impact. In each AZ, we use an Active-Active model, where LDs share the same connection state table. This allows traffic previously handled by a failed LD to be seamlessly redirected to another LD within the same AZ. Since LDs in the same AZ are closer in terms of network topology, frequent state synchronization incurs lower costs. The routing modules of every LD in an AZ cluster continuously send BGP advertisements with the same IP addresses to neighboring routers. If an LD fails and stops sending advertisements, routers recognize it as unreachable and reroute traffic to other LDs. The routers distribute traffic with a consistent hash algorithm [13] to minimize traffic redistribution and ensure flow affinity for ongoing connections. Thanks to mature BGP and BFD [30] technologies in data center networks, we can reliably achieve millisecond-level failure detection and failover delays of no more than a few seconds. Because of state synchronization (§6.1), re-diverted traffic is processed and correctly mapped to the VMs, ensuring continuity in service for unaffected connections.

Inter-AZ Active-Standby model. In extreme cases, such as when routers crash or an entire LD group fails, an entire AZ may become inaccessible. Given that intra-cloud traffic accounts for about 80% of our total traffic, the latency difference between AZs is significant. If AZs were set to Active-Active, different connections from the same tenant might be routed to different AZs, causing noticeable latency jitter. To recover from AZ-level failure, we implement an Active-Standby model for AZ pairs, where AZs operate on different network segments but back up each other's states. This ensures consistent latency for all connections from the same tenant, preventing jitter. Specifically, we configure AZs into redundancy pairs. These pairs synchronize their states, as outlined in §6.1, but handle traffic from distinct network segments. We achieve this by configuring IP prefix advertisements for each redundancy pair, where different-length prefix announcements are configured for a subnet in both AZs. For example, as shown in Fig. 4, AZ1 and AZ2 form a redundancy pair. AZ1 is responsible for the subnet a.b.c.d/26, while AZ2 handles e.f.g.h/26. To recover from an AZ1 failure, AZ2 additionally advertises the same IP prefix as AZ1, but with a shorter mask, such as a.b.c.d/25. Symmetrically, AZ1 advertises e.f.g.h/25. When both AZ1 and AZ2 are operational, they handle distinct traffic because of the longest-prefix matching behavior of the regional routers. However, if one AZ fails, traffic is seamlessly redirected to the other, ensuring uninterrupted services.

Inter-region failure reaction. A more disastrous case is the disability of an entire regional-level data center, meaning the complete TGW system in a physical region becomes unavailable. This is an extremely severe failure that is rarely encountered. In this case, the affected routing table is so large for synchronization that re-routing at Layer 3 is not feasible, as the routes converge too slowly. To counter this, we can modify the DNS records of the affected IP addresses to divert the massive traffic to other TGW regions or allow client applications to connect to access point IPs in other regions. This will inevitably bring higher loads to other regions, and all the connections will be broken due to a lack of backup. However, survivability is more important than performance in this case.

6.3 Decentralized Migration

When a failure or attack occurs, it is too late to react after localizing the issue. Furthermore, the backup-based fault tolerance model cannot handle all failures. For example, when abnormal packets or unexpected IP flags appear in the traffic destined for a VIP, bugs in the forwarding plane may be triggered, leading to an LD failure. Since the root of the failure lies in the traffic instead of TGW components, steering the traffic from a crashed LD to other LDs or AZs will only cause more LDs to fail due to abnormal or malicious traffic. To mitigate this as quickly as possible, we design a decentralized migration approach to isolate failures and defend against attacks. This decentralized migration is based on the observation that the vast majority of such failures are caused by traffic destined for a single VIP. This is because different VIPs correspond to different service types, each exhibiting distinct traffic patterns. The abnormal traffic that causes LD crashes may originate from client software associated with one of our services or from malicious attackers targeting a specific service. Specifically, when a set of LDs fails, the orchestrator will schedule the affected traffic by evenly dividing the corresponding affected VIPs into k parts. These parts of VIPs will be distributed to k standby LD sets, called buffer sets, respectively. The states of these VIPs will be concurrently migrated to these buffer sets. This migration follows a cold migration mechanism, as the crashed LDs can no longer proxy new connections and have lost their

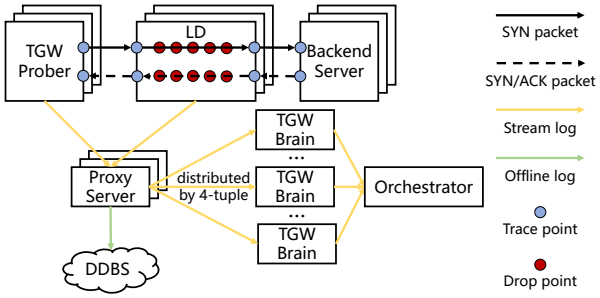

Figure 5: TGW's taint-based telemetry system.

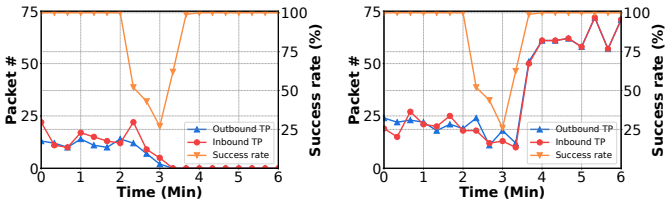
latest states. A decentralized migration using k buffered LD sets can be viewed as k concurrent cold migrations from the failed LD set to the k buffered sets. Through this, failure or attack will only affect one buffer set, reducing the impact by a factor of $1/k$. For the affected buffer set, we can continue to perform one or more decentralized migrations, exponentially reducing the impact of failure or attack. The number of buffer sets k is determined by the hot standby capacity of the cloud region and the priority of the affected traffic. In TGW, the typical value of k is 10. Decentralized migration is triggered when the backup-based recovery mechanisms fail, without the need to locate the root cause of the failure. After decentralized migration, most services will be restored, and the affected scope will be greatly reduced, which also facilitates subsequent failure location and recovery.

7 Failure Detection and Localization

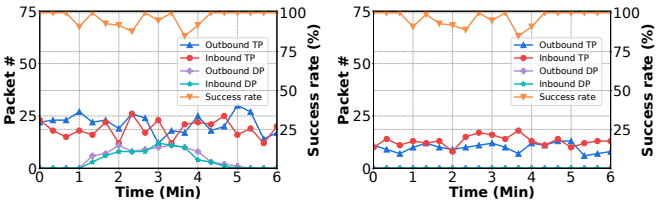
Although TGW can recover most services before we locate the failure, it is crucial to detect the failure as quickly as possible and gather sufficient logs for subsequent failure localization and improvement. However, achieving high observability is always challenging in such a large-scale, complex network. First, it is difficult to locate the exact failed LD when a cluster's performance decreases or experiences jitter. This is because, in our Active-Active fault tolerance model, the LDs within the same AZ cluster are equivalent and load-balanced. Second, when the root of the failure is not LD itself (i.e., the situation described in §6.3), it becomes harder to identify the root cause and reason. Third, our failure localization must be imperceptible to tenants and services, minimizing the impact of failure detection and localization on tenant traffic. To counter this, we design a taint-based telemetry system, inspired by taint checking in program analysis [14, 37]. We efficiently detect and locate failures by active probing and log analysis.



7.1 Taint-based Telemetry

As shown in Fig. 5, the taint-based telemetry system consists of TGW probers, probing proxy servers, and TGW brains. TGW probers continuously generate probing packets, while the LDs and backend servers apply taints to these packets according to the monitoring rules. These rules here are pre-configured static rules. They typically originate from two sources: abnormal forwarding rules that need to be inspected (based on user bug reports), and pre-configured forwarding rules specifically used for probing operational status. Logs are generated by both TGW probers and LDs, and are transferred through the probing proxy servers to the distributed TGW brains. The results are analyzed by the probing brain servers and stored in our data management system. After analysis, the orchestrator will automatically respond to the results.

Taint points. Naively assigning a unique rule to each LD solves the problem of locating a single LD, but it breaks the equivalence of LDs and introduces management overhead. To counter this, we set up several trace points (TPs) and drop points (DPs) to locate the failed LD. TPs are located at the RX and TX of TGW probers, LDs, and backend servers. When a probe packet arrives at a TP, it is tainted according to the rules. The LD also taints the packet with its unique LD ID. DPs are the points where an LD drops a packet. We have more than 20 types of DPs, such as *RX_ENQUEUE_FAIL*, *INVALID_VLANID*, *FLOW_LIMIT*, and *TUNNEL_ENCAP_FAIL*. When a packet is dropped in the LD, the DP is recorded in its statistics agent. The number of TPs in received probing packets and DPs from statistics agents helps us infer single-LD failure, and the type of DPs helps us pinpoint the root cause of the failure when misconfiguration or abnormal traffic occurs.



Handshake-based probing. Existing telemetry systems perform telemetry for web applications by constructing application-layer packets [19]. However, this method is not suitable for LDs with only L4 functions. In addition, it also requires more than three interactions with the backend servers, consuming bandwidth and CPU resources. Thus, we utilize the TCP handshake process for telemetry, just like in IP address probing [9, 60]. We use the $(CIP, CPort, VIP, VPort)$ tuple as a unique probing ID for probing packets. A TGW prober will probe a specific service, i.e., a certain $(VIP, VPort)$ tuple, every 5 seconds with a different CPort. For one probing process, the probing SYN packet is first sent by the prober. The tainted contents of the sending SYN packet are written into the response SYN/ACK packet by the backend server. To reduce overhead on bandwidth and CPU usage, we set up special firewall rules in advance to prevent the connection from being established on the backend server. Specifically, after the SYN/ACK packet arrives at the TGW prober, the prober drops the ACK packets for the third handshake and actively sends an RST packet to terminate the half-connection, thereby freeing the backend server resources.

Vantage points. To cover all LDs in the inbound direction, we deploy dozens of servers with public IP addresses as TGW probers. They are deployed across three geographic areas and connected to BGP-enabled routers to mitigate the impact of ISPs. To cover all LDs in the outbound direction, we also deploy dozens of backend servers for responses. These backend

(a) LD1 (b) LD2

Figure 6: Single-LD crash in an LD cluster.

(a) LD1 (b) LD2

Figure 7: Single-LD jitter in an LD cluster.

servers are distributed across multiple regions and racks.

Log analysis. Due to the large scale of TGW, the logs generated by TGW probers and LDs are vast. Aggregating them for analysis could result in GBps-level traffic and pose significant challenges for real-time processing. Therefore, we combine distributed streaming analysis with offline analysis for efficient log processing. For stream analysis, we aggregate and analyze probing logs from both probers and LDs every 20 seconds. These logs are transferred via proxy servers to distributed TGW brains. Logs sharing the same probing ID (i.e., the 4-tuple) are aggregated and directed to the corresponding TGW brain. Within seconds, the TGW brains analyze the logs and send the results to the orchestrator. For common failures, TGW can automatically complete detection, analysis, and decision-making within 1 minute, significantly reducing the need for manual intervention. In addition to online monitoring, we also inspect historical logs when diagnosing issues. These logs are stored in commercial distributed database systems (DDBS), with the total volume exceeding 10 TB per day. To facilitate fast queries, we utilize the inverted index algorithm that allows TB-scale data to be queried in under one second.

7.2 Case Study: Problematic LD location

We show how we figure out the problematic LD through our telemetry system in two real-world cases.

Single-LD crash. As shown in Fig. 6(a) and Fig. 6(b), we present the probe success rate of the cluster and the number of partial TPs during the failure of a single LD. When an LD crashes at 2 Min, the probing success rate of the cluster decreases. The number of TPs for inbound and outbound packets arriving at LD1 drops to nearly zero, significantly lower than that of LD2. This indicates that LD1 has completely crashed, and all packets fail to reach its RX. TGW detects and recovers this failure within 1 minute and responds at 3 Min, redirecting the traffic to LD2.

Single-LD jitter. As shown in Fig. 7(a) and Fig. 7(b), we additionally present the total number of DPs in both inbound and outbound directions during the failure of a single-LD jitter. In LD1, the number of DPs begins to rise at 1 Min, while in LD2, the number of DPs remains at zero. This indicates that the jittery packet loss is caused by LD1. Further analysis of the DP types allows us to pinpoint the root cause of the jittery packet loss.

8 Operational Experiences

Operating a large-scale gateway system is not a trivial task. TGW has been in operation for eight years, during which it has significantly evolved in forwarding performance and availability. Here, we share our operational experiences derived from our long-term operation of TGW.

Blast radius isolation. A crucial principle of availability is limiting the "blast radius" [16] that failures can impact: 1) We restrict the fault domain in architectural design. TGW is designed to be distributed and multi-layered, with different modules in regions, AZs, and clusters. Each module in a particular layer is decoupled from the others to reduce the impact of failures. Each module can be independently scaled or backed up. 2) We implement ad-hoc availability mechanisms at each layer, including customer service partitioning and placement (§6.3), routing or connection state management, and underlying hardware arrangements. 3) We divide the global controller based on geographic areas and deploy separate scheduler systems for each area. Each scheduler system only accesses the status of the data center it is responsible for and performs scheduling within that area.

Redundancy. Redundancy is always the best practice to ensure reliability. Considering the trade-off between cost and effectiveness, we use 50% redundancy, which ensures that: 1) At the AZ level, for two available zones as a redundancy pair, the clusters of one AZ can handle all traffic if the other AZ fails. 2) At the rack level, machines within a cluster are distributed across multiple racks, ensuring that the cluster remains available if half of the racks fail. 3) At the machine level, if half of the machines in a cluster fail, the remaining machines can carry all the traffic. 4) At the link level, the failure of half of the network cards or fibers of one or more machines does not affect the cluster.

Cluster construction. When a new cluster is set up after the machines and software are deployed, static parameter checks are first performed in a no-traffic environment. Once the cluster is in place, it will begin carrying traffic by sending BGP advertisements. After a batch of addresses is placed in the cluster, one of them is selected for long-term probing to monitor the forwarding status of the cluster before it becomes available for purchase. Our empirical cluster size is 4. At one point, we scaled a single cluster to support up to 8 LDs per AZ. However, we found that during operations, a small cluster composed of 4 LDs is sufficient for nearly all scenarios, while

also providing the advantage of a smaller failure domain.

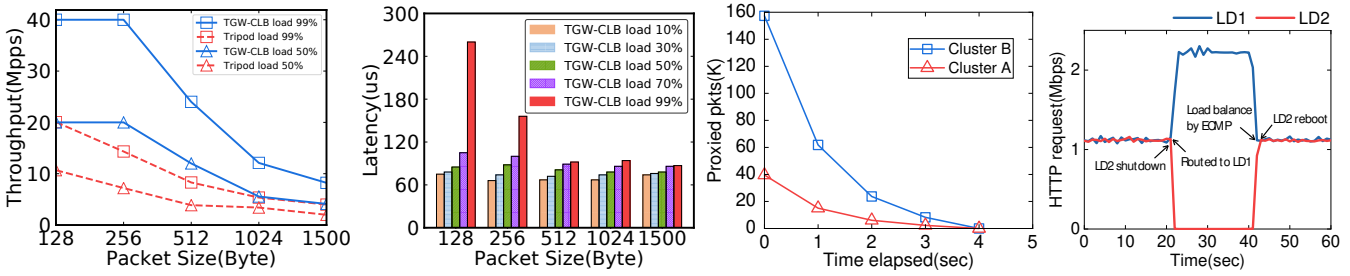
Cluster management. When an LD in the cluster needs to be maintained, its BGP advertisements will first be terminated, and the traffic originally handled by it will be automatically routed to other LDs. To manage dynamic changes in traffic volume, some gateway operators may choose to enable the CPU's low-power mode to reduce power consumption. However, we find that frequent mode switching introduces processing delays in the CPU and causes jitter. As a result, we adjust the capacity of the cluster by performing fast scaling instead of switching CPU C-States. When the traffic volume exceeds the threshold, we migrate part of the traffic to standby LDs (§5). When the traffic volume decreases, we first isolate the extra LDs' routing and then release them.

Odd-even routing. In the case of packet fragmentation and session persistence [49], we need to ensure that packets with the same IP pair are processed by the same LD. To achieve this, we configure odd-even routing between core routers and access routers, ensuring that packets with the same parity are forwarded by the same access router and distributed to LDs via the IP-pair-based ECMP protocol.

From multicast to unicast. In the early versions of TGW, we used multicast to transfer state synchronization and migration packets between LDs. However, we found that multicast was not suitable for large-scale gateways spanning multiple regions. Initially, small-scale TGW clusters were deployed in isolated environments within a single region, where multicast could be achieved reliably and stably by the data center network. However, as TGW evolved to support live migration functions and cross-region cluster configurations, the complexity of configuring multicast across regions increased, and its reliability diminished. As a result, unicast UDP packets became the preferred choice due to their lower OpEx and greater reliability. The trade-off of using unicast is that each LD must maintain its own list of peer LDs for communication.

DDoS defense. The main function of TGW is to schedule traffic. TGW's DDoS defense relies on the security gateway deployed between the Internet and TGW, which monitors and cleans attack traffic. TGW supports configuring rate-limiting functions across multiple dimensions, including bandwidth, packet volume, total number of connections, and new connection rate, all at the service granularity. This allows for fine-grained isolation when services are under attack.

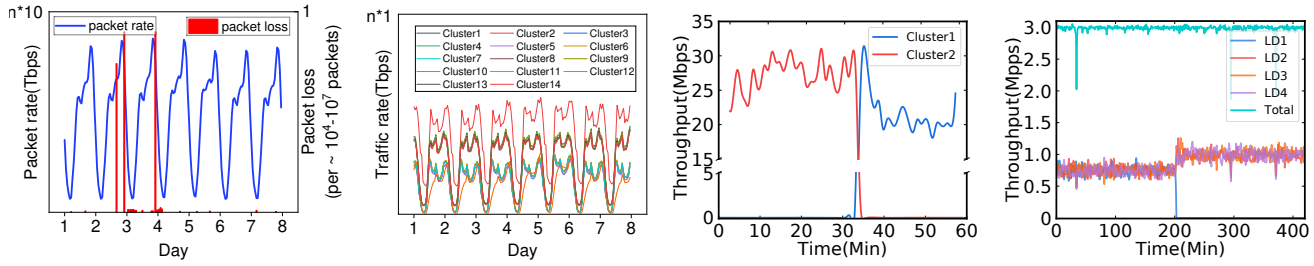
9 Evaluation



We demonstrate TGW's capabilities in performance, flow migration, and failure resilience. Our results are from two parts: experimental data from the testbed and real-world data from one of our regions. The testbed experiments are conducted on servers with 528 GB of RAM and 96 cores (AMD EPYC 7K62 Processor @2.6Ghz). They are connected via Mellanox MT28800 Family 100 Gbps NICs and commercial switches. In our testbed experiment, a single LD node is a test server running the LD forwarding plane along with the necessary management and control components.

9.1 Testbed Scenario

Single-node forwarding performance. We evaluate a single-node TGW-CLB instance in terms of throughput and latency. In this instance, 50 cores are used for two-stage pipelining forwarding, 18 cores are used for the first stage, and 32 are for the second. For throughput, we compare TGW-CLB with Tripod [58] under different loads with various packet sizes ranging from 128 B to 1500 B. Tripod is also configured with 50 cores for forwarding. We generate a huge amount of UDP traffic and perform at least 5 table lookups for each flow with O(1M) static rules and O(100M) dynamic connection states. As shown in Fig. 8(a), TGW-CLB achieves 2× (128 B) to 2.9× (512 B) throughput than Tripod for different packet sizes under the 99% CPU load and 1.9× (128 B) to 3.1× (512 B) under the 50% CPU load. TGW-CLB achieves a maximum of 96.8 Gbps bandwidth for the 1024 B packet. Although both TGW-CLB and Tripod are based on DPDK, TGW achieves significantly better performance due to extensive tuning and optimizations built on top of DPDK. These optimizations stem from long-term operational experience and testing, and include not only model and algorithmic optimizations discussed in §4, but also a range of engineering optimizations, such as memory management, code structure and code execution efficiency, as well as OS and hardware configurations. We also measure the average processing latency of TGW-CLB for each packet size under five different loads in Fig. 8(b). In most cases, for different packet sizes, TGW-CLB can provide a stable latency of 66 μs to 105 μs. The latency for the same packet size also increases slightly when the load rises.



Two-cluster migration. We prepare two clusters, A and B, each with 4 LDs deployed to measure TGW's LD proxy and state convergence. We set up 8M connections in cluster A and started the migration at 0 s, as shown in Fig. 8(c). The throughput of proxied traffic in cluster B is 4× of that of cluster A at the beginning because the LDs in cluster B will forward traffic to all four LDs in cluster A due to state miss, and only one LD in cluster A will process the proxied packet to reduce overhead. Since cluster B creates states based on the outbound traffic and each connection only has a few packets to be proxied, the migration process is greatly sped up and converges in less than 4 seconds.

Two-LD failure recovery. To illustrate TGW's failure resilience, we set up a cluster with 2 LDs, send HTTP requests to the LDs via ECMP, and monitor the traffic handled by each LD during a failure. As shown in Fig. 8(d), equal traffic passes through two LDs at the beginning. At 22 s, LD2 is shut down. The traffic through LD2 is immediately reduced to 0, while the traffic is almost immediately steered to LD1 via ECMP. Due to their advanced state synchronization, LD1 successfully handles almost all the incoming requests. At around 42

Figure 9: TGW's productive performance in one of our large cloud regions.

s, LD2 reboots. Since LD1 and LD2 use BGP to advertise the same IP addresses, the upstream sender distributes the traffic equally between the two LDs eventually.

9.2 Real-world Scenario

Throughput and packet loss rate. Fig. 9(a) shows the performance of TGW in a large cloud region during a one-week online shopping festival. Note that for privacy reasons, we muddle the integer n lying between 1 and 10. TGW has tens of Tbps of throughput and provides a low loss rate while carrying huge amounts of traffic. Even in the worst case, when certain cores are hit by heavy-hitter flows on day 3 and day 4, the packet loss rate only reaches 10^{-7} to 10^{-4}.

Traffic load distribution among clusters. The "80/20" rule makes it impossible to balance the load across clusters fully. Fig. 9(b) shows that the traffic is split horizontally among clusters within a region by TGW and is well balanced across most clusters at different workload levels. TGW sets different workload constraints among clusters according to the performance sensitivity of the deployed services and sets low-loaded clusters as hot backups so that traffic from high-loaded clusters can be quickly migrated to these clusters to maintain SLAs.

Live migration. We first evaluate the migration speed by recording one major state migration process of our productive cloud data center. In this process, we track the migration of 1371 VIPs, which host 130M connections. We find that 95.6% VIPs are migrated in 20 s, with 24.5% in 10 s and 71.1% in 10∼20 s. The left 4.4% VIPs are also completed in 20∼30 s. We secondly show the traffic migration process between two running clusters in Fig. 9(c). At 33 Min, we start migrating a /24 VIP segment from one cluster to another. Though new connections are continuously established on the old cluster, the migration process migrates the major traffic quickly and converges in 2 Min without any packet loss. Our real-time monitoring and customer feedback indicate that during the migration, no connections are interrupted, and the migration of services is not perceived by the customer.

Failure recovery. According to our record, TGW can synchronize 130M connections in 13 s with a peak bandwidth of 350 Mbps on each LD NIC. Fig. 9(d) shows one real-world failure in one of our commercial clusters with 4 LDs. The cluster carries 3 Mpps traffic and LD1 fails at 200 Min. Since the states of LD1 are synchronized in advance and the other LDs have redundant computing power and throughput, the traffic carried by LD1 is immediately taken over equally by other LDs. The total throughput is not affected, and the service is still available.

10 Lessons Learned

TGW has high scalability. Thanks to the distributed and modular design of TGW, it can be scaled at every level. TGW is currently scaled in more than 30 regions with the maximum scale of hundreds of clusters, thousands of machines, and tens of Tbps throughput. Our single cluster can support more than 200K rules and 100M connections. TGW carries almost all the public network traffic of our company's services and the public or load-balancing traffic of our cloud tenants.

TGW is proved easy to port. Compared to prior work [40], TGW's portability has been proved by practice. In addition to our own cloud gateway, we have already deployed TGW for dozens of other large custom companies, including famous

banks, TV stations, and car groups. The forwarding plane of TGW is a software component developed based on DPDK. It can be easily compiled and deployed on DPDK-enabled NICs and CPUs. The control plane and management plane components of TGW are hardware-independent application-layer logic that can run on general-purpose Linux OSes. Therefore, TGW can be smoothly ported to other data centers operated by large companies. Operators with knowledge of data center network management and DPDK programming can operate the entire system effectively. In contrast, hybrid solutions like Sailfish [40], which rely on P4 [1]-centric programmable hardware, present a high technical barrier due to the niche programming language and the immature compilation toolchain, requiring specialized hardware and professional expertise for deployment and operation.

TGW can be integrated with other solutions. Ease of integration with non-DPDK solutions and flexibility for future evolution are key design considerations in TGW. For example, when integrating TGW with alternative packet forwarding solutions, such as XDP and programmable switches (discussed in §2.2), we only need to implement corresponding APIs for the existing control plane and replace them with the DPDK-based forwarding plane.

The service type determines the properties of the infrastructure. As the most critical infrastructure of Tencent Cloud, TGW's properties are primarily determined by the service type. Tencent's core services—such as online gaming and live streaming—require TGW to guarantee low latency and jitter with high availability. It is worth mentioning that TGW-CLB supports port-segment-based configuration, i.e., a forwarding rule can specify a range of ports as a VPort, which maps to a corresponding port range on the backend server. This feature is particularly useful for multiplayer competitive games. Since each game room usually uses one port, a port segment forwarding rule can support multiple game room network connections in bulk. This capability is unique to TGW among cloud vendors and is driven by the specific requirements of our services.

11 Related Work

Cloud gateway. There are some related frameworks for cloud gateways: NVP [31] uses software to implement a cloud gateway to host thousands of tunnels, but does not support multi-tenancy in large-scale clouds. Tripod [58] provides an NF framework to host various NFs in cloud gateway scenarios. However, its unoptimized forwarding performance and coupled state management logic are insufficient for scaling in large-scale clouds. Protego [47] is a centrally controlled cloud-scale multi-tenant gateway. However, it does not solve the problem of heavy-hitter flows making certain cores overload. Arashloo et al. [3] use fixed-function switches to accelerate the cloud gateway, but the solution lacks the flexibility to meet our requirements in NFs. Sailfish [40] and Luoshen [39] use programmable switches and DPUs to enhance the performance of cloud gateways. However, they are suffering from supply chain breakdown by using P4-centric Tofino chips [10], lacking viability. DSR [45] is a disaggregated software-defined router system to provide reliable access. TGW can work with DSR when it acts as an edge access and steers the traffic to TGW, as Facebook [44] and Google [56] do.

Cloud load balancing. Load balancing is a fundamental building block in cloud gateway systems. Beamer [38] and Yoda [20] provide L4 or L7 load balancing in the cloud gateway using software methods. Ananta [42] focuses on the ECMP to scale, and Maglev [13] utilizes the consistent hash to map VIP and connections. These methods give less consideration to cooperation with public access. Large-scale deployment may cause considerable inter-AZ traffic because of the coupling with public access. They also sacrifice the flexibility of state management for different services in our practice. Alibaba Cloud [2] and AWS [4], as typical cloud providers, have similar services, including elastic IP address and cloud load balancing. Duet [21], SilkRoad [34], Prism [25], ConWeave [48] and Miresga [46] utilize programmable switches to accelerate load balancing. Tiara [57] and AccelTCP [36] use FPGAs and smartNICs to balance the traffic. However, they cannot support flexible DIP selection and are not general for all kinds of L4 traffic.

12 Conclusion

We introduce TGW, a long-term operated, large-scale cloud gateway system. It consists of efficient forwarding planes, a scalable state migration mechanism, a multi-level failure resilience mechanism, and a taint-based failure localization system. The experimental data from both the testbed and real-world scenarios illustrate TGW's capability in performance, scalability, and resilience. We believe that TGW's designs and the experiences gained from long-term, large-scale network operations are beneficial to both academia and industry. TGW will continue to evolve in the future as a key infrastructure of Tencent Cloud.

A Acronym Explanation

We provide explanations for technical acronyms whose full names do not appear in the main text, as shown in Table 1.

Acronym	Explanation
DPDK	Data Plane Development Kit, a high-performance packet processing library bypassing the Linux kernel protocol stack.
XDP	eXpress Data Path, a kernel integrated packet processor based on eBPF.
VPP	Vector Packet Processor, a packet processing framework providing rich routing functions, supporting DPDK as the forwarding plane.
GRE	Genetic Routing Encapsulation protocol that stipulates how datagrams under one network protocol are encapsulated in another.
BGP	Border Gateway Protocol, a routing protocol used to exchange network layer reachability information between routing domains.
BFD	Bidirectional Forwarding Detection, a high-speed network fault detection mechanism for fault recovery.
ECMP	Equal-Cost Multi-Path, a flow-based load balancing strategy, enabling packets with the same destination to be forwarded to different equivalent optimal next hops.
QUIC	Quick UDP Internet Connection, a multiplexed transport protocol built on top of UDP that aims to improve the speed and reliability of the network connection.
HTTP	Hypertext Transfer Protocol, a client-server request response protocol.
CapEx	Capital expenditures.
OpEx	Operating expense.

Table 1: Acronym explanation.

MARC: Motion-Aware Rate Control for Mobile E-commerce Cloud Rendering

Abstract

Mobile e-commerce platforms increasingly integrate cloud rendering to deliver immersive 3D shopping experiences, where users interact with the rendered scenes through the network. Our large-scale online measurements reveal that users' Quality of Experience (QoE) preferences dynamically evolve with user motions in cloud rendering sessions. However, latency spikes occur more frequently during peak periods of user engagement, resulting in early session abandonment. To address this issue, we propose *MARC*, a motion-aware rate control framework that aligns bitrate decisions with user QoE preferences in real-time. *MARC* sets dynamic QoE objectives based on real-world user engagement behavior, captures the different latency and quality requirements for motion and non-motion frames, and employs stochastic optimization to maximize QoE. Extensive deployment of over 1 million user sessions demonstrates that *MARC* reduces session freeze rates by 71% and increases user interaction time by 20%, significantly improving user engagement for e-commerce cloud rendering.

1 Introduction

As mobile e-commerce continues to flourish, an increasing number of merchants are turning to 3D rendering to deliver immersive product experiences [22,41,50]. By enabling users to interact with high-fidelity 3D models in real-time on their local devices, these technologies increase user engagement and purchase conversions [5, 67]. However, rendering 3D content locally requires substantial computing power, which conflicts with the limited performance and battery capacity of mobile devices. Additionally, downloading high-fidelity models imposes significant storage requirements and introduces considerable loading times. Cloud rendering has emerged as an attractive solution by offloading the computationally intensive rendering tasks to powerful remote servers and transmitting only the resulting video frames to the user. As a result, cloud rendering reduces the client's processing load and improves the overall user experience.

A key determinant of this user experience is the balance between motion-to-photon (MTP) latency and visual quality. Increasing the bitrate improves quality, but can also inflate MTP latency by causing network congestion. To this end, cloud rendering systems often use real-time communication (RTC) protocols such as WebRTC [6, 45]. Central to such systems is the rate controller [20, 37, 68], which adjusts the encoding bitrate based on estimated network bandwidth.

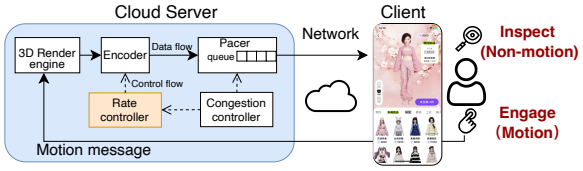

Figure 1: Architecture of the cloud rendering system. User behavior, including engage (motion) and inspect (non-motion) actions, follows an on-off pattern.

Although the cloud rendering system (Fig. 1) shares a similar technical framework with cloud gaming [53, 60, 69], our measurement on Taobao's mobile cloud rendering platform involving more than 100,000 users reveals unique QoE requirements for cloud rendering (§ 2.2). The results indicate that even with advanced optimization techniques, *users experience excessively high latency precisely when they are most actively engaged*, leading to early session abandonment. Specifically, user behavior follows an on-off pattern, alternating between "motion" phases (e.g., rotating or zooming in on a 3D product) and "non-motion" phases (e.g., inspection without manipulation). During motion phases, when users are most sensitive to high latency, video frames tend to be larger (22% on average) and tail latency increases significantly (1.9 times higher at the 99th percentile). Nevertheless, existing rate controllers, which use the same decision logic for both motion and non-motion phases, fail to distinguish between the different behaviors and QoE preferences of the two. Therefore, these solutions cannot optimize QoE for cloud rendering systems (§ 2.3).

Our observations highlight a key insight: *QoE requirements change dynamically with user motion, necessitating "motion-aware" rate control strategies.* Despite its simplicity, translating this insight into a practical system presents several design challenges:

***(i)* Mapping user engagement to QoE preference.** As observed in § 2.2, users prioritize low latency over high quality during motion phases, characterized by user engagement (e.g., session duration) decreasing more rapidly as latency increases.

*Co-first authors
†Corresponding authors

However, how to quantify this human-involved engagement pattern as a guideline for rate control remains unclear.

***(ii)* Striking a dynamic balance in bitrate adaptation.** The primary challenge in rate control is resolving the conflict between minimizing latency and maximizing quality under network dynamics. In addition, our measurements show that user behavior introduces QoE preference dynamics. These two types of system dynamics make it much more difficult to optimize QoE in e-commerce cloud rendering.

***(iii)* Enabling frame-level fine-grained decision.** Since user behavior exhibits an on-off pattern across frames, the rate controller must operate at the frame level, e.g., within 33.3 ms at a frame rate of 30 fps. This requirement imposes a severe time constraint on the decision logic.

To address the above challenges, we propose *MARC*, a dynamic QoE-driven **Motion-Aware Rate Control** framework for e-commerce cloud rendering. *MARC* sets a dynamic QoE objective function, which derives the importance of motion and non-motion frames directly from our measurements of user engagement as QoE preferences. *MARC* further models the dynamic QoE evolution of multiple future frames and utilizes stochastic optimization techniques to maximize cumulative QoE. In doing so, *MARC* incorporates a state predictor to predict user behavior and network conditions. Furthermore, *MARC* employs an efficient gradient-based method to determine the bitrate at the frame level.

We have implemented *MARC* in the WebRTC framework and deployed it in our real-world system. Extensive experiments based on simulation and large-scale A/B tests involving over 1 million user sessions demonstrate that *MARC* outperforms the state-of-the-art RTC rate control methods [6, 26, 28, 48]. Specifically, compared to baselines, *MARC* reduces the tail send duration and queueing latency for motion frames by 30% to 55%, tail frame latency by 22% to 60%, and session freeze rate by 71%. *MARC* also improves user engagement, with session durations increasing by 9% and interaction rates (i.e., the ratio of motion frames in all frames) rising by 20%. Moreover, *MARC* incurs no overhead on the client side and adds only a modest 1.3% CPU usage per session on the server side. These results confirm that *MARC* can achieve effective bitrate control in large-scale e-commerce cloud rendering systems.

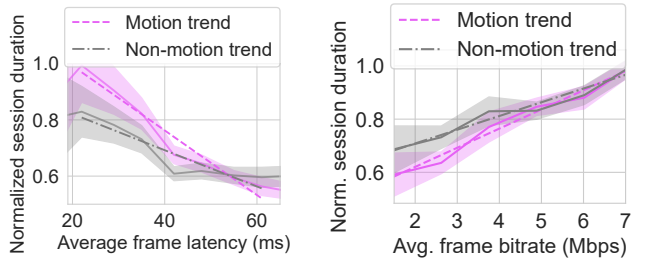
To summarize, the main contributions of this paper are:

- Identifying unique dynamic QoE requirements that evolve with user motion in e-commerce cloud rendering through a large-scale measurement study;
- Proposing a dynamic QoE-driven motion-aware rate control framework *MARC*, which integrates user-behavior modeling and multi-frame QoE optimization;
- Implementing *MARC* in production, ensuring frame-level bitrate adaptation under strict time constraints;
- Extensively evaluating *MARC* in a real-world cloud rendering system and demonstrating its efficiency.

Claim: This work does not raise any ethical issues. All data collected in this research are desensitized and include performance-related information only.

2 Background and Motivation

2.1 Background: Cloud Rendering in Mobile E-commerce Applications



Cloud rendering is an emerging technology adopted by e-commerce platforms to deliver interactive 3D visuals on mobile devices [22, 41, 50]. This technology increases user engagement by allowing users to interact with their favorite products and avatars in real-time, potentially boosting the revenue of e-commerce companies [5, 67].

Cloud rendering system architecture. A typical cloud rendering architecture is illustrated in Fig. 1. The mobile device acts as the client, capturing user motions for the server. Here, *motion* denotes intentional interaction events such as tap, pinch-to-zoom, or drag gestures that generate explicit control commands. The cloud server deploys a powerful 3D rendering engine (e.g., Unreal Engine [14]) to generate high-quality 3D graphics, which are then compressed into a video stream and transmitted to the client for playout. Inside the server, the encoder converts the rendered graphics into video frames that are further packaged into media packets. These packets are queued at the pacer, awaiting transmission over the network. The pacer follows the transport rate set by the congestion controller (e.g., GCC [6], Copa [3], Pudica [53], or SQP [48]), which estimates available bandwidth to avoid network congestion. The rate controller decides the target encoding bitrate based on the bandwidth estimation from the congestion controller.

Rate control for real-time communications. Video rate control significantly affects user experience [10, 68]. While higher bitrates can improve video quality and thus user satisfaction [10], they may result in increased latency due to inflating the send queue, especially when a sudden drop in bandwidth causes the encoder's output rate to surpass the transmission rate. To maintain low latency, current encoder rate controllers typically reserve a fixed portion of the available bandwidth as headroom. For example, commercial interactive video applications set the target bitrate 11% to 28% lower than the estimated bandwidth [28], which, however, sacrifices video quality. Therefore, video rate control must be carefully designed to balance quality and latency, which further relies on a deep understanding of the relationship between these QoE metrics and user engagement.

2.2 Characterizing User Behavior and QoE Preferences in the Wild

To investigate how the above QoE metrics affect user engagement in real-world cloud rendering systems, we conduct

(a) Frame latency vs. session duration.

(b) Frame bitrate vs. session duration.

Figure 2: Large-scale QoE study: Relationship between QoE metrics and session duration.

a large-scale QoE study on Taobao's mobile cloud rendering platform.

System setup. Our cloud rendering system allows users to dress up their 3D avatars, create dresses, and change background scenes. The server employs Unreal Engine (UE) [14] to render 3D graphics and leverages Pixel Streaming [15], a UE plugin, to stream these graphics to the client via WebRTC [45]. We use WebRTC because it is the de facto infrastructure for real-time video streaming [21] and is widely supported by major web browsers and platforms [58], facilitating large-scale production deployments. When users access the service, they are assigned to the nearest rendering server and then connected by WebRTC. Users can interact with the virtual characters on the screen, and their actions (e.g., motions like zooming in and out or changing viewpoints) are sent to the server via the WebRTC Datachannel using the SCTP [1].

Video encoding. Following common practice [34], our system operates at a fixed video resolution of 1560x720 with a frame rate of 30 fps and a maximum bitrate of 8 Mbps. The encoder works in CBR (constant bitrate) mode. We employ an infinite Group of Pictures (GOP) size, resulting in 99.9% of the frames being P-frames (non-keyframes). P-frames rely on preceding frames for decoding, which reduces redundancy and ensures efficient compression. Only 0.1% of the frames are I-frames (keyframes), which typically appear at the start of the session to initialize decoding. The stream is encoded in H.264 format, which is preferred for its superior decoding performance and energy efficiency, leveraging client-side hardware decoders.

Incorporating advanced optimization. Our cloud rendering system shares a similar technical infrastructure with cloud gaming [53, 60, 69]. Therefore, this system uses the same cutting-edge optimization techniques as cloud gaming. Specifically, edge servers strategically deployed near users [60], equipped with industry-leading hardware encoders [39] that support ultra-low latency and constant bitrate encoding modes [2]. The online configuration also includes pacing-based sending [56] (discussion in § 6) and forward error correction (FEC) [4]. Furthermore, the RTC framework incorporates the standard low-latency congestion control algorithm and rate controller [6], as well as innovative client-side buffer management [67].

Measurement methodology. We measure user engagement by two behavioral interaction metrics [42]: *(i) session duration*, which quantifies how much time a user spends on the service in a session; and *(ii) motion phase duration*, which is equal to the total duration of motion frames. A frame is marked as a motion frame whenever the server receives a user motion command from the client (see § 4.1 for details). Therefore, each motion phase contains a single frame or a series of consecutive motion frames[1]. In addition, other frame-level metrics are also collected, including the target bitrate, actual frame size, and send duration (the time taken from sending the first packet to sending the last packet of the frame). All metrics are collected on the server side and do not include any user-related or content-related information.

Dataset description. The measurement spanned from February 23 to March 27, 2024, covering 1.8 billion frames across 200,846 sessions, accumulating over 16,000 hours of video, and involving more than 100,000 users. To the best of our knowledge, this dataset represents the first large-scale and comprehensive measurement of a real-world cloud rendering system, uniquely capturing both video stream metrics and complex user motion behavior. By analyzing the dataset, we have made the following observations.

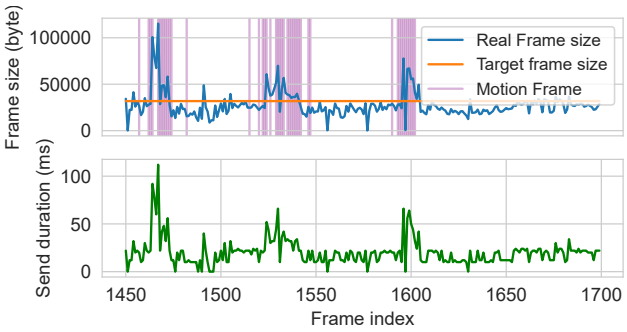
***Observation 1*: In motion phases, frame latency has a greater impact on user engagement than bitrate.**

We first focus on the relationship between QoE metrics (i.e., frame latency and bitrate) and user engagement in both the motion and non-motion phases, as illustrated in Fig. 2, where translucent areas represent 95% confidence intervals.

(i) **Frame latency**. It is defined as the time it takes for a frame to be sent from the server to be fully received by the client, namely the send duration plus the one-way delay (OWD), where OWD is estimated as half the round-trip time (RTT) on the server side. Although MTP latency also includes components from the rendering engine and client side, prior work [67] and our measurements indicate that client-side optimizations reduce its contribution to only 22% of total MTP. Consequently, the frame latency remains the dominant contributor.

In Fig. 2a, the trend lines represent linear regressions of the session duration data. It can be seen that session duration decreases as latency increases, which is consistent with the previous studies [53]. Additionally, the slope of the trend line is 75.7% steeper in motion phases than in non-motion phases. Looking deeper, increasing the latency of motion frames consistently decreases session duration. In contrast, once the latency of non-motion frames reaches a certain point (i.e., 42 ms in Fig. 2a), the session duration remains relatively stable.

[1]We have excluded single-frame user motions in our analysis to avoid the interferences from users' unconsciously tapping on the screen.



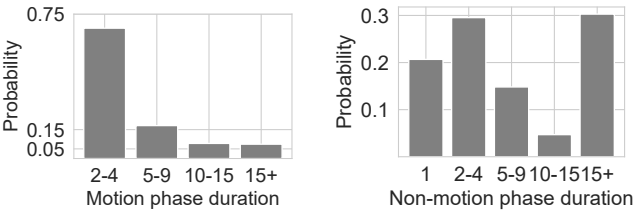


Figure 3: The on-off pattern of user motions.

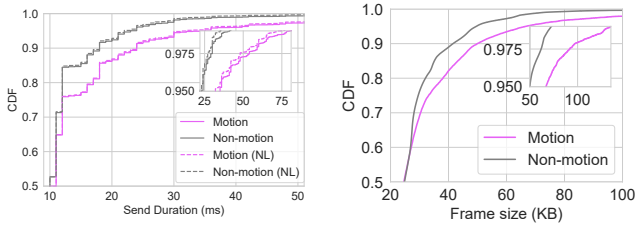
(a) Motion phase. (b) Non-motion phase.

Figure 4: The probability distribution of consecutive motion/non-motion frames.

These results suggest that *users are much more sensitive to the high latency of motion frames.*



(ii) **Frame bitrate.** As shown in Fig. 2b, session duration increases with frame bitrate. Overall, the slope is 37.8% steeper in motion phases than in non-motion phases. However, it is worth noting that when the frame bitrate is high enough (i.e., over 5 Mbps), session duration is hardly affected by user motion.

***Observation 2*: User behavior exhibits an "on-off" pattern, with short "on" (motion) and long "off" (non-motion) periods.**

Fig. 3 illustrates the "on-off" pattern of user behavior, where the "on" phase indicates successive motion frames while the "off" phase corresponds to the intervals between non-motion frames. Fig. 4 depicts the duration distribution of motion and non-motion phases. Motion phases are relatively short: 74% of them last 2-4 frames, while 15% last 5-9 frames (Fig. 4a). A non-motion phase may appear between two adjacent motion phases. 70% of non-motion phases are brief pauses (no more than 15 frames, i.e., 0.5 seconds), and 30% are prolonged stops (over 15 frames), as shown in Fig. 4b. This behavior pattern is typical in e-commerce applications, where users frequently change viewpoints and then pause to view their avatars or products.

***Observation 3*: Despite the same target bitrate given by the rate controller, motion frames tend to have larger sizes and longer send durations than non-motion frames.**

As defined, frame latency contains the send duration and OWD. In cloud rendering systems, OWD is typically very low,

(a) CDF of send duration. (b) CDF of frame size.

Figure 5: Send duration and frame size distributions for motion and non-motion frames. Motion increases the tail frame size and the send duration.

with a 95th percentile of only 29.5 ms in our measurements. This result is consistent with previous studies [60, 61], which can be explained by the fact that servers are edge-deployed and thus close to users. Nevertheless, the send duration is significantly longer, with a 95th percentile of 59 ms, which is 2 times the OWD. Therefore, we next examine the send duration, which is directly affected by the rate controller.

As shown in Fig. 3, the send duration generally increases with the actual frame size, which is different for motion and non-motion frames. The statistical results in Fig. 5 further support this intuition. Fig. 5a shows that the send duration of motion frames is consistently longer than that of non-motion frames after the 50th percentile (P50). In particular, the P99 send duration of motion frames can reach up to 82 ms, which is 1.9 times longer than that of non-motion frames, resulting in significant latency during motion phases.

Essentially, the root cause of increased send duration during motion phases is that *motion frames tend to generate more data than expected*. As a result, the actual bitrate of motion frames is more likely to exceed the congestion controller's pacing rate, causing packets to queue up at the sender and ultimately increasing the send duration. Fig. 5b indicates that motion frames are significantly larger than non-motion frames after the P50. Remember that both motion and non-motion frames use CBR encoding, and most of them are not keyframes. Therefore, the difference in their sizes is because motion frames have more variable content and require more bits to encode[2], as reported in previous work [47]. Notably, packet loss is not the main factor affecting send duration. Even in no-loss (NL) sessions, the tail (P99) send duration of motion frames can still reach 72 ms, which is 87.8% of the 82 ms in packet-loss sessions.

Unfortunately, existing rate controllers use the same decision logic to determine the target bitrate for both motion and non-motion frames, and thus cannot distinguish between their different behaviors and QoE requirements.

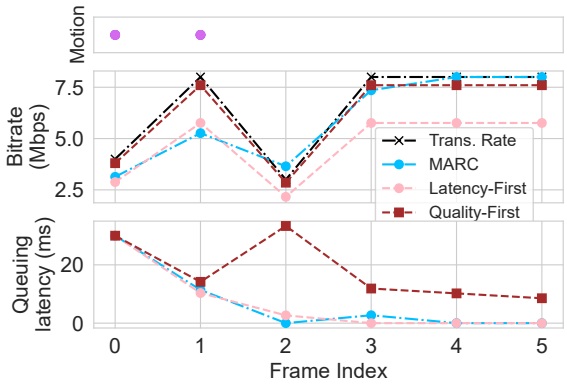


Figure 6: Frame bitrate and queuing latency. Queuing latency is the waiting time before transmission, determined by queue length, previous frame size, and pacing rate.

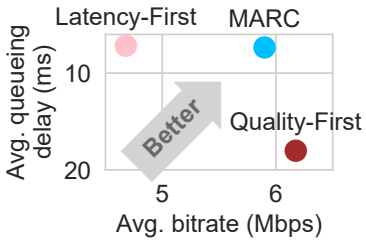

Figure 7: QoE performance comparison of *MARC* vs. existing rate controllers.

2.3 Pitfalls of Existing Rate Controllers

We provide a case study to illustrate how existing solutions fail to optimize QoE in the cloud rendering system due to ignorance of user motion.

Existing rate controllers typically use a fixed portion of estimated available bandwidth as video bitrate [28]. Two baseline strategies are considered in this controlled experiment (details in § 5.1): *(i) Latency-First* strategy, which allocates 72% of bandwidth as video bitrate (based on the measurement of a commercial video application in [28]); and *(ii) Quality-First* strategy, which uses 95% of bandwidth as video bitrate (an estimated value of GCC's [6] decision).

We also introduce our proposed method *MARC* (§ 3) as a comparison. To eliminate the effect of network conditions, we feed all strategies with the exact future bandwidth in the trace. In addition, all strategies begin with the same state, including user motion sequences and an initial sender buffer length of 15 KB (implying that a packet queue already exists on the sender). The performance is evaluated based on both *bitrate* allocation and *frame queuing latency*. Frame queuing latency is affected by the send duration of previous frames, referring to the time a frame spends waiting in the send queue before it is transmitted.

[2]However, this issue cannot be directly solved by modifying the video encoder, as discussed in § 6.

Fig. 6 illustrates the decision-making traces of these strategies. Note that frames #0 and #1 are motion frames. The Quality-First strategy outputs frames at higher bitrates and therefore struggles to drain the send queue quickly, especially when bandwidth suddenly drops (frame #2). On the other hand, the Latency-First strategy reduces queuing latency but does not effectively utilize the available bandwidth. While the queue is empty (frame #2), the Latency-First strategy still outputs low-level bitrates that reduce perceived quality.

Unlike the above, *MARC* maintains awareness of user motion. If the queueing latency is high, *MARC* timely reduces the bitrate/bandwidth ratio for motion frames (frames #0 and #1). Otherwise, for non-motion frames with low queueing latency, *MARC* chooses higher bitrates to improve quality (frames #2 to #5). As a result, *MARC* achieves the best balance between latency control and bandwidth utilization. Fig. 7 shows that compared to the Latency-First strategy, *MARC* improves the average bitrate by 26.1% for a similar average latency (2.5% higher). *MARC* also reduces queueing latency by 59.2% over the Quality-First strategy with only a 4.5% bitrate reduction.

2.4 Implications for Video Rate Control

As described above, we have identified characteristics of user behavior and factors that impact user engagement in mobile e-commerce cloud rendering systems. All three observations have important implications for rate control:

***Requirement 1*: Awareness of user motion.** Users are more sensitive to the latency of motion frames (Observation 1). Hence, the rate controller should be able to sense the motion phase, in order to dynamically adjust the bitrate based on the user's preferences.

***Requirement 2*: Frame-level decision.** Observation 2 indicates that the duration of the motion phase is typically short. Consequently, a fine-grained, frame-level rate control mechanism is essential to swiftly adapt to the short motion intervals and avoid unnecessary quality reductions or latency buildups.

***Requirement 3*: Differentiated bitrate assignment.** Given that motion frames are generally larger than non-motion frames (Observation 3), the rate controller should assign lower bitrates to motion frames to avoid excessive latency.

Summary. The technical framework of e-commerce cloud rendering system seems similar to that of mobile cloud gaming [18, 53], which typically needs a consistently low latency of 50 ms to 150 ms [9, 23] for all video frames. However, our large-scale QoE study reveals that *the QoE requirements of cloud rendering are quite unique*. Specifically, a cloud rendering session can be divided into alternating motion and non-motion phases. Users' QoE preferences differ significantly in these two phases. Therefore, the rate controller should be *motion-aware* to optimize dynamic QoE objectives. Unfortunately, existing solutions [8, 26, 28, 48] overlook this principle, which motivates our work in this paper.

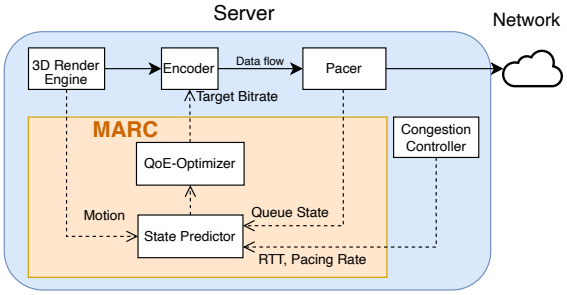

Figure 8: *MARC* system overview.

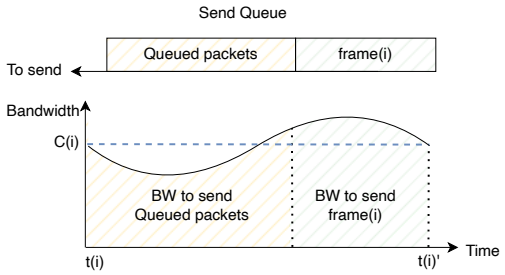

Figure 9: The relationship of frame enqueue time $t(i)$, frame departure time $t(i)'$, and avg. pacing rate $C(i)$.

3 *MARC* System Design

Based on our insights in § 2, we propose a Motion-Aware Rate Controller (*MARC*) for mobile e-commerce cloud rendering systems. *MARC* aims to maximize QoE by controlling the video encoding bitrate based on dynamic user preferences for quality and latency.

3.1 System Overview

Fig. 8 illustrates the high-level system architecture of *MARC*, which integrates several key components. First, the **Dynamic QoE Optimizer** (§ 3.5) determines the video bitrate on a per-frame basis, leveraging our time-based sending model (§ 3.3) and dynamic QoE objectives (§ 3.4). Second, the **State Predictor** (§ 3.6) provides short-horizon forecasts of user motion, pacing rate, and propagation delay.

Together, these components fulfill the three design requirements identified in § 2.4. Specifically, MARC is aware of user motion and makes frame-level decisions to optimize dynamic QoE preferences according to different user behaviors.

3.2 Mapping User Engagement to QoE Preference

Our analysis derives frame importance based on detailed online user interaction observations. We measure user engagement via *session duration* and study its relationship with latency and visual quality (bitrate). Specifically, we bin frames by latency/bitrate ranges, compute the average session duration in each bin, and then perform linear regressions separately for motion and non-motion frames, see Fig. 2.

Key findings. We observe that motion frames exhibit higher sensitivity to latency, with a slope ratio (non-motion : motion) $\approx 1:1.757$. Similarly, they also show moderately higher sensitivity to quality ($1:1.378$). This indicates that minimizing latency is particularly critical during motion phases, while maintaining adequate quality remains important for overall engagement.

3.3 Time-Based Formulation for Frame Sending Process

Our frame-level model captures the entire process from frame generation to transmission, accounting for encoding decisions, queuing, and transmission.

Frame generation and encoding. Video frames are generated at a nearly constant interval (e.g., 33 ms at 30 fps), denoted as I. For the i-th encoded frame, the encoding bitrate R_i is defined as Eq. (1). The encoded frame size is denoted by $d(R_i)$. Unlike typical VoD or live streaming scenarios [63,68] that have a set of discrete bitrates, *MARC* operates over a *continuous* bitrate space.

$$R_i \in \mathcal{R}, \quad \forall i = 1, \cdots, N. \tag{1}$$

In our implementation, we empirically derive $d(R_i)$ by performing separate linear regressions for motion and non-motion frames, based on real encoder output data. This approach more accurately captures the typically larger size of motion frames for the same bitrate, while still preserving a continuous domain for optimization.

Queuing and transmission. Fig. 9 illustrates the queueing and transmission process. The encoded frame(i) is packetized and added to the transmission queue, where the queue length is $b(i)$. We mark the moment of enqueueing as time $t(i)$. The frame(i) waits in the send queue until the previously queued packets have been transmitted. The time when the frame(i) finishes sending is marked as $t(i)'$. The duration from $t(i)$ to $t(i)'$, denoted as $s(i)$, corresponds to an average pacing rate $C(i)$ as defined in Eq. (4). This process is formulated in Eq. (2) and (3).

$$t(i)' = t(i) + s(i) \tag{2}$$

$$s(i) = \frac{b(i) + d(R_i)}{C(i)} \tag{3}$$

$$C(i) = \frac{1}{t(i)' - t_i} \int_{t_i}^{t(i)'} C_t dt, \tag{4}$$

Buffer state dynamics. We formulate send-buffer evolution by modeling the residual queue length $b(i)$, as shown in

Eq. (5). Here, $(x)_+$ means $\max(x,0)$, ensuring a non-negative queue size.

$$b(i) = \left(b(i-1) + d(R_{i-1}) - \int_{t_{i-1}}^{t_i} C_t dt \right)_+ \quad (5)$$

Total frame latency. The total frame latency includes queuing delay, send duration, and network propagation latency (denoted as $OWD(i)$) as defined in Eq. (6). Note that this differs from the "frame latency" defined in § 2, which does not account for queueing delay.

$$\mathrm{L}(i) = OWD(i) + s(i) \quad (6)$$

3.4 Dynamic QoE Objective Function

Based on the linear regression slopes in § 3.2, we normalize the base *non-motion* quality weight to 1.0, then we derive a *motion-to-non-motion* latency ratio of 1.275 (i.e., $\frac{1.757}{1.378}$). Concretely, for each frame i, we define:

$$\mathrm{QoE}(i) = q_R\big(R_i\big) - \gamma(i) \cdot q_L\big(L(i)\big),$$

where $q_R(\cdot)$ and $q_L(\cdot)$ are the respective quality and latency scoring functions. The latency penalty coefficient $\gamma(i)$ depends on whether the frame is non-motion ($M(i) = 0$) or motion ($M(i) = 1$):

$$\gamma(i) \;=\; \begin{cases} 1 & \text{if } M(i) = 0 \\ 1.275 & \text{if } M(i) = 1 \end{cases} \quad (7)$$

Equivalently, we may write $\gamma(i) = \lambda_s + M(i) \cdot \lambda_m$ with $\lambda_s = 1$ and $\lambda_m = 0.275$. (The impact of the two parameters is evaluated in § 5.2.)

To capture overall QoE across N consecutive frames, we sum the single-frame QoE as in Eq. (8):

$$QoE_1^N = \sum_{i=1}^{i=N} q_R(R_i) - \sum_{i=1}^{i=N} (\lambda_s + M(i) \times \lambda_m) \times q_L(L(i)) \quad (8)$$

This formulation *dynamically* places more weight on latency reduction in motion frames, aligning with users' observed engagement patterns.

3.5 Maximizing QoE with Stochastic Optimization

Given the constraints imposed by the frame-sending model and the QoE objective, we formulate the rate control problem as a QoE maximization problem:

$$\max_{R_1,\cdots,R_N} QoE_1^N \quad (9)$$
$$s.t. \text{ Equation (1) to (6)}$$

The *MARC* algorithm. The algorithm 1 shows a high-level overview of the *MARC*. Tab. 1 lists the key variables in the algorithm. The algorithm runs whenever a frame is encoded. It determines the target bitrate for *the next* frame. Thus, the decision time for the algorithm is about a frame interval (e.g., 33 ms in 30 fps). The algorithm employs an N-step lookahead strategy (moving horizon) to address a specific QoE maximization problem. The window size is set to $N = 10$, a fine-tuned parameter striking a good balance between performance and overhead, as evaluated in § 5.4 and Appendix A. This involves predicting motion ($\hat{M}_{[i,i+N]}$), propagation latency ($\hat{OWD}_{[i,i+N]}$), and pacing rate ($\hat{C}_{[i,i+N]}$) by the state predictor.

Table 1: Key Variables of the Model

Notation	Meaning
$q_R(R)$	Quality evaluation function
$q_L(L)$	Latency evaluation function
λ_m	Weight for motion frames
λ_s	Weight for non-motion frames
I	Frame interval (ms)
$d(R_i)$	Size of frame i
$b(i)$	Size of send queue when at $t(i)$
$t(i)$	Time when frame i is packetized
$s(i)$	Send time of frame i
$t(i)'$	Time when frame i departs from the send queue
$C(i)$	Average pacing rate from $t(i)$ to $t(i)'$
$L(i)$	Motion-to-photon latency of frame i
$M(i)$	Whether frame i is a motion frame (0 or 1)
C_t	Pacing rate at time t
$OWD(i)$	One way delay while sending frame i

Algorithm 1 *MARC*: Motion-aware Rate Control

input: $M_{[i-N,i]}$, $OWD_{[i-N,i]}$, $C_{[i-N,i]}$, λ_s, λ_m, $b(i)$
output: R_{i+1}: Encoder target bitrate for the next frame
On frame encoded

1: $\hat{M}_{[i,i+N]} = \texttt{MotionPredict}\,(M_{[i-N,i]})$
2: $\hat{OWD}_{[i,i+N]} = \texttt{OWDPredict}\,(OWD_{[i-N,i]})$
3: $\hat{C}_{[i,i+N]} = \texttt{PacingRatePredict}\,(C_{[i-N,i]})$
4: $R_{i+1} = f_{MARC}(b(i), \hat{M}_{[i,i+N]}, \hat{OWD}_{[i,i+N]}, \hat{C}_{[i,i+N]})$

In **Algorithm 1**, four functions act as the core building blocks. `MotionPredict(·)` takes the observed motion labels from the past N frames and predicts future labels ($\hat{M}[i,i+N]$). `OWDPredict(·)` uses recent RTT measurements to forecast propagation delay ($\hat{OWD}[i,i+N]$). `PacingRatePredict(·)` analyzes pacing rates from the previous N frames to estimate upcoming sending rates ($\hat{C}[i,i+N]$). Finally, $f_{MARC}(\cdot)$ combines these predictions with the current queue state $b(i)$ to determine the next-frame bitrate R_{i+1}, maximizing QoE by balancing latency and visual quality while adjusting to user motion.

3.6 State Predictor

The state predictor is crucial for forecasting user motion, pacing rate, and propagation delay, which are essential inputs for the *MARC* system.

User motion predictor. We have developed a Markovian model that predicts the motion sequence of user frames based on the types of the previous M frames. The model forecasts whether the next frame will be of type 0 or 1 and continues this prediction for future N frames. Its state transition probabilities are derived from statistical data observed online, as observed in § 2.2. Since each frame type is binary, the model encompasses 2^M states. We evaluate the M and the prediction accuracy in § 5.3.

Pacing rate predictor. While Eq. (4) provide a theoretical definition of the average pacing rate C(i), obtaining an exact solution for Eq. (4) in a real-time system is non-trivial. In our implementation, we approximate $C(i)$ by the current sending rate of recent pacing rates. This approximation assumes that over the short interval, the pacing rate does not fluctuate dramatically. Since our system primarily targets short pacer queues and a relatively stable sending rate, such approximation provides sufficient accuracy (see § 5.3).

Propagation delay predictor. We use the smoothed RTT to estimate the propagation delay (which is $1/2$ RTT). Similar to predicting the pacing rate, as the RTT variation within a short period is stable as evaluated in § 5.3. Note that the completion time of a frame may be delayed by packet disorder or jitter. We verified that 99.8% of disordered packets experience delays of less than 16 milliseconds. Therefore, packet disorders within a frame are less likely to severely increase the completion time. Thus, we can disregard the impact of the disorder.

4 System Implementation

4.1 Motion Frame Identification

The Unreal-Engine Pixel Streaming plugin [15] bridges the cloud renderer and its WebRTC transport. It passes video frames from the rendering application down to WebRTC for transmission and forwards user inputs received via WebRTC up to the rendering application. Among these inputs, each motion event is handled by our modified plugin, which forwards the event to a helper function added to WebRTC's `PeerConnectionInterface` [57]. The helper then notifies *MARC*, which marks the next encoded frame as a motion frame.

4.2 *MARC* System Implementation

The dynamic QoE optimization model is the core of the *MARC* system. It involves carefully designed QoE functions and an efficient solving process for real-time optimization. We implemented *MARC* within the PixelStreaming [15] and the WebRTC framework, using 1,246 lines of C++ code.

QoE functions. The principles for designing QoE objective functions are *(i)* they should be continuous and differentiable to allow adjustments in the continuous action space, and *(ii)* they should reflect the user's subjective experience.

Following these principles, we designed a non-linear quality QoE function as in Eq. (10). The first term in this function $(1-\frac{1}{R/a+1})$ characterizes the diminishing marginal effects of increasing bitrate on improving video quality, as observed in Vantage [49]. The second term $(\frac{R_{Max}+a}{R_{Max}})$ normalizes the QoE score to the [0,1] range. In our setting, $a=2, R_{max}=8$ *(Mbps)*. We evaluate the impact of QoE functions in Appendix B.

$$q_R(R) = (1-\frac{1}{R/a+1}) \times \frac{R_{Max}+a}{R_{Max}} \tag{10}$$

Similarly, the latency QoE function is defined as Eq. (11), following the same principles. It imposes minimal penalties for low-latency regions but increases progressively at high-latency regions, consistent with findings in the study [36]. In our setting, we normalize the maximum allowable latency with L_{max} = 150 ms.

$$q_L(L) = (\frac{L}{L_{max}})^2 \tag{11}$$

Continuous rate optimizer. To solve the problem in Eq. (9), we employ the `NLopt` [25] optimization library in C++. The optimizer treats the bitrates of the next N (default $N=10$) frames as real-valued decision variables, each box-constrained to the application-defined range $[R_{\min}, R_{\max}]$ ($[0,8]$ Mbps in our setting). Each call is warm-started with the optimal solution from the preceding frame, while the first frame is initialised with an initial bitrate of 1 Mbps. Optimization terminates when the relative change of all variables falls below 10^{-4}.

Reducing computing overhead. The primary computational cost arises from solving the N-step look-ahead optimization problem, which has a time complexity of O(KN), where K is the number of iterations per step. To improve performance, we *(i)* select a relatively small prediction window of N=10 (determined experimentally as the parameter that best balances overhead and solution quality; the computing overhead is evaluated in § 5.4, the quality is verified in Appendix A); and *(ii)* using `NLopt`'s gradient-based SLSQP [13] backend to reduce the number of iterations required per step (a comparison of different non-linear optimization solvers and their computational overhead is presented in § 5.4). Additionally, we further reduce computing overhead by designing a simple motion state predictor.

Motion state predictor. We represent the state of the M historical frames as the key by encoding the binary sequence $(S_{t-M},\ldots,S_{t-1})$ into an integer $k=\sum_{j=1}^{M} S_{t-j}\cdot 2^{j-1}$ and the probability of the next frame being a motion frame as the value, denoted as p_t, storing this data in a C++ map. The probability is built offline from a large dataset of interaction traces: for each context key k we compute $p_t = \Pr(S_t=1 \mid k) = \frac{N(k,S_t=1)}{N(k)}$, where $N(\cdot)$ counts occurrences in the dataset, thus p_t is the estimated conditional probability that a motion frame follows this context. Predicting the next frame

involves a simple hash lookup for the probability, followed by a Bernoulli draw with parameter p_t. This approach reduces computing overhead for online deployment.

The space complexity of storing the statistical user motion model is $O(2^M)$, where M is the number of historical frames. Each frame state is encoded as 1 bit (1 for motion, 0 for non-motion). The memory used for the map can be shared across multiple sessions, preventing linear scaling of costs as the number of concurrent sessions increases. The storage overhead for a single process is minimal, representing only a 3% increase in memory usage compared to the overall process.

5 Evaluation

This section comprehensively evaluates *MARC* using both trace-driven simulations and large-scale real-world deployments on mobile networks.

5.1 Evaluation Setup

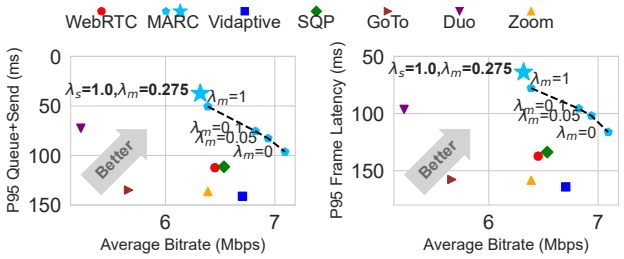
Trace driven evaluation setup. To accurately compare and replicate the bitrate control algorithms, we implemented the simulation environment based on the architecture depicted in Figure 1. This setup allows us to replay traces representing user behavior and network conditions.

Trace collection. We collect traces from our online system. These traces record the application, encoder, and transport models' behaviors. Specifically, the application layer data encompasses the user motions (as measured in § 4.1). The encoder model provides the encoding bitrate of each frame, the frame intervals, and the frame sizes. The transport layer information includes the pacing rate and the Round-Trip Time (RTT) for each of the frame's packets. Our dataset, collected from February 23 to March 27, 2024, comprises over 200,000 sessions and 1.8 billion frames.

Online evaluation setup. We deployed *MARC* in a production environment as described in § 2.2 to assess its real-world performance. To conduct an A/B test, the online experiment randomly assigns each user request to either WebRTC's default rate control algorithm or the proposed *MARC* algorithm.

Baselines. We compare *MARC* with the following bitrate control algorithm as baselines:

- *WebRTC* [45]. The default transmission framework in our environment. It contains the *EncoderBitrateAdjuster* [8] module. The encoder bitrate adjuster dynamically adjusts the target bitrate of the encoder based on the observed average network utilization over a specified period, typically reducing the bitrate if the actual frame sizes exceed expected values.
- *SQP* [48]. SQP uses 90% of available bandwidth as the target bitrate to prioritize low transmission latency. Note that we only compare the rate control strategy of SQP, while we keep the bandwidth estimation strategy the same as WebRTC.
- *Vidaptive* [26]. Vidaptive's rate control logic dynamically adjusts the encoder's rate discount factor α to ensure that the λ^{th} percentile of frame send durations over a defined time window T is closely aligned with the target send duration Δ. We use $\lambda = 90$, $T = 1s$, $\Delta = 33ms$ in the evaluation. To ensure fairness, the Vidaptive frame-skipping strategy is disabled because frame rate control and rate control are orthogonal.
- Commercial video applications models. We utilize the inferred rate control models from the study [28]. Specifically, we employ the video bitrate control model represented by the parameters γ and μ. The parameter γ is a scaling factor that indicates the ratio of video bitrate to available bandwidth, while μ is a constant with units of kbps. We evaluated the performance of all the six application models in the study and selected three representative applications for demonstration: *Zoom* ($\gamma = 0.88$, $\mu = -1.57$), *Duo* ($\gamma = 0.72$, $\mu = -1.91$) and *GoTo Meeting* (abbreviated as *GoTo*) ($\gamma = 0.78$, $\mu = -1.36$). The other models exhibit performance similar to that of these applications.
- MARC *derivatives*. We vary the weight of motion frames λ_m and non-motion frames λ_s.

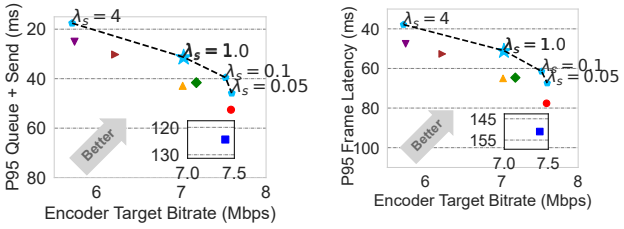


Metrics. We evaluate the quality by the target bitrate of each frame and the visual quality metrics like peak-signal-to-noise-ratio (PSNR), structural similarity index (SSIM) [55], and VMAF [29]. We evaluate latency by the send duration and frame latency.

5.2 Performance Improvement

We evaluate the performance of *MARC* and the baselines in the trace-driven simulation environment. *MARC* extends the performance boundary compared to the baseline algorithms.

Improving performance for motion frames. *MARC* achieves significantly lower motion frame latency compared to multiple baseline algorithms (e.g., Zoom, Duo, WebRTC, Vidaptive, etc.) under similar visual quality conditions. In particular, *MARC* reduces the 95th-percentile (P95) send duration plus queueing latency (shown in Fig. 10a) by 30% to 55% relative to the baselines, thanks to proactively allocating bitrate to consecutive motion frames and thus avoiding excessive queue buildup.



Additionally, *MARC* achieves better visual quality than the baseline under similar latency conditions. For instance, the optimal *MARC* configuration ($\lambda_s = 1, \lambda_m = 0.275$) boosts the average bitrate by 35% over Duo (see Fig. 10a), while simultaneously reducing the P95 frame latency (Fig. 10b) of motion frames by 33–101 ms relative to various baselines. We also examined *MARC*'s derivatives with $\lambda_s = 0.05$ (chosen for its high visual quality in Fig. 11b) and varied λ_m from 0 to 1, these variations are connected by dashed lines. Even without explicit motion awareness ($\lambda_m = 0$), *MARC* achieves the highest average bitrate among all tested methods, while maintaining a markedly lower P95 tail latency than most baselines.

(a) P95 send duration + queueing latency of motion frames.

(b) P95 frame latency of motion frames.

Figure 10: Bitrate and tail latency of motion frames.

(a) P95 queueing latency and send duration of sessions.

(b) P95 frame latency of sessions.

Figure 11: Encoder target bitrate and tail latency.

The gain arises from *MARC*'s queue-responsive optimization: a large frame inflates the queue length $b(i)$, increasing both its own send time (Eq. (3)) and the buffered data for subsequent frames (Eq. (5)). The larger send buffer lengthens the queueing delay of those later frames, which lowers the cumulative QoE in Eq. (8). To maximize QoE, *MARC* therefore lowers the bitrate of the upcoming frames. Because motion frames are typically large and arrive consecutively (see § 2.2), this mechanism implicitly prioritises motion phases even when $\lambda_m = 0$. As λ_m grows, *MARC* realizes better Pareto tradeoffs between quality and latency (i.e., moving closer to the lower-right corner in Fig. 10a and Fig. 10b), surpassing the baselines in both dimensions.

This indicates that *MARC*'s dynamic bitrate adjustment method utilizes bandwidth more effectively and reduces latency better than fixed-rate allocation methods or purely reactive methods. Compared to the Vidaptive method, which also adjusts the bitrate dynamically, *MARC* achieves lower motion frame latency. This is because *MARC* uses a motion predictor to allocate bitrate for motion frames ahead of time, whereas Vidaptive only reduces the bitrate upon detecting a latency increase. These results align with our analysis in § 2.4.

Improving performance across all sessions. To evaluate *MARC*'s overall performance, we collect the P95 queue+send latency and frame latency for each session and average these tail metrics across all sessions. Fig. 11(a) and (b) show the resulting tradeoffs between encoder target bitrate (x-axis) and tail latency (y-axis). By varying λ_s from 0.05 to 4, *MARC* traces out a Pareto frontier that clearly outperforms the baselines (Zoom, Duo, WebRTC, Vidaptive, etc.). At comparable

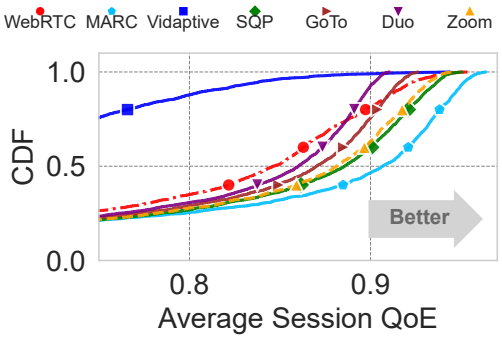


Figure 12: CDF of average session QoE across all sessions.

target bitrates, *MARC* achieves 22%–60% lower P95 frame latency than other algorithms. This performance gain arises primarily from λ_s, which governs all frames, whereas λ_m specifically targets motion frames (λ_m is fixed at 0.275 in this experiment).

When $\lambda_s = 0.05$, *MARC* achieves the best quality, while $\lambda_s = 4$ results in the lowest latency (Fig. 11b). Meanwhile, Vidaptive exhibits higher *P95* latency because its control logic focuses on keeping *P90* send duration below 33 ms; thus, the top 10% of frames can exceed the frame interval. Additionally, Vidaptive's frame-skipping mechanism was disabled to ensure a fair comparison. As a result, Vidaptive's more aggressive utilization of probed bandwidth, compared to other algorithms, leads to prolonged queueing delays and consequently the lowest overall QoE, as shown in Fig. 12. Overall, *MARC*'s approach provides a distinct advantage in both latency and video quality, validating our design hypothesis.

To further illustrate these QoE differences, Fig. 12 summarizes the overall QoE achieved by each algorithm. For every session, we first compute the per-frame QoE using the definitions in § 3.4, Eq. (10), and Eq. (11), and then average these values to obtain the average session QoE. The *MARC* curve corresponds to the default configuration of $\lambda_s = 1$ and $\lambda_m = 0.275$. As shown in Fig. 12, *MARC*'s curve is farthest to the right, indicating consistently higher QoE. Its median exceeds the baselines by 3%–36%, and its tail QoE at P95 is 1.3%–21% higher. The steeper rise of *MARC*'s CDF further suggests a smaller QoE variance across sessions.

5.3 *MARC* Deep Dive

The MPC algorithm's performance is influenced by *(i)* prediction accuracy [32, 62, 63] and *(ii)* QoE objectives [33, 63]. Therefore, we validate the impact of the state predictor and QoE functions on *MARC*'s performance.

Motion frame predictor. We first verify the accuracy of the motion frame predictor, followed by an analysis of its impact on the accuracy of the *MARC* algorithm.

To evaluate the accuracy of the predictor, we divided the dataset of user sessions collected online, allocating 80% of

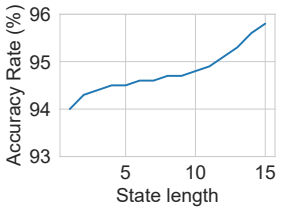

Figure 13: Accuracy rate of predicting the next frame's type.

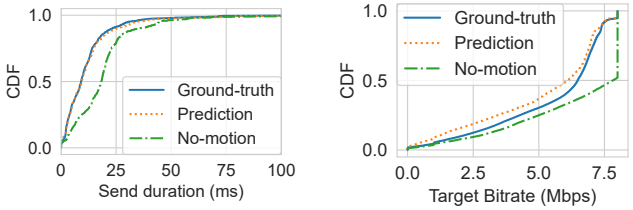
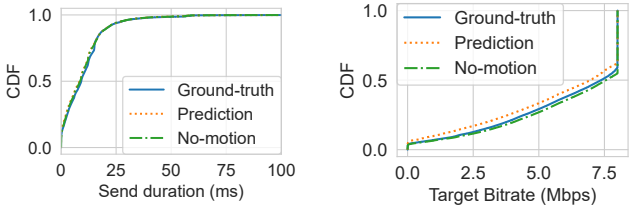
the sessions for training and the remaining 20% for prediction. Within each session, frames were sequentially organized into samples, where each sample consisted of M historical frames followed by a single prediction frame.



The accuracy of the motion frame predictor is affected by the state lengths (historical frame lengths). Fig. 13 illustrates the relationship between state length and prediction accuracy for the next frame type. As the state length increases, the accuracy of predicting the next frame type improves from 94% to 96%. The high accuracy is because most frames are non-motion frames, with motion frames constituting only 3.4% of all frames. However, the accuracy of predicting the start of a motion is relatively low, with a maximum of 36.8% and a recall of 36.7%. This is because the timing of the user's motions is random and therefore difficult to predict. Nonetheless, motion sequences tend to occur consecutively as observed in § 2.2, leading to a 72% improvement in the accuracy of predicting frames following an initial motion. This ensures the accuracy of *MARC*'s optimization for motion sequences.

To further evaluate the predictor's impact, we compared *MARC*'s performance under three scenarios: using ground-truth user motion sequences, predicted motion sequences, and without motion prediction (treating all frames as non-motion frames). Fig. 14a shows the CDF of send duration for these scenarios. The performance with predicted motion sequences closely matches that of ground-truth sequences, reflecting the high accuracy of our predictor. Without motion prediction, the median send duration doubles, emphasizing the importance of motion-aware rate control.

Fig. 14b compares the target bitrates for motion frames under these three strategies. Without motion frame prediction, the target bitrate is highest, increasing the likelihood of encoder overshooting and longer send durations. Using motion prediction results in a median target bitrate 5% lower than with ground truth, due to prediction errors.



We also examined the impact on non-motion frames, as shown in Fig. 15. The send duration distribution remains consistent across all three strategies (Fig. 15a). However, the median target bitrate with motion prediction is 3% lower than with ground truth or no-motion strategies (Fig. 15b), as approximately 2% of non-motion frames are misclassified as motion frames, resulting in more conservative bitrate control.

Pacing rate and RTT predictor. We analyze the pacing rate and RTT for each frame in the motion sequence. Fig. 16a

(a) Send duration (b) Target bitrate

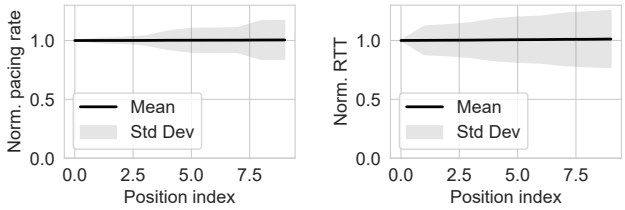


Figure 14: Performance of motion prediction model.

(a) Send duration (b) Target bitrate

Figure 15: Performance evaluation of the prediction model on non-motion frames.

illustrates the mean pacing rate for each frame position in motion sequences. The results show remarkable consistency, with the standard deviation remaining below 0.08 for the first four frames. This stability supports our strategy of using historical pacing rates to estimate future rates accurately. Similarly, in Fig. 16b, the mean RTT of consecutive frames remains stable with little variance, this consistency justifies our use of smoothed RTT values for future RTT estimation.

(a) Pacing rate (b) RTT

Figure 16: Stable pacing rate and RTT in motion phases.

5.4 Overhead Evaluation

Zero client-side overhead. *MARC* achieves efficiency with all functionalities implemented server-side, eliminating any impact on mobile device energy, storage, or computation, making it ready for large-scale deployment.

Minimal server-side overhead. We measure the inference time of two non-linear optimization solvers, SLSQP [13] and COBYLA [44], on our testbed server equipped with an Intel i9-13900KF CPU. In this experiment, the prediction window size was varied from 5 to 20 frames in increments of 5 frames.

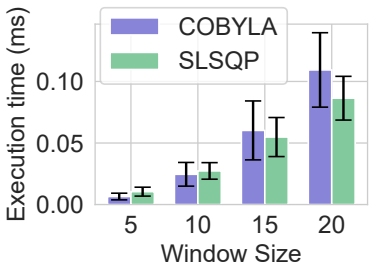

Figure 17: Per-frame execution time of two optimization solvers with different window sizes.

We varied the input transport rate from 0.1 to 8 Mbps in steps of 0.1 Mbps, and the send queue size from 0 to 150 KB in steps of 1.5 KB, as different inputs affect the execution time. Each input state was tested 1000 times, and the average execution time was recorded.

The results are presented in Fig. 17. COBYLA's execution time is lower than SLSQP's when the window size is 10 frames or fewer. However, the computation time of the COBYLA algorithm increases faster than SLSQP, resulting in longer execution times for COBYLA when the window size exceeds 15. During testing, we observed that COBYLA may reach its iteration limit without finding a solution for certain inputs when the prediction window is large. For these reasons, we choose to use SLSQP. Its average per-frame inference time is 24.6 µs, and the maximum time is 5.4 ms, both well within the frame interval (33 ms in our setting), with a prediction window size of 10. Furthermore, this results in only a 1.3% increase in absolute CPU utilization per session, making it suitable for multiple concurrent sessions in mobile cloud rendering scenarios. In practice, a rendering node already limits itself to about ten sessions per GPU, so server capacity remains GPU-bound; *MARC*'s extra CPU demand is well below the point where CPU becomes the scaling bottleneck.

5.5 Video Quality Evaluation

We assessed *MARC*'s impact on video quality by comparing original renderer output with received frames on a local testbed. The test uses 500-frame videos under various network traces. We employed three video quality metrics: PSNR, Structural Similarity Index (SSIM), and VMAF *phone model*. Tab. 2 shows that *MARC* has only a 1% decrease in PSNR (48.13 vs. 47.74) and VMAF (96.4 vs. 95.7) compared to WebRTC, while its average throughput demand differs by less than 3% from the baseline, indicating minimal perceived quality loss. *MARC* has a higher standard deviation in PSNR because *MARC* adjusts the bitrate for motion frames, resulting in minor quality fluctuations during the adjustment process.

Table 2: Video quality of *MARC* vs. WebRTC.

	PSNR	SSIM	VMAF
WebRTC	48.13(±0.82)	0.9937	96.4
MARC	47.74(±0.96)	0.9933	95.7

5.6 Large Scale Evaluation in the Wild

We deployed *MARC* in the online environment as described in § 5.1. *MARC* was compared with WebRTC in an A/B test. The test was conducted from April 4, 2024, to April 11, 2024, encompassing over 1 million sessions.

Metrics. Both latency and user engagement are evaluated. Latency measurements include the *send duration* of motion frames, the *proportion* of motion frames with an MTP latency exceeding 150ms, and the *session freeze rate*, which is the ratio of sessions that experience at least one freeze event. The freeze event count is provided by WebRTC [59]. User engagement is assessed using two behavioral interaction metrics [42]: *session duration*, which measures the total time each user spends on the service, and the *ratio* of interaction time to the session duration, which measures the user activity level.

Reducing latency. *MARC* reduces the frame latency by 20% at the tail (P99) and 29% at the median, as shown in Fig. 18a. Consequently, the proportion of motion frames with an MTP latency exceeding 150ms decreased by 20%. Additionally, the session freeze rate variance decreased, as illustrated in Fig. 18b, where the whiskers represent the 5th and 95th percentile values, and the average session freeze rate (denoted by a blue dot in the box) is reduced by 71%.

(a) Frame latency (b) Session freeze rate

Figure 18: Latency evaluation in online environment.

Improving user engagement. The latency reduction translates to improved user engagement. The session duration increased by 9%. The ratio of interaction time relative to the session duration increased by 20%, indicating that users were more willing to interact with the service under the *MARC* strategy. Such improvements in user engagement can potentially lead to increased profitability for e-commerce platforms [5].

Table 3: Comparison of user engagement metrics.

	Session Duration	Interaction Ratio
WebRTC	1	1
MARC	1.09	1.20

6 Discussion

Generalizability. *MARC*'s motion-aware bitrate adaptation extends beyond mobile e-commerce to interactive RTC workloads that alternate between active manipulation and passive viewing, such as cloud desktops, and remote VR/AR streaming. Porting *MARC* merely requires recalibrating the QoE mapping (Fig. 2, Eq. (7)) with engagement studies from the target application.

QoE function. In this study, we adopt a simplified QoE model that emphasizes two core elements of user experience: video quality and frame latency. Our results in Appendix B show that, even with this simplified model, the specific QoE formulation notably influences algorithm performance. Expanding beyond this formulation, a more sophisticated QoE model could integrate additional factors such as content complexity [47] and user expectations [19,31]. Metrics like bitrate switching could be explored under multi-dimensional QoE objectives to refine the framework further.

Controlling frame size. Our system uses existing encoder APIs to regulate encoding parameters, deliberately avoiding alterations to internal logic [17]. Certain frameworks offer the possibility of fine-grained frame size control by adjusting QP values [11] or through iterative re-encoding [12,40], *MARC* can extend its action space to incorporate these techniques. However, even with a perfect encoder that can encode frames at the exact target bitrate, users may still have different QoE requirements for motion and non-motion frames, which existing rate controllers cannot meet.

Paced sending and state predictors. Paced sending was employed to mitigate risks of queue buildup and network congestion when handling oversized frames [56]. Although pacing smooths network load, our simplified prediction of pacing rates may introduce latency estimation errors under extreme network bandwidth variations or prolonged queues. Several prediction modules, including pacing rate prediction, can still be improved by incorporating advanced time-series forecasting methods, such as those based on transformer [30]. We leave this part for future work.

Integrating other optimizations. Other techniques exist that target different components of the end-to-end pipeline in RTC systems, including loss recovery [36,51] and last-mile latency optimization [35]. While these techniques are promising to be combined with *MARC* to improve QoE performance, applying them in e-commerce cloud rendering systems may require further investigation.

QoE fairness. QoE fairness concerns dividing shared network resources so that users experience comparable satisfaction. Minerva [38] explores this for video-on-demand streams, a non-interactive setting where visual quality dominates and latency is largely secondary. In contrast, *MARC*'s measurements show that in interactive RTC workloads QoE priorities shift with the user's interaction phase § 2.2. This state-dependent insight provides a useful lever for future studies on fairness in multi-user interactive systems.

7 Related Work

QoE-related factors and metrics in video streaming. A substantial body of work has examined the impact of network conditions and video quality metrics on user engagement in streaming applications [10,27,53]. Building on these findings, *MARC* firstly correlates user engagement with user behavior and derives dynamic QoE preferences to guide rate control.

Rate control methods. Various rate control methods have been developed to optimize different aspects of Quality of Experience (QoE) in video streaming. For example, research has focused on dynamically adjusting bitrate based on factors such as dynamic network [52,64,65,68], content complexity [47], quality sensitivity [43,66], smoothness requirement [7] and visual attention [16,37,46,54]. However, these rate control methods typically rely on a fixed QoE model or predefined trade-offs. In contrast, *MARC* addresses intra-session QoE preference changes, continuously adjusting bitrate according to user behavior within the same session.

Congestion control for RTC. In RTC systems, congestion control algorithms (CCAs) aim to maximize bandwidth utilization and avoid network overloading [6,24,48,53]. CCAs typically probe bandwidth and adjust video sending rates based on delay, loss, or other congestion signals, but do not directly optimize for QoE objectives. Therefore, existing CCAs cannot solve the observed issue in § 2.

8 Conclusion

We have conducted a large-scale QoE study and identified that user behavior in mobile e-commerce cloud rendering exhibits unique QoE requirements, particularly in motion phases. Existing rate controllers often overlook the rapid QoE preference shifts in motion and non-motion phases, resulting in excessive latency exactly when users most value interactive responsiveness. To tackle this, we developed *MARC*, a dynamic QoE-driven motion-aware rate control framework that integrates user-behavior modeling and network dynamics, adjusting the bitrate at the frame level to optimize QoE. We implemented *MARC* and deployed it on Taobao's mobile cloud rendering platform. Millions of sessions demonstrated the efficiency of *MARC* in improving tail latency and user engagement.

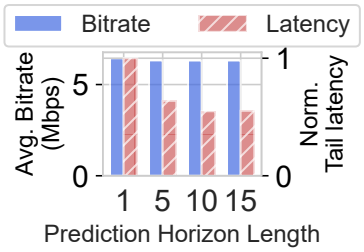
Appendix

A Finding the Best Prediction Horizon

In this section, we evaluate how different prediction horizon sizes (N) affect the performance of *MARC*. We vary N from 1 to 15 frames, measuring both the QoE gains (Fig. 19) and the additional computational overhead (Fig. 17). As shown in Fig. 19, using a horizon smaller than 10 frames can lead to suboptimal decisions that degrade tail latency (99.9 percentile), whereas increasing N beyond 10 frames yields only marginal QoE improvements at the cost of higher runtime overhead. Therefore, we select $N = 10$ as the default prediction horizon for *MARC*, striking a good balance between performance and complexity.



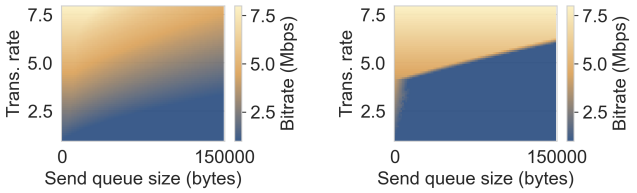


Figure 19: Impact of different prediction horizon sizes on overall QoE. Increasing N from 1 to 10 significantly reduces tail latency. Further increasing N yields diminishing returns.

B QoE Object Sensitivity

Sensitivity to QoE object. The QoE function defines the optimization objective and plays a crucial role in influencing *MARC*'s decisions. We investigate the impact of different QoE functions q_R on *MARC*'s bitrate selection by comparing the concave QoE function Eq. (10) with the linear QoE function Eq. (12). In our controlled experiments, we varied the send queue size and transport rate as follows: the transport rate ranged from 0.1 to 8 Mbps in increments of 0.1 Mbps, and the send queue size ranged from 0 to 150 KB in increments of 1500 bytes. The one-way delay was kept at 0, focusing solely on the impact of queuing delay on *MARC*'s decision-making. The delay QoE function q_L (Eq. (11)) remains unchanged with $\lambda_s = 0.1$, and motion frames are not considered.

$$q_R(R) = \frac{R}{R_{\max}} \tag{12}$$

(a) q_R (Eq. (10)). (b) Linear q_R (Eq. (12)).

Figure 20: The impact of different QoE object functions q_R on *MARC*'s bitrate decision (represented by color).

As shown in Fig. 20, both objective functions reduce the bitrate as the send queue increases. However, the algorithm using q_R makes more continuous bitrate decisions (Fig. 20a), while the algorithm using a linear q_R exhibits abrupt changes in bitrate (Fig. 20b). Such abrupt decision changes negatively impact the algorithm's overall performance. We evaluate the performance of these QoE objective functions on frame latency in our trace-driven evaluation environment. As shown in Fig. 21, the Pareto frontier of q_R outperforms that of Linear-q_R.

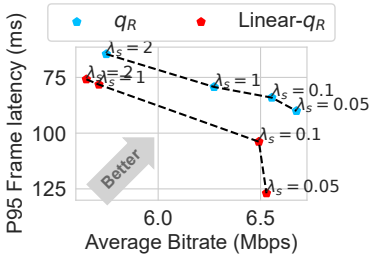

Figure 21: Comparison of the P95 frame latency with different q_R objective functions.

Accelerating Distributed Graph Learning by Using Collaborative In-Network Multicast and Aggregation

Abstract

Distributed GNN training systems typically partition large graphs into multiple subgraphs and train them across multiple workers to eliminate single-GPU memory limitations. However, the graph propagation in each iteration involves numerous one-to-many multicast and many-to-one aggregation operations across workers, resulting in massive redundant traffic and severe bandwidth bottlenecks. Offloading multicast and aggregation operations into programmable switches has the potential to reduce the traffic volume significantly. Unfortunately, the complex dependencies among graph data and the limited switch-aggregator resources lead to performance degradation. The graph-agnostic sending order results in excessive traffic in multicast operations, leading to a severe backlog. Additionally, a small number of vertices may consume the major part of aggregator resources, while most traffic misses the opportunity for in-network aggregation.

To tackle these challenges, we propose SwitchGNN, which accelerates graph learning through coordinated in-network multicast and aggregation. First, to alleviate the link underutilization and queue backlog, we design a graph-aware multicast reordering algorithm, which prioritizes the upload of multicast vertices with the higher number of neighbors to reduce the communication time. Second, to prevent aggregator overflow, SwitchGNN employs a multi-level graph partitioning mechanism that further partitions boundary vertices into independent blocks to perform in-network aggregation in batches while ensuring the correctness of the graph propagation. We implement SwitchGNN using P4 programmable switch and DPDK host stack. The experimental results of the real testbed and NS3 simulations show that SwitchGNN effectively reduces the communication overhead and speeds up the training time by up to 74%.

1 Introduction

In recent years, Graph Neural Networks (GNNs) are widely applied to graph-related downstream tasks such as recommendation systems [1], drug discovery [2], public health surveillance [3,4], and knowledge graphs [5] due to their ability to capture structured information from graph-based data. However, real-world graph data is becoming increasingly large. For instance, ByteDance observes over 2 billion vertices and 2 trillion edges with 100TB of graph data in production [6]. Training such massive graphs on a single worker or a single GPU is challenging because of memory limitations. To address this problem, a series of distributed GNN training frameworks [7–9] is proposed to partition the large graph into multiple subgraphs for parallel training on multiple GPUs.

Unfortunately, distributed GNN training generates massive communication traffic during the iterative graph propagation phase, which can account for up to 80% of the epoch time [10,11] and become a training bottleneck. Specifically, the feature of each vertex is multicast to its remote neighbors located on different workers. Meanwhile, the worker receives features of the vertex's remote neighbors in a many-to-one fashion, aggregates them, and applies neural-network operations to compute the new vertex embeddings. Several solutions [6,12–14] use sampling methods to reduce traffic volume. However, the absence of global graph information leads to low model quality. Existing full-graph training solutions alleviate communication overhead through efficient pipeline scheduling [15] or optimized graph partitioning algorithms [8]. However, these approaches rely on host-based multicast and aggregation, which still generate significant one-to-many redundant traffic and cause substantial many-to-one bandwidth bottlenecks, resulting in long epoch time.

With the emergence of programmable switches, a potential optimization for GNN training is to offload multicast and aggregation operations into the switches, thereby eliminating one-to-many and many-to-one bottlenecks, respectively. Specifically, each vertex is sent only once from the worker to the switch, and the switch then multicasts the vertex to the aggregators corresponding to its neighbors. Each aggregator, upon receiving all the required features, sends the aggregated result to the corresponding vertex. As a result, for each vertex, the worker receives only one single aggregated feature

from its neighbors. In the ideal case, in-network multicast and aggregation can significantly reduce the communication volume from $O(EM^2)$ to $O(EM)$, where E and M represent the number of boundary vertices and workers, respectively.

Existing in-network multicast and aggregation techniques are typically used in distributed DNN training [16–18] and word count [19], where the data is independent and can be multicast and aggregated in any order. However, graph-agnostic in-network multicast and aggregation are far from the ideal case. First, it is challenging to synchronize the multicast of these dependent vertices. Any straggling machine will cause aggregators to wait for long time until all necessary data arrives for aggregation. Second, the number of vertices with dependency is significantly large, creating an enormous demand for switch aggregator resources. For instance, the Reddit dataset with 32 workers needs approximately 500MB-sized aggregators for aggregation, while programmable switches typically have only around 10-100MB of memory [20, 21]. As a result, when a small portion of the graph data occupies all the switch's aggregator resources during multicast, the majority of the data must still be aggregated at the host, leading to substantial traffic.

To tackle these issues, we propose SwitchGNN, which leverages graph-aware in-network multicast and aggregation to reduce network traffic during graph propagation. First, to minimize communication time, we employ a graph-aware multicast reordering algorithm to determine the sending order of multicast vertices at the host. Vertices with a larger number of neighbors are prioritized for sending, ensuring a more efficient forwarding pipeline. Moreover, SwitchGNN addresses the limited aggregator resources by breaking a part of dependencies and partitioning boundary vertices from a large connected graph into multiple independent blocks. SwitchGNN aggregates vertices of each block in batches to ensure that switch-aggregator constraints are met.

In summary, the contributions of the paper are as follows:

- We identify that the one-to-many and many-to-one traffic generated during graph propagation in full-graph training is the key performance bottleneck. We reveal that though in-network multicast and aggregation techniques can eliminate this bottleneck, the complex dependencies between graph vertices still degrade performance.
- We propose SwitchGNN, a graph-aware in-network multicast and aggregation solution for GNN training. First, we introduce a graph-aware multicast reordering algorithm to reorder the sending sequence of multicast vertices, minimizing communication time. Then, it uses a multi-level graph partitioning algorithm to break the dependency within large connected boundary vertices and perform batch aggregation, preventing aggregator overflow and reducing traffic volume.
- We implement SwitchGNN using P4-programmable switches and DPDK-based host protocol stacks. Experimental results of testbed and NS3 simulations show that compared to the state-of-the-art GNN systems, we reduce epoch time by up to 74% without losing accuracy.

2 Background and Motivation

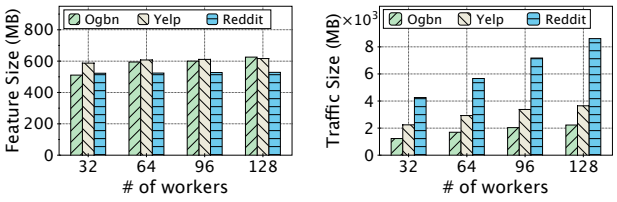
2.1 Distributed GNN

Graph Neural Networks are special neural networks designed to learn from graph-structured data. For example, Graph Convolutional Networks (GCNs) [22] extend convolution operations to graph domains. In each GCN layer, an aggregation operation (e.g., sum, mean, or max) collects features from each vertex's neighbors, followed by a neural network transformation that generates a new embedding for the vertex. This process is known as graph propagation. After multiple layers of graph propagation, the resulting embeddings, which encode structural information, are used for downstream tasks such as node classification and link prediction. Formally, a graph is defined as $G = (V, E, F)$, where V, E, and F represent the set of vertices, the set of edges, and the feature associated with each vertex, respectively. The graph propagation can be expressed as follows:

$$a_v^{(k)} = \text{AGGREGATE}^{(k)}\left(\left\{x_u^{(k-1)} \mid u \in N(v)\right\}\right), \quad (1)$$

$$x_v^{(k)} = \text{UPDATE}^{(k)}\left(a_v^{(k)}, x_v^{(k-1)}\right), \quad (2)$$

where $N(v)$ denotes neighbor vertices of vertex v, $x_u^{(k)}$ is the feature vector of vertex u at the k-th layer, $\text{AGGREGATE}^{(k)}$ is a function that aggregates features from neighbors of vertex v to produce the aggregated result $a_v^{(k)}$, and $\text{UPDATE}^{(k)}$ computes the new feature vector for vertex v.



GNN training can be categorized into two approaches: mini-batch and full-graph training. Mini-batch training (e.g., DGL [7] and PyG [12]) samples a subset of vertices and their neighbors in each iteration, addressing the GPU memory limitation issue. However, this approach lacks global graph information, leading to unstable convergence and low accuracy. Therefore, we focus on full-graph training, which leverages the entire graph's features for training, achieving higher convergence accuracy [15].

In distributed GNN training, large graphs are partitioned into multiple subgraphs and distributed across different workers for parallel training. During each iteration's graph propagation phase, when a vertex's neighbors are located on remote workers, the features are transmitted over the network, resulting in significant communication overhead. Existing frameworks commonly employ the graph partitioning algorithm such as METIS [23] to balance the number of vertices in each

subgraph while minimizing the number of edges across subgraphs. This algorithm balances computational load across workers and reduces inter-worker communication volume.

2.2 All-to-all Communication

In distributed full-graph training, each epoch involves all-to-all communication between vertices and their remote neighbors. This can be viewed from two perspectives: sending and receiving. From the sending perspective, for the vertex v with d_v neighbors, the host-based multicast must copy its data d_v times and send it to d_v remote neighbors, causing large redundant traffic. From the receiving perspective, d_v features from d_v remote neighbors are pulled for host-based aggregation, leading to many-to-one bandwidth contention. The more remote neighbors the vertices have, the greater the all-to-all traffic and communication overhead.

(a) Feature Size (b) Traffic Size

Figure 1: Feature size and traffic size of different datasets.

We next analyze the boundary vertex size and traffic volume in realistic datasets. We use METIS [23] to partition the graph across varying numbers of workers. Three different datasets Ogbn-products [24], Reddit [25], and Yelp [26] are partitioned. Figure 1 shows that, while the boundary vertex size remains relatively stable as the number of workers increases, the traffic volume grows significantly. This is because, although the number of vertices per worker decreases, the average number of neighbors per vertex increases. Since the Reddit graph is denser than the others, it has more average neighbor partitions, resulting in the highest traffic volume. Specifically, in Reddit with 128 partitions, the traffic volume is 16 times the boundary size, meaning that, on average, the worker generates 1-to-16 copies of each vertex when sending and causes 16-to-1 bandwidth contention when receiving. Thus, host-based multicast and aggregation will induce significant one-to-many redundant traffic and many-to-one bandwidth contention.

2.3 Promise of In-network Multicast and Aggregation

2.3.1 Strength and limitation of programmable switch

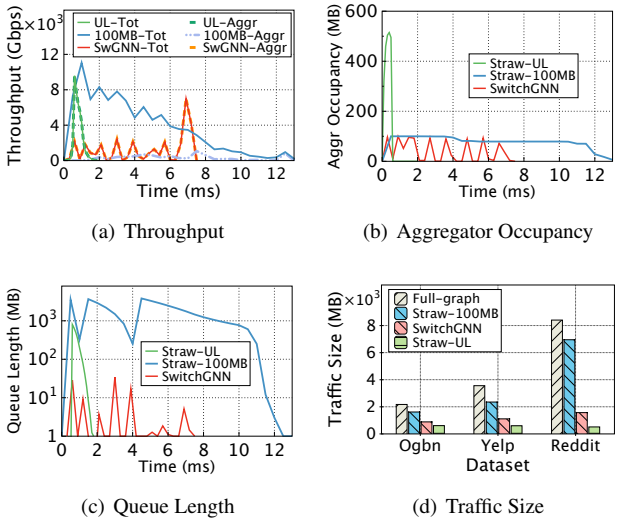
Programmable switches, such as Intel Tofino, offer flexible packet processing capabilities, allowing users to define custom packet-handling logic. These switches utilize memory (stateless metadata and stateful registers) to store packet states and perform basic calculations. Many existing works leverage programmable switches to improve transmission performance. For instance, flexible in-network multicast mechanisms [27–29] enable stateless or hybrid multicast by parsing routing information carried in packet headers. In-network aggregation protocols [16–19, 30] offload key-value aggregation functions to switches to accelerate distributed machine learning and typical MapReduce jobs. Specifically, the switch memory is organized as an array of aggregators. The values with the same key from different workers are stored and aggregated in the aggregator with the same index. Once aggregation is complete, the results are sent back to the host via packets, and the aggregators are reallocated for other keys. These approaches significantly reduce traffic volume and network latency by using the programmability of switches. This provides an opportunity to leverage in-network multicast and aggregation to accelerate distributed GNN training.

However, programmable switches still face several limitations. Limited memory resources (e.g., 10MB to 100MB [20,21]) restrict the switch's ability to buffer and process large-scale traffic. The limited number of pipeline stages constrains the deployment of complex dependency logic. A packet can only access a stateful register once during a single pipeline pass. These constraints introduce challenges for offloading more advanced network functions to the switch.

2.3.2 Strawman solution

Indeed, offloading the multicast and aggregation operations into the switch for sending and receiving data can significantly reduce traffic volume. Specifically, each vertex's feature only needs to be sent once to the switch. The switch then multicasts this feature to the corresponding workers. For any vertex, all its neighbor features are aggregated on the switch, mitigating the many-to-one bottleneck. Assuming the graph is partitioned across M workers, with each worker having E boundary vertices on average, in the extreme case where boundary vertices are fully connected, the host-based multicast and aggregation will generate $2EM^2$ traffic, with EM^2 for sending and EM^2 for receiving. However, the in-network multicast and aggregation will only generate $2EM$ traffic, EM for sending, and EM for receiving, thus reducing the traffic volume to $\frac{1}{M}$ of the former one.

Thus, we design a strawman solution that leverages in-network multicast and aggregation to accelerate GNN training. First, each worker sends the features of boundary vertices to the switch using a best-effort approach. On the switch, each feature is copied d_v times into d_v aggregators corresponding to its d_v neighbors. For each aggregator, the received features are accumulated and then dropped until it receives all required features from the neighbors of the destination vertex. Once the aggregation is complete, the result is forwarded to the



corresponding worker, and the aggregator is released for reuse by other vertices. If no aggregators are available when new data arrives at the switch, the current feature will be directly sent to the worker for aggregation.

2.4 Problem Insight

The strawman solution appears the significant potential to reduce traffic volume. However, directly applying in-network multicast and aggregation introduces two key problems: (1) The graph-agnostic multicast order results in link under-utilization and severe queue backlog. (2) The huge and inter-dependent vertex features are difficult to fit into the limited aggregators, leading to aggregator overflow and nullifying the traffic reduction.

2.4.1 Experimental observations

We conduct the NS3 simulations to reveal the problem of the strawman solution. We set up a star topology with 128 workers connected to one switch, and each link has 100Gbps bandwidth. We partition the Ogbn-product, Yelp, and Reddit datasets across 128 workers using the METIS [23] algorithm.

(a) Throughput (b) Aggregator Occupancy

(c) Queue Length (d) Traffic Size

Figure 2: The performance of strawman solution.

We evaluate the performance of the strawman solution with 100MB switch memory (aggregators) and with unlimited switch memory, respectively. We measure the real-time aggregation throughput, aggregator occupancy, and queue length under the Reddit dataset with 128 workers. To clearly observe the buffer requirements, we set the buffer size to 10GB to avoid the drastic performance fluctuations caused by packet loss and timeout retransmissions. As shown in Figure 2(a), although the total throughput under the 100MB constraint (100MB-Tot) is very high, the aggregation throughput (100MB-Aggr) is significantly lower than that of Straw-UL (UL-Aggr). During this process, as shown in Figure 2(b), the 100MB aggregator has been nearly fully occupied. Moreover, we observe that both the 100MB and unlimited cases experience significant queue backlog, as shown in Figure 2(c).

We further measure the traffic volume under the full-graph and strawman solutions. As shown in Figure 2(d), under the 100MB (Straw-100MB) aggregator constraint, the generated traffic volume of strawman is only slightly lower than that of the full-graph approach, but significantly higher than the unlimited case (Straw-UL). Specifically, for the Reddit dataset, the traffic volume in the Straw-UL is reduced by 94% and 92% compared to the full-graph and Straw-100MB, respectively.

2.4.2 Deep dive

Next, we dive into the causes of performance degradation in the strawman multicast and aggregation approach. Existing in-network multicast and aggregation techniques are commonly used to accelerate distributed machine learning jobs where data is independent. However, in GNNs, graph data dependencies are complex. The graph-structure-agnostic manner of the strawman solution leads to inefficient forwarding pipeline and severe aggregator overflow.

The graph-agnostic multicast order results in an inefficient forwarding pipeline. During the aggregation process, switch aggregators must wait for data from all participating vertices. Meanwhile, if a vertex completes multiple aggregations after being multicast to aggregators, multiple aggregation results are generated and sent to the workers. The strawman solution multicasts vertices to aggregators in random order. Due to the complex dependencies in graph data, some vertices are uploaded without timely completion of aggregation, leading to link under-utilization. Conversely, other vertices quickly complete a large number of aggregations after being uploaded, causing high queuing delays.

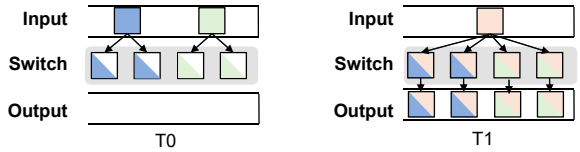


Figure 3: Graph-structure agnostic sending order leads to link under-utilization and queue backlog.

Figure 3 illustrates the link under-utilization and queue backlog due to graph-agnostic multicast order. At time T0, two vertices with a degree of 2 arrive to the switch and multicast to two aggregators, each waiting for aggregation to complete. During this time, the output throughput remains at 0. At time T1, although only one vertex is uploaded, it completes the aggregation for 4 aggregators simultaneously, however, causing a queue buildup at the output port. For instance, as shown in Figure 2(a) and Figure 2(c), under both Straw-UL and Straw-100MB, the queue backlog is severe. Specifically, from time 0ms to 1ms, the queue length rapidly increases from 0MB to 1000MB.

The huge and interdependent vertex features lead to aggregator overflow. A vertex's multicast on the switch consumes a number of aggregators equal to the number of its neighbors. However, the vertex required for these neighbors' aggregation also depends on their own neighbors. Due to the large number of dependent vertices (i.e., large connected subgraphs), multicasting these dependent vertices consumes far more aggregator resources than the programmable switch can support. As a result, a massive traffic is sent directly to the workers due to aggregator collisions, missing the in-network aggregation opportunities.

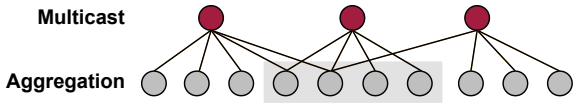

Figure 4: The memory demand of the large number of dependent vertices exceeds the switch memory size.

For example, as shown in Figure 4, when three dependent red vertices are simultaneously multicast at the switch, 10 aggregators are required, but the switch can only provide 4 aggregators, leaving the remaining 6 features unable to use in-network aggregation. The experimental results in Figure 2(b) show that when aggregator resources are unlimited, the aggregation resource usage is approximately 500MB. Therefore, under the 100MB resource constraint, severe aggregator overflow occurs. With a 100MB aggregator limit, the aggregation throughput is significantly reduced to only about 10% of the total throughput.

2.5 Summary

In distributed full-graph training, the graph propagation with host-based multicast and aggregation causes large redundant traffic and severe bandwidth contention, respectively. Using in-network multicast and aggregation can significantly reduce traffic volume, but the strawman solution suffers from queue backlog and aggregator overflow due to complex vertex dependencies. Therefore, we need to carefully design a collaborative in-network multicast and aggregation based on graph-structured data to fully leverage the potential of in-network multicast and aggregation.

3 SwitchGNN Design

3.1 Architecture and Workflow

We propose a solution to accelerate full-graph training using programmable switches. This solution performs collaborative in-network multicast and aggregation during graph propagation, thereby reducing network traffic volume.

Figure 5 shows SwitchGNN's architecture. We assume that the full graph has already been partitioned into multiple workers. First, the host reschedules the sending order of vertices to optimize the forwarding pipeline, alleviating the link underutilization and queue backlog. Second, to prevent aggregator overflow, we employ a multi-level graph partitioning mechanism to break the dependencies among boundary vertices. Moreover, we still transmit the traffic from cut edges to guarantee the correct graph propagation. The workers follow the predefined sending order to minimize communication time, while the switch stores the connectivity information between vertices for in-network multicast and aggregation. Third, we design the reliability and congestion control mechanisms to guarantee the correct aggregation and avoid network congestion in all-to-all transmission. Finally, the switch receives the feature of each vertex and multicast it to the aggregators corresponding to its neighbors. The aggregators aggregate the features from multiple workers and the aggregation results are sent back to the corresponding workers.

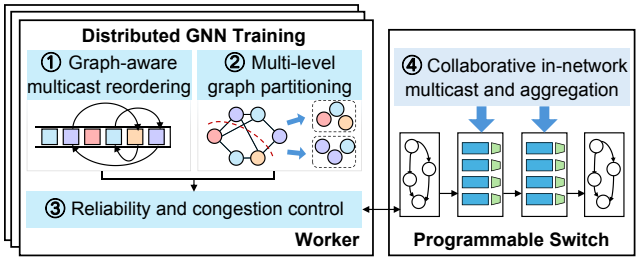

Figure 5: SwitchGNN's architecture.

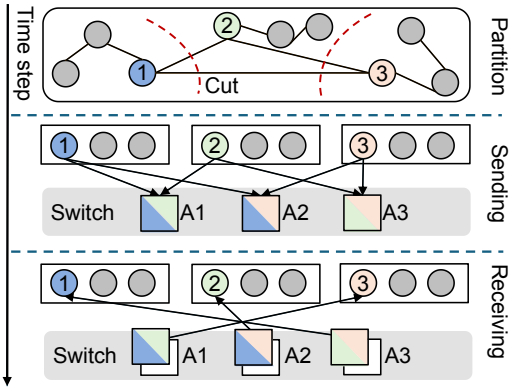

Figure 6: SwitchGNN's workflow.

We use an example to illustrate SwitchGNN workflow. As shown in Figure 6, we assume that vertices 1, 2, and 3 are interdependent and partitioned into three different workers. During the graph propagation, they need to exchange features over the network. In the feature sending step, vertices 1, 2, and 3 send their features to the switch, which multicasts them to the corresponding aggregators A{1,2}, A{1,3}, and A{2,3}, where aggregators A1, A2, and A3 correspond to destination vertices 3, 2, and 1, respectively. Once the aggregators have

received all the required neighbor features for each destination vertex, vertices 1, 2, and 3 receive the aggregated results from aggregators A3, A2, and A1. As a result, each of the three vertices sends only one feature and receives one aggregated feature. When all vertices have completed their transmissions, the communication for the current GNN layer is finished.

3.2 Graph-Aware Multicast Reordering

We reorder the multicast sequences of vertices according to the graph structure to minimize the communication time.

3.2.1 Problem statement

Given a graph $G(V,E)$ comprising n vertices, e edges, along with a designated vertex sequence $S = (v_1, v_2, ..., v_n)$ to be sent to a switch, assume that A_t denotes the set of vertices that arrive to the switch at time t. At most k packets can enter the switch and k packets leave the switch in each time slot. When $t \leq n/k$, the switch receives $v_{(t-1)k+1}$ to v_{tk}; otherwise, it receives $v_{(t-1)k+1}$ to v_n. Therefore, we have

$$A_t = \begin{cases} \bigcup_{i=(t-1)k+1}^{tk} \{v_i\}, & t \leq n/k, \\ \bigcup_{i=(t-1)k+1}^{n} \{v_i\}, & t > n/k. \end{cases} \tag{3}$$

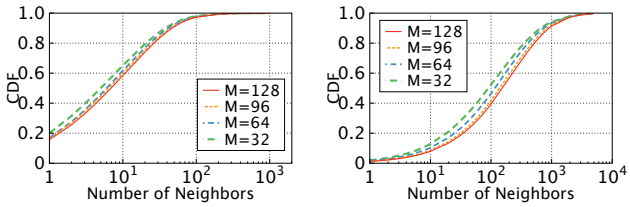
We define $g_t(v_i)$ as the number of aggregation results completed when vertex v_i arrives at switch at time t. Let $f(t)$ denote the number of aggregators that complete the aggregation at time t, with the resulting packets queued at the switch. Then we have

$$f(t) = \sum_{v_i \in A_t} g_t(v_i). \tag{4}$$

Let $Q(t)$ represent the number of packets waiting for transmission after time t, and assume $Q(0) = 0$. Then we have

$$Q(t) = max\{f(t) + Q(t-1) - k, 0\}. \tag{5}$$

The job completion time z is given by



$$z = \lceil \frac{n}{k} \rceil + \lceil \frac{Q(\lceil \frac{n}{k} \rceil)}{k} \rceil, \tag{6}$$

where $\lceil \frac{n}{k} \rceil$represents the time required for all vertices to arrive at the switch, and $\lceil \frac{Q(\lceil \frac{n}{k} \rceil)}{k} \rceil$ represents the time required to drain the remaining queued packets at the switch after the last vertex has arrived. The objective is to find an optimal vertex sequence S to minimize z.

3.2.2 Lightweight solution

Considering the high complexity and substantial time cost in deriving the optimal solution, we propose a heuristic algorithm that maintains a manageable level of complexity for graph-aware multicast reordering.

First, we aim to minimize the aggregation time for features to avoid a large number of features waiting for aggregation at the switch, which leads to link under-utilization. When the vertices multicast into the aggregators, completing these aggregations quickly requires that other vertices destined for the same aggregators are also multicast immediately. These vertices are connected through a common one-hop neighbor, which links them together in the aggregation process. Thus, we use a priority-based breadth-first search (BFS) scheduling approach. Starting from a randomly selected vertex, its neighboring vertices are added to the sending queue, ensuring that closely related vertices are transmitted in close time. This reduces the waiting time of aggregators.

(a) Ogbn-products (b) Reddit

Figure 7: The CDF of neighbor counts.

Second, to alleviate the queue backlog, we introduce priority scheduling based on vertex degree. We observe that vertex degrees are skewed. For example, Figure 7 shows the cumulative distribution function (CDF) of neighbor counts. In the Reddit dataset, with 32 workers, 20% of vertices account for 80% of the total neighbors. If high-degree vertices are sent later, there is a higher probability of triggering a large number of aggregations at once, leading to traffic bursts. However, by sending higher-degree vertices earlier, as smaller-degree vertices are uploaded, aggregations are completed gently, enabling a more efficient forwarding pipeline and reducing the queue backlog. Thus, we enhance the BFS approach by assigning priority based on vertex degree, where higher-degree vertices are transmitted earlier in the sequence.

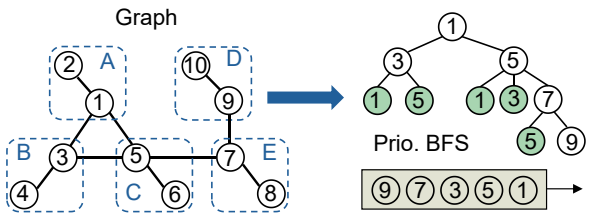


Figure 8: Priority-based BFS.

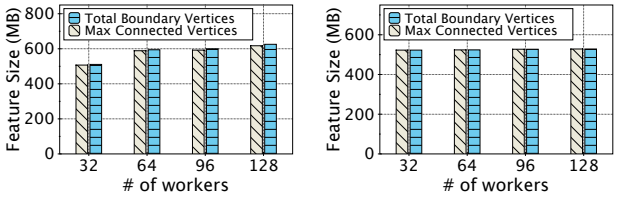
As illustrated in Figure 8, the vertex sequence is generated according to our priority-based BFS. We randomly select vertex 1 from the graph to enqueue. Vertex 1 is then dequeued, and its neighbor vertices 3 and 5 are enqueued. Since vertex 5

has more neighbors than vertex 3, vertex 5 will be dequeued first. Then, vertex 5's neighbor, vertex 7, is enqueued. As vertex 3 and vertex 7 have the same number of neighbors, the earlier enqueued vertex 3 will be dequeued before vertex 7. Vertex 9, with only one neighbor, will be dequeued last. Note that we track each enqueued vertex to ensure that each vertex is enqueued only once. The final vertex sequence is the order in which the vertices are dequeued. In non-in-network aggregation methods, high-degree vertices will generate more redundant traffic. However, in SwitchGNN, high-degree vertices uploaded to the switch do not immediately generate multicast traffic. Instead, they first occupy the aggregator's memory and trigger data transmission to the worker only after other required neighboring vertices arrive and complete aggregation. This multicast reordering strategy optimizes pipeline efficiency, mitigates queue backlog.



Next, to demonstrate the effectiveness of the graph-aware multicast reordering mechanism, we quantitatively analyze two typical graph structures of star graph (non-uniform) and ring graph (uniform), and discuss the performance difference between the priority-based BFS strategy (PB) and the random ordering (RO). In the star topology, consider the undirected graph $G_1(V,E)$, where vertex set is $V=\{v_1,v_2,...,v_n\}$, and edge set is $E=\{(v_1,v_2),(v_1,v_3),...,(v_1,v_n)\}$. The degree of the central vertex is $d(v_1)=n-1$, while all other vertices have degree 1, i.e., $d(v_2)=\cdots=d(v_n)=1$.. PB selects the vertex v_1 as the root of BFS, resulting in a traversal sequence $\{v_1,v_2,...v_n\}$. According to the derivation in 3.2.1, we assume that $k=1$, and the total execution time of PB is n. RO randomly selects vertices, and the total execution time of RO depends on the position of vertex v_1. The optimal case of RO is that v_1 is selected first, and the total execution time is n. In the worst case, the last choice is v_1, and the total execution time is $2n-1$; The average execution time is $\frac{3n-1}{2}$.

In the ring topology, we construct an undirected graph $G_2(V,E)$, where vertices is $V=\{v_1,v_2,...,v_n\}$, and edge set is $E=\{(v_1,v_2),(v_2,v_3),...,(v_{n-1},v_n),(v_n,v_1)\}$. All vertices have a degree of 2. When $n=3$, both strategies take the same execution time. When $n\geq 4$, the total execution time under PB is $n+2$, the best execution time under RO is $n+1$, and the worst execution time under RO is $n+2$.

The degree distribution characteristics of graph structures impact the performance of heuristic ordering strategies. SwitchGNN outperforms random ordering in graphs with non-uniform degree distributions, while both strategies show similar performance in graphs with uniform degree. Thus, SwitchGNN achieves greater benefits in skewed graphs, which is common in real-world scenarios [31].

3.3 Multi-level Graph Partitioning

The required number of aggregators is directly related to the maximum number of dependent vertices. Here, we analyze the size of related boundary vertices across different datasets.

(a) Ogbn-products (b) Reddit

Figure 9: The total boundary and max. connected feature size.

Figure 9 shows the total boundary and maximum connected vertices size under different datasets. The results show that nearly 99% of boundary vertices exhibit dependency relationships, thus the aggregator demand far exceeds the switch's memory capacity. To address this issue, in addition to partition the full graph across multiple workers, we further partition the connected boundary vertices into multiple blocks by cutting edges, thereby breaking their dependencies. These blocks are then transmitted one by one. The next block is processed only after the transmission of the previous one is complete. By ensuring that the number of vertices in each block does not exceed the available aggregator resources, we eliminate aggregator overflow. However, breaking the dependencies changes the original graph structure, leading to incorrect graph propagation and low model quality.

To maintain correct aggregation, data exchange is still required between cut edges. Thus, SwitchGNN groups the cut edges into a new block, and the partitioning continues until all blocks are small enough to fit within the aggregator limits. To fully utilize aggregator resources while minimizing the extra traffic caused by cut edges, we use the METIS algorithm for boundary vertices partitioning.

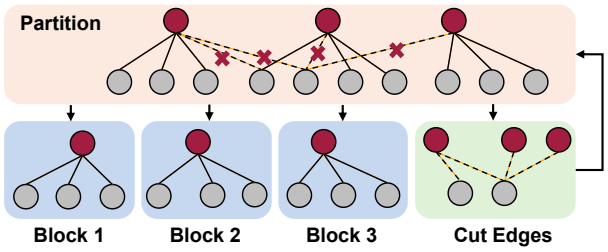


Figure 10: Multi-level graph partitioning.

Figure 10 shows an example of multi-level graph partitioning. We assume that a connected subgraph with 13 boundary vertices is to be multicast and aggregated on a switch with a limit of 4 aggregators. First, through graph partitioning, 4 edges are cut, resulting in 3 blocks, each with a size of 4 vertices. The subgraph formed by the cut edges has a size of 5, so it will continue to undergo the next level of partitioning until all blocks are smaller than 4. Then, by batch-processing the multicast and aggregation of vertices within each block, SwitchGNN completely avoids aggregator overflow. The time

complexity of METIS is $O(|E|+|V|)$, while the multicast reordering method has a time complexity of $O(|E|+|V|log|V|)$, where $|E|$ and $|V|$ denote the number of edges and vertices, respectively. For large graphs, Par-METIS method can be used to partition the graph in parallel. After multi-level partitioning is completed, vertices within each partitioned block can also be reordered in parallel, significantly reducing pre-processing time. Besides, SwitchGNN is still compatible with any advanced graph partitioning techniques to improve performance.

In the pre-processing phase, Graph-Aware Multicast Reordering and Multi-level Graph Partitioning mechanisms determine the multicast order and blocks of vertices, and this information is distributed to the corresponding hosts. Each host only needs to send its local vertices to the switch according to the predefined *block_id* and vertex order. Note that, each host must wait until the current block's transmission is completed before sending the next block. Once a host receives all the aggregation results in the current block, it sends the current *block_id* and its *host_id* to the switch. The switch keeps track of the current *block_id* and the number of hosts that have completed transmission for that block. When all hosts have completed the transmission of vertices for the current block, the switch multicasts the current *block_id* to all workers. Upon receiving the block completion signal from the switch, the workers send the vertices of next block.

3.4 Reliability and Congestion Control

In-network multicast and aggregation break the traditional end-to-end connections, where a single packet at the switch is replicated into multiple packets, and multiple packets are aggregated back into one packet by the switch. Therefore, we need to redesign the reliability guarantee and congestion control mechanisms to ensure correct and efficient transmission.

For reliability guarantee, when a vertex is sent, SwitchGNN maintains two bitmaps for each vertex to track the status of its neighbors at the host. One bitmap records the acknowledgment status of the sent vertex features, while the other tracks the reception status of each vertex's neighbor features. Upon receiving the aggregation result, the corresponding reception bitmap is set to all ones, and the worker multicasts ACKs to the vertex's neighbors. When the sending bitmap becomes all ones, it indicates that the vertex's transmission has successfully completed. When receiving a data packet of a vertex, the worker first determines whether the packet is a complete aggregation result from the switch. If a non-aggregated feature is received, the non-aggregated feature is cached in the worker. When other boundary vertices in the worker also need to participate in aggregation with this non-aggregated feature, they can share it from the local cache instead of fetching it again from remote workers, thereby reducing network traffic. Additionally, SwitchGNN employs a timeout mechanism to handle packet loss caused by network congestion. When a worker exceeds the timeout threshold without receiving features from the current block, it pulls the required features of the unaggregated vertices from other workers. Once the pulled packets arrive at the switch, the corresponding aggregators are released. The features pulled from the worker are marked as "bypass", meaning they no longer participate in switch-based aggregation but are directly forwarded to the host for aggregation.

For congestion control, SwitchGNN continuously sends vertices according to the scheduling order and adjusts the sending rate according to the Explicit Congestion Notification (ECN) marking, similar to DCQCN [32]. Upon receiving an ECN marking, the sending rate is halved. If the network is not congested, the sending rate increases additively.

4 Implementation

We implement SwitchGNN using Data Plane Development Kit (DPDK) protocol stack and P4-Programmable switch.

Host. On the host side, SwitchGNN is used as a plugin integrated with the DGL framework. We modify the communication context of DGL by using SwitchGNN with DPDK host stack. In the DPDK, we use $rte_pktmbuf_mtod_offset$ to add SwitchGNN's header fields after the IP header, which includes 32bit *Src_id*, 32bit *Dst_id*, 16bit *Block_id*, 16bit *Count*, 1bit *Is_ACK*, 1bit *Is_Fetch*, 1bit *ECN*, and 1bit *Resend* fields. The *Src_id* and *Dst_id* fields carry the IDs of source vertex and destination vertex, respectively. The *Block_id* field is used to notice the transmission batch, ensuring that the same block's features participate in in-network aggregation in the same batch. The *Count* field carries the number of boundary neighbors for the current vertices. The *Is_ACK* and *Is_Fetch* fields are used to identify the type of packet, indicating whether it is an acknowledgment or a fetch request, respectively. The *ECN* field is marked when the switch queue length exceeds a certain threshold, while the *Resend* field is set to 1 for retransmitted packets.

Switch. On the switch, we store the mapping relationship between each vertex ID and its corresponding aggregator indexes in the table. When a packet arrives, it can directly query the table using the source vertex ID to determine which aggregators should be aggregated at. In SwitchGNN, each aggregator is allocated 128 bytes for aggregation. The aggregator format is similar to ATP [16]. The difference is that instead of using a bitmap to track which vertices have been added in the aggregator, we determine aggregation completion according to the aggregation count. To avoid errors from duplicate accumulation due to retransmitted packets, we mark these packets with a *Resend* flag. When such a packet reaches the switch, it releases the corresponding aggregator and is directly forwarded to the designated worker for aggregation.

To multicast the packet into multiple aggregators, the same register needs to be accessed multiple times. However, Tofino switch allows a packet to access a register only once per pipeline pass. Therefore, after accumulating the payload into the first aggregator, we loop the packet back to the ingress

pipeline for subsequent aggregator operations until all multicast aggregators are accessed.

Moreover, SwitchGNN adopts in-network aggregation only for traffic that crosses hosts or racks, while GPUs within the same host use NVLink or PCIe for communication. When workers are distributed across multiple switches, multi-level aggregation is required. SwitchGNN uses a mechanism similar to existing in-network aggregation solutions [16, 18]. SwitchGNN needs to extend packet headers and aggregator fields to record the level of each switch. For example, in a two-level aggregation with three switches, two level-1 switches perform partial aggregation for directly connected workers, and their partial aggregation results are then forwarded to a level-2 switch for final aggregation.

5 Testbed Evaluation

5.1 Setup

Topology. We evaluate SwitchGNN using a star topology, which contains one switch and eight GPU servers. All servers connect to the switch via 100Gbps links. The switch is an Intel Wedge 100BF-32X programmable switch with 10MB memory. Each server has an RTX3090 GPU with CUDA 11.2, Ubuntu 20.04, 100GbE Mellanox CX5 NIC, 20 CPU cores and 64GB memory. We deploy one worker per server.

Datasets and models. We use three popular graph datasets in our evaluation, including Ogbn-products [24], Yelp [26], and Reddit [25]. The graph details are shown in Table 1. In addition, we train a 4-layer GCN with 128 hidden units and set the initial learning rate to 0.01 on the above datasets.

Table 1: Datasets Details.

Dataset	Vertices	Edges	Feature	Classes
Ogbn-products	2.4M	62M	100	47
Yelp	0.72M	7M	300	100
Reddit	0.23M	114M	602	41

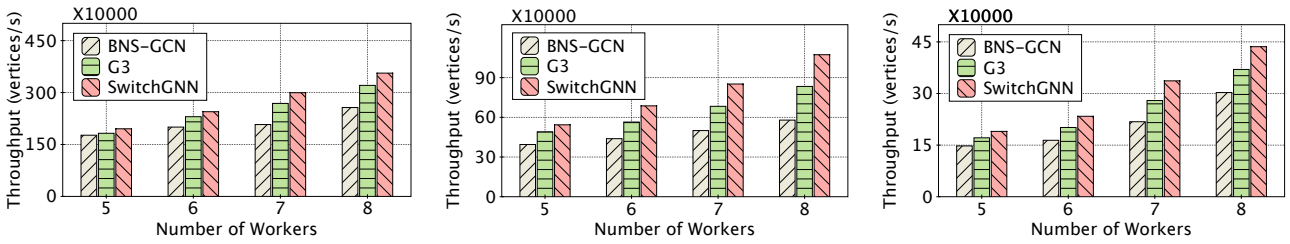
Baselines. We compare SwitchGNN with state-of-the-art full-graph GNN training systems, such as BNS-GCN [8] and G3 [15]. BNS-GCN reduces communication overhead during graph propagation by sampling neighbors with a sampling rate p. To ensure full-graph training, we set p in BNS-GCN to 1. For BNS-GCN and SwitchGNN, we use METIS for the graph partitioning. G3 uses locality-aware iterative partition [15] to balance the communication load among workers. For a fair comparison, we implement the transport protocols of all baselines using DPDK. The transport protocols of BNS-GCN and G3 are implemented according to DCQCN.

Metrics. We adopt three evaluation metrics, including training throughput, real-time loss and GPU utilization in our experiments. The training throughput is the number of processed vertices per second of all workers. Real-time loss is the curve of training loss changing with time. We select one of the workers to observe the real-time GPU utilization.

5.2 Training Throughput

We evaluate the training throughput (measured in 10^4 vertices per second) of SwitchGNN under varying numbers of workers (e.g., 5∼8) with 4 GNN layers, and under different numbers of GNN layers using 8 workers, respectively. We compare SwitchGNN with baselines such as BNS-GCN and G3.

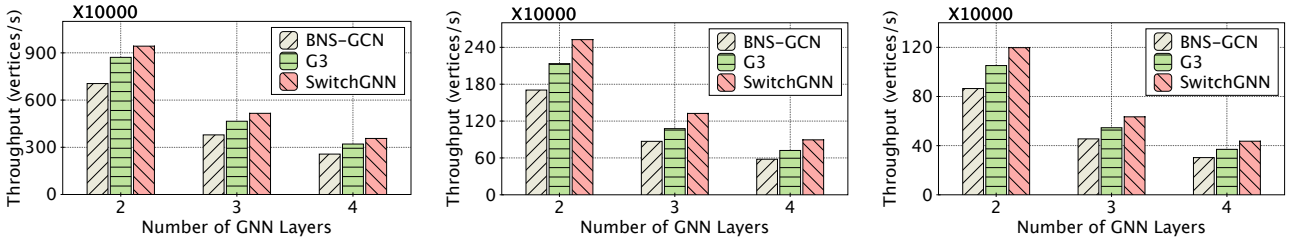
As shown in Figure 11 and 12, BNS-GCN achieves the lowest training throughput since it suffers from severe one-to-many and many-to-one bottlenecks. G3 outperforms BNS-GCN by balancing traffic volume among workers, avoiding the straggler problem caused by skewed traffic. However, G3 does not reduce the overall traffic volume, as there are still many redundant packets and significant many-to-one bandwidth contention in the network. SwitchGNN achieves the highest training throughput across all three datasets under different numbers of workers and GNN layers. This is because SwitchGNN eliminates the one-to-many and many-to-one bottlenecks by leveraging collaborative in-network multicast and aggregation, effectively reducing traffic volume. Moreover, as the number of workers increases, the benefits of SwitchGNN grow since the proportion of communication time relative to computation time increases. Specifically, SwitchGNN improves training throughput by up to 54% and 24% compared to BNS-GCN and G3, respectively.



5.3 Real-time Loss

Next, we compare SwitchGNN with baselines in performance of time-to-accuracy. All training systems are trained in an 8-worker cluster using three datasets: Ogbn-products, Reddit and Yelp. We record the real-time loss during the training.

As shown in Figure 13, SwitchGNN achieves the fastest convergence across different datasets, without any loss in accuracy compared to BNS-GCN and G3. This is because, although SwitchGNN partitions boundary vertices into multiple blocks for in-network aggregation using a multi-level graph partitioning algorithm, it still transmits features associated with cut-edges, ensuring the correctness of graph propagation. The performance improvement of SwitchGNN is more significant on the denser datasets such as Yelp and Reddit than on the relatively sparse Ogbn-products dataset, as dense graphs generate more redundant traffic and experience more severe many-to-one bandwidth contention under BNS-GCN and G3.



5.4 GPU Utilization

We evaluate the GPU utilization of one randomly selected worker from an 8-worker cluster. We use the Ogbn-products, Yelp and Reddit datasets to train the GCN model under SwitchGNN and our baselines. We show the GPU utilization over 10 seconds. Figure 14 shows the GPU utilization of SwitchGNN compared with full-graph training systems. We observe that SwitchGNN utilizes more GPU resources than BNS-GCN and G3. The reason is that SwitchGNN directly

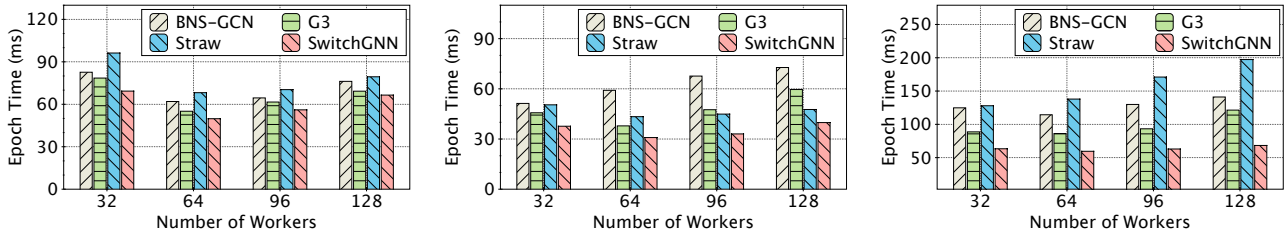
reduces the traffic volume, reducing the communication time and contributing to higher GPU utilization.



6 Simulation Evaluation

We conduct NS3 simulations to evaluate the performance of SwitchGNN in the large-scale scenarios. We use the star topology with 128 hosts and each host connects to the switch with 100Gbps bandwidth link and 2μs propagation delay. Based on the configuration of mainstream ASIC switches, the total aggregator size is set from 10MB to 100MB [20, 21]. By default, the switch memory size is 100MB. We compare the performance of BNS-GCN, G3, strawman solution (Straw), and SwtichGNN. We use three realistic graph workloads, including Ogbn-products, Yelp and Reddit. When scaling up the number of workers to 128, the dataset is re-divided into 128 partitions. The evaluation metrics include epoch time, traffic volume, queue length, and aggregation throughput. The epoch time consists of the communication time for a 4-layer GCN propagation in NS3 network combined with the average computation time per epoch during training in the testbed. Traffic volume refers to the data generated by one layer of GCN propagation.

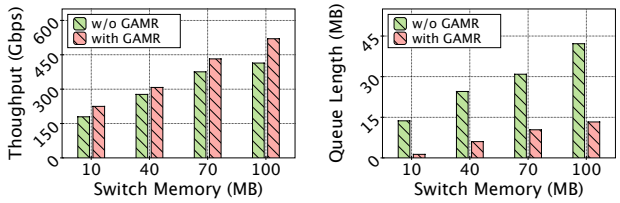
Figure 16: Epoch time under the varying number of workers with leaf-spine topology.

6.1 Basic Performance

First, we evaluate the basic performance of SwitchGNN using the same experimental setup as in the motivation section. As shown in Figure 2(d), across all three datasets, SwitchGNN significantly reduces traffic volume compared to the strawman approach. This reduction is achieved through multi-level graph partitioning, which effectively prevents aggregator overflow and thus substantially reduces traffic volume. However, to maintain correct aggregation after graph partitioning, SwitchGNN introduces some additional traffic, making its traffic size slightly larger than the UL case. Figures 2(a) and 2(b) demonstrate that SwitchGNN utilizes aggregator resources without overflow, maintaining high aggregation throughput. Moreover, due to the priority-based BFS algorithm that reorders the multicast sequence, SwitchGNN achieves a more efficient pipeline and avoids queue backlog, as illustrated in Figure 2(c).

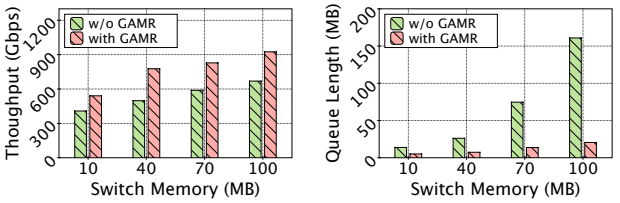
Note that, under SwitchGNN, the synchronization process of each block between hosts and switches can be affected by straggling workers. As shown in Figures 2(a) and 2(b), the observed fluctuations in throughput and aggregator occupancy are caused by per-block synchronization. However, since SwitchGNN significantly reduces traffic volume, it still achieves low communication time.

6.2 Performance under Different Conditions



Then, we measure the epoch time of BNS-GCN, G3, Strawman solution, and SwitchGNN under varying numbers of workers and different workloads. As shown in Figure 15, across all three datasets, the epoch time of BNS-GCN, G3, and the strawman solution increases rapidly as the number of workers grows. This is because more workers result in each vertex needing to be replicated to more neighbors, introducing the one-to-many and many-to-one bottlenecks. Although G3 balances the communication load across workers, it does not reduce the overall traffic volume, still leading to high epoch time. In contrast, SwitchGNN leverages in-network multicast and aggregation to reduce traffic volume, effectively eliminating the one-to-many and many-to-one bottlenecks, and preventing significant traffic increases as the number of workers grows. Specifically, under Reddit dataset, SwitchGNN reduces epoch time by up to 74%, 65%, and 83% compared to BNS-GCN, G3, and strawman solution, respectively.

Besides, we conduct the experiments on an 8×8 leaf-spine topology in a typical datacenter, consisting of 8 leaf switches and 8 spine switches. Each leaf switch connects to 16 hosts, resulting in a total of 128 hosts. Each leaf switch connects the same number of workers, with at most one worker per host. For SwitchGNN, the in-network multicast and aggregation operations are deployed on the leaf switches. As a result, the traffic undergoes up to two levels of aggregation. The experimental results are shown in Figure 16. As the number of workers increases, cross-rack communication traffic also grows. Once cross-rack communication becomes the primary bottleneck, the epoch time increases rapidly. SwitchGNN reduces traffic in each rack through hierarchical aggregation, achieving the lowest epoch time.

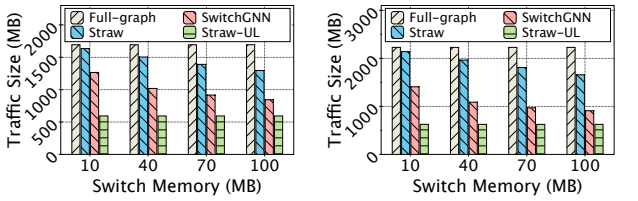


6.3 Effectiveness of GAMR

Moreover, we evaluate the effectiveness of the graph-aware multicast reordering (GAMR). We measure the maximum

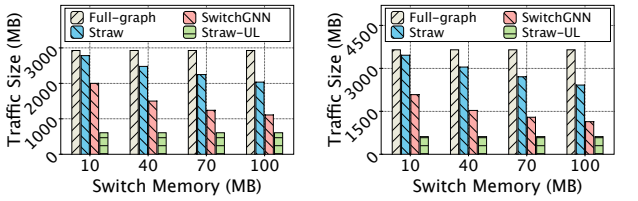
queue length and throughput for Ogbn-products and Reddit datasets under varying switch memory from 10MB to 100MB. We set the switch buffer size to a very large value to observe the buffer requirements of different methods.

(a) Aggr. throughput under Ogbn (b) Queue length under Ogbn



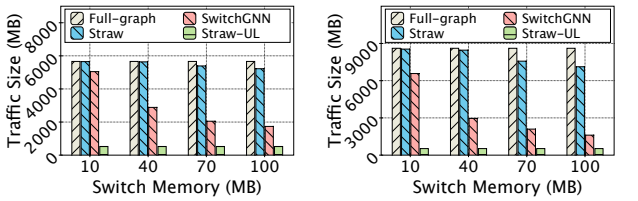
(c) Aggr. throughput under Reddit (d) Queue length under Reddit

Figure 17: Performance under different workloads.



As shown in Figure 17, the results show that the performance of SwitchGNN with GAMR is significantly better than that without GAMR. GAMR enhances the pipeline efficiency for each block, improving the overall aggregation throughput. Moreover, as the switch memory increases, the maximum queue length under SwitchGNN without GAMR grows rapidly. This is because larger switch memory can hold more features waiting for aggregation, and the graph-agnostic sending order may cause a small number of packets to trigger larger aggregation results, leading to a huge traffic volume and severe queue backlog in a short time. Without GAMR, SwitchGNN experiences more severe queue backlog and throughput loss under the denser Reddit graph than that under Ogbn-products. This is because each vertex in Reddit has a higher degree, resulting in longer wait time for neighbors to arrive at the switch. By prioritizing high-degree boundary vertices for transmission, GAMR improves the throughput and alleviates the queue backlog.

6.4 Traffic Size under Varying Switch Memory



In this section, we evaluate the traffic size under different switch memory with 64 and 128 workers, respectively. As shown in Figure 18, the benefits of SwitchGNN become more significant as the number of workers increases. This is because a higher number of workers results in more copies of features being generated; SwitchGNN eliminates this redundant traffic through in-network multicast and aggregation. Moreover, Figure 18(f) shows that with only 10 MB memory, the traffic reduction is limited to 23%, whereas with 100 MB memory, the traffic size is reduced by 81%. This is because, under the smaller aggregator size, the graph is divided into more partitions during the multi-level partitioning process, thereby increasing traffic due to cut edges.

(a) Ogbn-products under 64 workers (b) Ogbn-products under 128 workers

(c) Yelp under 64 workers (d) Yelp under 128 workers

(e) Reddit under 64 workers (f) Reddit under 128 workers

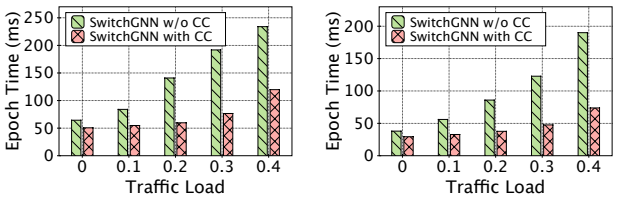


Figure 18: Traffic volume under varying switch memory.

As shown in Figures 18(b), 18(d) and 18(f), the dense graph (Reddit) generates more redundant traffic compared to the sparse graphs (Ogbn-products and Yelp). Thus, with larger memory size (100 MB), SwitchGNN delivers greater improvements for dense graphs. However, under limited memory (10MB), it is hard to partition dense graphs to eliminate inter-vertex dependencies, resulting in more cut edges. SwitchGNN shows better improvement for sparse graphs under limited memory.

6.5 Effectiveness of Congestion Control

Additionally, we validate the effectiveness of SwitchGNN's congestion control. We inject the background traffic under varying loads across 64 and 128 workers and observe the epoch time under the Reddit dataset with and without congestion control (CC). The background flows are randomly generated across all workers. The flow size follows the realistic datacenter workload of Hadoop and their arrival rate follows the Poisson distribution.

As shown in Figure 19, as the background traffic load increases, the SwitchGNN without CC suffers from significant

(a) 64 workers (b) 128 workers

Figure 19: Epoch time under varying traffic load.

performance degradation, whereas the SwitchGNN with CC can maintain a short epoch time.

7 Related Work

Mini-batch GNN training. DGL [7] distills several generalized sparse tensors from the GNNs' computation for massive parallelization. AGL [33] adopts a message transform method and is implemented on MapReduce [34] to support mini-batch GNN training. BGL [6] co-designs the caching policy and sampling order, reducing the communication overhead in feature retrieving. PaGraph [35] utilizes spare GPU memory as a cache for storing hot data to reduce the communication between CPU and GPU. GNNLab [36] proposes a pre-sampling cache policy for efficient storage and robust performance. P3 [37] combines model and data parallelism to reduce the communication overhead. However, the above approaches with mini-batch training mechanisms still face challenges such as sampling variance, neighbor explosion, and significant sampling overhead.

Full-graph GNN training. Full-graph training methods can overcome the above problems of mini-batch training methods. However, these methods suffer from large communication overhead. In recent years, numerous works have been proposed to reduce the communication overhead. Neugraph [38] combines dataflow-based deep learning frameworks to accelerate graph training through parallel computation. ROC [39] designs an online-learning-based graph partition algorithm to achieve a balanced workload and employs dynamic programming to optimize memory management. DGCL [40] proposes a shortest path spanning tree algorithm to schedule traffic, fully utilizing NVLink, PCIe, and other link bandwidths while balancing workloads and avoiding contention. BNS-GCN [8] randomly chooses the neighbors of boundary vertices to decrease the communication overhead. PipeGCN [41] achieves an efficient pipeline to overlap communication and computation while employing a smoothing algorithm to reduce errors incurred by stale features. Sancus [11] reduces communication overhead by adaptively caching historical embeddings. G3 [15] further balances the communication load among multiple workers while introducing finer-grained pipelining through partitioned vertices into smaller bins. This approach overlaps the communication and computation time. To address the high CPU-GPU communication overhead caused by duplicated traffic fetching during large-scale graph training, HongTu [9] employs a deduplication communication framework, which transfers the redundant CPU-GPU traffic on high-bandwidth inter-GPU links, accelerating the training.

Unfortunately, existing solutions still face the challenge of massive traffic volume. Our design introduces in-network multicast and aggregation for GNN training, significantly reducing traffic without sacrificing training accuracy.

In-network aggregation. DAIET [42] is the first INA algorithm and aggregates gradients at the switch to reduce network traffic. Sharp [43] and Sharpv2 [44] reduce the traffic by aggregating it in an aggregation tree deployed within the switches. However, Sharp does not consider the packet loss, which makes it unsuitable for lossy networks. SwitchML [17] proposes a packet loss recovery mechanism to aggregate gradients while providing a static and fair aggregator allocation mechanism. PANAMA [30] supports floating-point value for INA by using FPGA. Nevertheless, the static resource allocation of SwitchML and PANAMA leads to aggregator underutilization. ATP [16] addresses this problem with dynamic hash allocation. To further improve aggregation efficiency, A^2TP [18] decouples the control of link bandwidth and in-switch aggregators, and independently allocates the resources according to the job and network status.

However, none of the existing INA solutions are designed for GNN. SwitchGNN coordinates in-network multicast and aggregation according to the graph-structure relationships, achieving more efficient transmission.

8 Conclusion

In this paper, we propose an in-network accelerated framework SwitchGNN for distributed GNN training. SwitchGNN coordinates the in-network multicast and aggregation to reduce the traffic volume. First, to minimize the communication time and alleviate queue backlog, SwitchGNN uses graph-aware multicast reordering to schedule the multicast sequence, achieving an efficient pipeline. Then, SwitchGNN employs the multi-level partitioning method to avoid aggregator overflow. The experiment results show that SwitchGNN reduces the epoch time by up to 74% compared to the state-of-the-art full-graph training systems.

Opening Up Kernel-Bypass TCP Stacks

Shinichi Awamoto and Michio Honda
University of Edinburgh

Abstract

We have seen a surge of kernel-bypass network stacks with different design decisions for higher throughput and lower latency than the kernel stack, but how do they perform in comparison to each others in a variety of workload, given that modern stacks have to handle both bulk data transfers over multi-hundred gigabit Ethernet and small request-response messages that require low latency? We found that even representative kernel-bypass stacks have never been compared for a set of basic workloads, likely because of difficulty to run their implementation. This paper takes the first step towards answering that question by comparing six in-kernel or kernel-bypass stacks. We show that existing stacks cannot handle those workloads at the same time or lack generality. We then use those observations to discuss possible pathways towards practical kernel-bypass stacks.

1 Introduction

TCP has been widely used in both the Internet and datacenters. It is not just an interconnect, but a part of the network; TCP interact with applications, physical and virtual networks often operated by SDN controllers, and middleboxes, such as load balancers, firewalls, network observability and telemetry systems, prevalent in cloud infrastructure. Being part of an operating system kernel, TCP has performed reasonably well with the aid of hardware offloading for checksum computation and segmentation. Most of issues raised over time have been remedied by protocol or stack extensions; for example, TFO [63] enables data transmission over SYN packets, MPTCP [65] supports simultaneous use of multiple paths, and Minion [53] preserves application message boundaries. To support modern ML workloads, MLTCP [66] incorporates the application behavior in the TCP congestion control.

Meanwhile, some applications have suffered from slow kernel network stack performance evolution at the *system level* to meet tight latency or throughput requirement over high speed datacenter network fabric. Major criticisms are low throughput and high latency when the server handles a large number of connections [59, 79], often cited as the C10K/C10M problem [37], low throughput scaling to multiple CPU cores due to contentions at CPU caches or locks [24, 32], and high software overheads posed by generality that supports many features and abstractions [23, 45, 21].

Some hyperscalers thus have attempted to deploy a *kernel-bypass* TCP stack built on top of a fast raw packet I/O engine like DPDK [46, 82, 16] and we have seen a surge of such stacks also from academia. Indeed, kernel stacks are primarily optimized for high throughput of bulk data transfers, but at the same time, generality and patch-based development cycle have bloat software complexity and data structure footprint. As a result, the stack cannot drive 100 Gb/s or higher bandwidth networks, respond to millions of RPCs (request-response messages) per second, or save enough CPU cycles for application-level tasks or energy efficiency.

Operators and application developers now face a problem with what network stack they would build or adopt with an understanding of performance characteristics and trade-offs of design options. As it turns out, it has been increasingly apparent that no one knows which stack design or implementation makes a difference in a range of workloads, or even whether they really need a kernel-bypass stack. When a new stack is proposed in the literature, it typically compares against the regular Linux stack and one existing kernel-bypass stack or two. The comparison is thus limited, and the metrics often highlight their strengths or main focus.

Although a new stack is usually designed to solve problems that appear in a specific workload, it is rare that operators can completely ignore performance in another workload—especially in networks or applications where the highly generic TCP protocol is used, rather than in those where specialized non-TCP transport can be adopted for specific workloads [34, 44, 55, 26, 74]. Also, even for the workloads that a proposed stack focuses on, we found that several stacks exhibit opposite results from their reports. This is unsurprising, because the performance of stacks depend on many factors, including application architecture, workload, and hardware or software configuration whose optimal one differs between the stacks.

The implication of adopting or building a new stack is not just moving the TCP implementation out of the kernel and adapting the applications to the new stack (although that is already a substantial engineering effort). Today's systems heavily depend on the kernel stack in both the *software* and *protocol* aspects. The software aspect includes system-wide and application-level resource accounting, fault isolation between the application and stack, protection against application or network protocol misbehavior, and support for queuing disciplines or packet filters controlled by familiar tools or orchestration frameworks. The protocol aspect includes extensions, which mostly rely on TCP options negotiated with the remote

endpoint, and new algorithms for congestion control and loss recovery, which interplay with other traffic in the network.

A new kernel-bypass stack would need to support those features when they are used in production. It is not just an addition of features, but requires development and operation cycles over time, perhaps with a continual community effort, as we have seen in the evolution of the Linux kernel stack that has continually changed by 5–25% LoC modification in each component, each year, at least 2010–2020 [61]. Given that relatively few stacks could afford such an effort for a long term, what would those stacks look like?

Once a high quality, general enough kernel-bypass stack supported by a wider community is available, the clear implication is accelerated evolution of it both in development and deployment, much like what we have seen in success of QUIC often shipped with web browsers. Some users would fork it and some would contribute back the enhancement they made, and new features could be used without OS upgrade, which has lead to slow stack evolution and option deployment in the Internet [48, 28].

We present performance measurement results of six different in-kernel or kernel-bypass network stacks—regular Linux, mTCP [32], TAS [36], F-Stack [16], IX [7] and Demikernel [80]—running on the same hardware, serving the same workloads and using the same application whose I/O is optimized for individual stacks. Selection of the stacks is made based on their design decisions (Figure 1 and Table 1) and availability, although we still needed to implement new features, fix bugs or figure out optimal configuration without document in some to enable fair comparison with their best possible performance.

We examine the effect of network stack design decisions on *basic* workloads, such as simple bulk data transfers and RPCs over different degrees of parallel connections with varying number of CPU cores, which surprisingly have not been studied. As we will describe in § 4–§ 7, those workloads stress varying aspects of the stack. We discuss untested stacks and workloads in § 8.5.

This paper makes three contributions.

- The first is a snapshot of the performance of different network stacks on modern hardware as of 2024, showing none of the stacks perform well for both large and small data transfers at a range of concurrency levels.
- The second contribution is our measurement methodology that allows us to make fair comparison between different stacks for variety of workloads with simple hardware requirements. It also shares our experience of writing an application over multiple stacks with largely different APIs or even programming models.
- Last but not least, we enable third-party software artifact of five representative kernel-bypass stacks for all the basic workloads under a unified application; this would enable others to start research or development on those stacks. We believe this is a crucial step. Alibaba has reported that fixing problems with existing stacks is more expensive than building a stack from scratch due to limited community support [82], but such an approach is only affordable for hyperscalers with a large amount of engineering resources.

2 Motivation

Kernel-bypass stacks are designed and implemented to outperform kernel stacks, but we observe two problems to understand the status quo as a whole. First, most of those are evaluated in a limited set of workloads, disregarding one or more of basic yet salient stack properties that we detail in § 2.1; for example, none of the stacks we test are evaluated for large data transfer[1]. Although datacenter traffic contain many small RPCs, large transfers are also common in storage traffic [4] and machine learning [66]. Second, those stacks are compared only against one or two other stacks, likely due to the lack of practical availability of other stacks.

There exists a growing trend of releasing the artifact to ensure reproducibility of research output, but artifact does not necessarily mean software release supposed to be used by others in their own way. We first review how the kernel stacks have evolved towards better performance by addressing emerging challenges. We then describe the representative stacks we evaluate in this paper, if any, including our modifications required to evaluate their basic stack properties.

The rest of this section describes the key properties used in the kernel TCP stack to serve various workloads. We then review the kernel-bypass stacks we test in terms of their design highlights and usage by the original authors and others, which we also summarize in Table 1.

2.1 Kernel Network Stack

Large sends. Kernel network stacks have been optimized primarily for throughput of bulk data transfer. It is motivated by file transfers over the Internet, which thus has been the common networking performance metric measured by popular tools, including prominent `iperf` [52].

The basic primitive of the kernel stack is the packet data structure (`sk_buff` in Linux and `mbuf` in FreeBSD). It represents arbitrary-sized packet data that can span across multiple packets or kernel pages and can be moved between the layers without data copy, while maintaining shared metadata like pointers to packet headers or sockets and reference counts. When the application writes data on the TCP socket, it is copied to the kernel socket buffer. The kernel then allocates a packet metadata, which is passed down through the stack.

The TCP implementation creates a larger segment than the MTU size preceded by a single TCP and IP header so as to reduce the number of network layer operations required to

[1] Only brief report is provided in [38].

send the same amount of data. This segment is split into MTU-sized packets while adjusting their sequence numbers, packet length and checksum fields at the NIC with TSO or the bottom of the software stack with GSO. The kernel stack can send the next data in the socket buffer, which would have been held due to the lack of the available window, as soon as it receives a positive ACK, because the ACK packets are processed in the interrupt context invoked by the NIC (`softirq` in Linux and `isr` in FreeBSD).

Multi-hundred gigabit Ethernet fabric requires large transfers also to cope with high packet rates, whose problems are discussed next. BigTCP [18] enables TSO for larger segments than 65 K B to further reduce the network layer processing per unit data. High bandwidth networks also create congestion in the host interconnect and memory subsystems, and [2] mitigates it.

Small messages. It is easy for kernel stacks to fill a 10 Gb/s link with large transfers [24], because the transmission time of a 1.5KB packet is 1.2 µs, which is sufficient for the sender to prepare the next segment and push it to the NIC. However, that of a 64 byte packet is 67 ns, which is too short to prepare the next packet, because of software overheads in the protocol stack [24, 32, 72]. Those overheads include system call, packet metadata (de)allocation, socket manipulation such as state update, file descriptor lookup on receive, many of which rely on atomic operations or locking. Short messages are common in datacenters due to RPCs, for example, to retrieve remote in-memory caches, commit database queries and run consensus protocols [70].

Concurrent connections. Concurrent TCP connections are common in the Internet servers, whose challenges are cited as C10K or C10M problem [37, 42, 49]. Those are also common in datacenters due to parallel RPCs [70]. In addition to request processing throughput, tail latency also matters, because it is common that a server accesses many other servers to generate the response to a single request, meaning that one server-server communication delay blocks the response to the client.

Concurrent connections reduce CPU cache locality (e.g., of the connection data structure). Another problem is that the application (thread) needs to process many (per-connection) file descriptors that receive a request. In the conventional `epoll`-based programming model, each thread processes those descriptors in turn, reading the request and writing a response using two syscalls, whose overheads are significant for small data. Concurrent connections thus create request backlogs at the application, leading to queuing delay [79]. The new I/O multiplexing APIs, `io_uring`, reduces the request handling syscalls.

Multiple CPU cores. Modern NICs are equipped with multiple queues processed by different CPU cores to improve request handling throughput over concurrent connections. On receive, Receive Side Steering (RSS) distributes the packets to different queues based on the source-destination 4-tuples to avoid packet reordering in each connection. Those queues

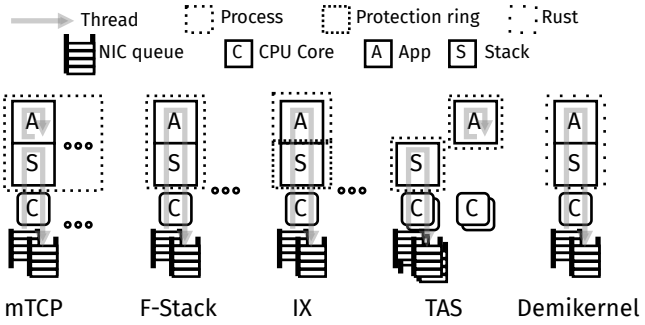

Figure 1: Stack architectures. Details in § 2 and Table 1.

interrupt the corresponding CPU cores (e.g., same index) to parallelize the subsequent packet processing. The send syscall context typically chooses the NIC queue based on the current CPU core to avoid lock contention. However, locks, atomic operations and large memory footprint of data structures impair parallelism across multiple CPU cores, limiting the whole-server throughput. Also, multiple queues do not increase the parallelism inside the NIC; packets across the queues are still serialized at the NIC hardware [73].

2.2 mTCP

mTCP implements the TCP/IP protocol suite from scratch and runs it in user space on top of a raw packet I/O framework (ShaderIO [23], DPDK or netmap [67]) that achieves packet I/O at a very high rate by enabling *batch* packet processing. Although mTCP provides socket-like APIs, scanning connections to process the requests needs just lightweight library calls for every connection, instead of expensive real `read`/`write` syscalls.

The most unique aspect of the mTCP architecture is extensive resource partitioning between the CPU cores. It allocates a *stack thread*, which performs packet I/O and protocol processing, to every application thread, and co-locates the thread pair on the same CPU core to enable lock-free data sharing between the stack and application, as illustrated in the leftmost part of Figure 1. mTCP stack threads even do not share the TCP connection instances; if a stack thread receives a packet that belongs to a connection handled by another thread, it simply discards the packet.

The implementation of mTCP is relatively stable. We have seen its usage or extension in other research projects, some with the mTCP authors [31, 50, 38], but many without [3, 7, 36, 81, 41]. However, the workload is limited; for example, the maximum transfer size per request is 8 K B and the number of CPU cores is at most 8 in the original paper and 24 without application-stack thread pinning in other work [36]; [41] uses 24 cores, but at low request rates (up to 0.2M requests per second). We test mTCP with transfer size up to 2 MB (§ 4) and up to 24 CPU cores (§ 7).

	Architecture	API	TCP impl.	Use by author(s)	Use w/o author(s)
mTCP [32]	App-stack thread pair on the same core	Socket-like (no semantics)	Custom	Up to 8 K B data and 8 cores [32, 31, 50, 38]	Up to 8 K B data or 24 cores [3, 41, 7, 36, 81]
F-Stack [16]	App-level processing in the stack thread	Event callback to the stack	FreeBSD	–	Up to 8 K B data [57, 81], 8 cores [10] or 64 conns. [58]
IX [7]	App-level processing in the stack thread	Packet-level TX/RX buffers	`lwIP` [19]	Up to 8 K B data [38]	Up to 64 B data [36], 4 K B w/ 8 cores [81] or low data rate [41]
TAS [36]	Dedicated threads for TCP data path	Socket-like	Custom	Up to 2 K B data and 24 cores [36, 72, 75]	Up to 0.3 MReqs with high overhead apps [41]
Demikernel [80]	App-level processing in the stack thread in Rust	Packet-level TX/RX buffers	Custom	Up to 16 conns. [64] and 256 K B data [80, 15]	Up to 64 conns. [58]

Table 1: Design and usage summary of the network stacks we test. Their details are in § 2.

mTCP has a significant deployment issue. When it initiates the connection (i.e., used as a TCP client), returning packets must arrive at the same CPU core by carefully choosing the local port number based on the RSS hash function. This restricts the number of usable local ports per destination or compromises the flexibility of choosing the local port. Further, its specific RSS hash seed required at both the client and server also results in poor connection distribution among the cores, which would be problematic when a large number of cores is available. Further, mTCP does not support applications that use different threads for sending and receiving [36].

In our measurement, we needed to simulate the distribution with various seeds and modify mTCP to use the pre-calculated seed. In the real world, the user may need to implement a dynamic load balancing or thread migration mechanism. Therefore, mTCP is easy to use in terms of I/O APIs because those are similar to socket APIs, but its shared nothing architecture complicates the application model and system configuration. We also needed to select, with mTCP code modification, busy-polling or interrupt to handle packet input for each workload to achieve best possible performance.

2.3 F-Stack

F-Stack [16] is a production-quality kernel-bypass stack developed and used by Tencent Cloud. It runs on top of DPDK but ports the FreeBSD TCP implementation to benefit from its advanced TCP features, including RACK [14], TFO [63], ABC [5] and SACK extensions [47, 8], to name a few.

This is a stark contrast to mTCP, which implements optimized TCP from scratch at the expense of supporting only basic features. It should be noted that, since the current TCP has a number of extensions widely used, just implementing RFC793 [77] and RFC1323 [9] does not mean being a *fully-fledged* TCP implementation.

F-Stack employs the architecture where the stack and application run in the per-core process (see Figure 1). Unlike mTCP, both stack processing and application-level tasks are executed in the same thread. Although F-Stack intends to provide socket-like APIs to minimize the porting effort of existing applications, we found that it is not as easy as it sounds due to their core architecture. Since the address space is not shared between processes by default, application-level contexts would need to be relocated to explicit shared memory. Further, event handlers that are registered by the application as callbacks must return control to the stack to restart the stack activity, further hardening the application port. This is a stark contrast to the applications that are running on top of the kernel stack where the OS appropriately schedules the application and stack tasks.

F-Stack is used by several external research projects for either bulk data transfers briefly [38], small messages up to 8 K B [57, 81], 8 CPU cores with up to parallel 1120 connections [10], up to 64 parallel connections [58] or functional test [83]. However, it is unclear how F-Stack works for variety of workloads in the same setup.

2.4 IX

IX runs the stack in a protected CPU ring domain usually used for virtualization. It runs on top of DPDK and employs `lwIP` [19], a portable TCP/IP protocol implementation, thereby inheriting its protocol features and extensions. IX provides a low-level APIs based on event conditions, and operates based on the run-to-completion execution model throughout the stack and application; when a series of packets (in the same or different connections) arrive at a NIC ring, the busy-polling thread processes those packets in the stack, executes the application-level request processing, and then sends the responses through the stack (Figure 1). The thread restarts waiting for new packets after consuming all the packets. IX [7] reports much lower average and tail latency, as well as higher request throughput, than mTCP.

Since IX does not support socket-like APIs, porting existing applications to IX requires significant effort, including changes in both I/O APIs and the application execution model.

IX is the basis of following projects by the original authors, including ZygOS [62], which reduces the tail latency by work stealing, and Shinjuku [33], which further cuts latency with preemptive scheduling. IX has also been used by several research projects without the authors [81, 36, 41]. However, their use of IX is limited to 64 B messages [36], 4 K B messages [81] or low request rates of up to 0.4M per second [41].

In our experiment, since the original IX implementation is unstable, we use the one included in Reflex [39] which is also the work of the common authors. IX in Reflex removes the dependency on Dune and thus the use of protected CPU domain [6]. This actually prevents IX from being disadvantaged by the overheads caused by extra protection that other stacks do not offer, enabling fair comparison in our study.

2.5 TAS

TAS takes a unique approach that replaces the *datapath* of the TCP stack, while leaving control to the kernel. The TAS datapath runs dedicated *acceleration* user-space threads, which execute the packet I/O using DPDK and TCP/IP protocol processing and post the data to the application that runs in separate threads (Figure 1). Therefore, TCP datapath functionalities, such as congestion control, loss recovery and packet filtering, are not inherited from the kernel stack and must be implemented in TAS.

Application porting effort required to use TAS is relatively low. TAS preloads the POSIX I/O library to move the data between the acceleration and application threads with ease, meaning that the application can still use the POSIX system call. While some socket options are not supported, no major modification to the application source code was needed. Unlike the stacks mentioned earlier, it does not use the shared-nothing architecture or run-to-completion, which significantly contributes to the low application porting effort. On the other hand, it does not support modern TCP extensions.

TAS has been used in following projects by its original authors [72, 75], but to the best of our knowledge, without the TAS authors, it was used only at low request rates [41].

TAS had a significant problem to test. First, we noticed that TAS does not implement the Window Scaling (WS) option when we observed very low bulk data transfer throughput. The lack of large window usage does not only limit the throughput, but leads to incompatibility with stacks that do not support WS-incapable remote endpoint, which is the case for mTCP. Even after implementing this option, we found that TAS cannot use the resulting large window; we further added support for that.

Moreover, TAS is sensitive to configuration. Since its default internal buffer (equivalent to kernel socket buffer) size is very small, the application needs to call write commands repeatedly until the data is fully written, causing inefficiency. TAS limits the bandwidth usage by default to optimize for load balancing among multiple connections. However, it is harmful for bulk data transfers. Finally, the user can manually assign CPU cores to the application and stack threads. This means that there exist a large search space for optimal core assignment where the optimal setting depends on workload and application and can be verified only based on measurement of the resulting performance. This is a stark contrast to the kernel stack that shares cores between the stack and applications. We searched for the optimal split of cores between the stack and application in multi-core experiment (§ 7).

2.6 Demikernel

Demikernel augments various kernel-bypass I/O frameworks like DPDK and RDMA, and protects the stack and application by Rust. It is designed to achieve ultra-low latency. Demikernel supports generating Rust coroutine, a lightweight context switching mechanism, which is advantageous compared to the POSIX thread-based context management. It provides a new asynchronous I/O API and employs the run-to-completion execution model. Its TCP/IP protocol implementation is built from scratch, similar to mTCP and TAS.

Demikernel has been used by the original authors for their following projects [64, 15], but also by other authors [58]. Demikernel has been tested only with small numbers of concurrent TCP connections, up to 16 by the original authors [64] or 64 by others [58].

Porting existing applications to use Demikernel is difficult in several aspects. Demikernel assumes that the application has already segmented their data into MTU-sized chunks. This would be troublesome for bulk data transfers. Its I/O event model also differs from that of regular kernel stacks, which is particularly relevant when handling concurrent TCP connections. For example, in contrast to Linux `epoll_wait` that notifies the caller of ready-to-process events, the equivalent function of Demikernel sends event completions. To follow this model, the developer might not only just replace API calls but restructure the application. Finally, due to its single-threaded design, it is hard to utilize stack-level multi-core parallelism. Therefore, although the I/O interfaces could be wrapped to resemble POSIX APIs, it would be hard to use Demikernel in terms of application threading and event handling.

3 Methodology

Flexible yet simple measurement methodology is crucial to characterize stack performance. Existing stacks typically use their own custom application for basic measurement, which utilizes the underlying stack most efficiently with minimum overheads. However, since those applications use their own application-level protocol, one cannot be used to evaluate another stack. Further, those applications do not support all the workloads we would like to test.

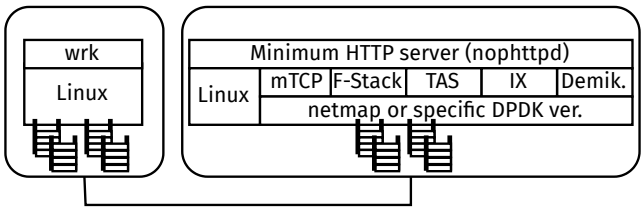

Figure 2: Experiment software architecture in the client and server machine connected back-to-back.

Some of the stacks are ported to an existing HTTP server application, such as `lighttpd` or `nginx`, but it includes significant application-level overheads, which is undesirable to highlight performance characteristics of the stack itself. Further, different stacks are ported to different HTTP servers, whereas those HTTP servers have different architectures and complexity, meaning that we cannot compare "HTTP server X on stack A" against "HTTP server Y on stack B". Memcached has been ported to all the stacks, but they are different in versions and exhibit high application-level overheads, similar to HTTP servers.

Server. We thus implement `nophttpd` (Figure 2 right), a custom TCP server that simply serves a static in-memory data in response to an HTTP request. Exploiting the advantage of building the application by ourselves, `nophttpd` is optimized for individual stacks—Linux, mTCP, F-Stack, IX, TAS, and Demikernel (Catnip TCP stack)—to handle all of bulk data transfer, small RPCs, concurrent connections as efficiently as possible and well utilize multiple CPU cores, while addressing most of the API challenges posed by those stacks, described in § 2.2–§ 2.6. When running on regular Linux, `nophttpd` uses `epoll`-based event loop. For Demikernel, we implement `nophttpd` in Rust to use its native APIs directly.

We do not opt for implementing a wrapper that unifies the interfaces of all the stacks and the minimum HTTP server logic on top of it. This is because the stack's execution model largely differs between the stacks, not just the function names or arguments. Therefore, such an unified wrapper approach would advantage or disadvantage particular stacks, making the comparison unfair. Our approach of tightly coupling the application logic with the native API of each stack might be impractical when building an application in practice, but this approach is suitable for the purpose of fair comparison between the stacks.

Client. Another challenge is the client. Some existing work [36, 32] employ multiple client machines that run regular Linux stack to saturate the kernel-bypass server, because the kernel-bypass stack is faster than in-kernel one by a large margin particularly for small messages. However, the use of multiple clients complicates the measurement workflow and requires additional hardware resources.

We thus use a single client machine. When we test multi-core scalability of the server stack, we *downclock* the server CPU clock frequency, as done in [67, 27], to prevent the client from becoming the bottleneck. We use the `wrk` benchmark tool for its useful stat report and straightforward implementation. However, we found it has multi-core scalability issue in its stat management mechanism, which creates a contention between threads when their number is high. We thus modified `wrk` to aggregate the stats across the threads in a more coarse granularity and use thread-local buffers to store intermediate records. `wrk` establishes one or more persistent TCP connections to the server and repeats sending a request and receiving a response in every connection. Our methodology might seem limited, but as we will show in the next sections, we can characterize stacks with variety of workloads.

Workload. We measure bulk data transfer throughput, small message latency with unloaded client and server, and concurrent message throughput and latency over multiple connections that stress the server. Those workloads are simple, but stress different parts of the server network stack, including per-byte or per-message transfer efficiency, connection scalability, and multi-core scalability. We believe our measurement is worthwhile, because existing work does not test the stacks across all these aspects simultaneously in a consistent setup, as discussed in § 2.

Hardware and system configuration. We use a pair of identical machines connected back-to-back. Each machine is equipped with Intel Xeon Gold 5418N (Sapphire Rapids) clocked at 1.8Ghz and Intel XXV710-DA2 25GbE NIC. Both machines run Linux kernel 5.18 unless otherwise stated. We deactivate unused cores with CPU hotplug in Linux to prevent the kernel from performing relevant activity to the test on those cores. We disable segmentation offload (TSO) for all the stacks for fair comparison, as mTCP and Demikernel do not support it; if it was enabled, it would provide larger degree of improvement in stacks with higher per-packet processing costs (i.e., lower small message throughput), because TSO reduces the packet rate in the stack. We run each benchmark for 8 seconds.

4 Bulk Data Transfer

We first measure bulk data transfer performance of the stacks. Since we test each stack running at the server, the client issues a small request that triggers a large response to test the ability of the server stack to send large packets continually, which is clocked by receiving ACK packets. Many kernel-bypass stacks do not consider this workload much, although large transfer still happen in many scenarios; storage, search and web systems are a few of the examples [56, 1].

On the regular socket `write`, the kernel copies up to as much application data as the available kernel socket buffer. Partial write is not a problem, because the socket informs the caller of how much the data is written, and TCP semantics is a byte stream, like a file. In other words, the application can `write` arbitrary sized data into the socket. Kernel-bypass

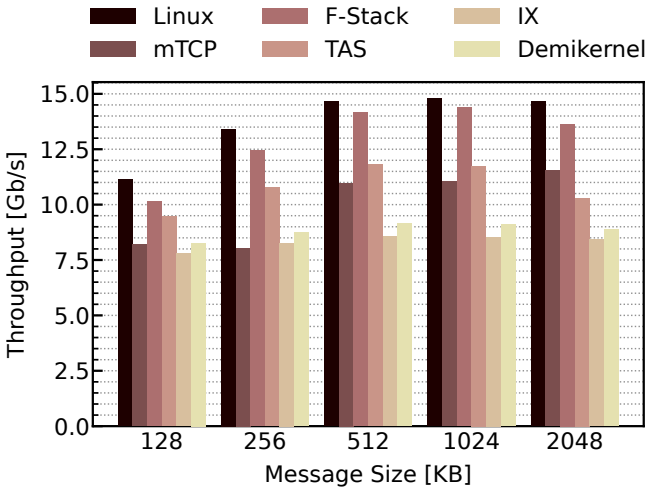

Figure 3: Bulk transfer throughput over a single connection.

TCP stack APIs vary. IX and Demikernel require the application to split the data so that each fits into a single packet, as described in § 2.4 and § 2.6, respectively. We omit the large receive performance measurement, because it is more lightweight than sends for large data. Receive-side processing performance matters for small messages due to high packet arrival rates; our experiment with small messages in the next sections stresses the receive path of the stacks.

Figure 3 shows the throughput of Linux stack, mTCP, TAS, F-Stack and Demikernel. `nophttpd` sends up to 2MB of a message over a single connection as the response to a small request issued by the client. All the stacks use a single CPU core, except for TAS, which requires minimum two cores, one for the application and the other for the accelerated datapath.

The Linux stack achieved the highest throughput, peaking at 14.69 Gb/s with 2 MB messages over a single connection. This is unsurprizing, because it has long been optimized for it. F-Stack achieved 13.66 Gb/s, following the Linux stack.

To shed light on this observation, we profiled mTCP and F-Stack using Linux `perf`. The Linux stack consumes 50.5% of the CPU time in TCP, IP and Ethernet protocol processing, whereas F-Stack consumes 52.5%; `memcpy`, whose overheads are dominant in large buffer processing, is not included in those overheads. Since the Linux stack and F-Stack can process 880 and 735 requests per second, respectively, this translates that the Linux stack can process TCP packets 19.6% more efficiently than F-Stack $(1-(50.5/880)/(52.5/735))$.

Given that the FreeBSD TCP implementation is optimized as much as Linux [71], our results suggest that the overhead of emulating the kernel environment to run the FreeBSD stack could offset the I/O efficiency of DPDK, at least for this workload. Further, it is also possible that the run-to-completion execution model of F-Stack fails to push the next packets fast enough in response to the ACK packets.

Other stacks largely fall behind. mTCP and TAS exhibit 10–12Gb/s in throughput. Those stacks are not particularly optimized for bulk data transfer, but significant performance penalty for such workload would prevent operators from adoption of them. Demikernel and IX exhibit the lowest throughput. This is partly due to their inefficient APIs that the application must fill the packet-sized data fragments, resulting in poor interaction between the application and network I/O for multi-packet data. Also, similar to mTCP and TAS, their run-to-completion model could fail to ACK-clock the large transfer efficiently.

5 Small Messages

Latency of small messages has been crucial in datacenters, because servers handle many RPCs, such as in-memory key-value cache access for small items and API calls. In this section, we discuss *unloaded* latency, where the message or packet is never queued in the network, host interconnect or the host software stack, to directly highlight basic software overheads of the stack; we discuss latency in the presence of concurrent requests and connections in the next section.

To take the lowest possible RTT of each stack whose performance is determined by the software and context switch (if any) overheads, the client triggers a small response (64 B payload preceded by the HTTP header) for a small request over a single connection and CPU core. We disable interrupt moderation at the NIC in this experiment, so that the receive interrupt can be caught quickly, which is crucial for mTCP and Linux stack. For the Linux stack, the application busy-polls the event descriptor (i.e., on `epoll_wait`) to avoid the wake-up procedure of the application that is blocking.

Figure 4 plots the P50 request RTT over a single connection with varying response size; we indicate P99 RTT with a number on each bar. Surprisingly, the kernel stack latency is comparable to other kernel-bypass network stacks, achieving 17 µs for 64 B messages. However, it is still higher than Demikernel, which achieves 13 µs, the lowest among all the stacks we test.

mTCP's high latency is expected, although the paper [32] does not report the latency. This is because one of its design decisions is to aggressively exploit packet-level batching. Further, the mTCP stack and application threads run on the same CPU core in user space, which would exhibit high context switching overheads, although maximizing cache locality and enabling lock-less stack-application communication for high multi-core scalability. F-Stack's high latency could come from the same reason with the lower bulk transfer throughput in comparison to Linux—the kernel emulation overheads to run the FreeBSD TCP/IP implementation would incur high software overheads. Low-latency stacks such as IX and Demikernel start showing higher P50 and P99 latency than Linux when the message sizes are larger than 32 K B, perhaps due

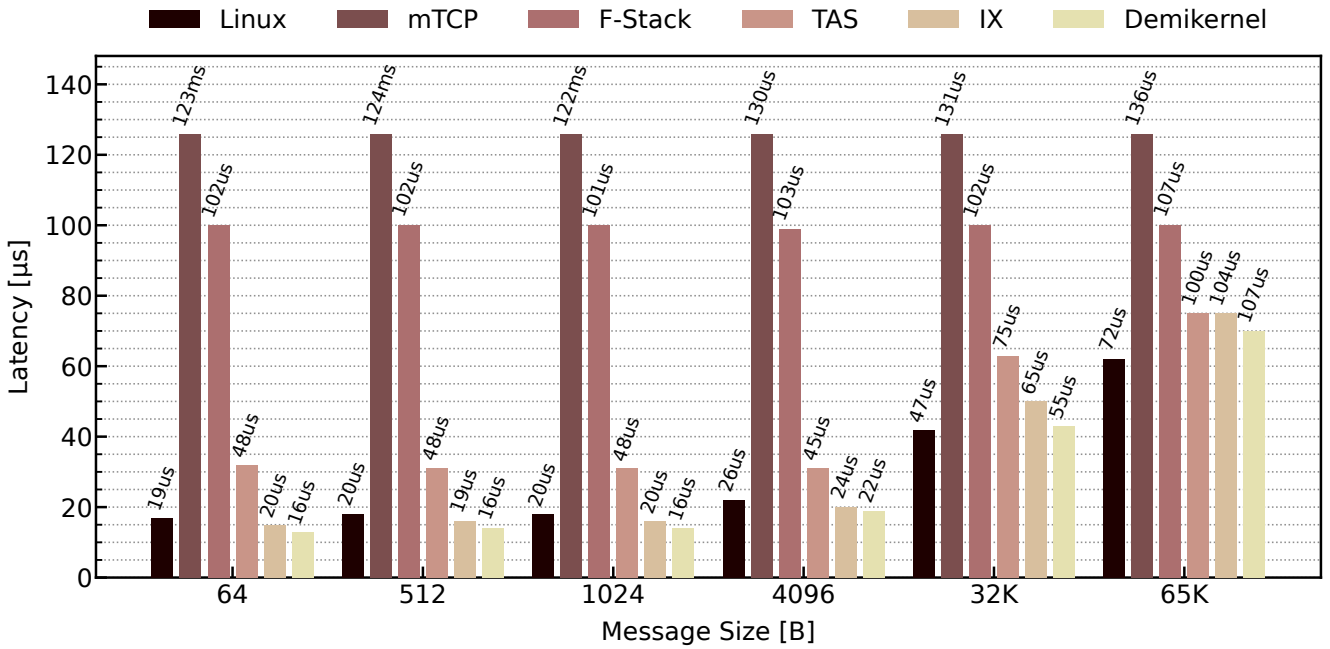

Figure 4: RTT at P50 (bars) and P99 (numbers on the bars) in a single connection.

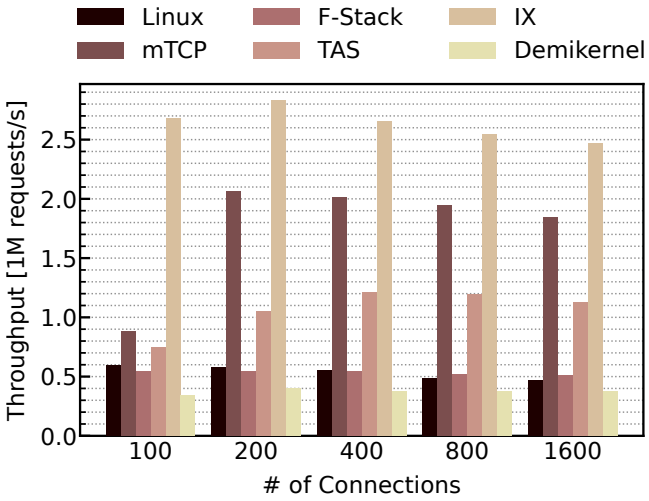

Figure 5: Throughput over concurrent TCP connections.

to the same reason with their low bulk transfer performance discussed in § 4.

We observe similar characteristics of P99 latency to P50 overall, but mTCP exhibits extremely high tail latency, for example, as much as 124 ms.

6 Concurrent Connections

We now turn our attention to concurrent requests over multiple connections, as it is a common pattern for datacenter RPCs (§ 2.1). In the stack that executes receive packet processing in a separate thread from the application (Linux, mTCP and TAS), when the stack drains the NIC queue more slowly than the packet arrival rate, the queue forms at the NIC; when the application consumes the requests more slowly than the stack, the queue forms at the application. In the stack that processes both receiving packets and application-level task in the same thread in a run-to-completion manner (F-Stack, IX and Demikernel), the backlog forms at the NIC.

Figure 5 plots the throughput with the single CPU core, except for TAS which requires at least two cores; we discuss the multi-core cases in the next section. Figure 6 plots request latency at P50 (bars) and P99 (numbers on the bars).

In throughput, IX consistently outperforms others by a large margin, 30–684%. mTCP outperforms TAS by 17–95% although TAS uses one more core in total. Those results differ from the report of the TAS paper. For those numbers of TCP connections, the TAS paper reports similar throughput between TAS and IX, which also differs in our experiment. Those observations are likely due to the different CPU core allocation, where we allocate the minimum number of cores in this experiment.

Interestingly, F-Stack and Linux perform almost the same, again implying the overheads of kernel emulation that offsets the effect of efficient DPDK packet I/O.

TAS achieves low P50 latency, close to IX, but it could be due to almost only half of the IX throughput. Linux exhibits low throughput and high latency, which exacerbates with increasing numbers of concurrent connections. This could be attributed to both high stack processing overheads and application-level per-request processing costs with syscalls.

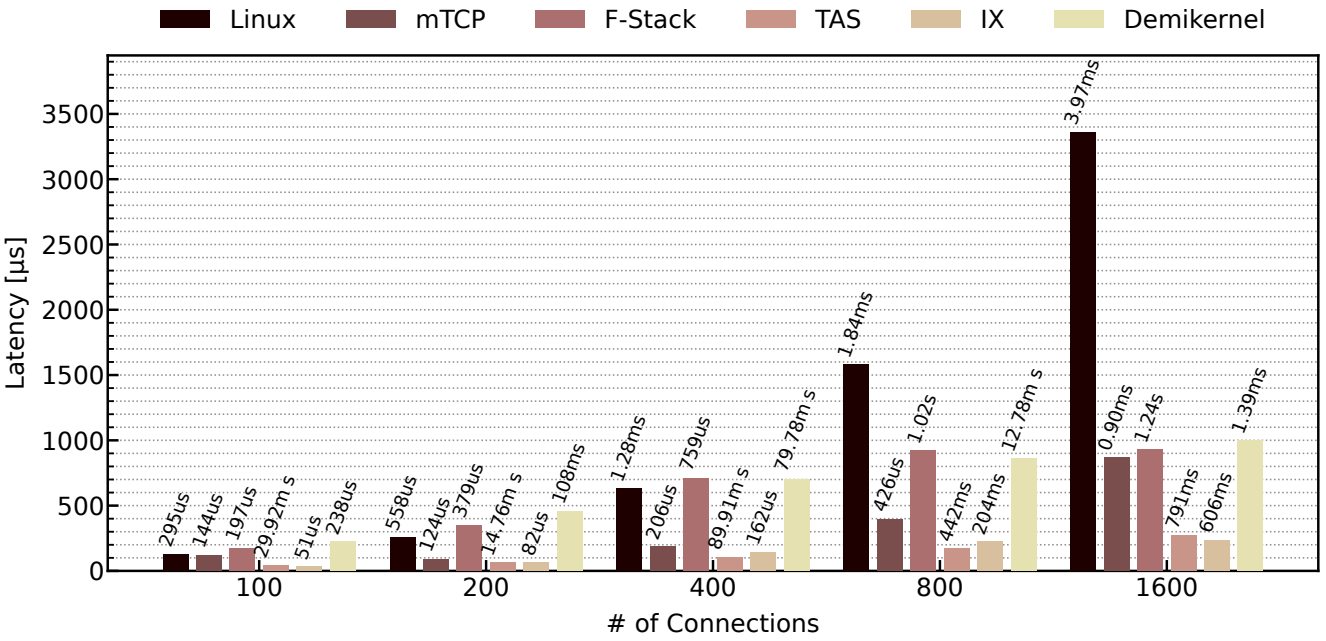

Figure 6: RTT at P50 (bars) and P99 (numbers on the bars) over concurrent connections.

IX achieves 73–85% lower P50 latency than Demikernel, which was introduced later than IX for low latency, while achieving much higher throughput; IX also achieves lower tail latency than Demikernel for up to 400 connections, where the results invert. Note that Demikernel is not compared against IX in their paper. F-Stack, TAS and Demikernel exhibit high tail latency when the connection count is high.

7 Multicore Scalability

Finally, we test how the single-core performance of each stack scales over multiple CPU cores.

Figure 7 plots the throughput over increasing numbers of CPU cores; since the server is unsaturated in many cases (i.e., the client becomes the bottleneck), we also plot the results with the server whose CPU cores are *downclocked* in Figure 8, which we use for discussion in this section. We use 4800 concurrent connections for all the cases. We were unable to test Demikernel, because it does not support multi-core parallelism in the stack. The low throughput of IX at 24 cores is due to a bug in IX, which we were unable to fix. For TAS, we report the numbers with the best-performed stack/application core assignment, which we manually identified; as a result, we assigned half of the total CPU cores to the stack and the rest to the application. More complex applications would need more cores in the application.

IX performs the best in many cases up to 16 CPU cores, outperforming TAS by 16–384% and mTCP by up to 456%. Note that the IX paper [7] reports multi-core scalability up to 8 CPU cores. TAS [36] reports slightly higher throughput than IX in their test with up to 16 CPU cores, but our result shows the opposite. The possible reason is that [36] uses their own custom key-value store, so it might be more optimized for their proposal, or that they could have used different IX implementation, where we use Reflex (§ 2). On the other hand, TAS indicates a sign of the best multi-core scalability, exhibiting 67% throughput increase when the number of cores increases from 16 to 24.

mTCP scaling decays at 24 cores, increasing throughput only by 8.7% when the number of cores increases from 16 to 24 cores, although it improves the throughput by 71% when the cores increase from 8 to 16 cores. The original mTCP paper [32] measured up to 8 cores and scaled well. Therefore, the scaling limit we observed could be due to higher degree of CPU cache contention, which is insignificant when the number of cores is small.

F-Stack scales relatively well, but always stays at a lower side in comparison to IX, TAS and mTCP.

8 Takeaway Lessons

In this section we discuss lessons learned in our work and possible directions towards practical network stacks.

8.1 Application Development Effort

Although mTCP, TAS and F-Stack argue compatibility with existing applications or minor porting effort, our experience suggests significant engineering effort for their adoption. F-Stack enforces a multi-process model for concurrency. Although our application is multi-threaded, it was straightfor-

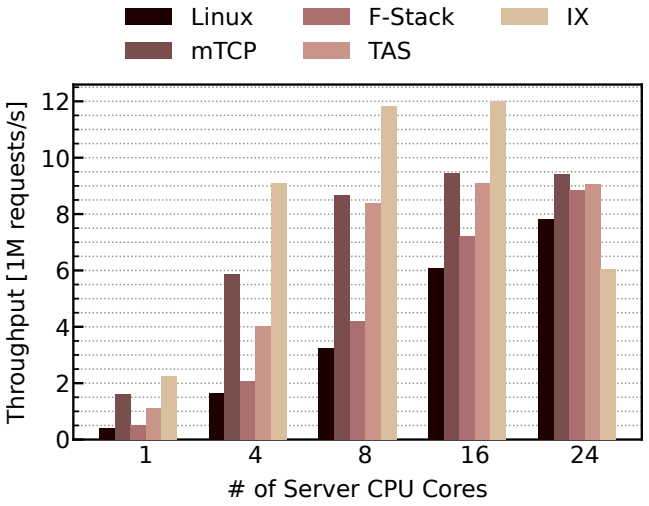

Figure 7: Throughput over multiple CPU cores.

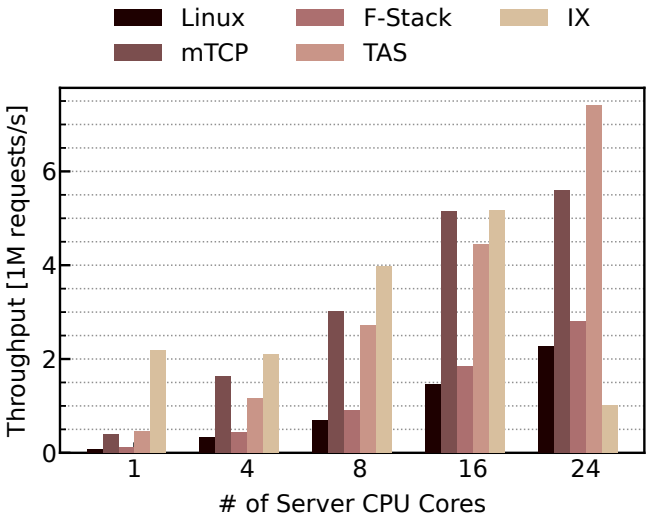

Figure 8: Throughput over multiple CPU cores downclocked to 800MHz.

ward to switch to multi-process model, because it does not have shared state. However, this would be a significant burden for most of the real-world, more complicated applications.

mTCP uses a context structure to identify the connection, instead of an integer descriptor for the kernel stack. Since it is a common practice for applications to index connections by descriptors, which also increase from the lowest value, those applications could need to redesign connection management.

TAS transparently redirects system calls issued by the application to its own library using LD_PRELOAD. However, the lack of many kernel TCP features led to runtime errors, for example, for unsupported `setsockopt`s, which would be problematic real-world, more complicated applications than ours. Nevertheless, its application porting effort is still relatively low.

Demikernel uses asynchronous calls to communicate with applications, requiring many existing applications to be rewritten. Although it provides C interfaces alongside the Rust interfaces, manual data segmentation and unusual event handling require a significant effort to port existing applications. We experienced similar issues in IX. Moreover, since Demikernel is single threaded and enforces Rust co-routines to exploit parallelism, the application cannot exploit I/O-level parallelism, which is the reason why we were not able to test multi-core scalability of Demikernel.

8.2 Configuration and Parameter Tuning

Kernel-bypass stacks fail to keep up with updates of their depending library. Although Demikernel, F-Stack, and TAS rely on DPDK, since those stacks require different versions of DPDK or other libraries, we were unable to reuse the same kernel or I/O-related library installation. We also found that some hard-coded parameters in the stack's source code negatively impact performance. Most stacks also require specific NICs, and porting those stacks to another (newer) NICs could require unpredictable engineering effort, as reported in [82]. In particular, IX requires the custom compilation and link process, using a custom linker script. This further complicates the stack porting process to another environment. Also, stack traces taken by `perf` were collapsed in IX, making our performance analysis harder. The authors might have their in-house updates for their newer projects, but we were unable to find those. Research community would significantly benefit as a whole if we somehow incentivize software maintenance and update of research output.

A sub-optimal stack configuration also leads to lower performance. As discussed in § 2.2, mTCP needs a specific RSS hash seed for both the client and the server just to function due to its resource partitioning; likewise, as discussed in § 2.5, TAS required significant configuration effort for buffer tuning, rate limit deactivation, and stack/application CPU core ratio.

We conclude that there is no one-size-fit-all configuration for kernel-bypass stacks. The optimization methodology for the Linux stack is relatively well-known, but for kernel-bypass stacks, their distinct architectures (e.g., Figure 1) make prediction of their performance characteristics difficult. Therefore, we needed to employ some degree of *brute-force* approach to find a combination of optimal configuration options.

8.3 Understanding Stacks Better

It is essential for operators and application developers to understand their stacks and debug or optimize them when opportunities are found. Two challenges have been observed in this work.

Profiling and code knowledge dependency. The Linux stack has a range of tools, such as `perf`, Kernelshark [68] and PacketDrill [13], but the kernel-bypass stacks do not have any

of those. Those tools require the users to know where to look in the source code, because those are based on trace points. However, they are still useful, as kernel stacks are reasonably well documented and code organization is well known. This is not the case for kernel-bypass stacks. Therefore, even if the equivalent tools were available, it is questionable how practical they are.

NSight [22], although not publicly available at the time of this writing, would remedy this problem. It traces application-level messages between the application and NIC even across multiple threads (e.g., stack thread and application thread in TAS or mTCP), whose interplay is difficult to track. Crucially, NSight can diagnose the source of latency without understanding of the code, except for the API layer of the stack for message identification.

Fine-grained performance analysis. We used Linux `perf` to generate CPU flame graphs that visualize the amount of CPU resources that specific functions in the kernel or user space have been consuming and to see the function call graphs. It was helpful to find the performance bottleneck, or identify unexpected idle states in the stack. Note that the live per-core CPU usage stat is useless particularly for kernel bypass stacks, because most of them busy-poll the NIC I/O queues and shared memory regions and thus exhibit 100% utilization irrespective of request arrivals.

Since it is sampling based, `perf` has several limitations. First, since its flame graph only shows the average processing time of each function, not its variation, it cannot identify the source of tail latency. Further, context switches can not be traced, even though recent stacks have more complex thread models or scheduling policy that affect the performance directly. Those problems would be remedied by NSight.

However, since the time granularity of NSight is a few 100s of ns, it would not be suitable for fine-grained software overhead analysis. Although it is common to measure stack software overheads by directly taking timestamps in the kernel stack by source code modification (e.g., [60] and [11]), NSight would not ease such measurement. SimBricks [43], a network and host hardware simulator, could be useful for fine-grained performance profiling, if the problem can be reproduced in the simulation environment and accommodated by the single-core host simulation, which is a limitation of SimBricks. For example, it could be used to understand interaction between mTCP's stack and application thread co-located on the same core, which we struggled during this work.

8.4 Optimizing Kernel or Kernel-Bypass Stack

We observed that the kernel stack performed the best for bulk data transfers, outperforming IX by 1.7×, whereas IX achieved the best for the rest, for example, outperforming the kernel stack in small message throughput by 5.2×. If a larger community wants a general-purpose, fast TCP stack for datacenters or cloud, should we optimize the kernel stack for small messages, or IX for large transfers?

Our results show that the most serious issue with the Linux stack is scalability to large numbers of connections. Linux stack latency under unloaded resource is not the same but still comparable to kernel-bypass stacks as long as it employs busy-polling like kernel-bypass stacks (§ 5). It scales relatively well over multiple CPU cores, at least up to 8M requests per second (§ 7). Multi-core scalability and its stability under mixed workloads will be further improved with flexible resource allocation techniques like NetChannel [12].

Connection scalability of the kernel stack would be improved by new APIs like `io_uring` that reduce the request backlog at the application, but it is still questionable, because F-Stack, which uses the FreeBSD TCP implementation but eliminates the syscall overheads, still experience limited connection scalability (§ 6). We thus expect similar issues in other kernel enhancement techniques, like MegaPipe [24] (tested with up to 100 connections) and Stackmap [79] (tested with up to 250 connections in [29]).

An operational implication of low connection scalability is that alleviating this problem requires reducing the number of connections per sever, which necessitates installing more servers at the expense of additional space and power footprint, in addition to the server hardware cost.

Since connection scalability and multi-core scalability of kernel-bypass stacks—particularly IX and TAS—are promising, enhancing them for bulk transfer could enable general kernel-bypass TCP stacks. However, there are several challenges. First, it is unclear whether IX's run-to-completion model suits bulk transfers, because the stack's activity to push new data packets is paused while the application processing is happening. Finer-grained scheduling, as done in Shenango [54], ZygOS [62], Shinjuku [33] and Junction [21], could be repurposed for this task, but the actual effect is an open question, because those are designed for low tail latency of small RPCs. Optimizing TAS would be easier in this aspect, because the stack uses dedicated threads separated from the application. It also tolerates skewed loads between the connection. On the other hand, this architecture compromises the advantage of the run-to-completion model that can partition the core resource between the application and stack in a work-conserving manner.

Operators would save hardware, space and energy costs with those stacks, but it comes at the expense of additional stack software development and maintenance, application porting effort, and configuration at deployment. To see real-world deployment of kernel-bypass stacks outside hyperscalers with a large amount of internal engineering resources, we believe that a stack needs to attract heavy community involvement for a long term, much like what we have seen in kernel stacks and other network software, like XORP [25].

We may want multiple stacks in the same address and port number space and on the NIC, as in MultiStack [28],

but offloading expensive (de)multiplexing between the stacks into the NIC hardware, which is trivial today (e.g., Linux `tc-flower` offload). This approach could enable application-specific specialization, as in Sandstorm [45].

8.5 Untested Stacks and Workloads

Since primary motivation is to explore the kernel-bypass stacks that are viable in the real world and evolve long-term, this work has not tested kernel-enhancement approaches. Those approaches include MegaPipe [24], which improves short-lived connection performance and multicore scalability, Stackmap [79], which improves small message performance, and NetChannel [12], which improves various aspects of the stack performance. All of those approaches define new APIs.

We did not cover stacks that utilize specific hardware, including AccelTCP [50], which needs flow processing units at the NIC, and FlexTOE [72], which requires SmartNICs equipped with general purpose CPU cores, as we do not have. However, FlexTOE is based on TAS, and AccelTCP is based on mTCP, which we tested. iip [78] is a portable TCP/IP implementation, potentially replaces `lwip` and thus improves IX. Warpcore [20] is a kernel-bypass UDP/IP stack designed for QUIC, which could also be used to implement kernel-bypass TCP on top of it. LKL [76] runs the Linux kernel stack in user-space, but reports very low performance; once optimized, we expect similar performance to F-Stack at best.

We did not test the short-lived TCP connection performance, because many applications today reuse the connections over many RPCs. We leave the latency measurement under capped throughput as future work. This workload is tricky, because that needs to make the load on each stack, rather than the request rate, identical to make fair comparison. Finally, we did not test the parallel bulk transfer throughput, because our NIC bandwidth is limited to 25Gbps.

9 Related Work

Stack performance characterization.. Linux kernel performance is extensively studied in [11], but no comparison to kernel-bypass stacks. [67] and [60] analyze the UDP stack overheads in FreeBSD and Linux, respectively, both highlighting the syscall overheads. [79] and [7] measure the TCP stack overheads in Linux and report latency posed by software overheads. A recent study [10] analyzes the performance of Linux and F-Stack, and attempts to bring the techniques used in the kernel-bypass stacks, such as polling. [17] reports deployment experience of (Linux kernel) DCTCP in Meta's datacenters, and discusses their improvement based on eBPF, providing useful insight about network stack features required in production systems.

Host hardware performance characterization.. A body of work characterize host interconnect behavior, which would help understand the TCP stack performance at very low latency and high throughput. [51], [30] and [40] characterize data transfer performance of PCIe bus. [69] emulates the emerging CXL-based PCIe communication performance. [35] characterizes the RDMA performance.

10 Conclusion

Summary of findings in this paper are:

- Linux kernel stack achieves highest large send performance, but its high software overheads incurs low throughput and high latency with small messages over a large number of connections. Its bulk transfer performance would be further improved by modern optimizations [18, 12], but those software overheads would not.
- mTCP [32] achieves relatively high connection scalability, only outperformed by IX. It outperforms TAS at up to 16 CPU cores. However, it exhibits high latency and limited multi-core scalability. Further, mTCP's requirement of symmetric RSS hashing would impose significant practical constraints.
- F-Stack [16] is stable, but porting existing applications is not easy, and performance improvement over Linux is small. It also underperforms on bulk data transfer workloads.
- TAS [36] indicates the best multi-core scalability with low application porting effort. Its asymmetric core assignment between the stack and applications have both pros, which allow the use of heterogeneous CPU cores like those in DPUs [72], and cons, which requires careful core assignment. Further, it does not perform as good as IX overall, despite its datapath implements TCP from scratch and thus minimum extension support.
- IX [7] performs overall the best except for large transfers. Its low-level APIs incur high application porting effort, and its implementation is unstable, as it does not work with some numbers of cores. IX is also hard to debug due to its specific compilation and linking process. IX's tail latency is relatively high, but its successor, such as ZygOS [62] and Shinjuku [33] would mitigate it.
- Demikernel [80] achieves the lowest latency but only with a small numbers of TCP connections, and its clean-slate APIs would incur significant engineering effort to run existing applications or write new ones. Its single-threaded stack design would also limit large transfer throughput even with a substantial optimization.

Network stack performance measurement is a needed area. Although detailed analysis of many results have been left for future work, we believe this work is valuable because it has opened up the first step towards studying kernel-bypass network stacks through the case study. The application and stack code used in this paper are available at https://github.com/uoenoplab/stackbench.

Acknowledgments

We are grateful to anonymous NSDI and ATC reviewers and our shepherd, Kartik Gopalan for their insightful feedback. We thank Steven W.D. Chien and Marios Kogias for initial setup to run IX and Suhas Narreddy for testing mTCP over netmap. This work was in part supported by EPSRC grant EP/V053418/1.

Abstract

GPUs support various workloads with different peak periods and diverse service level agreements (SLA) requirements, including latency-critical tasks and best-effort tasks. Co-locating tasks with diverse SLA demands can enhance resource utilization, yet it introduces the risk of performance interference. Prior work employs preemption strategies to enforce SLAs for latency-critical tasks. These strategies can be classified into two categories: wait-based and reset-based approaches. The wait-based strategy ensures broad generality but suffers from significant preemption latency. In contrast, the reset-based strategy necessitates the idempotence of preempted kernels, limiting its generality.

This paper presents GPREEMPT, a preemption mechanism that breaks the trade-off. GPREEMPT implements a *timeslice-based yield mechanism* to facilitate context-switch preemption on GPUs. To mitigate the overhead associated with context-switching, GPREEMPT employs a *hint-based pre-preemption* technique to overlap the preemption process with the essential data-preparation phase. Our evaluation demonstrates that GPREEMPT achieves within 40 µs low-latency preemption comparable to executing only latency-critical tasks while remaining applicable to non-idempotent workloads, where reset-based mechanisms prove inadequate.

1 Introduction

GPUs have become essential for a wide range of computing tasks, including computer vision [15, 34], machine learning [14, 22], graphic rendering [5, 27], and scientific computing [23, 30]. Their large-scale parallelism provides exceptional computing throughput, making them a preferred choice in both enterprise and research environments.

These above GPU workloads often experience fluctuating peak traffic periods [9, 32]. Statically allocating dedicated GPU resources to a single task leads to under-utilization during low-traffic periods, resulting in significant resource wastage. Furthermore, GPU tasks typically exhibit varying Service Level Agreement (SLA) requirements [11, 36], including latency-critical (LC) applications (e.g., real-time recommendation, autonomous driving and virtual reality) and best-effort (BE) workloads (such as offline inference and data analytics). A common practice [12, 18, 29] is to co-locate multiple tasks with different SLA requirements on shared GPU resources to improve GPU utilization. However, co-locating also introduces a significant challenge: When LC tasks arrive, BE tasks may still occupy the GPU, interfering with the execution of LC tasks, and potentially violating SLA guarantees.

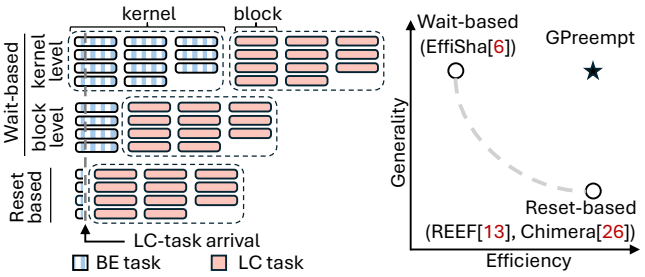

Figure 1: Existing Preemption Mechanisms and Trade-off of Them. A GPU task typically consists of multiple kernels, where each kernel is made up of several thread blocks.

Previous studies [6, 13, 17, 26] have proposed several preemption approaches to ensure the execution latency of LC tasks. However, these approaches usually make a trade-off between *efficiency* and *generality*. As Figure 1 shows, these works can be classified into two categories: wait-based and reset-based preemption strategies. Wait-based preemption, such as block-level preemption [6, 38], passively waits for the running GPU thread block to finish. These preemption methods are highly general. However, they operate at a coarse granularity, introducing a long waiting latency (e.g., up to 5 ms in block-level preemption, see §2.3 for detail). Reset-based preemption strategies [13, 26] aggressively terminate running kernels to facilitate rapid task preemption, capitalizing on the idempotency of certain DNN kernels. However,

*Corresponding author: Youyou Lu (luyouyou@tsinghua.edu.cn)

this idempotency requirement limits their applicability to non-idempotent tasks (such as graph computing and scientific computing) and modern graph kernel launch techniques (e.g., CUDA graph [8]), restricting their generality.

We aim to introduce a switch-based preemption mechanism to break the trade-off between generality and low-latency preemption. Drawing inspiration from CPU scheduling, context-switch provides a fine granularity and general preemption approach (e.g., coroutine), which is widely adopted in CPU task scheduling. Directly applying such an approach to GPUs, however, is non-trivial: (1) GPU scheduling is opaque to users, and no scheduling interface is provided. Once a kernel is launched, users are unable to *yield* the GPU computing resources allocated to that kernel; (2) The large GPU context (tens of MB) can introduce significant switching overheads.

To overcome the challenges, we designed GPREEMPT, a general-purpose GPU preemptive scheduling mechanism. To enable the *yield* primitive, GPREEMPT adopts a *timeslice-based* approach. Through a thorough analysis of the GPU open-source driver and the GPU hardware scheduling mechanism, we identified and repurposed an internal timeslice allocation mechanism in the GPU driver as the foundation for implementing the *yield* primitive, abstracting it into a general interface that enables fine-grained control over task scheduling. GPU cycles through tasks according to the timeslice of each task. By reducing the timeslice for low-priority tasks, these tasks can yield GPU resources in a short duration, making user-controlled context-switch feasible on the GPU. To mitigate the cost of context-switching, GPREEMPT integrates *Hint-based Pre-preemption*. We exploit the data-preparation phase – an unavoidable step before launching GPU kernels. During this interval, GPREEMPT can initiate the preemption procedure, thereby hiding much of the switching overhead.

We evaluate GPREEMPT on 7 workloads (including DNN, graph computing and scientific computing) on NVIDIA and AMD GPUs. Evaluation shows that GPREEMPT achieves comparable latency and throughput to reset-based methods in idempotent kernel preemption scenarios, with less than 40 µs preemption latency on the NVIDIA platform. Moreover, in non-idempotent scenarios where reset-based methods are inapplicable, our system can still achieve preemption with a latency of only 30% compared to wait-based approaches.

2 Background and Motivation

2.1 GPU Computing Tasks

Offload Computing Task to GPUs. Offloading a computing task to GPUs often involves three procedures: Data preparation, where input data is transformed into a format suitable for GPU computing; data transfer, which involves moving the processed data from the host memory to the GPU memory; and kernel execution, where the actual computing takes place on the GPU. A GPU task often consists of multiple computing kernels, which collectively require execution times ranging from a few milliseconds to several tens of milliseconds [20]. Modern GPU computing frameworks utilize CUDA graphs [8] (and AMD HIP graphs [3]) to reduce the kernel launch overhead. These graph launch approaches consolidate multiple GPU kernels into a directed structure that defines execution order and dependencies, allowing the runtime to treat the kernel sequence as a single executable unit to avoid launch overhead.

Characteristics of GPU Computing Tasks. GPU computing tasks have demonstrated remarkable versatility across diverse application domains with varying latency requirements. In latency-critical scenarios like autonomous vehicle control and real-time robotic manipulation, GPU effectively processes sensor data to make split-second decisions. Conversely, in best-effort applications like offline inference, medical image analysis and climate modeling, GPUs excel at complex pattern recognition tasks where computing time is less constrained. For example, both OpenAI and Amazon provide asynchronous batch APIs [25, 31], which will give users responses within 24 hours.

Co-locate Multiple Computing Tasks on GPU. Running multiple computing tasks on a single GPU is a prevalent demand [12, 18, 29]. Modern data center inference clusters employ strategic task co-location to maximize GPU resource utilization. The GPU workload typically fluctuates dynamically, and the gaps between inference tasks can easily lead to idle GPU resources [18]. Modern data centers typically interleave best-effort tasks with latency-critical workloads.

While this co-location strategy enhances GPU resource efficiency, it introduces complex scheduling challenges. The primary challenge lies in simultaneously satisfying the stringent SLAs of latency-critical tasks while optimizing the throughput of best-effort workloads, given their heterogeneous latency requirements and resource consumption patterns.

2.2 Existing GPU Preemptive Scheduling

With the emerging demand for running multiple tasks on GPUs, GPU scheduling [6, 13, 17, 26] becomes a widely studied research topic. Existing preemption approaches can be primarily categorized into two types: wait-based and reset-based methods. These approaches make a trade-off between general-purpose preemption and fast preemption.

Wait-based Preemption. Prior work [6, 10, 38] introduced wait-based preemption mechanisms that enforce exclusive GPU access for LC tasks by waiting for BE tasks to complete their execution. It is important to note that 'preemption' in this context often carries a different meaning than in operating systems; here, the emphasis is on achieving an effect similar to preemption (e.g., LC tasks can be executed with minimal delay), rather than an identical preemption process. These approaches operate at kernel or block boundaries. For example, SRM [10] treats the GPU as a globally shared resource

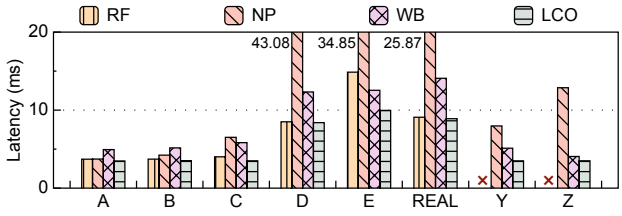

Figure 2: End-to-end Latency of LC Tasks. RF: REEF (reset-based), NP: No preemption, WB: Block-level preemption (wait-based), LCO: Execution LC task only.

protected by a semaphore, executing each kernel sequentially. Effisha [6] relinquishes GPU resources by transforming each computation kernel to check at the block boundary if any LC tasks are arriving. The LC task still needs to wait for the running thread block to complete execution. Wait-based preemption approaches are prone to long waiting times since LC tasks may still be blocked by running tasks.

Reset-based Preemption. Prior research efforts [13,26] have introduced reset-based methodologies for GPU task preemption, leveraging the idempotent characteristics inherent in specific DNN operators. These approaches enable immediate kernel termination to liberate GPU computing resources, facilitating the expedited execution of LC workloads. The idempotent nature of these operations ensures that BE tasks can be recomputed during periods of GPU inactivity without compromising computing correctness or output integrity. Nevertheless, this methodology exhibits fundamental limitations tied to the prerequisite of kernel idempotency.

2.3 Motivation

While existing GPU preemption approaches have made important strides in addressing scheduling challenges, they continue to face fundamental limitations in either generality or performance. Figure 2 illustrates the end-to-end latency of block-level wait-based and reset-based approaches. While the block-level preemption strategy significantly reduced preemption latency (reduced 30 ms on workload D) compared to a no-preemption baseline, the overhead associated with task preemption remains considerable (e.g., a 66.4% (5 ms) increase in latency for LC tasks under workload C). In workload C, the large number of BE tasks means multiple may be running when LC arrives. Although block-level preemption allows quick exits for new blocks, ongoing ones must finish, causing stalls. Moreover, LC is blocked by the slowest BE task, leading to longer average latency than in workloads with fewer BE tasks (e.g., A, B). The reset-based approach, by contrast, demonstrates lower latency. However, the idempotency constraints of kernels significantly limit the applicability of this approach. For instance, in domains such as scientific computing (Y) and graph computing (Z), the global state changes during execution, rendering the process non-idempotent. In these cases, the reset-based preemption strategy is not feasible. Additionally, the integration of advanced kernel launch mechanisms, particularly CUDA Graph, introduces further complexities in maintaining idempotent properties, which can substantially increase the overhead of reset operations.

Key Idea. Motivated by CPU scheduling, we propose a switch-based preemption mechanism to address the trade-off between generality and low-latency preemption. Context-switching is a well-established preemption technique in CPU scheduling, which ensures task transparency and fine preemption granularity. However, directly adapting context-switching to GPU scheduling poses significant challenges:

- *GPU scheduling is opaque to users.* Unlike CPU-based systems, GPUs lack a user-facing context-switch interface, making resource preemption more complex.
- *High context-switch overhead.* GPU task contexts are much larger than CPU (44 MB in NVIDIA A100 GPU vs. less than 1 KB in x86 CPU), and the overhead associated with context switching is considerable. To mitigate these challenges, a meticulously designed preemption strategy is essential to minimize the impact of this overhead.

3 GPREEMPT Design

To achieve both generality and low-overhead GPU preemption scheduling, we present GPREEMPT, a general and efficient scheduling mechanism. GPREEMPT introduces a *timeslice-based general preemption* (§3.1) to provide a fine-granularity and transparent context-switch preemption mechanism. By leveraging the common GPU computing paradigm, GPREEMPT further employs an innovative *hint-based pre-preemption* technique (§3.2), which strategically overlaps preemption operations with non-computation phases, thereby minimizing observable preemption latency.

3.1 Timeslice-based General Preemption

To facilitate rapid preemption, a fine-grained preemption mechanism is essential. While a reset-based approach can seize GPU resources at any moment, it imposes significant constraints on computational kernels. We aim to enable switch-based preemption in the GPU. Through a thorough analysis of NVIDIA open GPU kernel source [24], we discover an undocumented and little-known hardware resource allocation mechanism: timeslice allocation. GPREEMPT fully exploits the power of timeslice allocation, indirectly implementing *yield* primitive in GPU through timeslice rotation, thus enabling switch-based preemption.

Timeslice-based Yield Mechanism. When multiple independent tasks or tenants run on a GPU, the hardware cycles through them based on predetermined timeslices, ensuring fair computing time for each task. Leveraging this hardware cycling mechanism and timeslice reconfiguration, GPREEMPT

implements a passive *yield* mechanism. Specifically, GPREEMPT adjusts the timeslice of a BE task to a very short duration (e.g., 200µs) to ensure that when LC tasks arrive, BE tasks will consume the time quota quickly and *yield* GPU resources within a time frame. Correspondingly, GPREEMPT extends the timeslice for LC tasks longer than the lifespan of the LC task, ensuring that LC task execution will not be interrupted by other tasks. This approach is effective even without knowing the LC task's lifecycle in advance; thus, setting the timeslice to a very long duration (e.g., even a few seconds) is fine. When a LC task finishes, its remaining timeslice is automatically dropped, and the GPU immediately switches to the next task. This configuration is set up during system initialization, and no need to change afterwards. Although the timeslice for BE tasks is reduced, their throughput remains unaffected when no LC tasks launch. Because BE tasks are placed within the same scheduling group. When only BE tasks are present, the GPU does not forcibly switch between them, avoiding unnecessary overhead. BE tasks run uninterrupted until completion or until a LC task preempts them.

Scheduling Overhead. Scheduling overhead includes two parts, time for BE to *yield* and context-switching. According to the GPU hardware scheduling mechanism, a task relinquishes the GPU after consuming its timeslice. Let t_1 denote the timeslice for BE tasks. When a LC task arrives, the BE task will yield GPU resources within an average time of $\frac{t_1}{2}$ and a maximum time of t_1, which is about 160 µs. Context-switching overhead is fundamentally bounded by GPU context size and memory bandwidth parameters, representing a fixed cost for each GPU architecture. This overhead continues to diminish in significance as GPU memory bandwidth capabilities advance. Take NVIDIA A100 GPU as an example: each of its 108 Streaming Multiprocessors (SMs) contains 164 KB of shared memory and 64 K 32-bit registers, resulting in a per-SM context footprint of 420 KB and an aggregate GPU context of approximately 44.3 MB [1]. With the memory bandwidth of 1.1 TB/s, context-saving is completed within 40 µs. Our empirical evaluation reveals a combined overhead of approximately 100 µs (§5.3) for these operations. Additionally, we introduce a pre-preemption technique in §3.2 to further minimize preemption latency.

3.2 Hint-based Pre-preemption

Data preparation is a prerequisite for GPU computing tasks before kernel execution, as illustrated in Figure 3(a). Many tasks involve data preprocessing (such as image crop and data normalization), which can extend to hundreds of µs, and all tasks necessitate data transfer from the CPU to the GPU. Even minimal data transfers via `cudaMemcpy` introduce an overhead of approximately 80 µs [16]. **These preparatory stages offer predictive signals for the imminent arrival of LC kernels, facilitating proactive resource reservation through pre-preemption.** Typically, data preparation is executed by the

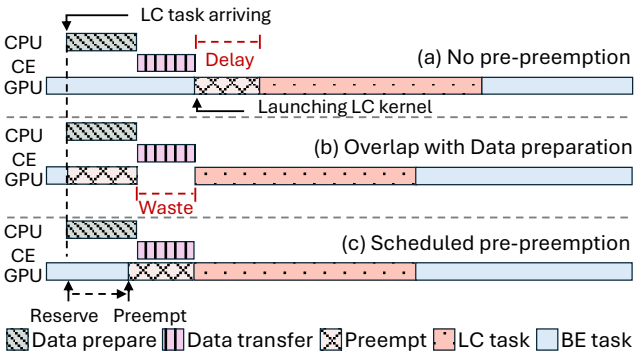

Figure 3: Hint-based Pre-preemption Example. CE: GPU copy engine.

CPU and GPU copy engines, operating independently of the GPU computing engines. In a GPU, the computing engine and copy engine can be occupied by different tasks. They will not block each other [4]. Leveraging these characteristics, GPREEMPT introduces a hint-based pre-preemption mechanism that enables LC tasks to reserve GPU computing resources in advance, seamlessly overlapping task-switching overhead with ongoing data preparation.

Overlap Preemption with Data preparation. GPREEMPT enables users to issue GPU reservation commands when LC tasks are anticipated. As shown in Figure 3(b), upon receiving such commands, GPREEMPT strategically injects a preemption kernel that consumes the timeslice of the best-effort task at a predetermined instant, concurrent with preprocessing operations. This preemption kernel orchestrates a controlled wait state until the corresponding computing kernel is ready for execution. Leveraging GPU stream semantics, the computing kernel seamlessly initiates execution upon the preemption kernel's completion. GPREEMPT leverages GDRCopy [33], which enables direct CPU-GPU memory access by mapping GPU HBM to the CPU address space, to notify the preemption kernel, achieving remarkably low latency to finish the preemption kernel (approximately 1 µs). This pre-preemption strategy effectively masks context-switching overhead by overlapping it with essential data preprocessing steps, minimizing end-to-end latency.

Scheduled Pre-preemption. Preempting GPU resources too far in advance may result in tasks remaining in the preprocessing phase for extended periods even after GPUs become available. Benefiting from §3.1, GPREEMPT provides a deterministic preemption latency. Leveraging this, GPREEMPT implements a scheduled reservation mechanism whereby users can specify their anticipated GPU resource requirements when submitting a preemption request. GPREEMPT launches the preemption kernel through a background thread based on the scheduled timing. As Figure 3(c), this avoids GPU resource waste while providing pre-preemption support.

Table 1: Workload configuration of LC and BE tasks

WL	LC Tasks	LC Rate	BE Tasks	BE Rate
A	VGG	100 (C)	ResNet	100 (C)
B	VGG	220 (C)	ResNet	220 (C)
C	VGG	100 (C)	DM*	100 (C)
D	DM*	20 (C)	DM*	100 (C)
E	DM*	20 (P)	DM*	100 (P)

Y	VGG	100 (C)	WS	150 (C)
Z	VGG	100 (C)	GM**	100 (C)

DM: {ResNet, DenseNet, VGG, Inception, BERT}
GM: {BFS, SSSP, PageRank, CC}.
(C): Constant rate, (P): Poisson rate. "100 (C)": 100 requests/sec per task.

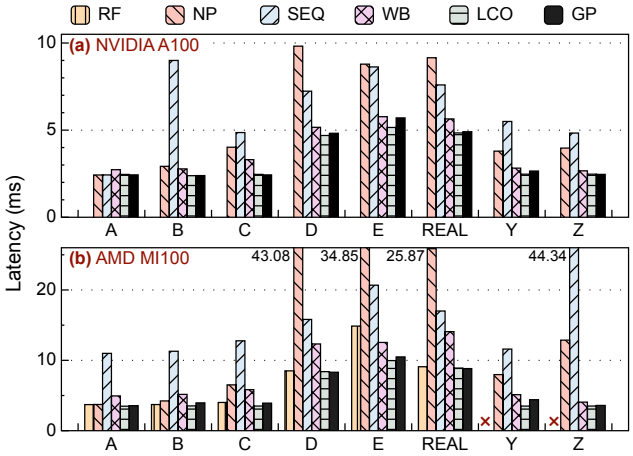

Figure 4: End-to-end Latency of LC Tasks. NP: no preemption, SEQ: sequential execution (wait-based), WB: block-level preemption (wait-based), LCO: latency-critical tasks only, RF: REEF (reset-based), GP: GPREEMPT.

4 Implementation

GPREEMPT consists of two primary components: 1) The GPU driver code modifications that enable necessary low-level functionality to support timeslice reconfiguration. 2) Building upon these driver modifications, GPREEMPT provides ready-to-use APIs that can be directly integrated into user programs without modifying the computing kernel code.

GPREEMPT on AMD GPUs. AMD has introduced the MES hardware scheduler since RDNA 3 [2]. Similar to NVIDIA, MES uses timeslices to cycle through tasks by hardware, in which the driver dedicates the timeslice for each compute context. GPREEMPT can implement this preemptive scheduling in a similar way to how it is implemented on NVIDIA GPUs. For earlier AMD GPUs, we implemented GPREEMPT by modifying the ROCm driver code and repurposing its debugging mechanism, using it to switch between contexts manually.

5 Evaluation

5.1 Evaluation Setup

Setups. Experiments are conducted on a system equipped with an Intel(R) Xeon(R) Gold 5420+ CPU, 256 GB DRAM, and an NVIDIA A100-40GB GPU. An AMD-based version of GPREEMPT was evaluated on a platform with identical CPU, memory and an AMD Instinct MI100 GPU.

Comparing Targets. On the NVIDIA platform, we compared GPREEMPT with a LC-task-only baseline (representing the ideal latency boundary), two wait-based preemption approaches (sequential execution and block-level preemption), and a no-preemption baseline (using multiple streams to maximize task parallelism, representing ideal GPU utilization). On the AMD platform, we included an additional baseline, a reset-based preemption approach (REEF [13], without dynamic kernel padding, constrained by the open-source implementation capability with specific AMD GPUs, which will not affect the preemption latency).

Workloads. As detailed in Table 1, we evaluate GPREEMPT using DISB [13] and two synthetic workloads. DISB contains 6 typical DNN inference workloads, including LC-task with uniform distribution (A, B, C, D), poison distribution (E) and real-world trace (REAL). Synthetic workloads include scientific computing [23] (Y), and graph computing tasks [21] (Z), which are co-located with LC DNN inference tasks.

5.2 Overall Performance

LC-task Latency. Figure 4 shows the end-to-end latency of LC tasks on NVIDIA A100 (4(a)) and AMD MI100 (4(b)) GPU. Reset-based approach (RF) only supports the AMD platform and idempotent workloads.

On the NVIDIA platform, compared to executing LC tasks only (LCO), no preemption (NP), sequential execution (SEQ), block-level preemption (WB), and GPREEMPT (GP) introduce average latency increases of 58.4%, 96.3%, 15.3%, and 2.4%, respectively. On the AMD platform, compared to LC, NP, SEQ, WB, reset-based preemption (RF) and GPREEMPT introduce average latency increases of 170.1%, 297.9%, 43.5%, 13.2%, and 10%, respectively.

In scenarios with high task arrival frequencies (B, E, Z), sequential execution methods are prone to resource monopolization by BE tasks, leading to the highest latency. Additionally, sequential execution fails to exploit the parallelism between tasks, further exacerbating the queuing delay. For block-level preemption, in scenarios with numerous BE tasks (C, REAL), preemption latency is influenced by the slowest BE task, resulting in higher average latency compared to scenarios with fewer BE tasks. The reset-based method achieves low preemption latency for DNN workloads (A-E, REAL) that consist entirely of idempotent kernels. However, it is un-

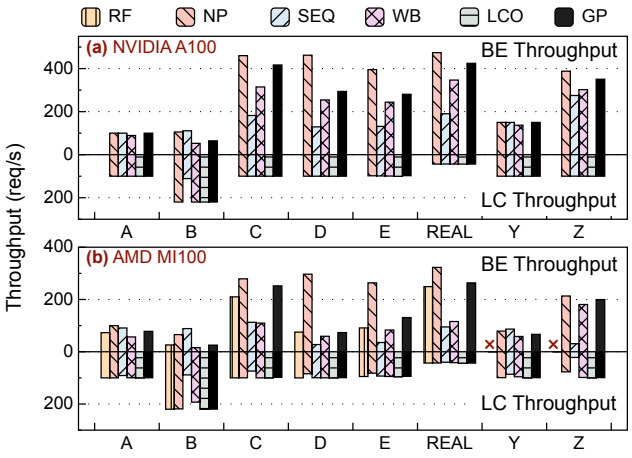

Figure 5: LC and BE Task Throughput on Various Workloads. Above the x-axis is the BE tasks throughput, and below the x-axis is the LC tasks throughput.

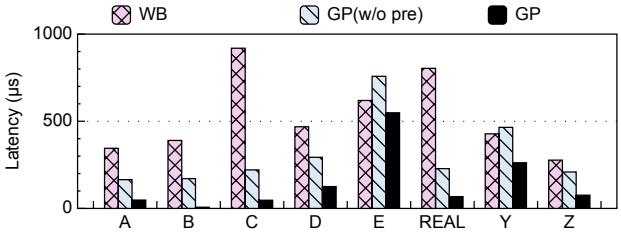

Figure 6: Additional Latency Compared to LC Task Only. GP(w/o pre): GPREEMPT without pre-preemption.

suitable for workloads Y and Z, including non-idempotent kernels. Under all workloads, GPREEMPT achieves near-ideal preemption latency while still maintaining generality.

GPU Utilization. Figure 5 illustrates the total throughput across different preemption strategies on NVIDIA (5(a)) and AMD (5(b)) GPUs. Executing all tasks without preemption (NP) achieves the highest overall throughput in all scenarios, as GPU parallelism is fully exploited when task preemption is absent. We use NP as the baseline to calculate the relative throughput of other methods.

On the NVIDIA GPU, SEQ, WB, LC, and GPREEMPT achieve throughputs of 66.0%, 79.7%, 30.3%, and 88.6%, respectively. On the AMD GPU, RF, SEQ, WB, LC, and GPREEMPT achieve throughputs of 72.4%, 53.1%, 65.7%, 38.8%, and 82.2%, respectively. GPREEMPT guarantees that the throughput of LC tasks remains unaffected across all workloads while striving to keep the throughput of BE tasks close to the ideal scenario. This demonstrates the efficient utilization of GPU resources by GPREEMPT in co-located LC and BE task scenarios. The throughput when executing only LC tasks is the lowest, as only LC tasks are unable to fully utilize GPU resources, leading to considerable idle time. While the Sequential execution strategy provides some throughput improvement, the throughput of LC tasks decreases in this configuration. This occurs because LC tasks are likely to be blocked by BE tasks, leading to high latencies. When using block-level preemption, additional checkpoints are inserted into the BE kernels to determine whether they should exit, decreasing the performance of BE tasks.

5.3 Technical Analysis

Performance Breakdown. Figure 6 shows the additional latency for different workloads. Comparing the block-level wait-based preemption, GPREEMPT without hint-based pre-preemption (GP (w/o pre)), and GPREEMPT. In most cases, enabling only switch-based preemption achieves a preemption latency with an average of just 200 µs. Only in complicated workloads like E and Y, GPREEMPT without pre-preemption shows relatively high preemption latency. After adopting the pre-preemption technique, GPREEMPT consistently achieves the lowest latency across all workloads. For single-LC-task workloads (e.g., A, B, C, Z), the average preemption latency of GPREEMPT is less than 40 µs. In multiple LC and BE tasks co-locate scenario (workload E, 10 concurrent tasks in total), the average latency increase introduced by GPREEMPT is only about 500 µs. The hint-based pre-preemption mechanism results in an average latency reduction of 160 µs.

Analysis of Hint-based Pre-preemption. As introduced in §3.2, GPREEMPT utilizes the data preparation phase of LC tasks to overlap with preemption to mitigate the preemption latency and leverage scheduled pre-preemption to further decrease the preemption influence on BE throughput. Using workload A, we varied both the data preparation time and the arrival frequency of the LC tasks to assess their effects on additional latency and BE task throughput.

As shown in Figure 7(a), the additional latency introduced by preemption decreases significantly as the data preparation time increases. When there is no data preparation time, GPREEMPT incurs an additional latency of approximately 100 µs. However, when the data preparation time exceeds 100 µs, the additional latency stabilizes to below 40 µs. The latency is mainly caused by cache interference when colocating tasks, which is negligible compared to the duration of LC tasks, which typically span several milliseconds [20].

Figure 7(b) highlights the impact of LC task frequency on BE task throughput. Compared with the block-level wait-based preemption approach, GPREEMPT improved BE task throughput by 17%-26%. To validate the effectiveness of scheduled pre-preemption, we compare GPREEMPT with a version (GP(w/o sched)) that removes this technique. This optimization results in a throughput improvement of 4%-10% across varying LC task frequencies.

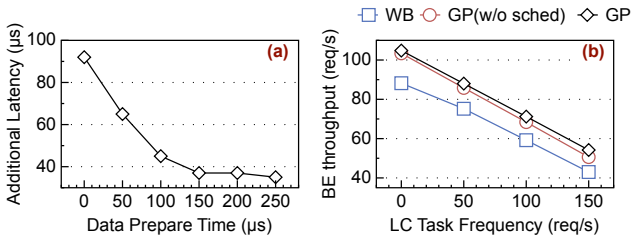

Figure 7: Analysis of Hint-based Pre-preemption: (a) Additional latency on various data prepare time and (b) BE tasks throughput on different LC task frequency. GP (w/o sched): GPREEMPT without scheduled pre-preemption.

6 Related Works

GPU Task Preemption. Previous studies [19, 35] have proposed extending GPUs to provide preemption mechanisms to reduce the context switch overhead and enable user-initiated preemption, but these were only implemented on GPU simulators. Such approaches require modifications to hardware logic, making them difficult for manufacturers to integrate into real-world GPUs. Some works [17, 37] also propose software-based preemption mechanisms by inserting checkpoints into the application to detect the arrival of high-priority tasks. Software checkpoints incur additional overhead and fail to achieve timely preemption. In contrast, GPREEMPT retrofitted the GPU internal timeslice allocation into a passive yield mechanism to achieve task preemption. GPREEMPT requires no hardware mechanism modification, making it directly applicable to commercial GPUs.

Multi-task GPU Co-location Strategies. Significant research efforts have been directed toward optimizing GPU resource utilization through strategic task co-location. DeepBoot [7] implements an adaptive scheduling mechanism that dynamically alternates between training and inference tasks, effectively recycling GPU resources. The DAG-based Scheduler [28] employs directed acyclic graphs to automatically determine inter-task data dependencies, eliminating the need for manual dependency specification and facilitating optimal parallel task execution through comprehensive resource utilization analysis. Differently, GPREEMPT focuses on preemption which is one of the foundations of multi-task scheduling.

7 Conclusion

This paper introduces GPREEMPT, a general-purpose priority scheduling approach for GPU. Unlike previous wait-based and reset-based preemption mechanisms, GPREEMPT employs a context switch-based strategy to deliver efficient and transparent preemption support on both NVIDIA and AMD GPUs. Evaluations demonstrate that GPREEMPT effectively preempts GPU resources for LC tasks while striving to keep the throughput of BE tasks across various scenarios.

A Artifact Appendix

Abstract

The artifact consists of the code of GPREEMPT and baseline used in evaluation, runner scripts for reproducing the experiments, plotter scripts for visualizing the results, and related workload trace and description files. It is intended for validating the claims made in the paper and facilitating further research on GPU preemptive scheduling. The code of GPREEMPT is host at https://github.com/thustorage/GPreempt.

Scope

The main claims of this paper, which can be verified through the provided artifact, are:

- GPREEMPT achieves low preemption-induced latency for latency-critical (LC) tasks when co-located with best-effort (BE) tasks.
- GPREEMPT maintains high system throughput for BE tasks even when co-located with preemptible LC tasks.
- GPREEMPT effectively supports preemption for a diverse range of GPU applications, including complex, non-idempotent workloads.

Hosting

GPREEMPT's artifact repository is hosted on GitHub at https://github.com/thustorage/GPreempt on the mas-

ter branch. The first usable commit version is the initial commit (59ab51e). However, please always use the latest commit due to possible future bug fixes and updates.

Contents

Our artifact contains the following components:

- `README.md`: A top-level guide for installing dependencies, building the system, and reproducing all experimental results described in the paper.
- `src/` and `include/`: Source code of GPREEMPT and the baseline system, including core implementation and interfaces.
- `patch/`: Patches for modifying the NVIDIA driver to support GPREEMPT's mechanisms.
- `scripts/`: Scripts to run the experiments, parse experiment logs, analyze performance metrics, and generate evaluation figures as presented in the paper.
- `config/`: Configuration files for different workloads and experimental settings.
- `third_party/`: External dependencies and modified third-party components required to build and run the system.

This structure is intended to facilitate reproduction of the paper's results and to help researchers extend GPREEMPT for their own experiments.

Requirements

- Ubuntu 22.04 LTS
- NVIDIA Open GPU Kernel Module 550.120
- glog
- jsoncpp
- disb [13]
- GDRCopy
- NVIDIA Ampere Architechture GPU

μEFI: A Microkernel-Style UEFI with Isolation and Transparency

Le Chen, Yiyang Wu, Jinyu Gu✉*, Yubin Xia, Haibo Chen*

Institute of Parallel and Distributed Systems, School of Computer Science, Shanghai Jiao Tong University

Abstract

The Unified Extensible Firmware Interface (UEFI) has established itself as the leading firmware standard in modern devices, offering enhanced extensibility, user-friendly graphical interface, and improved security capabilities. At the core of UEFI security is UEFI Secure Boot, designed to ensure that only trusted drivers and applications are loaded during system startup. However, the growing number of UEFI-related CVEs and the emergence of attacks that bypass UEFI Secure Boot have highlighted its limitations, exposing vulnerabilities that could be exploited by attackers.

We propose μEFI, the first isolation framework for UEFI firmware that can transparently run UEFI modules in sandboxes. Drawing inspiration from microkernel design, we deprivilege UEFI modules to user mode and isolate them in different address spaces (sandboxes). To enable the transparent execution of UEFI modules, we propose *trampoline injection* and *protocol analysis*. To further strengthen UEFI security, we incorporate a seccomp-like mechanism to restrict module capabilities and perform automated input validation to detect and prevent invalid inputs. Evaluation results demonstrate that our system can run complex UEFI modules without modifications, which incurs a small overhead of 1.91% for UEFI boot phase.

1 Introduction

The Unified Extensible Firmware Interface (UEFI) [92] has replaced the legacy BIOS and become the standard firmware interface in most devices, including servers, personal computers, and mobile devices [55, 58, 65]. It offers a modern interface that initializes the hardware, loads the operating system and provides runtime services for the OS. To strengthen the security, the UEFI specification introduced the Secure Boot feature, which verifies the integrity and authenticity of all modules before allowing them to load and execute [42], and becomes an essential security feature in the boot process [47, 73].

However, UEFI Secure Boot cannot protect against vulnerabilities within those legally signed modules, which may persist despite testing and auditing [34, 35, 71]. Besides, improper management of cryptographic keys may allow attackers to bypass UEFI Secure Boot [11]. A publicly disclosed UEFI bootkit capable of bypassing Secure Boot was reported in 2022 [84]. Furthermore, UEFI-related CVEs have been increasing in number, reflecting a concerning trend [24, 25, 29, 31, 32, 34–37, 39, 71, 72]. Exploiting these vulnerabilities enables attackers to gain unauthorized access to data or even take full control of the system.

A major factor driving the increase in vulnerabilities is the growing complexity of the UEFI ecosystem. The UEFI Forum community includes 365 vendors by 2025 [46]; The open-source project EDK2 [88], the most widely used framework for UEFI development and the base for most production firmwares, witnessed the total lines of code expand 9× between 2018 and 2025. The growth is largely driven by the rapid development of ARM architecture, as emerging ARM-based devices adopt UEFI firmware to improve system extensibility [2, 74, 83]. Consequently, the expansion of the codebase and proliferation of UEFI modules have significantly heightened the security risks within the ecosystem.

Moreover, the firmware supply chain is inherently intricate, involving multiple stakeholders such as original equipment manufacturers (OEMs), independent hardware vendors (IHVs), chip manufacturers, and BIOS/firmware providers. Downstream vendors build new modules atop firmware supplied by upstream sources [14]. This complexity increases the risk of introducing vulnerabilities into firmware and allows upstream flaws to propagate downstream, potentially compromising all devices that depend on the affected firmware.

To address the security risks of UEFI, we propose μEFI, a microkernel-style isolation framework for UEFI firmware which can run UEFI modules in sandboxes, based on the following observation: In UEFI, the majority of firmware logic resides in *modules* such as device drivers and bootloaders, while the UEFI *core* remains minimal, providing only essential functionalities. This pattern aligns with the microkernel design philosophy [12, 52, 63], which is widely recognized for its effectiveness in isolating errors in kernel modules.

Many UEFI modules, like the device drivers embedded in option ROMs[1], are available only as binaries. This makes compatibility a critical requirement for any new design. Applying microkernel-style isolation to UEFI while maintaining transparency for existing modules presents two challenges.

One key challenge is that the control flow transfer across modules and the UEFI core is hard to determine statically.

[1] An option ROM is a piece of firmware that stored on an external card.

UEFI module callouts are limited to two types: core-provided *services* and *protocol* interfaces offered by other modules, both accessed via function pointers. While services expose a fixed set of core functionalities, protocols represent capabilities of modules and are dynamically discovered through runtime lookup. The dynamic nature of interface discovery makes static analysis techniques used for analyzing Linux kernel module interactions [56, 69, 75] inadequate for resolving UEFI module control flow.

Another challenge stems from UEFI modules being designed with unconditional data sharing, without standardized format for inter-module data transfer. Consequently, data transfer between isolated modules must be explicitly coordinated. Since inter-module communications occur through protocol interfaces, and the type information of protocols is only available at compile time, the absence of such information at runtime makes data synchronization infeasible.

Fortunately, we make two key observations that inform our solution to the aforementioned challenges. First, both services and protocol interfaces are accessed through a centralized data structure known as the system table: services are retrieved directly via fixed pointers, whereas protocol interfaces are retrieved indirectly through service functions such as *LocateProtocol*. This unified access point allows us to intercept and redirect module callouts. Building on this insight, we introduce *trampoline injection* to dynamically generate and inject codes into modules, enabling seamless control flow redirection. Second, UEFI protocols are predefined and well-specified, allowing developers to rely solely on their interface contracts without requiring knowledge of the underlying module implementations. We leverage this by performing offline analysis of protocol definitions to extract type and structure information, which is then used to coordinate safe and structured cross-module data transfer at runtime.

To further enhance UEFI security, we incorporate a mechanism inspired by seccomp [68], which enforces capability restrictions at both the service and protocol levels. Additionally, our in-depth analysis of UEFI-related CVEs reveals that a significant portion of vulnerabilities stem from memory safety issues and inadequate input validation. To mitigate these risks, we implement *automatic parameter validation* for cross-module communications, which further strengthens the security of the firmware.

We have implemented a prototype of μEFI upon EDK2 [88] on both the x86_64 architecture using QEMU/KVM [6] and the AArch64 architecture using Raspberry Pi 4 Model B [80]. We perform security evaluations on potential vulnerabilities and, evaluate the performance of μEFI with six widely-used UEFI modules, ranging from simple modules like EnglishDxe to complex ones such as FAT and DiskIo. The performance results indicate that running all six modules in isolated sandboxes incurs only a small overhead of 1.91% on the UEFI boot time.

2 BACKGROUND AND MOTIVATION

2.1 Role of UEFI

UEFI has become the dominant firmware standard in modern devices. Most Windows machines [70], Mac with Intel processors [4], and even IoT devices [13] are using UEFI in their boot process. It plays a vital role in hardware initialization, system booting, and security. During system startup, UEFI initializes the hardware, ensuring all essential components are ready for OS handoff. For instance, UEFI detects, enumerates, and initializes USB devices, SSDs, and other peripherals. It also loads option ROMs from more complex devices like graphics cards, network adapters, and storage controllers. With the help of UEFI, users can configure the hardware and prioritize boot options conveniently. As for security, modern products default enforce the use of UEFI Secure Boot [94], which verifies the integrity of UEFI modules and ensures only trusted code is loaded. The use of UEFI Secure Boot has made UEFI a crucial part of the boot chain of trust, which is verified by hardware root of trust and responsible for validating subsequent OS bootloaders.

2.2 Security of UEFI

UEFI was designed to replace the legacy BIOS and featured for its support for larger storage devices, graphical user interface support, and enhanced extensibility. As malwares like rootkits and bootloader attacks became more sophisticated, UEFI Secure Boot was introduced as a defensive measure in 2011 [91]. It is considered to be the most important security feature concerning UEFI boot-time security and has become an industry-standard feature.

UEFI Secure Boot employs a signature and verification mechanism, ensuring that only signed UEFI modules can be loaded and executed during the system startup process. An essential prerequisite for the effectiveness of UEFI Secure Boot is that all trusted code must be free from vulnerabilities. This prerequisite is mainly supported by the following three reasons. First, in the early times, the codebase of UEFI ecosystem is rather small. As a result, the likelihood of vulnerabilities is relatively low. Second, most UEFI driver codes for specific devices are proprietary and closed-source, making it difficult for attackers to identify and exploit potential vulnerabilities. Third, before a UEFI module is certified to be used with UEFI Secure Boot, it typically undergoes code audit, which may include static analysis and testing to identify security vulnerabilities, logical errors, and non-compliance issues in the code [89, 90].

Increasing CVEs. In recent years, we have witnessed an increasing trend of UEFI-related vulnerabilities in the Common Vulnerabilities and Exposures (CVE) database. As shown in Figure 1, not only the number of UEFI-related CVEs is increasing, but also their criticality. The number of CVEs reached 72 in 2022, and 73 in 2023. Out of 45 vulnerabilities in 2024, 24 of them are rated with high severity. Besides,

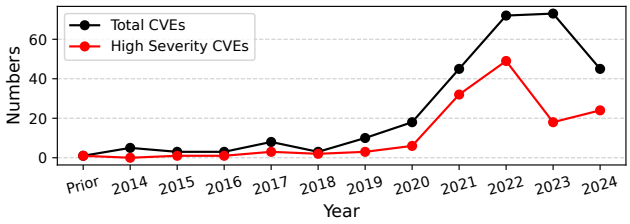

Figure 1: *Annual count of UEFI-related CVEs. The CVE count for each year is determined based on the year indicated in the CVE ID. The latest CVE ID for 2024 is CVE-2024-8105.*

many CVEs are disclosed only after fixes, suggesting that the number of 2024 CVEs is likely to increase in future updates. This trend can be attributed in part to the growing complexity of the UEFI ecosystem. On the one hand, the adoption of UEFI standards has expanded, with an increasing number of manufacturers using UEFI firmware for device management and initialization. The number of UEFI Forum members has grown from 236 in 2013 to 365 by 2025. On the other hand, the complexity of firmware modules has increased due to the introduction of more advanced and diverse devices, such as high-performance GPUs and smart NICs [78, 79], which demand enhanced capabilities and functionality.

2.2.1 Exploitation of UEFI Vulnerabilities

UEFI-related attacks typically have three main goals: obtaining control over the operating system, maintaining stealth to evade conventional security mechanisms, and achieving persistence that can survive operating system reinstallation and hard drive replacement. To gain a deeper understanding of UEFI-related threats, we further analyze how UEFI vulnerabilities are exploited by attackers to achieve the objectives.

Bypassing Secure Boot. While UEFI Secure Boot prevents the execution of unauthorized code, one prominent technique to circumvent Secure Boot involves exploiting vulnerabilities in legitimate, signed components. For example, the well-known BlackLotus bootkit [84]—previously sold on underground forums for approximately $5,000—exploited a vulnerability in older versions of the Windows bootloader [71] to overwrite memory regions containing Secure Boot policy data, effectively disabling Secure Boot enforcement. Another notable case is CVE-2024-7344 [40], where a signed third-party UEFI application embedded a custom image loader that bypassed standard secure UEFI loading functions, allowing the execution of unsigned binaries [82].

Compromising signed modules. Beyond exploiting the trust conferred by a signature to bypass Secure Boot directly, attackers also target inherent code-level vulnerabilities within signed UEFI modules, particularly DXE (Driver Execution Environment) drivers, to achieve arbitrary code execution or privilege escalation. Common examples include stack-based buffer overflows arising from the improper handling of UEFI services. For instance, vulnerabilities [17–20, 27, 28] have been identified in signed DXE drivers where sequential calls to the *GetVariable* service occur without correctly re-

Table 1: *Category of vulnerabilities and severity of corresponding CVEs.*

Severity	Memory Safety	Improper Input Validation	Uninitialized Data	Improper Access Control	Others
HIGH	44	34	5	17	40
MEDIUM	33	49	5	10	28
LOW	1	2	0	3	4
UNKNOWN	3	3	1	0	4

initializing size parameters, leading to stack overflows that can overwrite critical data, including return addresses [43].

Hooking mechanisms. Hooking mechanisms are extensively employed by UEFI firmware implants to intercept and redirect system execution flow. For instance, rootkits like LoJax [81] and MosaicRegressor [61] register malicious callback functions for specific UEFI events, such as *EFI_EVENT_GROUP_READY_TO_BOOT*, which is triggered just before the operating system bootloader is invoked. Another approach involves patching function pointers within UEFI service tables, redirecting calls to legitimate services towards malicious routines. The CosmicStrand rootkit, for example, was found to patch the entry point of a DXE driver and deploy a multi-stage hooking process that extended control into boot manager, OS loader, and even kernel functions [62]. Such deep-seated hooks allow firmware implants to subvert operating system-level security controls, maintain persistence across reboots, and operate with a high degree of stealth.

2.2.2 Vulnerability Analysis

By analyzing UEFI-related CVEs (as shown in Table 1), we identify four major categories of vulnerability causes: memory safety issues, improper input validation, uninitialized data, and improper access control. The statistics show that memory safety issues and improper input validation stand out in terms of both frequency and severity. Improper input validation [26, 36, 38] accounts for the largest proportion, representing 30.8% of all UEFI-related CVEs. And memory safety issues [15, 16, 21–23, 27, 30] are particularly critical, constituting 31.4% of high-severity CVEs. While the types of vulnerabilities are consistent with those commonly found in traditional software, their impact is significantly amplified in the context of UEFI firmware, primarily due to three factors:

- **Privileged execution environment**. All UEFI modules execute with high privileges, such as in System Management Mode on x86 or EL1 on ARM. Although this privileged execution is necessary for managing hardware and configuring the boot process, it also provides a convenient and powerful vector for malicious code.
- **Lack of inter-module isolation**. UEFI modules share a common address space and communicate via global variables or protocols. The absence of isolation allows a flaw in one module to compromise others, potentially affecting the entire firmware.
- **Coarse-grained access control**. The access control mechanisms in UEFI are less sophisticated compared to modern operating systems. Concerning the interactions between

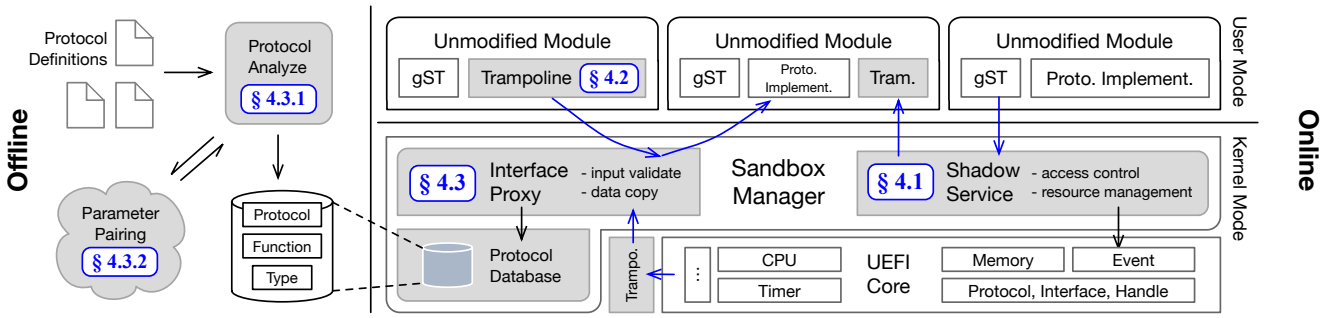

Figure 2: *µEFI's architecture.*

modules and the core, services and protocol interfaces are both globally accessible, potentially leading to unauthorized modifications.

Given these inherent limitations, we propose that a more robust isolation mechanism is needed to enhance the security of UEFI firmware beyond its current design.

2.3 Driver Isolation in UEFI vs. OS

Device driver isolation is a critical topic for enhancing the reliability and security of operating systems. The core principle involves executing drivers within protected environments to contain faults and prevent unauthorized access to kernel resources. Research in this area spans decades, leading to a diverse array of approaches. These include architectural strategies like user-mode drivers and microkernel design [8, 45, 49, 53, 54, 67], software-enforced methods such as software fault isolation [10, 44, 69, 95] and language-based safety [48, 76], virtualization-based containment [9, 50, 66, 77], and hardware-assisted mechanisms like memory protection keys [51, 52, 93]. Early systems like Nooks [85] demonstrated the feasibility of fault isolation within monolithic kernels. More recent efforts, exemplified by KSplit [56], focus on automating the complex process of isolating existing drivers and rely on static analysis to identify shared kernel driver states and generate synchronization logic.

Although driver isolation techniques has been extensively explored in traditional operating systems, the differences between the execution environment of UEFI modules and that of OS drivers bring new challenges and opportunities. There are three key differences. *First*, dynamic interface discovery. The UEFI core does not provide runtime symbol resolution for modules. Each module is a self-contained image, and its provided or required interfaces are identified only at runtime through protocol installation and lookup. As a result, static code analysis alone is insufficient for automating UEFI module isolation. *Second*, single-threaded execution. UEFI follows a single-threaded, event-driven execution model. There are neither synchronization primitives nor complex atomic operations, greatly simplifying concurrency concerns. *Third*, well-defined parameter scheme. All of the interfaces used by UEFI modules belong to pre-defined protocols, which means the parameter types and semantics are explicit. This characteristic enables effective data synchronization without reliance on static analysis of source code or binaries.

3 OVERVIEW

To address the security threats faced by UEFI while accounting for its unique characteristics, we present µEFI, providing transparent and fine-grained isolation for UEFI modules.

Design Goals. µEFI has four goals, focusing on the characteristics of UEFI vulnerabilities and the shortcomings of existing security measures.

- *G1: module memory safety.* µEFI must guarantee memory safety across modules. A UEFI module can only access its own memory and those legally shared by other modules.
- *G2: full module transparency.* µEFI should require no modification to the modules. Firmware images can be transparently loaded and executed with µEFI.
- *G3: module access control.* µEFI aims to provide seccomp-like mechanism in UEFI firmware, restricting modules' capabilities while ensuring that they can still perform their intended functions.
- *G4: automated input validation.* µEFI should be capable of automatically validating parameters for cross-module calls without the need for custom handling logic for each individual interface.

Approach: Isolation with microkernel architecture. UEFI follows a modular design in which modules interact through well-defined protocol functions. The majority of firmware code resides within UEFI modules, while the UEFI core remains minimal, performing only essential functionalities. The modular design principles of both microkernel and UEFI align closely, with the isolation of microkernel architecture fulfills the missing parts in UEFI. As a result, we apply microkernel architecture in UEFI firmware, deprivileging UEFI modules to user mode and isolating them with separate page tables.

Architecture. Figure 2 presents the architecture of µEFI. µEFI is composed of two parts: an offline analyzer and an online sandbox manager. The offline analyzer parses the definitions of protocols and constructs a database containing protocol-related information (§4.3.1). The sandbox manager controls the capabilities of sandboxed UEFI drivers and applications and serves as the supervisor of all sandboxed UEFI

modules. To facilitate the integration of the sandbox manager into existing UEFI firmware, the sandbox manager is implemented as a UEFI module operating alongside the core, thereby minimizing the need for modifications to the core. In the sandbox manager, we first introduce shadow service (§4.1) to manage the resources of sandbox and impose seccomp-like restrictions on sandboxed modules. Then we use trampoline injection (§4.2) to support cross-module calls without modifying existing UEFI modules. Before a cross-module call can be actually handled, interface proxy (§4.3) intercepts the call, validates the parameters to prevent error propagation, and performs necessary data transfer.

Threat model and security guarantees. μEFI assumes the UEFI core[2] is free of vulnerability and all preceding phases work as expected. UEFI drivers and applications loaded after the initialization of the core are not trusted, even if they are signed by legal third-party certificate authority, as these modules may have potential vulnerabilities.

As for security guarantees, μEFI ensures the memory safety of UEFI modules. During execution, a module cannot access memory not belong to it, and the corresponding memory attributes must be set (read/write/execute). μEFI also restricts the services and protocols a module can use. Modules should only be granted the capabilities they need to perform their work. In addition, μEFI provides the ability to validate the parameters for cross-module calls, making sure that the parameters are legally used by the caller. With the above guarantees, μEFI addresses the shortcomings of UEFI Secure Boot and further strengthens UEFI security.

3.1 Challenges and Insights

Transparent sandbox callout. The sandbox's callouts include invocations of services provided by the core and calls to protocol interfaces implemented by other modules. Originally, all the communications across UEFI modules and the core are conducted through function calls. With the deprivileging and isolation of UEFI modules, direct function calls are no longer feasible. However, the original calling convention must be preserved to ensure compatibility with existing modules.

Insight-❶: unique callout gate. System table is a central data structure in UEFI that provides access to services and configuration tables. Through the system table, we can manage all the callouts directly or indirectly, as services are accessed through the system table and protocol interfaces are obtained through services (depicted in Figure 3).

Transparent data transfer. UEFI modules communicate via protocol interfaces, with data shared directly across modules. Once isolation is enforced, explicit data synchronization becomes necessary. Since protocol type information is only available at compile time, the lack of such metadata at runtime makes synchronization across sandboxes infeasible.

[2]Specifically, the UEFI DXE Core, which is responsible for loading and managing DXE phase drivers.

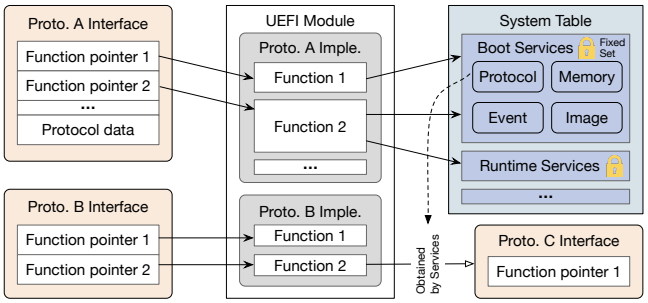

Figure 3: *Construction of protocols [87] and UEFI system table. Protocol defines a set of functions and data structures. Interface refers to the implementation of protocol. All the callouts of a module have to go through the system table directly or indirectly.*

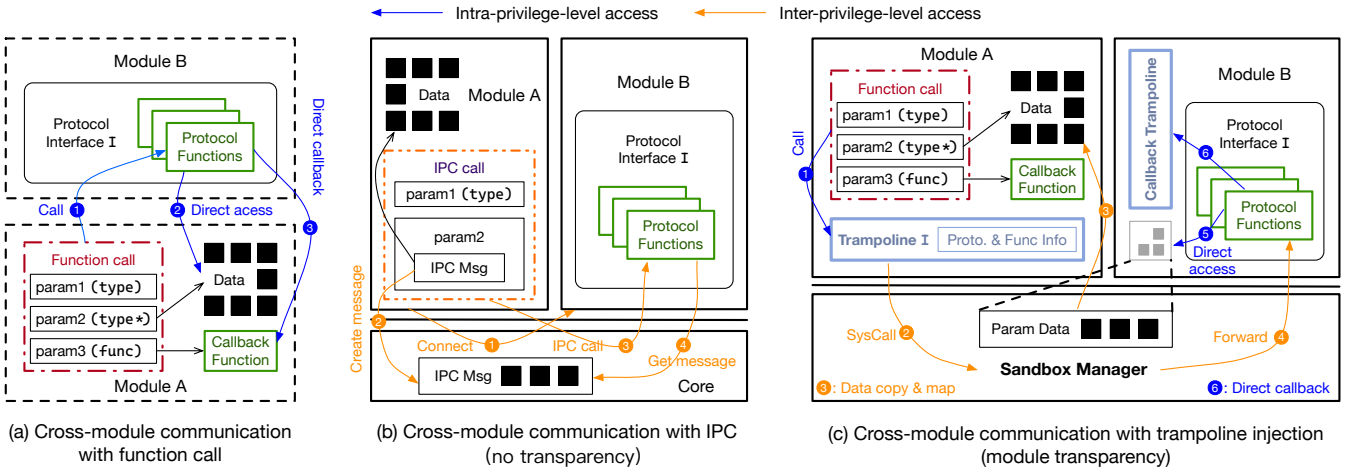
Insight-❷: standardized protocols. To facilitate the independent development of UEFI modules, the UEFI specification defines standardized protocols for various types of drivers and applications. Thus, a caller module can interact with target modules without concerning about their specific implementations, and device drivers by different vendors can achieve compatibility with existing systems simply by implementing the standard protocols.



4 DESIGN

We employ a combination of techniques to achieve transparent isolation of binary-form modules. By controlling a unique callout gate, μEFI transparently redirects service calls to a corresponding set of system calls (§4.1). It also supports transparent protocol function calls between isolated modules by replacing original protocol function pointers with injected trampolines (§4.2). Leveraging the standardized nature of protocol definitions, μEFI extracts type information through offline analysis and stores it in a protocol database (§4.3.1). To enable correct data transfer and automatic input validation, μEFI employs a heuristic-based technique known as parameter pairing (§4.3.2). It further adopts customized tracking strategies for different types of data involved in the invocation process (§4.3.3).

4.1 Shadow Service

The UEFI core provides a standardized set of services to UEFI modules, including Boot Services and Runtime Services. These services offer essential functionalities throughout the lifecycle of a UEFI module, such as memory allocation, event registration, and protocol interface acquisition and installation. In the original architecture, the core focuses solely on providing capabilities without imposing restrictions on their usage, allowing UEFI modules to access most system resources without limitations. Therefore, we present shadow service to delegate the core services and manage the resources.

UEFI services are presented to modules as a set of function pointers contained within the system table, a global variable initialized by the core and passed to modules during initializa-

(a) Cross-module communication with function call

(b) Cross-module communication with IPC (no transparency)

(c) Cross-module communication with trampoline injection (module transparency)

Figure 4: *Cross-module communication workflow with (a) function call, (b) normal IPC, (c) trampoline injection. Trampolines are dynamically generated according to the associated protocol and function.*

tion. As μEFI isolates each module in its own address space, the old manner of function call is no longer feasible. Combining with the fact that the set of core services is rather stable, the primitive system call is perfectly suitable for providing services to sandboxed modules. To achieve full transparency, during the loading process of sandboxed modules, we replace the origin system table pointer with a per-sandbox shadow system table, and the services with functions that perform system calls. Every time the services are called in the sandbox, the control flow is redirected to the shadow service. Inspired by seccomp, the shadow service enforces two levels of access control before handling the request.

Service-level access control. The shadow service first regulates the sandboxed module's access to core services. Among the services provided by the core, fundamental capabilities such as memory allocation, protocol installation and acquisition, and event creation and signaling are universally required by all modules. However, services like *LoadImage* and *StartImage* provide more sensitive functionalities and are only necessary for a limited number of modules, such as the UEFI shell or GRUB. Therefore, the shadow service determines whether to grant access to high-privilege services based on the type of each module.

Protocol-level access control. Protocols serve as the fundamental mechanism for interaction between modules. An important fact is that the proper functioning of a UEFI module requires interaction only with modules directly related to its functionality. For instance, a UEFI driver responsible for hard drive I/O may invoke block device drivers, but has no need to access network-related features. Thus, every time a sandboxed module attempts to acquire or install a protocol interface, the shadow service evaluates the request and determines whether to grant access based on its type and the protocol involved.

Unfortunately, under the current specification, it is not feasible to directly determine a module's type and functionality during the process of loading its image. To address this limitation, we employ two distinct approaches:

- **Explicit declaration.** Each module is uniquely identified by a GUID, and developers are required to explicitly declare the services and protocols a module is allowed to invoke. This enables strict, seccomp-like sandboxing and enforces a security-by-contract model.
- **Heuristic detection.** Modules are restricted to access protocols of a specific type. The module type is inferred based on the first non-generic protocol interface it attempts to acquire or install. This approach adopts a fail-stop execution model upon missing or unexpected protocols, with type classification resolved during pre-deployment testing.

By combining these two approaches, the system establishes a tiered security model that balances strict least-privilege enforcement with backward compatibility for legacy modules.

4.2 Safe Trampoline Injection

When a module intends to use the functionality of other modules, it obtains the corresponding protocol interface through the core services, and directly invokes functions in the protocol interface to fulfill its job. As illustrated in Figure 4 (a), references provided in call parameters are accessed directly, and callback functions are invoked without intermediaries.

Since μEFI isolates different modules, we can no longer access the functionalities within protocol interfaces through direct function calls. In the microkernel architecture, interprocess communication (IPC) is introduced to enable cross-module interactions. However, IPC cannot be seamlessly applied to UEFI modules because it relies on dedicated interfaces and requires explicit cooperation between the client and server. The IPC client must know the IPC server's identity, intentionally establish a connection, request the kernel to prepare IPC payloads, and invoke the server using a specialized IPC call, as illustrated in Figure 4 (b). Moreover, the approach of shadow service is not suitable for managing protocol inter-

faces. Unlike core services, the functions provided by protocol interfaces cannot be encapsulated within a fixed set, as they represent the diverse functionalities of UEFI modules.

μEFI introduces trampoline injection to enable transparent cross-module protocol function calls. Trampoline injection is implemented with the assistance of shadow service. When a sandboxed module attempts to acquire a protocol interface provided by another module, the sandbox manager does not provide the actual protocol interface. Instead, it dynamically generates trampolines that includes metadata about the protocol functions and injects it into the sandbox. Figure 4 (c) illustrates the workflow of cross-module communication facilitated by trampoline injection. When a sandboxed module invokes a protocol function, the call is transparently redirected to the injected trampoline (❶). The trampoline then issues a system call, carrying the parameters and transferring control to the sandbox manager (❷). The sandbox manager processes the parameters (❸) before forwarding the call to the target module (❹). For the target module, data passed through the cross-module call is also directly accessible (❺), and even callback functions can be invoked directly with the aid of another trampoline (❻).

Trampolines are injected into the sandbox without introducing security risks. Generation of a trampoline signifies that access to the protocol is approved by the shadow service. Furthermore, trampolines are configured as read-only upon injection, ensuring that their logic cannot be modified.

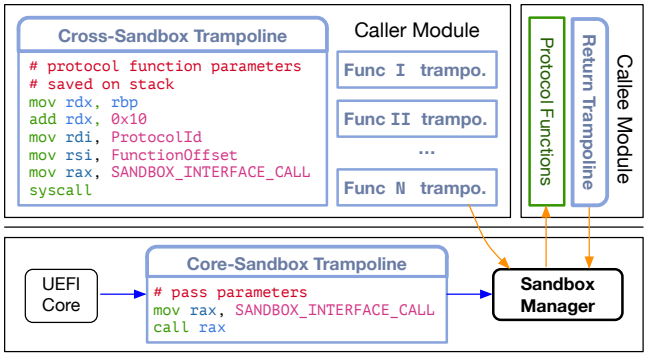


Figure 5: *Three types of trampolines with different use cases and the work mechanism of trampolines.*

Three types of trampolines. In addition to facilitating cross-module communication, trampolines are also employed within the core to enable transparent invocation of sandboxed modules by the core, as well as within the callee sandbox to ensure the automatic return of control after function execution. During module management, the core leverages several basic protocols to retrieve module information and control module lifecycle operations, such as obtaining the module's name or checking whether a driver supports a specific device. These protocol interfaces are also obtained through core services and accessed via function pointers. To minimize modifications to the core, the shadow service generates trampolines for the core every time a sandboxed module installs its protocol interface. When the core invokes these interfaces, the calls are routed to the sandbox manager.

Figure 5 illustrates the three use cases of trampolines and highlights their differences in detail. In summary, trampolines provide a transparent mechanism for cross-module calls and support different kinds of interfaces. For instance, asynchronous processing logic is implemented using events, and callback functions for sandbox events can be executed via trampolines. Although their application scenarios differ, all trampolines redirect the control flow to the sandbox manager. Within the sandbox manager, the interface proxy handles the preprocessing of parameters before invoking protocol functions and synchronizes data upon completion of the calls.

4.3 Interface Proxy

The interface proxy is responsible for validating the parameters of the call and, when necessary, copying the parameters. Although the UEFI core manages the installation and acquisition of protocols, it only records basic information about the installed protocols, such as the module that installed the protocol, the corresponding interface that implements the protocol, and a unique GUID used to identify the protocol. Lacking information related to the contents of the protocol, it becomes challenging to validate the parameters of protocol function calls without modifying the module's code. To address this issue, the interface proxy needs to cooperate with the offline analyzer. During online execution, the interface proxy identifies the protocol GUID corresponding to a protocol function call and queries the protocol's metadata with the GUID from the protocol database, which is constructed in the offline process. With the metadata, the interface proxy can validate the call parameters and, guided by this metadata, formulate data transfer strategies.

4.3.1 Protocol Database

Protocols are basic building blocks in UEFI firmware designed to facilitate communication and functionality between various components, drivers, and applications. Their definitions include both data structures representing device-specific configurations and functions for invoking device functionalities. The offline analyzer reads the protocol definition, parses the data structures, functions, and type definitions, and generates the protocol database. To reduce the size of the protocol database and avoid excessive query latency, the analyzer records only the essential information. We define three tables in the protocol database to store different types of information: *protocol*, *function*, and *type*. The protocol table records the name and GUID of each protocol, and variables contained within each protocol. The function table stores information about the function parameters, including their types, names, and input/output attributes. The type table captures other custom data structures and macro definitions. Figure 6 illustrates an example protocol definition of SerialIOProtocol, which is defined with the above three types. Once generated, the pro-

```
# @param Control      A pointer to return the control signals
Func GetControlBits:
  OUT Type *Control

# @param BufferSize   Input: size of the Buffer.
#                     Output: amount of data returned.
# @param Buffer       The buffer to return the data into.
Func Read:
  IN OUT Type *BufferSize
  OUT Type *Buffer

Func Write:
  IN OUT Type *BufferSize
  IN Type *Buffer

# Used to communicate with all UART-style serial devices.
Protocol SerialIOProtocol:
  Func GetControlBits
  Func Read
  Func Write
  Type *Mode  # pointer to mode data
```

Figure 6: *Example protocol definition for serial I/O device.*

tocol database is included in the sandbox manager's firmware image at compile time and contains all the information required by the interface proxy during runtime.

At runtime, the interface proxy does not load the entire protocol database at once; instead, it employs a lazy loading approach. During the initialization process, only the protocol table is parsed, while the types and functions associated with each protocol are not recursively analyzed. When the interface proxy processes a cross-module call request for the first time, it dynamically queries the necessary function and type definitions required to handle the request.

4.3.2 Call Parameter Validation

The interface proxy begins with validating the parameters of cross-module calls. A key observation is that severe vulnerabilities caused by improper input validation often stem not from logical errors (i.e., valid inputs that are logically incorrect), but from a failure to verify the validity of input parameters. For instance, a caller might pass a memory address to the callee that it is not authorized to access, or set the buffer size in parameters (example in Figure 6) to 128 bytes when the actual buffer size is only 64 bytes. Such invalid behaviors can result in unauthorized memory access or overwrite. Thus, the interface proxy focuses on validating the legitimacy of pointers within parameters.

Before initiating validation, the interface proxy must determine whether a pointer references a memory buffer, represents an array, or serves as an identifier handle/token. However, at runtime, it is impossible to determine this solely based on the values passed by the caller. To address this, μEFI employs a heuristic method in the offline analyzer to decide how to validate a given pointer. The information is recorded in the function table and is later utilized by the interface proxy to verify whether the pointer references a valid address and whether the caller has necessary access permissions for the passing memory region.

Offline parameter analysis. When analyzing function parameters, the offline analyzer begins by checking the data type of pointers. If the data type of a pointer is a protocol, the analyzer interprets it as a handle. This approach is based on the observation that protocols are seldom used in function parameters to transfer data. Instead, the protocol itself serves as an identifier, similar to the 'this' pointer in C++ class.

Then, the analyzer tells if a pointer references a buffer or an array, using a heuristic method named *parameter pairing*. Due to the inherent limitations of the C language, passing an untyped pointer to represent a memory buffer in a function call does not allow the callee to determine the buffer size unless both parties have established a standard logic for handling parameters. After analyzing numerous protocol definitions, we observe that when an untyped reference to a memory buffer is passed, it is often accompanied by an additional parameter specifying the buffer size. Similarly, for pointers that have a deterministic type size, the analyzer checks whether there is another parameter indicating the number of elements in the array. For pointers that need to be parsed with specific methods (e.g. string and device path), the offline analyzer leaves the job to the interface proxy, and the buffer size is determined at runtime using standard library functions (e.g. *StrLen* and *GetDevicePathSize*).

Approach of parameter pairing. The offline analyzer utilizes parameter names and function comments from protocol definitions to perform parameter pairing. It first examines whether the parameter names conform to certain patterns (e.g., *Buffer* and *BufferLength*, or *Data* and *DataCount*). If they do not, the offline analyzer proceeds to analyze the function comments. Since developers typically focus on protocol definitions rather than implementation details when they use protocols, function comments within protocol definitions often provide detailed explanations of the function's purpose and the roles of its parameters. This enables the offline analyzer to leverage large language models (LLMs) to identify potential relationships between parameters.

Limitation. The offline analyzer fails to resolve parameters of type void* when they cannot be unambiguously classified as handles, data buffers, or arrays. Such cases, which account for less than 2.5% of instances, typically involve implicit payload semantics between caller and callee—for example, parsing packets passed via void* in network modules. In these scenarios, manual effort is required to correctly process the parameters. At runtime, the sandbox manager flags unhandled interface arguments when such ambiguous cases are encountered without proper handler.

4.3.3 Interface-aware Data Transfer

Given that modules in different sandboxes cannot access each other's memory, the interface proxy not only validates the parameters of protocol function calls but also carries out data transfer and synchronization during the process. Without the use of specialized hardware features, memory isolation is typically maintained at the page level. As a result, when handling memory references in cross-module calls, the interface proxy needs to allocate a memory region for the callee and copy the data from the caller's address space to the callee's.

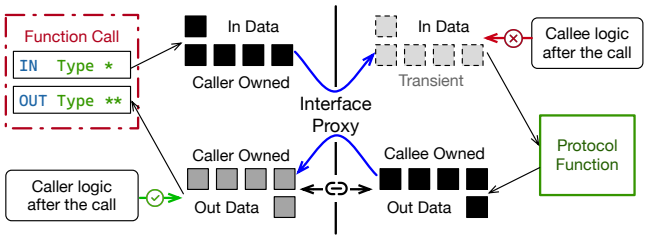

Figure 7: *Example of data transfer in cross-module protocol function call and the lifecycles of the memory buffers.*

By utilizing information from the protocol database and results of parameter pairing, the interface proxy is capable of recursively dissecting complex data structures and handling parameter transfer seamlessly, thereby obviating the need for UEFI modules to explicitly manage data transfer.

Cross-module memory management. During the handling of protocol function calls, the callee might allocate a memory region for the caller, write the data to be returned into this memory, and then return a reference to this memory to the caller—utilizing multi-level pointers. In such scenarios, the interface proxy needs to resolve the contents of multi-level pointers layer by layer until it accesses the actual data, and then allocates a buffer for the caller to store the data.

The key difference between memory buffers returned by the callee and those used for input data lies in their lifecycles. As illustrated in Figure 7, the memory allocated for transferring input data can be immediately released after the call finishes. In contrast, memory buffers returned by the callee are intended for use in the caller's subsequent execution and thus have a lifecycle extending beyond the scope of the current protocol function call. Moreover, the caller only accesses the data without managing it. Memory allocated by the callee for the caller is typically released by the callee itself, often through another protocol function. For instance, *OpenFile* returns a pointer of an *EFI_FILE* structure which should later be freed by calling *CloseFile*.

To prevent memory leaks, it is necessary to continue tracking the memory buffer even after the current protocol function call has completed. Since all memory in sandboxed modules is managed by the shadow service, additional metadata can be recorded for allocated buffers. When the interface proxy allocates memory for the caller to transfer returned data, the shadow service binds this buffer to the memory that is previously allocated by the callee, establishing a hierarchical relationship (depicted in Figure 7). When the callee module releases its allocated memory, the shadow service ensures that dependent memory is also freed in a cascading manner.

5 IMPLEMENTATION

We implemented a prototype of μEFI on both the x86_64 and the AArch64 architectures. To avoid invasive modifications to the core, the sandbox manager is implemented as a UEFI module running at the same privilege level as the core. The core is modified to ensure that the sandbox manager is prioritized during the module loading process. It interacts with the sandbox manager to schedule the sandboxed modules exclusively through interfaces defined by *SANDBOX_PROTOCOL*, facilitating operations such as *CREATE_SANDBOX* and *START_SANDBOX*. The sandbox manager module consists of 4,773 SLOC in C and 253 SLOC in assembly, while the modification to the core is less than 100 SLOC.

In terms of the offline analyzer, we leveraged LLVM Frontend Infrastructure, more specifically, LibClang, to directly traverse and parse all the protocol headers of UEFI drivers primarily in the MdePkg of EDK2 Repository. We programmed the offline analyzer in C++ to extract all the types info and function signatures used by all protocols and selectively filter the protocols based on the INF sections defined in firmware's FV definition. After the process of type extraction, the offline analyzer is set to dump the protocol definitions inside a JSON file which is later statically embedded inside the Sandbox Manager Driver. The offline analyzer consists of 907 LOCs in C++ and the generated JSON file is less than 20000 LOCS.

6 EVALUATION

We evaluated μEFI to answer three major questions:

- Can μEFI protect UEFI firmware from vulnerability exploitation and real-world attacks? (§6.1 & §6.2)
- To what extent can μEFI achieve generality in ensuring module transparency? (§6.3)
- How much overhead does μEFI incur? (§6.4 & §6.5)

Experimental Setup. Our system is based on the edk2-stable202402 release version of UEFI EDK2. For evaluation, we utilize two distinct platforms:

- Intel i7-13700 Desktop: This platform supports the VT-x virtualization feature. We use the EDK2 OVMF package to run μEFI within KVM-enabled QEMU virtual machine. In this setup, the core operates at Ring 3, while sandbox modules run at Ring 0. Execution cycles are measured by reading the TSC (Timestamp Counter).
- Raspberry Pi 4 Model B: This platform features a quad-core Cortex-A72 (ARM v8) 64-bit SoC. On this system, the core executes in EL1, and sandbox modules are confined to EL0. Execution cycles are measured by reading the PMU (Performance Monitoring Unit) registers.

6.1 Empirical Security Evaluation

To evaluate the effectiveness of μEFI in defending against various vulnerabilities, we constructed multiple test cases based on known CVEs. These cases target potential issues within modules, including memory safety vulnerabilities and improper input validation.

Security protection for memory safety. Memory safety issues, such as stack overflow, heap overflow, and use-after-free, can lead to the corruption of critical data structures and potentially enable arbitrary code execution. To evaluate the

effectiveness of our defense mechanisms, we designed two test cases targeting stack and heap overflow scenarios.

Stack-based buffer overflow. CVE-2021-39297 is a stack overflow vulnerability found in the UEFI firmware of certain HP laptops [43]. Exploiting this vulnerability allows an attacker to overwrite the return address of the parent function. In μEFI, a temporary stack is allocated each time control is transferred to a sandboxed environment. Upon function return, a return trampoline is employed to securely redirect control back to the sandbox manager. Combined with the fact that a sandboxed module can only access its own code and data, this design ensures that malicious code outside the vulnerable module cannot be injected or executed via stack overflows.

Heap-based buffer overflow. Heap overflow vulnerabilities occur when a program allocates dynamic memory on the heap but fails to properly validate buffer lengths, allowing an attacker to overwrite adjacent heap data or metadata [21–23]. In μEFI, the heap memory of each sandbox is managed by the sandbox manager independently. Even if an attacker exploits a vulnerability to overwrite heap data, the access is confined to the heap data of the compromised module itself.

Security protection for improper input validation. We design two types of protocol function call inputs, each representing common scenarios that require different levels of input validation by the callee. The first type involves cases in which the caller passes a memory pointer that it does not own, potentially resulting in unauthorized memory writes. The second category involves cases where the caller supplies a valid memory buffer but specifies a *BufferSize* parameter that exceeds the actual buffer size. This can cause out-of-bounds memory access and unintended data corruption.

In μEFI, the interface proxy addresses these issues by leveraging parameter pairing to associate *Buffer* with its corresponding *BufferSize*. It then consults metadata maintained by the shadow service's memory management subsystem to verify the legitimacy of the input buffer, thereby preventing illegal memory operations.

There are a few cases in which the interface proxy may fail. For instance, in CVE-2023-39538 [33], two input parameters are used to initialize a buffer without proper validation. This can lead to an integer overflow, resulting in the allocation of a buffer that is too small to hold the intended data and ultimately causing heap overflow [7]. Because the vulnerable buffer is not directly passed as a function parameter, the interface proxy cannot detect this issue. Nevertheless, the exploit is still mitigated by the memory isolation enforced by μEFI.

6.2 Security Analysis

We further demonstrate how μEFI mitigates vulnerability exploitation by analyzing UEFI-specific attacks in the wild and PoC attacks proposed by researchers.

ThunderStrike represents an early firmware attack targeting UEFI. It is launched via a compromised Thunderbolt peripheral, which leverages its Option ROM to inject malicious code into the firmware. A critical step in its execution involves the malicious module altering the normal boot sequence. Specifically, it replaces the *ProcessFirmwareVolume* function pointer in the DXE services table with its own function pointer. This manipulation allows the bootkit to seize control over subsequent stages of the boot process [57]. As μEFI utilizes the shadow service to ensure that the service table accessed by each sandboxed module is an independent copy, even if a malicious module modifies a function pointer in its service table, the hook will not affect other modules.

BootHole exploits a buffer overflow vulnerability within the GRUB2 bootloader, triggered when parsing a maliciously modified grub.cfg configuration file by an attacker with administrative or physical access. This buffer overflow overwrites critical structures in the heap and allows for arbitrary code execution. As GRUB2 itself is signed and verified, this effectively bypasses Secure Boot and enable the loading of untrusted code or the installation of persistent bootkits [41]. If μEFI is deployed, the memory isolation enforced between sandboxes prevents an attacker from overwriting memory belonging to other modules or the core. This significantly raises the difficulty of exploiting such vulnerabilities.

BlackLotus is a sophisticated UEFI bootkit recognized for its capacity to circumvent Secure Boot by leveraging vulnerabilities like 'BatonDrop'. A key aspect of its methodology is that it loads a malicious module ('grubx64.efi') and intercepts the execution of components included in the typical Windows boot flow, such as Windows Boot Manager, Windows OS loader, and Windows OS kernel, and hooks some of their functions in memory. This deep level of interference allows BlackLotus to effectively neutralize various security mechanisms, including BitLocker and Hypervisor-protected Code Integrity (HVCI) [84]. With μEFI in place, even if Secure Boot is bypassed, running 'grubx64.efi' within a sandbox prevents it from inserting malicious hooks into other modules.

6.3 Generality of Offline Analysis

A critical question is how general can μEFI be used for providing isolated execution environments for UEFI modules. To answer this question, we employ the offline analyzer to examine all protocols within the UEFI EDK2 project. Because the key to achieving module transparency is to support different interfaces and correctly handle the pointers, we focus on analyzing pointer parameters in functions and pointer fields in the definition of protocols and compound types. We also include non-pointer types in the analysis to reflect the

Table 2: *Number of different types of pointers in the definition of Functions, Protocols, and Compound Types in UEFI EDK2. Total Fields contain the parameters that are not pointers.*

Definition	Buffer w/ Size	Array w/ Count	Handle /Token	Parse w/ Library	Manual Effort	Total Fields
Protocol	0	0	22	10	2	1147
Compound Type	28	1	85	189	87	33278
Function	159	6	369	101	90	3639

broader applicability of μEFI, since most interface parameters are plain data structures in production firmware.

The offline analyzer recognizes four types of pointers that need to be specially handled, as detailed in Table 2. Among all the protocol fields, only two fields require manual intervention for adaptation. This is because the definitions of most protocols are composed of function pointers and a few simple data structures that represent the hardware configurations. Similarly, the failure rate for analyzing compound types is as low as 0.26%. Regarding functions, 17.4% of all parameters are classified as belonging to the four special pointer types, with a failure rate of 2.5%. Moreover, many failure cases are clustered within a few modules that contain multiple data structures requiring manual effort.

6.4 Performance Evaluation

6.4.1 UEFI Boot Performance

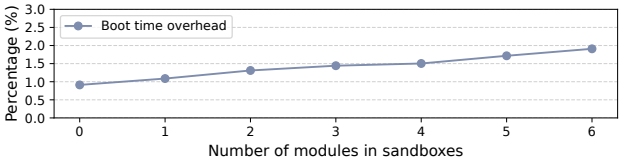

Figure 8: *The impact of the number of sandboxed modules on UEFI boot time (measured from the entry of DxeMain to the completion of ExitBootServices).*

To evaluate the performance impact of running modules in sandboxes, we first measure and compare the boot time of UEFI [3] with and without sandboxed modules. The comparison of boot latency focuses on the UEFI boot process, from the entry into the DXE phase to the handover of control to the operating system. We select six widely used UEFI modules, ranging from simple modules such as EnglishDxe to complex ones like FAT, which is among the most complex in EDK2, interacting with other modules via a rich set of protocols and intricate data structures.

As illustrated in Figure 8, running six modules in different sandboxes only incurs an overhead of 1.91%. When no modules are executed within the sandbox, the loading of the sandbox manager introduces a latency of 0.91%. This overhead arises from the sandbox manager's initialization process, during which it preloads portions of the protocol database. The loading of each individual module incurs an average overhead of 0.17%, with the overheads of running different modules ranges from 0.06% to 0.22% (more details in §6.4.2). These differences arise because modules perform distinct tasks. Modules are occasionally invoked by the core via the *EFI_DRIVER_BINDING_SUPPORTED* interface to determine whether they support specific protocols. In certain cases, modules may be loaded but their interfaces are never invoked due to a failed driver binding process. In contrast, modules such as FAT are both loaded and executed. The more complex the protocol interfaces they expose, the higher the runtime overhead they incur. Moreover, during system boot process, the operating system's boot time significantly exceeds the boot time of the UEFI firmware, rendering the overhead of μEFI more negligible.

[3] We failed to configure to boot Linux with GRUB on Raspi4, the boot time is only tested on the x86_64 platform.

6.4.2 Module Execution Performance

To evaluate the performance impact of μEFI on UEFI modules, we conduct experiments on two frequently invoked and highly interactive modules during the boot process: FAT and DiskIo. The protocols provided and consumed by these modules are sufficiently representative to cover all the parameter cases discussed in §4.3. The end-to-end test involve creating a file using FAT-provided interfaces, writing to and reading from the file, and then deleting it.

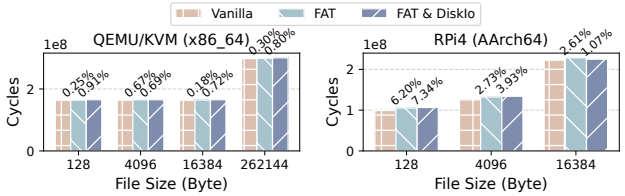

Figure 9: *Execution time for end-to-end test with and without FAT and DiskIo in sandboxes.*

As illustrated in Figure 9, in the x86 virtual machine, running FAT with μEFI incurs an average overhead of only 0.35%, while isolating FAT and DiskIo into separate sandboxes results in an average overhead of 0.78%. This increased overhead is attributed to the additional context-switching and data transfer involved in interactions between sandboxed modules compared to those between sandboxed and core modules On the Raspberry Pi 4 platform, the corresponding overheads are 3.85% and 4.11%, respectively.

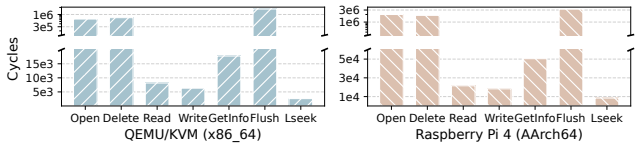

Figure 10: *Execution overhead of various FAT interfaces when executing FAT and DiskIo within μEFI.*

Figure 10 shows the execution overhead of various FAT interfaces by comparing baseline performance with that observed when both FAT and DiskIo modules are executed within sandboxes. On the x86_64 platform, Read, Write, and Lseek operations each take less than 9,000 additional cycles. As for others, Open, Delete, and Flush involve I/O operations, where the time consumed by the driver's internal logic significantly exceeds the overhead introduced by μEFI. The overheads shown primarily reflect the natural fluctuations in the interface execution times, which are less than 5% compared to the baseline.

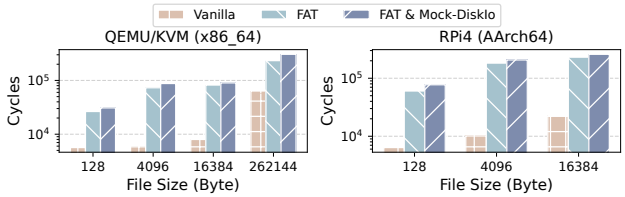

Figure 11: *Execution time for end-to-end test with and without FAT and Mock-DiskIo in sandboxes.*

Mock test excluding I/O operations. UEFI primarily initializes hardware and sets up the environment for OS booting. As such, most UEFI modules inherently involve I/O operations through direct or indirect hardware interaction. To better test the overhead introduced by μEFI, we conduct a mock test that excludes all I/O operations.

In this test, we substitute the I/O operations in the DiskIo module with equivalent memory operations, and the results are shown in Figure 11. Since the test involves only memory copies and function calls, the baseline execution on x86_64 with a file size of 128 bytes takes 5,646 cycles. When FAT is sandboxed, the execution time increases to 26,437 cycles. When both FAT and Mock-DiskIo module are sandboxed, the execution time further rises to 30,870 cycles. Similar results are also observed on the Raspberry Pi 4 platform.

This increase stems from two primary sources: (1) Additional context switches. All service and protocol interface invocations from sandboxed modules must enter the kernel. For instance, FAT uses locks during file operations, implemented via *RaiseTPL* and *RestoreTPL*, which each incur a system call. (2) Interface parameter synchronization. The sandbox manager is responsible for pre-invocation input transfer and post-execution output synchronization. These operations introduce overheads that scale with interface complexity and the buffer size. This partially explains why sandboxing Mock-DiskIo on top of FAT results in less than 20% overhead.

6.4.3 Overhead Breakdown

To assess how different sources of overhead contribute to the overall performance impact, we examine the latency of interface calls involving different parameter types. Four distinct types are included:

- Simple call performs a call without parameters.
- Input object uses an input pointer to pass an integer object.
- Input buffer uses an untyped input pointer to pass a buffer.
- Output buffer passes in the reference of an untyped pointer and retrieves the pointer with buffer allocated by the callee.

The combination of the four types collectively represents all possible interface scenarios. The latency of switching between the caller and the core is not included, as it is roughly the same as the switch latency between the core and the callee.

As illustrated in Figure 12, when running on x86_64 architecture using QEMU/KVM, context switching introduces an average latency of 1,126 cycles. The average latency for DB query is only 55 cycles, as protocol database entries are

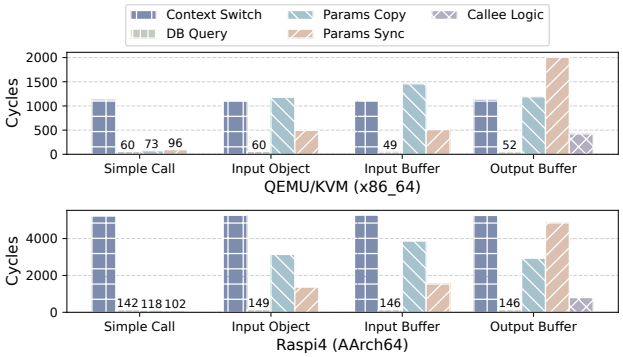

Figure 12: *Overhead breakdown for different kinds of cross-sandbox calls.*

cached after the first analysis, making subsequent queries nearly instantaneous. Even for initial queries, DB query requires only 200–300 cycles. Handling an integer pointer in the input consumes 1,178 cycles, which includes the allocation of transient memory and data transfer. For an input buffer of 800 bytes, the latency increases by an additional 280 cycles. After returning from the callee, 500 more cycles are consumed to free the transient memory. If there exists an output buffer, the overhead of synchronization accounts for the largest proportion, which includes caller memory allocation and data transfer. In the test case of the output buffer, the callee performs a system call to allocate memory for the caller, introducing an additional overhead of 420 cycles.

On the Raspberry Pi 4, the proportional distribution of overhead across different components is similar to that observed with QEMU/KVM. However, context switching incurs an average overhead of 5,262 cycles. This increased cost arises because, for different sandbox calls, the transient return trampoline and jump buffer used for redirection may be allocated to the same physical address. As a result, cache invalidation is required before invoking sandbox functions.

6.5 Memory Consumption

Table 3 summarizes the additional memory consumption of sandboxed modules. When loading a UEFI module, the core allocates at least 32 KB memory. For more complex drivers, such as FAT, the allocation can reach up to 112 KB. On top of this, the additional memory overhead introduced by each sandbox typically remains below 40 KB. Given that modern firmware environments generally support up to 4 GB of physical memory, this overhead is negligible. The additional memory primarily consists of two parts: The memory required for sandbox management and the memory necessary for interface calls.

Part 1: Each sandbox maintains its own page table and independent heap manager, resulting in a memory management overhead of 17 KB, which increases proportionally with future allocation. To safeguard the core against malicious hooks, system tables are not shared among sandboxes which takes up 8 KB. Additionally, the metadata of protocol interfaces

Table 3: *Memory consumption of a sandboxed module.*

Source	Size	Detail usage of the memory
Memory Management	17 KB	Pagetable and heap metadata
Sandbox SystemTable	8 KB	Shadow system table and shadow services
Interface Management	520 B	Every acquired/installed interface
Core-Sandbox Trampoline	128 B	Every installed protocol function
Cross-Sandbox Trampoline	128 B	Every acquired protocol function
Sandbox Stack	32 KB	Every call to the sandbox (transient)
Return Trampoline	64 B	Every call to the sandbox (transient)
Jump Buffer	352 B	Every call to the sandbox (transient)
Call Parameter	Dynamic	Every call from/to the sandbox

and the generated trampolines require 648 bytes of memory.

Part 2: The memory overhead of a sandbox interface call includes a dedicated sandbox stack, a return trampoline for transferring control back to the sandbox manager, a jump buffer for storing core context, and memory allocated for transferring call parameters. Except for the output values, all of these memory occupation are transient, collectively requiring 33 KB.

7 Discussion

μEFI TCB. Our implementation considers the core as the trusted computing base (TCB) and assumes that all preceding phases, including the SEC and PEI phases, are secure. While vulnerabilities exist in the core and these earlier phases, their prevalence is significantly lower compared to other components. Moreover, as modules in the PEI phase primarily handle basic hardware initialization, we implement μEFI to monitor the modules loaded after the core.

Privileged instruction handling. Since UEFI firmware interacts directly with hardware, UEFI modules may rely on privileged instructions to perform their tasks. Executing such instructions in user mode triggers system exceptions. Previous research [1,60,64] on transitioning high privilege components to lower privileges has explored solutions to address this issue. In μEFI, we adopt a similar approach to trap and emulate the execution of privileged instructions.

Usage of μEFI during OS runtime. μEFI primarily works in UEFI boot phases to ensure the modules are loaded and executed safely. Beyond this, the techniques employed by μEFI can also be utilized in the firmware runtime to monitor calls to UEFI runtime services and SMM handlers. For instance, μEFI can serve as a proxy to validate SMM call parameters.

8 Related Work

In addition to UEFI Secure Boot, UEFI incorporates a range of methods and features aimed at enhancing security.

Data flow and control flow protection mechanisms used in operating systems, such as stack guards, address space layout randomization (ASLR), and control flow guard (CFG), can be employed in UEFI [86, 96]. Microsoft, for instance, introduced Enhanced Memory Protection [5], which enforces section-level security by applying execution-protection flags to data sections and read-only flags to code sections. While these methods increase the difficulty of attacks, they fail to address fundamental issues. All modules still operate with high privileges, and their capabilities remain unrestricted. Consequently, attackers can exploit module vulnerabilities to carry out actions such as loading malicious images or hooking malicious functions.

Static analysis and fuzzing of driver source code or binaries are common approaches for uncovering firmware vulnerabilities. Intel's Host Based Firmware Analyzer (HBFA) is an open-source fuzzer targeting EDK II, leveraging manually crafted harnesses to test protocol interfaces [59]. While this design facilitates targeted protocol analysis, its dependence on manual setup and limited input diversity hampers both efficiency and scalability. SPENDER [99] applies static analysis to identify SMM privilege-escalation vulnerabilities in UEFI firmware but faces challenges with precision when analyzing stripped binaries. RSFUZZER [98] adopts a hybrid fuzzing strategy to discover vulnerabilities in SMI handlers, but suffers from the overhead and slow performance of emulation and is incapable of detecting silent vulnerabilities. While these tools seek to discover vulnerabilities, our work takes an orthogonal approach by focusing on attack surface reduction via module isolation, thereby complementing existing analysis-based defenses.

Apple has proposed using OROM Sandbox to constrain the execution of unsigned option ROMs [3]. However, its approach focuses solely on limiting the capabilities of option ROM invocation interfaces and does not address the challenge of achieving module transparency. Rust for UEFI suggests leveraging Rust's memory safety features to enhance UEFI security [97]. However, this requires rewriting the existing codebase. As current firmware codes are predominantly written in C and assembly code, integrating Rust would inevitably introduce significant portions of unsafe code, undermining its benefits in memory safety.

9 Conclusion

μEFI adopts a microkernel architecture to deprivilege and isolate the execution environments of UEFI drivers and applications. To address the challenge of maintaining compatibility with existing firmware modules, μEFI incorporates key techniques such as trampoline injection and protocol analysis. Additionally, it strengthens UEFI security by implementing a seccomp-like mechanism and enabling automated input validation.

Abstract

To increase platform memory efficiency, hyperscalers like Google and Meta transparently demote "cold" application data to cheaper cost-per-byte memory tiers like compressed memory and NVMe SSDs. These systems rely on standard kernel paging policies and mechanisms to maximize the achievable memory savings without hurting application performance. Although the literature promises better policies, implementing and deploying them within the Linux kernel is challenging. Delegating policies and mechanisms to user space, through `userfaultfd` or library-based approaches, incurs overheads and may require modifying application code.

We present PageFlex, a framework for delegating Linux paging policies to user space with minimal overhead and full compatibility with existing real-world deployments. PageFlex uses eBPF to delegate policy decisions while providing low-overhead access to in-kernel memory state and access information, thus balancing flexibility and performance. Additionally, PageFlex supports different paging strategies for distinct memory regions and application phases. We show that PageFlex can delegate existing kernel-based policies with little (< 1%) application slowdown, effectively realizing the benefits of state-of-the-art policies like Hyperbolic caching [18] and Leap [12] prefetching, and unlocking application-specific benefits through region- and phase-aware policy specialization.

1 Introduction

Memory cost as a fraction of hyperscalers' total cost of ownership (TCO) has been growing at an alarming rate [25, 32, 48]. Offloading cold memory to cheaper cost-per-byte memory tiers like compressed memory and NVMe SSDs offers a promising way to increase platform memory efficiency. Recent hyperscale deployments like Google's `g-swap`[1] [32] and Meta's Transparent Memory Offloading (TMO) [48] demonstrate that significant (20–30%) memory savings can be achieved with minimal impact to application performance. These systems rely on the OS's page reclamation mechanisms to offload "cold" application pages (pages that haven't been accessed recently) and minimize the chances of costly page refaults from the swap backend, which directly impact application performance. Consequently, correctly inferring what pages are cold and whether to offload them—i.e., the page offload or reclamation[2] policy—is crucial to improving memory savings without hurting application performance. Similarly, prefetching the offloaded pages before they are reaccessed can hide the cost of refaults, making prefetching equally important.

Existing deployments leave the critical page offloading decisions in the kernel: they maintain page ordering based on page access information using kernel mechanisms, and use control loops in user space to determine the threshold for offloading pages based on application impact. For page ordering, they rely on traditional Linux kernel LRU mechanisms like active/inactive lists [48]; multi-generational LRU (MGLRU) [6]; or implicit ordering through per-page "age" fields [32], where orderings are updated based on page access information that is checked periodically [32]. However, many more sophisticated eviction algorithms have been proposed in recent work [15, 18, 35, 42, 50] that could potentially further improve memory savings. Our measurements show that there is a significant gap between LRU and the optimal decisions for real-world accesses from page access traces (§2.3). Similarly, for prefetching, existing systems rely on Linux's default read-ahead, while more advanced prefetching policies like Leap can improve performance by 7—75% [12].

Linux currently offers limited paging policy choices, and improving these policies or implementing new ones in kernel code brings significant challenges. Deploying kernel changes across a large fleet is a slow and risky process, and experimental or application-specific policies are harder to upstream [28, 34]. Existing user-space designs, such as those that rely on Linux `userfaultfd` [3, 38, 40, 54] or custom

[1] We adopt [48]'s terminology for Google's swap infrastructure.

[2] We use the terms *offload* and *reclaim* (Linux term) synonymously.

libraries [26, 41, 45, 53], can *externalize* (i.e., allow out-of-kernel implementations for) paging, but introduce new problems. By migrating the entire paging infrastructure to user space, `userfaultfd` dramatically increases the cost of refaults (e.g., by more than 50% for zswap (§ 2.4)). Additionally, it imposes a high deployment barrier by requiring user-level swap implementations—along with the effort to maintain them—since it cannot leverage the kernel's mechanisms.

Custom memory management libraries such as DiLOS or Application-Integrated Far Memory (AIFM) [23,26,41,45,53] completely avoid kernel paging for flexibility and lower paging overhead, but pose similar challenges. They often require modifying applications, and while their slow path (i.e., refault from swap) is generally much faster, they introduce considerable performance overhead even when no memory is offloaded, as they force a custom interface [52]. Both `userfaultfd` and custom libraries introduce significant operational overhead at scale, where maintaining stability, efficiency, and seamless integration with existing infrastructure is critical. Thus, in this paper, we ask the following question: *Can we delegate paging policies to user space without slowing down the application or compromising compatibility with existing deployments (i.e., avoiding application modifications and the need to reimplement swap infrastructure)?*

Our solution is **PageFlex**, a framework designed to delegate the paging policy outside of the kernel, while keeping it compatible with existing kernel-based swap deployments like `g-swap` [32] and TMO [48]. To achieve these goals, PageFlex only delegates non-performance-critical policy decisions made for prefetching and proactive reclamation outside the kernel code. Enabling policies requires tracking the state of memory and how it is being accessed (e.g., paging activity and page access information), which could introduce considerable overhead if significant kernel state needs to be exported to and processed in user space. To address this issue, PageFlex uses eBPF programs [10] to provide a flexible, low-overhead view of in-kernel memory state to externalized policy code.

At a high level, PageFlex implements policies by observing the changes to memory state and access information, and making decisions based on them. To track memory state, PageFlex traces various paging events (page status changes like page allocations, frees, swap-ins and -outs) and access signals (through page faults and periodic checks on access bits) and exposes them to the policies implemented as eBPF-based event handlers. To enable policies to efficiently track and maintain metadata based on observed state, PageFlex provides event handlers with safe, overhead-free access to a small amount of in-kernel metadata for each page. Policies subscribe to only the events they need, providing handlers to process them and optionally communicate with user-level code for more complex decision making. Any policy decisions made in user space are enforced by PageFlex through paging hints (page in or out) using the `madvise` syscall interface.

To make it easier to write policies, PageFlex provides generic reclamation and prefetching policy models that support a variety of policies with a simple interface. Our reclamation model generalizes `g-swap`'s per-page, age-based ordering to instead employ generic, per-page weights. In this model, most existing eviction heuristics can be implemented as custom weight-update functions that consume the page-access information PageFlex periodically exports. Our prefetching model enables customized trend detection, allowing the implementation of state-of-the-art policies like Hyperbolic caching [18] and the Leap [12] prefetching. Our re-implementations require no changes to the kernel and only a handful of lines of policy code (17 for Hyperbolic caching and 21 extra lines for Leap in addition to 160 borrowed from its original implementation [1]). Going beyond a single static policy for an application, PageFlex supports specialization for memory regions within a process and runtime policy adjustments.

We evaluate PageFlex with a variety of workloads and policies. PageFlex introduces very little additional application slowdown compared to kernel implementations of the same policies. For page reclamation, we show that Redis and synthetic benchmarks run at most 1% slower when using PageFlex's LRU implementation as compared to `g-swap`'s functionally-equivalent but kernel-based variant. For prefetching, a PageFlex-based implementation of Linux's read-ahead policy provides similar benefit to the native in-kernel implementation: when measuring the page refault rate from an SSD-like swap backend, Linux's kernel-based read-ahead is 82% faster than no prefetching, while PageFlex delivers a 76% improvement with minimal (0.8%) overhead when there are no prefetching benefits.

Going beyond these default policies, we implement various policies from the literature and demonstrate their memory savings and performance benefits. PageFlex's LFU policy offloads up to 2× more memory than LRU at any given performance slowdown for a synthetic LFU-friendly workload. Similarly, PageFlex-based Hyperbolic caching allows up to 5% more memory savings for real-world workload traces. PageFlex-based Leap prefetching improves the refault rate with strided accesses by 75.4% over the Linux default, which cannot capture strided patterns. Our workload-aware, specialized policies show up to 36% more memory savings for a key/value store, and 6% for the GAPBS PageRank workload, compared to LRU for the same performance target. Moreover, PageFlex enables these flexibility and performance benefits despite modest overheads from its supporting infrastructure. For example, compared to the in-kernel implementation of `g-swap`, PageFlex's periodic page table scans are 17% slower due to eBPF overheads, and enforcing paging actions from user space through syscalls takes 14% longer.

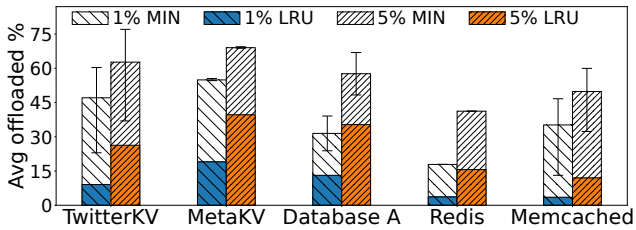

Figure 1: Average memory offloaded (% of total memory usage) with periodic LRU eviction (colored bars) simulated on page access traces of real workloads (detailed in Table 2) at two different allowed page refault rates (1% and 5%), overlaid against Belady's MIN. The white space in each bar shows the opportunity for more memory offloaded at the same performance target.

2 Background and Motivation

We begin by motivating the need for a platform to easily explore novel paging policies. We then discuss the requirements for investigating paging policies in the data center. We describe paging alternatives, including kernel-based, user-level, and library-based implementations, showing that current solutions fall short of meeting these requirements. Additionally, we survey paging policies from the literature and provide a background on eBPF.

2.1 Motivation for policy investigation

We begin by exploring the potential for improving on standard reclamation policies like LRU by comparing its effectiveness against an optimal policy based on Belady's MIN [16]. We evaluate these policies by simulating the proactive reclamation approach used in hyperscaler data centers using the traces described in Table 2. These deployments [32,48] proactively offload application pages to swap devices like NVMe SSDs [48] or in-memory compressed caches like zswap [7]. Rather than reclaiming pages in response to memory pressure, which can be disruptive to application performance (since reclamation happens on the critical path of memory allocation), these systems proactively reclaim data in a manner that limits the impact on application performance.

Figure 1 shows the difference in the fraction of memory offloaded for two different performance constraints. To simulate the policies, a target amount of memory is offloaded at the end of each interval (similar to TMO [48] and `g-swap` [7]) based on each algorithm (i.e., ordered by the last access time for LRU and the next access time for MIN). As a proxy for application impact, we use `g-swap`'s *promotion rate*[3], the rate of page refaults normalized to the working set, averaged for all intervals. We vary the memory offload targets and measure the largest target that results in a refault rate below 1% and 5%. Even at these low refault rates, the gap between LRU and MIN is significant for all traces, ranging from 14–37% at 1% refault rate and 22–38% at 5%, strongly suggesting that there is opportunity to design better eviction algorithms. Our goal is to make it easier to experiment with and adopt such algorithms—both existing research algorithms and novel ones—to close this gap.

[3]We use the terms *promotion rate* and *refault rate* synonymously.

2.2 Hyperscaler paging goals

When experimenting and adopting a new paging policy, hyperscalers have several goals. Application portability without source code modifications increases ease of adoption for new policies. Hyperscalers need the ability to easily develop and debug a new policy implementation. To aid in this goal, they want to reuse existing swap stack implementations for components that are not critical to the policy (e.g., swap device implementations, swap device sharing, swap accounting). Once policies are developed, hyperscalers need the ability to roll them out to their fleet of servers; given fleet sizes, deployment speed of new policies (and any fixes to critical bugs) is critical. Once deployed, policy enforcement should operate with minimal overheads to limit potential regressions in application performance. Finally, if the policy has bugs, their impact should be limited in scope. Table 1 summarizes various paging designs with respect to these criteria. In the subsequent sections, we dig into these alternatives in more detail.

2.3 Kernel-level paging

Page reclamation. Page faults can be expensive (e.g., 4–10 μs for zswap [32] to tens/hundreds of μs for SSD), so minimizing refaults is crucial to avoid hurting application performance. The page reclamation policy determines what pages to reclaim and when, relying on past page access information to predict future demands. Reclamation policies rely on two key mechanisms: (1) per-page measures to order pages based on their re-access probability and (2) a control loop that determines which pages to offload by enforcing a threshold based on the perceived application performance impact.

Current hyperscaler reclamation reuses existing Linux kernel mechanisms based on various LRU approximations to

maintain page ordering. TMO [48] reuses Linux's active/inactive lists to track pages for on-demand reclamation. While efficient, these lists track page coldness at a very coarse granularity (active vs. inactive) and do not track page access counts. Recent improvements like MGLRU [6] enable a configurable number of levels, allowing for more fine-grained page coldness tracking. MGLRU also introduces page "aging" scans to scan page tables and constantly move pages from younger to older generations, rather than relying on memory pressure events. Another approach, employed by `g-swap` [32], maintains an implicit ordering based on a per-page coldness "age", which tracks time since the last access for every page. Similar to MGLRU, `g-swap` employs aging scans using its *kstaled* kernel thread; the resulting aging allows bucketing pages by coldness at a fine granularity. `g-swap` relies on a pre-configured age threshold to trigger reclamation.

To determine how many pages to offload, hyperscaler systems employ control loops to constantly monitor application performance impact metrics (e.g., `g-swap`'s refault rate or TMO's pressure stall information (PSI)) and adjust the offloading threshold accordingly. These control mechanisms are implemented in user space, and they use cgroup knobs like `memory.reclaim` or `g-swap`'s reclaim age threshold to inform kernel mechanisms.

Page prefetching. Prefetching offloaded pages that are likely to be accessed into local memory hides the high cost of refaults, which is especially useful for high-latency swap backends like SSDs. Current prefetch policies detect historical patterns in refaulted pages to guess simple trends like sequential or strided accesses. For example, Linux uses a simple read-ahead policy that looks for successive refaults to adjacent pages for sequential patterns; even minor levels of noise can throw off its trend detection. Prefetch aggressiveness, the number of pages to prefetch, depends on the number of hits seen for the previously prefetched pages.

As with reclamation policies, we want to support easy adoption of experimental policies. For example, the Leap [12] policy uses a more complex trend detection that can handle both sequential and strided patterns even in the presence of noise. Leap can achieve up to 0.7—37.5% higher prefetching coverage over Linux read-ahead, while maintaining similar accuracy for some workloads [12].

Challenges with kernel-based policies. Experimenting and adopting new policies written in the kernel is challenging. Deploying kernel changes across a large fleet is difficult, analogous to what warehouse-scale operators like Google already observed for CPU scheduling [28] and networking stacks [34]. Kernel rollouts even at a monthly cadence are "not well-tolerated" at Google [28]. This prevents both fast roll-outs for any critical bugs as well as rapid iteration with new policies. Furthermore, experimental policies or policies tailored to specific workloads are harder to upstream, requiring maintaining separate forks for new policies and a constant developer effort to keep them in sync with the upstream kernel. These challenges motivate the need for moving paging policies out of the kernel.

2.4 User-level paging

User-level paging is a well-known technique used to transparently manage OS pages from user space [2, 20, 27, 38, 40, 43, 54], typically supported by an interface like Linux's `userfaultfd` [3]. With `userfaultfd`, a user-space handler process can register to manage sections of an application's address space, causing the kernel to synchronously route all page operations (page faults, map, unmap, `madvise`, etc.) for these regions to user space. Combined with the ability to write-protect and unmap the pages at any time (using `madvise`), the handler can transparently back the registered memory regions with a custom swap mechanism. Policies can then be implemented in the handler process without any kernel involvement. However, this approach has several limitations, both in terms of overheads and compatibility.

First, by routing page faults through the user-space handler, the approach increases refault costs, directly impacting application performance. This overhead comes from the additional user-kernel transitions and the extra copy required to move the page data from the buffer provided by the user-space handler into the destination page. To quantify this overhead, we measure the cost of a zero-page fault (a fault that does not require servicing by the swap backend) for both `userfaultfd` and the kernel, focusing on the per-page fault overheads due to the interface. Figure 2 shows the median cost; while a kernel zero-page fault takes 1.2 μs, the same fault handled by `userfaultfd` takes 5.6 μs, with up to 4 μs spent waiting for the handler. For reference, fetching a page from zswap backend takes 6 μs at the median; `userfaultfd` would add more than 50% overhead to this cost. In §6.2, we show that overheads of even a few microseconds can entirely erase the performance benefit gained by avoiding refaults.

Second, memory regions managed through `userfaultfd` require custom swap backend implementations in the handler. Normally this is an advantage, as it allows for non-standard swap backends like cloud-based storage [2]. However, existing large-scale deployments like `g-swap` and TMO heavily rely on the kernel's swap subsystem for paging mechanisms, swap device implementations (like zswap [7]), swap device sharing, cgroup-based memory and swap accounting, etc. Moving this functionality outside the kernel requires significant development effort.

2.5 Custom library-based approaches

Flexibility in memory management has been well-explored in the RDMA-based far memory space [13, 19, 26, 39, 41, 45, 47, 53, 56]. Systems like DiLOS [53] and AIFM [41] and its derivatives [26, 45] completely bypass the OS and provide libraries/user-level runtimes for applications to use directly.

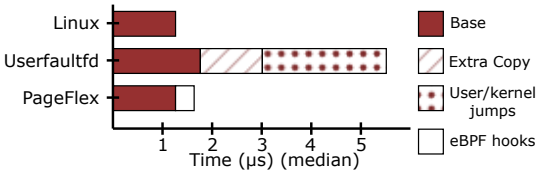

Figure 2: Cost of zero-page fault served from the kernel and from the `userfaultfd` handler.

By parceling everything within the application, they also limit the blast radius of any policy implementation bugs to the application.

However, library-based approaches introduce a custom memory interface that requires application modifications. They also introduce performance overhead even without any memory offloading, as they bypass the highly-efficient address translation hardware (TLB & MMU) and introduce additional dereferences for memory indirection in software, resulting in up to a 40% slowdown [45]. Note that, unlike the overhead caused by refaults (which can be traded off with memory savings), this overhead cannot be avoided. Like user-level paging, library approaches face compatibility challenges, as they, too, lift the entire swap infrastructure into user space and do not offer a clear solution for swap device sharing.

2.6 eBPF

eBPF (Extended Berkeley Packet Filter) allows user-defined programs to run within the Linux kernel, offering the flexibility to observe kernel activities and even customize their behavior without any overhead [10]. These programs are written in a C-like language, compiled into bytecode, and then verified by the kernel to ensure they are safe to execute. The programs are then "hooked" to specific points in the kernel (e.g., tracepoints, kprobes, etc.), triggering synchronous execution at those points. Data can be shared efficiently between eBPF programs and user space using eBPF maps. For safety, access to kernel data structures is not permitted unless explicitly whitelisted through specific access points, such as writable tracepoints [5]. eBPF has been widely used to unlock customization for various kernel subsystems like packet processing [24,46], file systems [17], process scheduling [28,31], storage [51,55], kernel locks [37] and even prefetching [21].

3 PageFlex Design

In this section, we first discuss our design goals and how they motivate PageFlex's design, followed by a detailed overview of PageFlex's mechanisms.

3.1 Design Goals

Our key goal is to enable writing new paging policies while meeting the hyperscaler paging goals discussed in § 2.2. More concretely, our solution requires the following considerations:

1. Compatibility: Our solution must coexist with current kernel-based policies and swap backends; i.e., some workloads running with the default policies and others using PageFlex but sharing the same swap backend.

2. Fail-safety: Failure of any PageFlex components (e.g., due to policy bugs) should not affect other workloads or even crash the apps whose policy is handled. This allows for safe, non-disruptive policy upgrades that are crucial for warehouse-scale deployments [28].

3. Minimal overheads: Any overheads introduced by the PageFlex infrastructure must be minimal. More importantly, overheads that directly impact the application performance must be negligible (i.e., background overheads are more tolerable).

To achieve these goals, PageFlex only externalizes non-critical policy decisions for prefetching and proactive reclamation to user space, while the kernel continues to provide core mechanisms for page access tracking, on-demand page fault handling and page reclamation. This division of labor achieves compatibility (1), unlike `userfaultfd` and library-based approaches. Also, because policy decisions are not critical to application functionality, PageFlex failures will not crash the application (2). Finally, PageFlex uses eBPF programs to provide a flexible, low-overhead view of in-kernel memory state to the externalized policy code. More specifically, policies run their performance-critical code inline with the kernel paths using eBPF to flexibly process the page events as they occur, without incurring the overheads of exporting large volumes of page event metadata to user space (3).

3.2 System Overview

Figure 3 provides an overview of PageFlex's design. At a high level, PageFlex consists of a kernel component (left half of the figure) with eBPF programs where policies run in-band with the kernel events to get a low-overhead memory view and arrive at paging decisions. This information is then shared out-of-band with a user-level component (right half) which is used to enforce these decisions and implement any non-performance critical policy infrastructure.

3.2.1 In-kernel policy execution

To provide a memory view, PageFlex tracks various basic paging events with explicit kernel tracepoints. Policies then subscribe to (any subset of) these events and provide event handlers that PageFlex runs synchronously with the paging events in the kernel as eBPF programs. We discuss these components below.

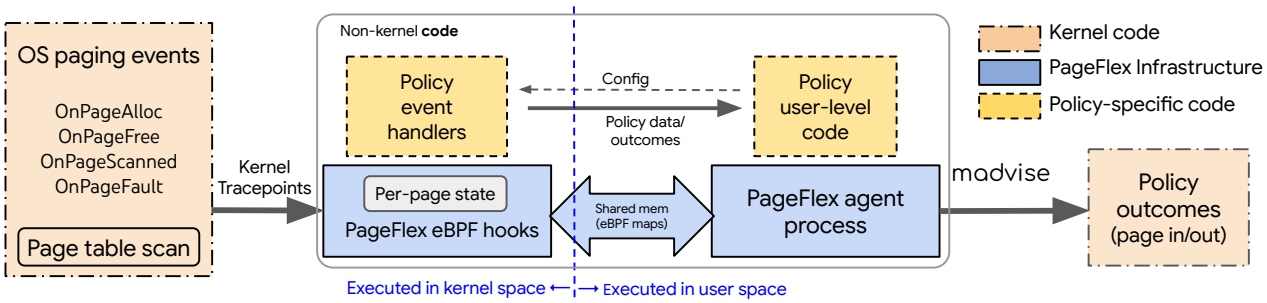

Figure 3: An overview of PageFlex's design showing various components. The policy control flows from left to right. The box in the middle indicates the components that support the policy code written outside the kernel code.

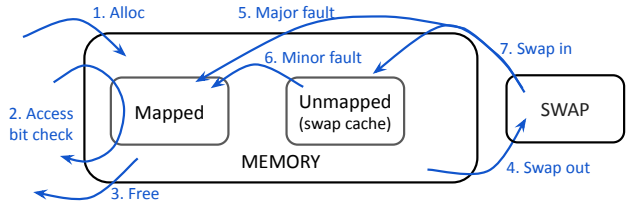

Figure 4: Paging paths (blue arrows) that PageFlex's events track for each page, as the page transitions between various memory states and the swap backend.

Kernel paging events. The left-most box in Figure 3 shows the set of in-kernel page events PageFlex provides for policy handlers to subscribe to. (Figure 4 shows all the page state transitions these events cover.) `OnPageAlloc` (arrows 1 and 7 in Figure 4) and `OnPageFree` (arrows 3 and 4) events are raised when a page enters or leaves the memory, either due to allocation or freeing by the application or being moved in from/out to the swap backend. These events are useful for keeping track of the current memory and swap state. For access information, PageFlex tracks two sets of events: for unmapped pages, `OnPageFault` (arrows 5 and 6) is raised when an unmapped page is requested by the process through a page fault (regardless of whether the page is mapped from the swap backend or the swap-cache)—it reports both swap-cache hit and miss events as both are useful access signals for prefetching (§2.3). For mapped pages, PageFlex periodically collects page access bits similar to `g-swap`. `OnPageScanned` (arrow 2) is raised for each page with information on whether it is accessed. Combined, these events provided the necessary information for all the policies we implemented (§6.3).

eBPF-based custom event handlers. Policies subscribe to (any subset of) the above events and provide custom handler functions that PageFlex runs inline with the events as eBPF programs. Allowing policy-specific handlers with eBPF avoids the need for indiscriminately tracing and communicating everything to user space. In fact, we will show that most policies can make their decisions in their event handlers and only export digested data (like policy outcomes to enforce or statistics for policy tuning in user space). The event handlers run synchronously with paging paths, potentially impacting application performance (e.g., slower page fault handling due to `OnPageFault` events). However, the overhead of eBPF programs is very little (<50 ns per eBPF invocation), allowing PageFlex to use them aggressively even in high-frequency paths. (We quantify the overhead of eBPF in §6.5.)

Low-overhead per-page state. Policies generally need to maintain per-page metadata as they learn from page accesses and make decisions over time. For example, `g-swap` keeps track of page ages for LRU ordering. As we will see in §4.1, most reclamation policies assign per-page scores that are updated over time based on page accesses. Such state can be maintained in user-space data structures (e.g., a hash table) or eBPF maps, however, these introduce overheads (i.e., lookups, additional memory). Fortunately, all the events traced in PageFlex are page-specific and the kernel page structures are already available for these events. Thus, PageFlex reserves a small space (4 bytes) in the kernel page structure for each page and provides safe and exclusive read/write access from the event handlers. This space also allows PageFlex event handlers to mark or track events for only a subset of pages based on policy-specific criteria. For example, online learning policies like LRB [42] may want to sample a subset of pages and track only those pages through their lifetime (e.g., send their access events to user space) for training their models. The state is limited (a 4-B state per each page incurs a fixed 0.1% memory cost, same as `g-swap`), however it is more than enough for most policies. By default, the state is reset when the page is swapped out, but policies can optionally persist the old state across reclamations if needed (at an additional memory cost of 0.1% incurred for swapped-out pages as well).

3.2.2 User-level policy control and enforcement

PageFlex employs a dedicated user-level agent process to initialize and run policies for the applications that opt in for PageFlex. The agent process loads the policy's eBPF handlers and lets policies configure them through eBPF maps. Policies

```
// Reclaim interface (per-page)
struct {} state; // 4B max
UpdateWeight(state, accessBit): {}
OnSwapIn(state, oldState): {}
  default { state = 0 }
OnSwapOut(oldState): {}
  default { oldState = 0 }

// Prefetch interface (per-page fault)
PredictTrend(page, isHit): {}
```

```
// Hyperbolic caching
struct { u8 hits; u8 age; } state;
UpdateWeight(state, accessBit):
    if (accessBit) state.hits++;
    state.age++;
    return (state.hits / state.age);

OnSwapIn(state, oldState): default
OnSwapOut(oldState): default
```

```
// Linux read-ahead
PredictTrend(page, isHit):
  if (isHit and page in prevWin) nHits++;
  // re-use linux function
  newWin = __swapin_nr_pages
        (lastPage, page, nHits);
  prevWin = newWin; lastPage = page;
  if (newWin) nHits = 0;
  return newWin; // to prefetch
```

Figure 5: PageFlex simplified interface for most policies (left) and example policy implementations (center and right).

can push events (e.g., page in/out decisions) to user space and handle them asynchronously with user-level handlers (e.g., issuing paging actions). Additionally, policies can perform any non-critical and complex functionality in their user-level code using the information passed from the event handlers, e.g., control loops used in page reclamation (§ 2.3). PageFlex enables two-way shared-memory communication between user space and the eBPF event handlers with eBPF maps.

Enforcing policy outcomes. PageFlex acts on the policy outcomes using `madvise` hints from the user-level agent to page in (for prefetching) or page out (for reclamation). Specifically, the agent process uses the `process_madvise()` wrapper to issue `madvise` hints against a different (process') address space. Using a hardened interface like `madvise` lets us avoid introducing new kernel infrastructure while still making the decisions outside the kernel. However, this introduces additional overhead due to extra user/kernel crossings when compared to the policy decisions made in pure kernel designs. E.g., in `g-swap` a kernel thread, *kreclaimd*, reclaims pages. We amortize these overheads by issuing `madvise` calls on batches of pages. (As shown in the results in §6.5, both prefetching and proactive reclamation paths do not directly affect application latency, allowing us to batch aggressively.)

Policy isolation. As in ghOSt [28], PageFlex provides separate "enclaves" for running different policies simultaneously for different groups of processes. Each enclave binds to a single Linux kernel cgroup and applies a single policy to all the processes in that cgroup. The enclave separation is provided in the event handlers (in eBPF), user-space code and in the communication between the two. This enables targeted policy application for select workloads while the rest continue to use the default kernel policy (while sharing the same swap backend). And, if at any point PageFlex fails (or during upgrades), the cgroup bindings are gracefully released without any effect on the attached processes. Additionally, because PageFlex uses the kernel's swap subsystem, existing kernel-based reclamation like `g-swap` can be configured to take over on failure, a feature `usefaultfd`-based designs cannot provide.

4 Policies in PageFlex

In this section, we first show how PageFlex enables writing prefetching and reclamation policies with varying degrees of specialization, followed by a discussion on the limits of its policy expressibility.

4.1 Unlocking policy customization

Proactive reclamation. We start with a goal of unlocking various eviction algorithms for hyperscaler reclamation systems like `g-swap` (described in §2.3) with PageFlex. To that end, PageFlex replaces `g-swap`'s per-page LRU age that defines eviction ordering with generic per-page *weights* that are policy-specific. PageFlex then lets the policies provide custom functions to update these weights—and the way weights are updated can implement a variety of policies. For example, an LRU ordering maintains the time since last access as the weight while, for LFU, it is the number of hits. Many other traditional eviction heuristics such as LRU-K [36], LRFU [33], LIRS [30], Hyperbolic [18], LHD [15], etc. can be similarly expressed as simple functions of the page accesses. Even more complex ones based on multiple queues [50] can be modeled by partitioning the weight space to represent different queues (our 4-B per-page state allows a 32-bit weight which is large enough in practice). PageFlex runs these policy-specific functions through its (eBPF) event handlers while maintaining the page weights in the low-overhead per-page state (described in §3.2), thereby achieving the flexibility to implement various eviction algorithms for `g-swap` without kernel changes.

Along with policy flexibility, PageFlex's mechanisms can also easily support policy-agnostic infrastructure that is required to support the reclamation policies. Like `g-swap`, PageFlex employs periodic page-table scans to collect page access bits and allow page weight updates, exports page-weight distributions using eBPF maps, and runs the control loop in the user-level agent to determine the eviction threshold. To simplify policies, PageFlex abstracts away this common infrastructure and provides the interface shown in Figure 5 for most polices (like above) that can work with simple update functions. The only required function is `UpdateWeight`, which is called periodically for each page after checking its access bit (provided as `accessBit`) and returns a new weight (see the example

for Hyperbolic caching [18] in the center). The function can maintain a small state (`state`) persisted as long as the page is in memory. By default, the `state` is reset once the page is swapped out. This works for most policies as they do not need the access history after a page gets reclaimed. Some policies, however, remember the order of recently reclaimed pages to maintain a ghost queue [50], while a learning-based policy may want to remember the tracked pages across reclamations, and `g-swap` remembers the page age when it was reclaimed, etc. To enable such policies, PageFlex optionally lets the policies customize the behavior at `OnSwapIn` and `OnSwapOut` to persist and retrieve the state (`oldState`). More specialized policies, however, may bypass this simplified interface and directly work with the core paging events described in § 3.2.

Prefetching. As discussed in §2.3, prefetching policies require page refault history for trend detection and predicting the next pages in the trend to prefetch, and the number of prefetching hits (through minor-faults) to adjust the predictions. PageFlex can provide both the signals with `OnPageFault` events. Similar to reclamation, PageFlex takes care of the policy-agnostic support like enforcing prefetching decisions while only requiring the policies to define a `PredictTrend` function, where they can detect any trend and return the pages to prefetch. The function could be marked to run directly in the eBPF event handler or in user-level code depending on complexity. Figure 5 (right) shows the Linux read-ahead policy implemented with PageFlex's simplified prefetching interface.

4.2 Application-specific policies

PageFlex further supports applying distinct paging policies to different continuous memory regions and execution phases within a user application. This capability is particularly beneficial for workloads with diverse memory access patterns. For example, two memory regions with distinct memory access patterns might exist in a graph processing application: graph edges are traversed sequentially, while vertices are accessed randomly. In such scenarios, applying separate prefetching (and reclamation) policies to the two regions can significantly enhance performance and memory savings.

Specialization in PageFlex is guided by application-provided hints. PageFlex offers an inter-process communication (IPC) interface, enabling authorized agents to provide these hints. Each hint message associates an existing PageFlex policy, along with specific parameters, to a designated memory region represented by memory addresses. With PageFlex's IPC client library, agents can be developed to monitor and analyze applications' memory access patterns (e.g., detecting sequentiality) and translate these observations into corresponding PageFlex hints (e.g., applying lookahead prefetching with a step size of *N*). Agents can be implemented within the application process or as independent, authorized processes running alongside the application. By providing hints

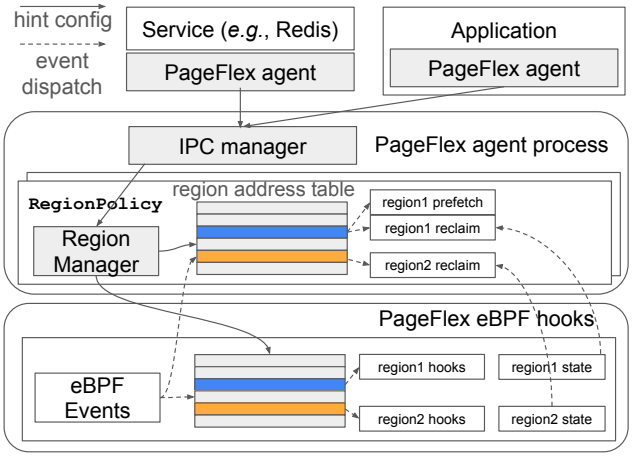

Figure 6: Control (solid line) and event dispatch (dotted line) paths for application specialization support.

to PageFlex for region creation/deletion or adjustments to prefetching/reclamation policies, applications can create specialized spatial and temporal and paging policies.

As illustrated by Figure 6, PageFlex enforces specializations through a new policy, *RegionPolicy*, which composes existing PageFlex policies and dynamically manages isolated sub-policies for specific memory address regions. Upon receiving a hint from an agent, PageFlex dynamically creates, updates, or removes sub-policies. Internally, PageFlex maintains a mapping table that associates memory regions with their corresponding sub-policies. To ensure correctness, the regions in this table are non-overlapping, and each region can be linked to at most one prefetching policy and one reclamation policy. PageFlex dispatches events to the appropriate sub-policies based on the virtual address of the accessed page, operating seamlessly across both user and kernel space.

4.3 Limits of policy expressibility

To avoid the CPU and memory overheads of exporting page access data to user space, PageFlex makes the design choice to limit the policy to eBPF programs which need to work with very limited state in the kernel. This may limit policies in some ways. First, writing complex policies could be challenging with eBPF due to verifier restrictions on program complexity (§ 2.6), limiting some policies such as LRB [42] which require ML model inference. Second, limited state such as the 32-bit per-page weights available to summarize a page's access history that are only accessible to eBPF code (as opposed to complex user-level data structures) could also limit the policies which work with more "information context". For example, a hypothetical policy that looks for spatial access patterns across the address space over time may be challenging to implement.

For such policies, PageFlex may still be used by shifting

the policy complexity to user space while the eBPF handlers merely export the necessary state instead of running the policy. However, in such cases, policies are left to account for the CPU/memory costs of exporting the state when weighing against the potential memory savings. It is worth noting that policy complexity generally translates to increased cost in making policy decisions to which paging policies are highly sensitive; as a result the increased cost may discourage such complex policies regardless of where they are implemented.

5 Implementation

PageFlex is implemented with a combination of Linux kernel changes, a user-space agent written in C++, and a collection of eBPF programs. We made 608 lines of changes to kernel code with most of it defining and introducing tracepoints at various paging events, and supporting the reserved field in the page `struct`. Excluding the policy-specific component, the agent constitutes 2,900 lines of C++ code and the eBPF programs are 700 lines of code to support the key components and the simplified policy interfaces.

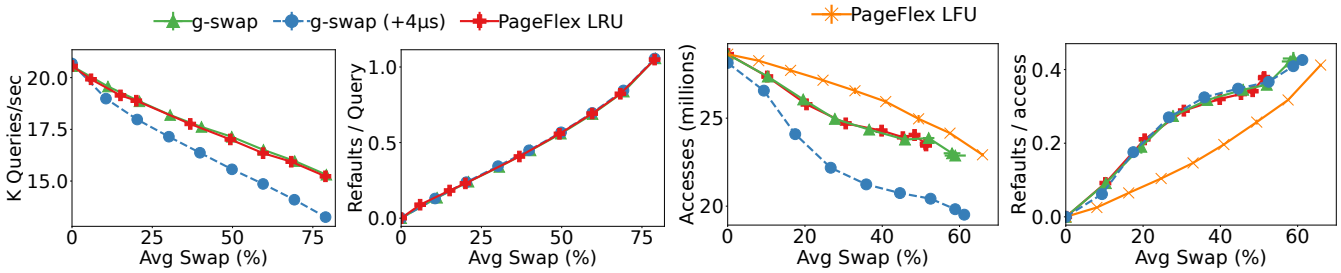
Tracepoints. We add tracepoints in the kernel code to support PageFlex's events (sometimes at multiple places for each event) and attach eBPF programs to run the event handlers where needed. Page allocations, frees, swap-ins and swap-outs are traced from cgroup page charge and uncharge functions that already track all possible ways pages enter and leave memory. Page-fault events are traced from page-fault handling code. For page-access scans, we depend on a kernel thread similar to `g-swap`'s *kstaled* whose period can be externally controlled. Currently, the thread scans all physical pages in the system in each scan; in future, this can be made cgroup-specific by moving to the (already-upstreamed) MGLRU's page-table-based scans [8]. All tracepoints export the `memcg` id of the page so PageFlex can target required cgroups and a writable pointer to the reserved field in the page `struct` (described below).

Per-page persistable state. To provide low-overhead per-page state for eBPF code, we reserve a 4-byte field in the kernel page `struct` (associated with for each page in memory) exclusively for eBPF use. By default, eBPF disallows writing to kernel data structures exported through the tracepoints. To allow write access, we use writeable tracepoints [5] that allow explicitly whitelisting specific (section of) kernel data structures (in our case, the reserved 4-byte field in the page `struct`) to be writable by eBPF programs. This is safe because we make sure this field is never read by the kernel so any data written by the eBPF programs has no effect on the kernel's operation. To persist the state across swap-outs (the page `structs` are freed for swapped-out pages), we re-use swap cgroup maps that already maintain cgroup ids for swap entries for cgroup-level swap accounting. When a page is swapped in, we retrieve the old state and provide it to the policy through the `OnPageAlloc` event.

eBPF maps. PageFlex extensively uses eBPF maps for eBPF/user space communication. For each policy, we use a `BPF_MAP_TYPE_HASH` map for policy configuration, `BPF_MAP_TYPE_ARRAY` map for statistics, and `BPF_MAP_TYPE_RINGBUF` for event notifications to trigger user-level handlers if needed. Policies may employ maps where needed, too. For policies in § 4.1, we use histograms modeled on hash maps to communicate page weight distributions. Region-aware policy in § 4.2 maintains a hash map to store the VMA segment to sub-policy association, which is traversed to find the right policy handler at each event. (Current implementation reserves 256 slots per enclave.)

6 Evaluation

In this section, we evaluate PageFlex for its flexibility and performance overheads. Specifically, we focus on the following high-level questions:



- Can PageFlex externalize current (kernel-based) policy implementations without negating their benefits?
- Is PageFlex flexible enough to support new policies? Specifically, can PageFlex enable specializing the policies, from general policy improvements that go beyond the current defaults like LRU to more tailored application-specific ones, and show improved memory savings?
- What overheads does PageFlex introduce, if any?

6.1 Testbed

We run experiments on a server fitted with two 24-core Intel Xeon E5-2696 CPUs each with 128 GB of memory. The server runs Linux 5.10 with PageFlex kernel changes discussed in §5. We use `g-swap` [32] as our kernel-based baseline for comparison. To ensure a fair comparison, we use the same kernel rebased with `g-swap`. Unless otherwise mentioned, we use zswap [7] as the swap backend. For a fast SSD-based swap emulation (with a 50-μs mean access latency), we use a block device supported by the Linux ublk driver using an SPDK Ublk target [11]. We use a combination of real-world benchmarks like Redis [4], RocksDB [22] and the GAP benchmark suite [14], and various synthetic workloads with a memory-access generator when evaluating application-level performance impact. For some long-running workloads, we first collect page-level access traces and replay them faster with the access generator (along with commensurate speedup in policy execution) where we need to collect a large number of data points; in such cases, we take care to only compare policy effectiveness (e.g., cache miss rate) and not raw performance (§ 6.3). Table 2 shows the list of workloads for which we collected page-level access traces by periodically scanning the page tables and logging the accessed

Trace group	#Traces	#Pages (M)	Max RSS (GB)	Span (hrs)	Scan interval (s)	Description
Redis	1	10	40	1	10	10-M keys, zipf skew = 0.5 workload
Memcached	4	1.3	5.2	1	60	10M 1024-B and 8-KB objs, sliding hotset
Database A	2	1	4	1	30	Proprietary SQL DB (like [44]) benchmark
Twitter KV	3	2.9–11.2	11.6–44.8	24-100	10	Twitter KV traces [49] played on Redis
Meta KV	4	2.8	11.2	24	10	MetaKV traces [9] played on Redis

Table 2: Traces used for evaluation of PageFlex policies. We collect the page-level access traces by periodically scanning the page tables, at a fine granularity (10-60 seconds) compared to their total running time (hours to days).

(a) Redis (b) Synthetic

Figure 7: Performance comparison of PageFlex's LRU with `g-swap`'s kernel-based implementations for (a) Redis with a zipf(0.5) client and (b) a memory access generator with an LFU-friendly workload. In each case, the left plot shows the raw application performance at various memory offloading targets and the right plot shows the refault rates for the same.

pages in each scan. We get these traces at a fine granularity (10–60 seconds) compared to their total running time which varies from hours to days. Where possible, we always batch the `madvise` calls to issue page-in or page-out hints for up to 64 pages. (We quantify the benefit in § 6.5).

6.2 Existing policies on PageFlex

We start with implementing existing policies on PageFlex to show that PageFlex can support these policies without causing any application slowdown compared to their functionally-equivalent kernel-based implementations.

PageFlex LRU vs `g-swap`. We use `g-swap`'s age-based reclamation as our kernel baseline and compare with PageFlex's LRU, which fully implements `g-swap` outside the kernel (§ 4.1). We run Redis with the memtier client, loaded with 10M keys with 1024-byte values (12 GB total memory), and measure its performance for requests drawn from a zipf(0.5) distribution. To compare policies at different degrees of memory offloading, we configure both systems to tune the age threshold based on a static memory reclamation target (i.e., a fraction of total process memory that should be swapped out).

Figure 7a (left) shows the Redis performance (queries per second) at various memory reclamation targets for both systems. The overall performance degrades with the increasing memory offloading as expected, as the refault rate per query (shown in Figure 7a right) increases. The performance of PageFlex's LRU is similar to `g-swap`'s LRU (within 0.98% of baseline) for all memory reclamation targets. The refault rates are also similar, showing their functional equivalence as well. To give a sense of the potential impact of `userfaultfd`-like overhead in the page swap-in path, we show the performance of `g-swap` modified to inject an additional 4-μs delay for each page fault, the overhead that `userfaultfd` introduces (§2.4). (Note that drawing an apples-to-apples comparison with real `userfaultfd` was infeasible, as it cannot use a kernel-based swap backend as PageFlexdoes; additionally, page access information is not yet available in `userfaultfd`). This result is significantly worse, slowing down the application by up to an additional 13.3% (for a similar refault rate), showing the importance of avoiding overheads in the page fault path. For reference, even a policy that randomly reclaims pages, which increases the refaults per query by 40% (to 1.4) at the rightmost point (80% swap), only incurs a 8.1% additional slowdown. Note that we only look at the direct impact to application performance here; we discuss the overheads added to the asynchronous policy work, which is similar across benchmarks, in §6.5.

To show another example where PageFlex can support a policy better suited for the workload, we use a synthetic memory access generator that generates page accesses from a skewed distribution interleaved with large sequential scans—a workload where pure recency-based eviction algorithms like LRU do poorly and LFU does better as it can filter out the noisy scans more effectively. We take measurements similar to Figure 7a, with the number of pages accessed in a fixed time (5-minute runs) as the performance metric. Figure 7b shows the results for the same configurations as above, as

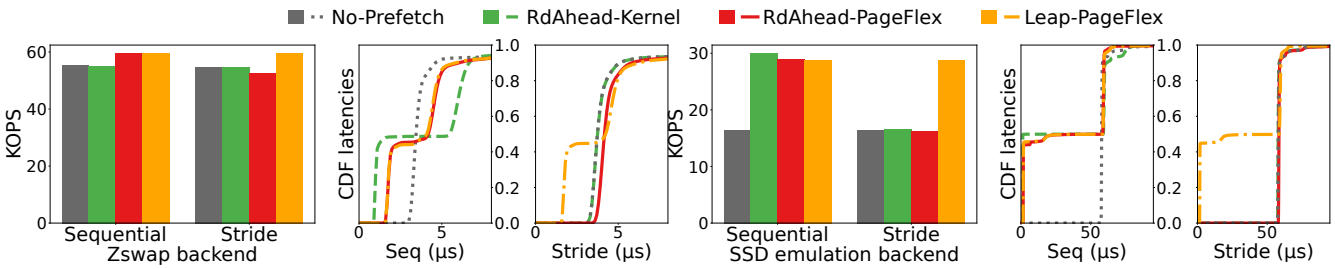


Figure 8: Page refault rate (pages/sec) and page fault latency distributions of a sequential and strided memory access patterns when working with various prefetching policies on two very different swap backends. Both kernel and PageFlex-based read-ahead improve the sequential performance but only Leap helps the strided one. The improvements are more significant with the emulated SSD backend.

well as LFU implemented with PageFlex. Both LRUs perform similarly worse compared to LFU, which degrades more gracefully with increasing memory offloading, due to the better miss rate shown in the right graph. For example, for a 10% slowdown (25.8 million accesses), LFU achieves 41% swap usage compared to LRU's 20% swap usage, providing 2× the memory savings. Emulated `userfaultfd` performance is again significantly worse than the baseline, potentially negating LFU's benefit (if it were to be implemented as a `userfaultfd`-based policy).

Linux default read-ahead with PageFlex. We externalize Linux's default read-ahead policy with PageFlex to quantify the overheads of running a prefetching policy on PageFlex. We implemented Linux's simple sequential trend detection and window size calculation in the `PredictTrend` function provided by our prefetching interface, which runs in the user-level code. The implementation consists of 61 lines, 41 of which were borrowed from the kernel code to perform window-size estimation.

To show policy equivalence and overheads, we use a synthetic benchmark with sequential and strided access patterns. The benchmark starts with a large dataset in the swap backend and promotes the data into memory with various fault patterns. Figure 8 (left) shows the rate at which the benchmark can promote the pages (with a 10-μs no-op work between the accesses) from a zswap backend. With sequential accesses, both kernel and PageFlex read-ahead prefetch half the pages as expected—we limit the prefetch window size to 1 in all cases. Figure 8 (second) shows the swap-in latency distribution. The no prefetching case (`No-Prefetch`) sees the standard zswap swap-in latency (3.5 μs at median) for most pages. For both read-aheads (`RdAhead-Kernel` and `RdAhead-PageFlex`), half of the pages see lower (minor-fault) latency due to a prefetching hit (1.08 μs for kernel and 1.85 for PageFlex at p25), whereas the other half see higher latency compared to `No-Prefetch` due to a miss. The kernel's miss latency (6.2 μs at p75) is twice as high as usual major fault, as the prefetches are synchronously issued with the original page fault and (unlike a block device-based swap backend) zswap's swap handling is also synchronous. PageFlex, however, prefetches asynchronously, incurring a miss latency closer to that of a major fault (`No-Prefetch`). For both hits and misses, PageFlex's latency is still slightly (0.5–1 μs) higher than the usual minor and major faults respectively—while a small fraction of it is PageFlex's eBPF overhead, we noticed that the interleaved `madvise` calls that do the prefetching from PageFlex's agent thread contribute to this overhead. Still, PageFlex's read-ahead is (inadvertently) faster than the kernel because of its asynchronous prefetching in the `sequential` case, but is slightly (3%) slower than the kernel, as expected, in the `strided` case with no prefetching.

The benefits of prefetching are more apparent with an SSD-like swap backend, where the cost of a major fault is much higher and prefetching makes a huge difference. Figure 8 (right half) shows the same results with an SSD emulation backend, where the swap-in latency is 58 μs at the median (for `No-Prefetch`) and both the read-aheads avoid this cost for half the prefetched pages. The kernel read-ahead promotes pages 82% faster than `No-Prefetch` for the `sequential` benchmark, and PageFlex's read-ahead is similarly (76%) faster. When not prefetching (in the `stride` case), PageFlex (at 16228 ops per sec) is only 0.8% slower than `No-Prefetch` (16364), adding very little overhead. In the figure, we also show the performance of the Leap [12] prefetching implemented with PageFlex (details in §6.3), which can capture strided patterns that the default read-ahead implementations cannot. In the `stride` case, only Leap prefetches (half) the pages as expected, and delivers higher performance over the both read-aheads on both the backends; the difference is starker in SSD emulation case with a 75.4% improvement (at 28,710 operations per second).

6.3 Beyond default policies

To demonstrate PageFlex's flexibility, we implemented two additional paging policies, Hyperbolic caching [18] and a version of Belady's MIN [16], as well as the Leap prefetching [12]. Table 3 shows the implementation complexity of

Kind	Policy	eBPF (LoC w/ simple interface)	User-level (LoC w/ simple interface)
Reclaim	LRU (`g-swap`)	6	0
	LFU	8	0
	Hyperbolic [18]	17	0
	Belady's MIN [16]	33	100
	Region-aware (§6.4)	95	204
Prefetch	Linux default	0	61
	Leap [12]	0	187

Table 3: Policies we implemented with PageFlex.

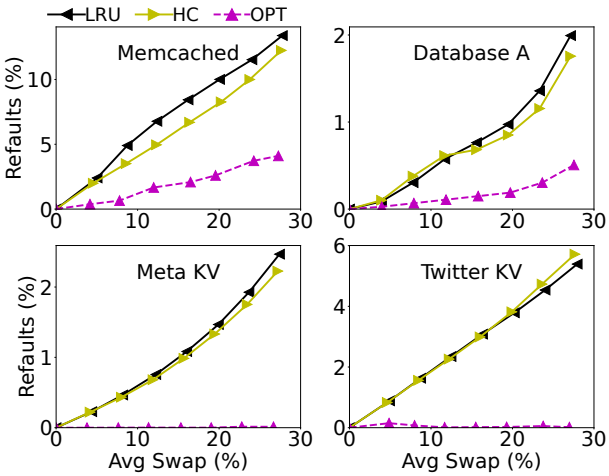

Figure 9: Refault rates for LRU, Hyperbolic (HC) and Belady's MIN policies with PageFlex for various page access traces, for memory offload targets up to 30%.

each.

Hyperbolic caching [18] is a recent cache eviction policy that introduces *hit density*, a new metric defined as the ratio of the number of accesses seen to the age of the page in the cache, to order the pages for eviction (lower hit density gets evicted first). Hyperbolic requires 17 LoC as shown in Figure 5 (center).

Belady's MIN [16]. We also implemented Belady's MIN [16] with a page access oracle based on the traces; this policy is not practical for real applications, but serves as a good representative for complex learning-based policies like LRB [42] from an implementation flexibility standpoint. Our MIN implementation re-uses our generic model with one difference: the `UpdateWeight` function performs a lookup to a table with distance to the next access for all pages (installed before each scan by the user-level code with access to the trace); one can imagine a policy that uses a learned ML model like LRB [42] to predict the same information.

We evaluate the performance of the above policies (i.e., refault or miss ratio at a given amount of offloaded memory) on the traces shown in Table 2. Figure 9 shows the observed refault rate (normalized to trace length) against average swap usage for one representative trace from each group (the results for other traces in the group are similar). Hyperbolic caching (HC) does slightly better than LRU for Memcached, Meta KV and in some regions of Database A. With Memcached, for example, Hyperbolic allows up to 5% more memory savings at a certain refault rates (e.g., 7%). For all the traces, there is a big gap between either of these policies and MIN, suggesting opportunity for better policies, as we also noted in §2.3.

Leap prefetching [12]. To show prefetching flexibility, we re-implemented the Leap prefetching with PageFlex. We implemented Leap's complex trend detection (§2.3) entirely in the `PrefetchTrend` function provided by our prefetching interface, where we re-used most of the trend detection logic from the original Leap implementation [1]. This required 187 lines of policy-specific code, out of which 160 were copied from the original Leap code. We discussed the resulting prefetching improvements at the end of §6.2.

6.4 Application-specific policies

We demonstrate PageFlex's flexibility in supporting specialized policies with spatial/temporal workload awareness with the help of two case studies.

Policy specialization in a key/value store. Meta's study [22] demonstrates that key/value store access patterns exhibit significant non-uniformity, with strong key-space and temporal locality. We reproduce the access patterns from the original study [22] using the db_bench tool, focusing on two scenarios: 1) *Region (key-space) hotness pattern*, where different memory regions are assigned varying eviction thresholds. We implement a PageFlex agent that monitors the hotness in different application-defined regions. This agent uses an LRU policy for all regions but sets distinct reclamation thresholds based on observed region hotness. We assume the KV store logically maps its key space onto the address regions (hence patterns), for example, by using key-range-based heap segregation or by re-organizing/compacting key/value pairs. 2) *Phase change pattern*, where the access pattern changes from random access to sequential scan during the runtime. We implement an agent that dynamically switches the reclamation policy from the default LRU to MRU accordingly. We then compare the average memory savings for these specialized policies with the default LRU policy, while keeping the KV performance target the same for all policies. As shown in Figure 10-left, the specialized policies achieve up to 36% more memory savings than the default LRU policy.

ExtMem [29] policies for PageRank. ExtMem introduced a specialized compound reclaim and prefetch policy designed for the PageRank workload within the GAP benchmark suite [14]. This policy targets a specific memory region within the application, the "edge array", applying sequential eviction and prefetching to optimize performance. To leverage this policy with PageFlex, we implemented an agent within the application that sends hints to PageFlex upon creation of

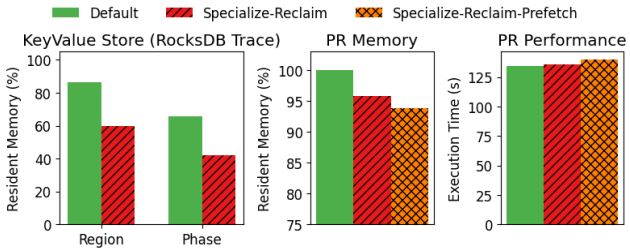

Figure 10: Specialized policies in KV store and GAPBS PageRank.

the edge array. This agent assigns a lookahead prefetching policy and an MRU reclamation policy to the edge array region. All other regions use the default LRU reclamation policy. This agent requires adding approximately 10 lines of code to the application, with no modifications required within PageFlex. This specialized policy reduces memory usage by 6.4% (Figure 10-middle) compared to a uniform LRU policy, with a performance overhead of less than 2% (Figure 10-right).

6.5 PageFlex Overheads

PageFlex runs most policy infrastructure asynchronously and overheads introduced in these paths do not directly cause application slowdown (as we have seen so far), but they still increase the resource usage, which could be a concern. We discuss these overheads below.

Page table scanning overhead. Recall that PageFlex employs a kernel thread to periodically scan page tables to inform page access information with `OnpageScanned` events. These scans are CPU-intensive and any increased overhead could limit how often a policy can choose to run these scans, affecting its efficacy. To isolate the overhead added by PageFlex's eBPF hooks, we compare the CPU usage for each scan in the Redis experiments from §6.2, where we compared PageFlex LRU and `g-swap`. While `g-swap`'s scans take 0.72 seconds (on 1 CPU core) on average to scan 12 GB of memory, PageFlex scans average 0.87 secs, a 17% increase due to the eBPF invocation for each page scanned (≈50 ns per invocation). Note that the relative overhead is constant regardless of the application's memory footprint. Unlike PageFlex, `userfaultfd` does not provide page access information.

Paging from user space. Unlike kernel-based policies, policy outcomes in PageFlex are enforced from the user-level agent, incurring extra syscall overhead for calls to `madvise`, which we amortize with batching. To quantify the overhead, we compare the work done by PageFlex's agent for reclaiming pages to that of `g-swap`'s *kreclaimd* thread which reclaims pages directly in the kernel. While *kreclaimd* spends an average of 4.3 μs to offload a page to zswap, PageFlex takes 6.9 μs to do the same from the agent, a 57% increase. However, after batching the offloading with one `process_madvise` call per 64 pages, the cost comes down to an amortized 4.9 μs per page, a 14% overhead. Note that, assuming similar paging costs, `userfaultfd` would incur a similar user-kernel crossing overhead for its syscalls, in addition to the cost of extra page copying per syscall.

7 Conclusion

Paging policies determine how much memory can be offloaded within a performance target. Existing deployments employ OS-based policies, making it slow and risky to evolve them in hyperscaler data centers. User-level designs such as `userfaultfd` and library-based approaches can provide better policy flexibility by completely externalizing paging, but they introduce practicality concerns such as significant performance overheads or incompatibility with existing deployments. To address these issues, PageFlex carefully separates the paging policy from the underlying mechanisms, and delegates the policy to eBPF programs, thereby providing policy flexibility while keeping the overheads low. We show that PageFlex enables writing prefetching and reclamation policies with varying degrees of specialization, and with virtually no impact on application performance.

Abstract

How can one build a *feature-rich*, *general-purpose*, Rust-based operating system (OS) with a *minimal* and *sound* Trusted Computing Base (TCB) for *memory safety*? Existing Rust-based OSes fall short due to their improper use of `unsafe` Rust in kernel development. To address this challenge, we propose a novel OS architecture called *framekernel* that realizes Rust's full potential to achieve *intra-kernel privilege separation*, ensuring TCB minimality and soundness. We present OSTD, a streamlined framework for safe Rust OS development, and ASTERINAS, a Linux ABI-compatible framekernel OS implemented entirely in safe Rust using OSTD. Supporting over 210 Linux system calls, ASTERINAS delivers performance on par with Linux, while maintaining a minimized, memory-safety TCB of only about 14.0% of the codebase. These results underscore the practicality and benefits of the framekernel architecture in building safe and efficient OSes.

1 Introduction

Despite three decades of research into defending against memory safety bugs in operating systems (OSes) written in C, achieving true memory safety remains elusive. This was starkly demonstrated by the recent CrowdStrike outage [11], where millions of Windows PCs crashed due to an out-of-bounds memory access in a faulty driver. It is estimated that 60-70% of security vulnerabilities in system software written in C stem from memory safety issues [30].

In recent years, as the Rust programming language matures and becomes popular, the development of Rust-based, memory-safe OSes has gained momentum. Rust offers memory safety guarantees through innovative language features such as ownership, borrowing, and lifetimes, enabling safe memory management without relying on garbage collection. Many now see Rust as a potential successor to C and C++ as the dominant systems programming language. With the endorsement of Linus Torvalds, the Linux kernel has officially adopted Rust as its second programming language [18] and integrated the Rust for Linux [41] (RFL) project to facilitate writing "leaf" kernel modules in Rust. Additionally, new OS kernels like Tock [38], RedLeaf [49], and Theseus [16] are built from the ground up using Rust, further demonstrating Rust's potential in this domain.

Table 1: The `unsafe` keyword is widely utilized in the crates (or kernel modules) of existing Rust-based OSes. The statistics were derived from an analysis of the latest source code of these OSes at the time of writing.

Rust-based OSes	Linux	Tock	RedLeaf	Theseus
`Unsafe`-utilizing crates	6 / 11[1] (55%)	91 / 98 (93%)	36 / 58 (62%)	54 / 171 (32%)

[1] This includes the RFL crate and 10 notable Rust-written kernel modules [3].

While adopting Rust is a significant step toward achieving kernel memory safety, this is insufficient on its own since Rust-based OSes must include unsafe Rust code. The safety of the kinds of low-level controls required by kernel programming cannot be statically verified by the Rust compiler and thus is only allowed by Rust within special code blocks marked by the `unsafe` keyword. Despite the Rust language team dedicating an entire book [25] to the "dark arts of unsafe Rust", developers are still prone to misusing it, and the RustSec Advisory Database has recorded hundreds of bugs stemming from `unsafe` misuse [60].

To mitigate the risks associated with `unsafe` in Rust, two widely accepted best practices have emerged [12]: (1) use `unsafe` sparingly and (2) encapsulate `unsafe` code within safe abstractions. However, we have found that existing Rust-based OS kernels often fall short of these standards. Unsafe Rust code permeates a significant portion of a Rust-based OS. We observe that `unsafe`-utilizing crates make up 55%, 93%, 62%, and 32% of all crates in Linux, Tock, RedLeaf, and Theseus, respectively (as shown in Table 1). Although

*Co-first authors.

†Co-corresponding authors: Yinqian Zhang (yinqianz@acm.org); Shoumeng Yan (shoumeng.ysm@antgroup.com); Yingwei Luo (lyw@pku.edu.cn).

kernel developers generally view `unsafe` as a "necessary evil", we question whether such widespread use of `unsafe` is truly necessary. In particular, we challenge the necessity of `unsafe` in device drivers (as seen in all existing Rust-based OSes), which account for the majority of the codebase of a mature OS (70% in Linux [17]). Details about the pitfalls of `unsafe` handling in existing Rust OSes will be present in §2.

Given the limitations of prior work, we pose the question: is it possible to build a feature-rich, general-purpose, Rust-based OS kernel almost entirely in safe Rust? We introduce *framekernel* (§3), a novel OS architecture designed to achieve a minimal and sound TCB for a Rust-based OS. In the framekernel architecture, the entire OS resides in a single address space (as in a monolithic kernel) and is implemented in Rust. The kernel is logically divided into two parts: the *privileged* OS framework (akin to a microkernel) and the *de-privileged* OS services. Only the privileged framework is allowed to use `unsafe`, while the de-privileged services must be written in safe Rust completely. As the TCB, the privileged framework encapsulates all low-level, hardware-oriented `unsafe` operations behind safe APIs. Using these safe APIs, the de-privileged OS services can implement all kinds of OS functionalities, including device drivers. A framekernel minimizes the TCB size without incurring extra overheads due to hardware isolation. Thus, we claim that a framekernel combines the benefits of both a monolithic kernel and a microkernel (see Figure 1).

We enforce this *language-based, intra-kernel privilege separation* by systematically identifying *sensitive* OS resources, namely those that can be mis-programmed or misused to compromise memory safety – even with safe Rust. Thus, the design principle of a framekernel is to *keep sensitive OS resources within the privileged framework for soundness, while delegating insensitive OS resources to the de-privileged OS services for minimality*.

To realize the vision of framekernels, we develop OSTD (§4), the privileged OS framework required by a framekernel. OSTD provides a *small yet expressive* set of safe OS development abstractions, covering safe user-kernel interactions, safe kernel logic, and safe kernel-peripheral interactions. Of particular note is the *untyped memory* abstraction, which addresses the challenge of safely handling *externally-modifiable memory* (e.g., MMIO or DMA-capable memory) – a longstanding obstacle in safe driver development. In addition, we introduce *safe policy injection*, a technique that separates potentially complex "policy" components (e.g., task schedulers, page allocators, and slab allocators) from the core "mechanisms" of OSTD, thus containing the growth of OSTD's complexity over time. Furthermore, we define a set of key *safety invariants* that collectively ensure the soundness of OSTD's privilege separation.

To demonstrate the practicality and benefits of framekernels, we develop ASTERINAS (§5), a Linux ABI–compatible framekernel built on OSTD. ASTERINAS implements a rich

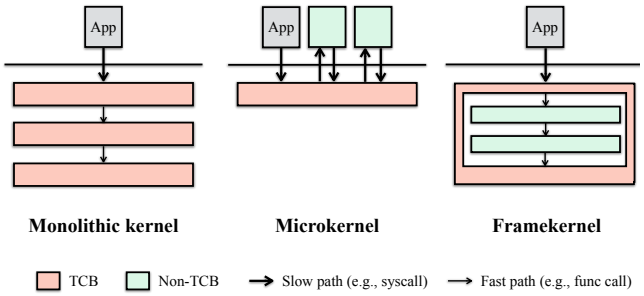

Figure 1: A framekernel combines the speed of a monolithic kernel and the security of a microkernel. The memory-safety TCB of a framekernel is reduced to the privileged OS framework (akin to a microkernel) without any communication overheads due to extra hardware-based isolation (similar to a monolithic kernel). We depict the TCB portion of a framekernel as a "frame" to highlight the fact all low-level interactions of non-TCB with the hardware (beneath the "frame") and the user space (above the "frame") is mediated by the TCB.

subset of Linux functionality: it supports over 210 Linux system calls, multiple file systems and socket types, and a variety of peripherals (e.g., disks and NICs). All these features are written in safe Rust, leveraging OSTD's APIs. ASTERINAS has been under development for three years. The repository of ASTERINAS and OSTD is open source [1, 2], containing over 100K lines of Rust code contributed by more than 50 individuals.

We conduct a thorough evaluation (§6) of ASTERINAS and OSTD across three dimensions: performance, TCB size, and soundness. ASTERINAS delivers performance on par with Linux: on LMbench, a syscall-intensive microbenchmark, ASTERINAS achieves a mean normalized performance score of 1.08 (relative to Linux, higher is better); for three I/O-intensive applications, Nginx, Redis, and SQLite, it delivers a normalized performance of 1.17, 1.31, and 0.85, respectively. The framekernel design also yields a lean TCB: ASTERINAS's TCB accounts for just 14.0% of its codebase, versus 43.8% in Tock, 62.4% in Theseus, and 66.1% in RedLeaf. Finally, to strengthen our confidence in OSTD's soundness, we develop KERNMIRI, a retrofitted version of Miri [48] for Rust OSes, which is used to detect potential safety issues in OSTD systematically.

Contributions. In summary, this paper makes the following contributions:

- We propose framekernel, a novel OS architecture that combines the benefits of both monolithic and microkernels by enforcing Rust-based intra-kernel privilege separation.
- We develop OSTD, a small and sound OS framework to facilitate OS development in safe Rust.
- We develop ASTERINAS, a highly-optimized, Linux ABI-compatible OS based on OSTD.

- We conduct extensive evaluations to show the performance, TCB size, and safety of both ASTERINAS and OSTD.

2 Background and Motivation

2.1 The Rusty Way to Safety

Rust is an efficient system programming language that offers strong guarantees for memory, type, and thread safety without compromising runtime performance, thanks to its strong type system and unique ownership model.

Ownership, borrowing, and lifetime. In Rust's ownership model, each value has a single owning variable, and the value's lifetime is tied to the owner's scope [10]. When the owner goes out of scope, the value is dropped. Ownership can be borrowed through references, subject to lifetime constraints enforced by the compile-time borrow checker.

Type system. The Rust compiler implements a tailored type system coupled with comprehensive compile-time checks [7, 9]. Utilizing type information, the compiler ensures that all accesses occur within valid lifetimes, generates correct memory offsets, and performs bounds checking, thereby guaranteeing both temporal and spatial memory safety.

Unsafe Rust. To offer additional expressive power, Rust provides the `unsafe` keyword, enabling programmers to bypass compile-time checks and thus shifting the responsibility for ensuring safety to those using `unsafe` code blocks [8].

Undefined behaviors. Undefined behaviors (UBs) in Rust refers to operations that compromise the language's correctness and safety guarantees, including memory safety, thread safety, and type safety. The Rust Reference book enumerates common UBs [6], e.g., data races, memory access based on dangling or misaligned pointers, out-of-bound memory access, breaking the pointer aliasing rules, and mutating immutable bytes. However, this list is neither comprehensive nor precise due to Rust's lack of a formalized specification. The Rust language team maintains an official UB detection tool called Miri [48], which, as part of the Rust toolchain, serves as a de-facto executable standard for UBs. Although Miri can effectively detect UBs in standard Rust applications, Miri is not applicable to Rust-based OSes as its design does not take into account the needs of low-level system programming, particularly in areas of memory management and hardware interaction. This work aims at systematic identification and prevention of UBs in the context of Rust OSes.

2.2 Rustification of Mainstream OSes

The efficiency and safety of Rust make it an attractive choice for developing OSes, leading to several mainstream OSes [29, 41, 54] integrating Rust into their codebases. The Rust for Linux (RFL) project [41] stands out as a prominent example.

RFL aims at establishing Rust as the second official language of the Linux kernel, allowing developers to write "leaf" kernel modules in safe Rust. Officially merged into Linux in 2022, RFL has laid the groundwork for Rust integration by 2024 [40]. Notably, three Rust-written device drivers, albeit basic, have already been added to the kernel tree [39].

Despite this progress, the unsafe nature of Linux remains. By design, RFL has to offer safe Rust abstractions over Linux's extensive legacy C APIs, resulting in substantial use of `unsafe` Rust. A recent study [39] notes that RFL already has 19K lines of Rust code upstream, with an additional 112K lines staged for upstream inclusion. A great portion of RFL is devoted to unsafe Rust code that interacts with the legacy C APIs. As RFL expands to cover more subsystems and their C APIs, we expect its codebase to grow to hundreds of thousands of lines. Therefore, the TCB size of RFL is substantial, even not considering Linux's huge C core and the countless C kernel modules around it.

> **Lesson Learned:** Constructing safe Rust abstractions on a legacy monolithic kernel inevitably requires a substantial use of `unsafe` Rust.

In addition to the inflated TCB size, the burden of a huge legacy codebase - its status quo and established philosophy - constrains the effectiveness of Rust and the soundness of RFL. This constraint leaves known soundness vulnerabilities unresolved in RFL. For example, Rust explicitly excludes memory leaks from its memory safety guarantees, permitting objects to be forgotten. However, it was discovered that forgetting RFL's mutex guards can trigger use-after-free vulnerabilities [55]. This vulnerability arises from conflicting API contracts between C and Rust regarding mutex unlocking obligations, so neither side is willing or capable to fix it. Another example of a soundness issue stems from Linux's (and by extension RFL's) tolerance for sleeping in atomic contexts such as spinlock or RCU-lock held regions. Sleep-in-atomic-context bugs may cause data races in RCU-protected memory accesses, undermining Rust API safety guarantees [31]. These unresolved soundness issues reflect the Linux community's traditional value of "pragmatism over safety" [31], creating fundamental tensions with Rust's security-first paradigm.

> **Lesson Learned:** Achieving sound memory safety requires a clean-slate OS that prioritizes safety above all else.

2.3 Clean-Slate Rust OSes

Clean-slate Rust OSes like Tock [38], RedLeaf [49], and Theseus [16] strive to fully leverage Rust's features to improve OS safety and reliability. However, they face a notable limitation: inadequate support for safe driver development. As shown in Table 2, device drivers in these systems frequently rely on `unsafe` code to manage low-level resources, such as raw data buffers, MMIO, I/O ports, and DMA regions. Given that drivers typically constitute the largest portion of

Table 2: Representative `unsafe` Rust code pattern in drivers

	Resource *access* within `unsafe` blocks	Resource *acquisition* within `unsafe` blocks
Tock	`// chips/nrf52:` `buf[idx] = *byte_ptr`	`// chips/nrf52:` `StaticRef::new(ptr)`
RedLeaf	`// lib/devices/ixgbe:` `ptr::read_volatile(addr)`	`// lib/devices/tpm:` `MmioAddr::new(base,len)`
Theseus	`// kernel/pci:` `pci_port.write(val)`	`// kernel/ixgbe:` `Box::from_raw(ptr)`

an OS codebase, extensive use of `unsafe` code significantly heightens the risk of memory safety vulnerabilities.

Lesson Learned: Safe driver development requires safe abstractions for acquiring and accessing low-level system resources.

Among the three Rust OSes, Theseus minimizes `unsafe` code through its `MappedPages` abstraction, which represents the *exclusive* ownership of a virtually-contiguous memory region backed by some *exclusively*-owned physical frames. This exclusiveness alone (seemingly) preserves the safety of Rust references (e.g., `&T`) borrowed from that range. However, this design overlooks *sensitive* or *externally-modifiable* memory. For example, using `MappedPages` to modify the sensitive memory of Local APIC may cause unpredictable CPU behavior (e.g., sending an IPI that resets a CPU). Similarly, Theseus drivers create Rust references (`&T`) to MMIO device memory, an unsound practice since such references assume no external modifications, which hardware may violate.

Lesson Learned: Rust OSes must develop safe abstractions for memory that is subject to external modifications, such as hardware, user programs, or DMA.

Finally, while language-level UBs are effectively addressed by Rust's safety guarantees, UBs stemming from execution environments or CPU architectures remain unresolved in existing Rust-based OSes. For example, a malicious device could corrupt kernel memory via DMA [44] or spoof interrupts to manipulate CPU trap handlers [63]. Similarly, a stack overflow could compromise the execution environment—an issue beyond the detection capabilities of safe Rust.

Lesson Learned: Rust OSes should safeguard against UBs not only at the language level but also at the architectural and environmental levels.

3 Framekernel Architecture

We introduce *framekernel*, a novel OS architecture that combines the benefits of both monolithic kernels and microkernels by fully leveraging the modern safe system language of Rust. In a framekernel OS, the entire OS kernel resides within a single address space, akin to a monolithic kernel, and is implemented in Rust. The kernel is logically divided into two parts: the *privileged OS framework* (similar to a microkernel) and the *de-privileged OS services*. Only the privileged framework may use Rust's `unsafe` features, while the de-privileged services are built entirely in safe Rust. The privileged framework encapsulates low-level, hardware-oriented unsafe operations into safe APIs, using which the de-privileged services implement most OS functionalities, including drivers, in safe Rust. Like a monolithic kernel, all components within a framekernel communicate efficiently (e.g., via function calls or shared memory). By restricting the privileged framework to a minimal set of functionalities, framekernels, like microkernels, reduce the size of the TCB, thereby enhancing safety, security, and reliability.

Design philosophy. At the heart of the framekernel architecture is *intra-kernel privilege separation*: although OS services operate in privileged CPU mode, their behaviors are constrained by safe Rust and the privileged framework, maintaining their de-privileged status. Only flaws within the privileged framework can jeopardize the kernel's memory safety. This intra-kernel privilege separation must uphold two key properties: soundness and minimality.

Soundness: The OS framework guarantees the absence of UBs under all circumstances, irrespective of interactions with OS services, user code, or peripheral devices.

This property aims to prevent all forms of UBs, which may originate at three levels (from high to low). First, **language-level UBs** in Rust are described in §2.1. Second, **environment-level UBs** arise when the code, stack, or heap is corrupted. Programming languages have implicit assumptions about their execution environments; UB occurs if those assumptions are compromised. Third, **architecture-level UBs** stem from incorrect use of CPU or hardware devices, such as improperly saving/restoring CPU registers, misconfiguring page tables, or allowing peripheral DMA to corrupt memory.

Minimality: A component is tolerated inside the OS framework only if moving it outside would prevent the implementation of OS services' required functionality or compromise soundness of the framework.

This property focuses on minimizing the principal component of the *runtime TCB* responsible for kernel memory safety. Naturally, the whole TCB extends beyond the OS framework itself, also including the Rust toolchain, the Rust core libraries, bootloader, and firmware involved in loading a framekernel, as well as the CPU plus some core devices (e.g., interrupt controller and IOMMU). The software and hardware outside the TCB, including the safe OS services, user-space programs, and peripheral devices (e.g., disks, NICs, and GPUs), are not trusted.

Towards effective privilege separation. Realizing intra-kernel privilege separation prompts a key question: *What must stay inside the framework (for soundness), and what can be moved outside (for minimality)?*

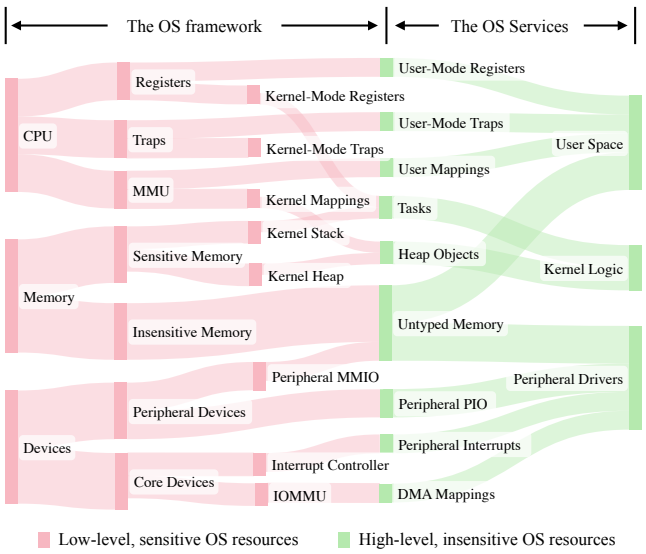

Figure 2: A blueprint for framekernel construction in a *resource*-centric view. The nodes represent OS resources, while the edges depict classification and encapsulation. The concept of untyped memory will be introduced in §4.2.

To answer this, we view framekernel construction from a *resource*-centric perspective, as shown in Figure 2. Fundamentally, an OS manages three classes of resources: CPU, memory, and devices. At first glance, these resources are all **sensitive** because the kernel code could misuse them (even in safe Rust) and break memory safety. However, deeper inspection shows that some subsets of these resources are actually **insensitive**. Thus, we *must keep sensitive resources inside the framework (for soundness) and should move insensitive ones outside (for minimality).*

All three classes of fundamental resources can be split into sensitive and insensitive subsets. **CPU** resources involve kernel-mode and user-mode control; the former is considered sensitive, while the latter (e.g., user-mode registers, user-mode traps) is insensitive because it cannot directly undermine kernel state. Furthermore, the user virtual address space is insensitive as manipulating the user virtual memory does not affect kernel memory safety. **Memory** resources include sensitive memory used for the kernel's code, stack, heap, and page tables, whereas memory dedicated to untrusted user processes or devices is insensitive because kernel safety does not depend on its integrity. **Devices** present a similar division, as core devices (e.g., APIC, IOMMU) are sensitive due to their machine-wide control, but peripheral devices (e.g., NICs, GPUs) are generally insensitive; a misconfigured core device can compromise the entire kernel, but failures in a peripheral device are typically confined to that device itself.

These observations inform a blueprint for framekernel construction (Figure 2). The blueprint *classifies* OS resources into sensitive and insensitive ones at a fine granularity, with low-level, sensitive ones *hidden* inside the privileged OS framework or *encapsulated* into high-level, insensitive ones. The net result is that the privileged OS framework only exposes to the de-privileged OS services a small set of insensitive resources that is sufficient to support the three primary needs of safe OS development: (1) safe user-kernel interactions, (2) safe kernel logic, and (3) safe kernel-peripheral interactions. This blueprint guides the design of OSTD.

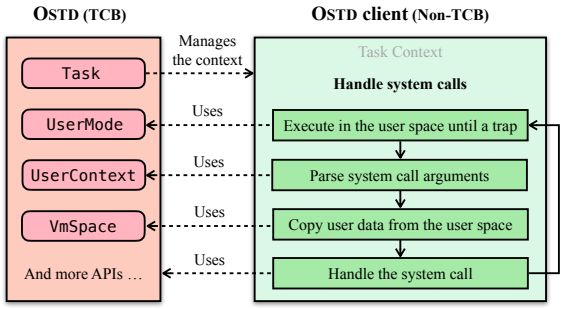

Figure 3: An example of OSTD APIs: system call handling

4 OSTD

In this section, we present OSTD, which is our implementation of the framework required by a framekernel. First, we provide an overview of OSTD's APIs. Then, we describe how OSTD manages physical memory pages (frames), a key foundation of OSTD's soundness. Next, we define the key safety invariants for OSTD to achieve the language-based, intra-kernel privilege separation. Lastly, we introduce the technique of safe policy injection, which confines the complexity growth of OSTD as it evolves.

4.1 Expressive APIs

OSTD provides a small set of expressive abstractions to meet the needs of safe OS development. These abstractions are implemented as OSTD APIs, which are utilized by OSTD clients – safe kernel code that interacts with the OSTD. For **safe user-kernel interactions**, it allows an OSTD client to jump into the user space and execute until a trap occurs (`UserMode`), manipulate user-mode CPU registers (`UserContext`), and manage user address spaces (`VmSpace`). For **safe kernel logic**, it includes synchronization primitives (e.g., `SpinLock`, `Rcu`, `Mutex`, `WaitQueue`, and `CpuLocal`) and efficient data collection types (e.g., `LinkedList` and `RbTree`). For **safe kernel-peripheral interactions**, it offers mechanisms to register interrupt handlers (`IrqLine`), perform MMIO and PIO (`IoMem` and `IoPort`), and create coherent or streaming DMA mappings (`DmaCoherent` and `DmaStream`). All three of these OS development aspects may allocate and access physical pages, referred to as **frames**, via `Frame` (one frame) or `Segment` (multiple contiguous frames).

We illustrate a simplified workflow of how system calls may be handled safely with OSTD in Figure 3. Another example on how device data is requested with OSTD is shown in Figure 10 in Appendix A. For a more concrete example, see our sample project "Write a Hello World OS Kernel in ∼100 Lines of Safe Rust with OSTD" [23].

4.2 Frame Management

OSTD employs a **frame metadata system** to track the state of each page frame, including a reference count and a customizable metadata field. All per-frame metadata are stored in a large static array, which is allocated and initialized in an early bootstrap phase. The reference count equals the total number of `Frame` and `Segment` instances that refer to that frame, enabling OSTD to manage frame lifetimes correctly.

Inv. 1: *Any newly-allocated `Frame` or `Segment` originates from currently unused memory.*

OSTD further supports custom per-frame metadata by taking a type parameter `M` in `Frame<M>` (or `Segment<M>`). The client can attach a metadata object of `M` to a `Frame<M>` object, enabling features like a page cache to efficiently maintain some extra per-frame states (e.g., the status of data synchronization between memory and disk). This mechanism is also used in page allocators and slab allocators (see §4.4).

Both `Frame` and `Segment` can represent either sensitive or insensitive memory. Internally, OSTD uses them to allocate sensitive memory for kernel resources such as page tables, stacks, or slabs. Externally, an OSTD client can request a special form of insensitive memory called **untyped memory** with `UFrame<M> = Frame<M: AnyUFrameMeta>` or `USegment<M> = Segment<M: AnyUFrameMeta>`, where the trait `AnyUFrameMeta` marks metadata types suitable for untyped memory usage.

Untyped memory deals with the fact that externally modifiable memory (e.g., user-mapped or DMA-capable memory) cannot uphold the strong guarantees of Rust references or the type safety of arbitrary Rust types. As such, we design `UFrame` (or `USegment`) to have a **read-write style interface** [24] that only permits copying **plain old data** (POD) [4] from or into it. A POD type (e.g., `u32`) can hold a value of any bit pattern, without invalidating any Rust invariants.

4.3 Privilege Separation

Intra-kernel privilege separation requires *preventing all sensitive resources from being tampered with by non-TCB entities*, including safe clients, user programs, and peripheral devices. OSTD achieves this by enforcing the following key invariants.

Inv. 2: *Kernel-mode CPU states cannot be tampered with by* OSTD *clients.*

To expose only user-mode CPU operations to clients, OSTD provides `UserMode`, `UserContext`, and `VmSpace`. The first two handle traps and registers at user privilege level, while the third manages user-mode virtual memory. Kernel-mode registers are hidden, and only safe portion of user-mode CPU registers are accessible. For instance, on x86, `UserContext` exposes only the non-sensitive subset of `RFLAGS`, excluding bits like `IF` or `IOPL` that control interrupts or I/O privilege.

Inv. 3: *Kernel-mode CPU states cannot be tampered with by peripheral devices.*

On x86 hardware, devices can spoof exceptions, traps, or inter-processor interrupts [63]. To protect against such attacks, OSTD configures the IOMMU to enable interrupt remapping, preventing rogue devices from influencing kernel control flow.

Inv. 4: *Sensitive memory cannot be tampered with by* OSTD *clients.*

All `Frame`s or `Segment`s allocated by OSTD clients originate from insensitive physical memory. Sensitive pages, such as those used for kernel code, stacks, or page tables, remain fully within OSTD's control.

Each `Task`'s stack includes a guard page to detect stack overflows. If the stack pointer touches the guard page, a page fault is triggered, preventing further execution and thwarting potential malicious behavior. Additionally, the OSTD-based OS enforces a compile-time stack usage analysis, ensuring each function's stack frame remains smaller than the guard page. This prevents malicious attempts to bypass the guard page and exploit stack overflows.

Inv. 5: *Sensitive memory cannot be tampered with by user programs.*

User-mode mappings are created through `VmSpace`, which can only take `UFrame` or `USegment` as inputs. This design rules out exposing sensitive memory to user space because untyped memory are, by definition, insensitive.

Inv. 6: *Sensitive memory (including I/O memory) cannot be tampered with by peripheral devices.*

OSTD leverages IOMMU to prevent peripheral devices from writing to unauthorized physical regions. Initially, no part of physical memory is DMA-accessible. Drivers can create DMA mappings (`DmaStream` or `DmaCoherent`) only over untyped memory (`UFrame` or `USegment`), so sensitive regions stay protected.

Inv. 7: *Sensitive I/O memory or ports cannot be tampered with by* OSTD *clients.*

Clients interact with MMIO and PIO through `IoMem` and `IoPort`. OSTD uses information from the architecture, firmware (e.g., ACPI tables on x86), and core device drivers to label ranges of I/O memory and ports as either sensitive or insensitive. `IoMem` and `IoPort` can only be instantiated for insensitive regions, preventing accidental or malicious misuse of sensitive I/O registers.

Table 3: Increased complexities in some Linux components

Linux Components	Early Version (2.1.23, 1997)	Latest Version (6.12.0, 2024)	
Task scheduler	1.6 KLoC	27.2 KLoC	17×
Slab allocator	1.6 KLoC	8.7 KLoC	6×
Frame allocator	1.2 KLoC	7.1 KLoC	6×

4.4 Safe Policy Injection

One's confidence in the correctness of any safe abstraction ultimately hinges on the size and complexity of its TCB. In this section, we explain how to contain OSTD—even if its implementation adopts increasingly sophisticated strategies and policies over time.

Specifically, OSTD consists of the following components, each of which makes decisions based on particular strategies or policies: (1) **Task scheduler** determines which task to run next, (2) **Frame allocator** decides how to allocate large chunks of memory, and (3) **Slab allocator** decides how to allocate smaller chunks of memory. These components can grow significantly when equipped with advanced features. For instance, their counterparts in Linux have grown in size and sophistication over the years, as summarized in Table 3.

Intuitively, a TCB should contain only mechanisms rather than policies for minimality. We therefore propose **safe policy injection**, a technique that removes complex policies from a Rust TCB without compromising functionality, efficiency, or soundness. To apply the technique, a developer identifies components inside the TCB that might use complex strategies or policies, then determines whether a complete policy implementation can be written in safe Rust. If it can, the developer designs abstractions for acceptable policies plus APIs to register those policies, a process we refer to as "injection".

Although the idea of safe policy injection appears simple, ensuring soundness can be challenging because these policies affect the behaviors of TCB code. For example, a safe-but-buggy scheduler could inadvertently schedule the same task on two CPUs at once – a catastrophic mistake for memory safety. Similarly, the choice of which memory page or slot to allocate next directly affects memory safety. All mainstream OSes include frame and slab allocators within their TCBs for precisely these reasons. The rest of this subsection describes how we overcome such challenges.

4.4.1 Task Scheduler

Our goal is to support advanced schedulers, such as Linux's Completely Fair Scheduler (CFS) [5], atop OSTD. We introduce to OSTD two new traits: `Scheduler` and `RunQueue`. Their APIs are summarized in Table 4. A type implementing `Scheduler` should be registered once at an early stage of kernel initialization (when no tasks exist). Whenever a task becomes runnable (e.g., is spawned or woken), OSTD hands it over to the scheduler via the `enqueue` method.

Table 4: Select APIs for task scheduler injection. `Scheduler` represents a task scheduler, and each CPU's local run queue is represented by `RunQueue`.

APIs	Descriptions
`Scheduler::enqueue(&self, task)`	Enqueue a task
`Scheduler::local_rq_with(&self, closure)`	Access to the local run queue with a closure
`RunQueue::update_curr(&mut self)`	Update current task
`RunQueue::pick_next(&mut self)`	Pick the next task
`RunQueue::dequeue_curr(&mut self)`	Remove the current task

Table 5: Select APIs for frame allocator injection. The `FrameAlloc` trait abstracts any injectable frame allocator.

APIs	Descriptions
`FrameAlloc::alloc(&self, layout)`	Allocate frames
`FrameAlloc::dealloc(&self, addr, size)`	Deallocate frames
`FrameAlloc::add_free_memory(&self, addr, size)`	Add a range of usable frames

We require schedulers to be SMP-friendly by keeping per-CPU run queues, accessible through `local_rq_with`. To replace the current task, OSTD calls `pick_next`, and if the current task becomes unrunnable (e.g., it sleeps), `dequeue_curr` removes it from the queue. At each scheduling event (e.g., sleep, yield, or timer tick), OSTD invokes `update_curr` to notify the scheduler, which can then update the scheduling information about the current task.

For efficiency, the scheduler API takes ownership of runnable tasks (`Arc<Task>`). Because the task objects are clonable, they can be stored in advanced data structures (e.g., red-black trees) or moved between CPU queues for load balancing. Each task may also carry custom data (`Box<dyn Any>`) for storing scheduling attributes, making these attributes cheaply accessible.

The client-provided `pick_next` method could return an invalid task. In particular, returning a task that is already running on another CPU may lead to severe consequences, as running one task on two CPUs corrupts its stack. We must thus preserve this key invariant:

Inv. 8: *A `Task` runs on at most one CPU at any given time.*

To enforce this, OSTD gives each `Task` a private flag, `is_running`, which is checked and set prior to a context switch. After switching, the previous task will have its flag cleared.

4.4.2 Frame Allocator

An injectable frame allocator is abstracted by the `FrameAlloc` trait, whose APIs are shown in Table 5. During the initialization phase, OSTD passes the information of all usable physical memory to the injected frame alloca-

Table 6: Select APIs for slab allocator injection. A `Slab` represents one or more memory pages arranged into fixed-size slots, with free slots represented by `HeapSlot`.

APIs	Descriptions
`Slab::new()`	Create a new slab
`Slab::alloc(&self)`	Allocate a new `HeapSlot`
`Slab::dealloc(&self, slot)`	Recycle a `HeapSlot`
`HeapSlot::into_box(self, val)`	Convert into a heap object

tor (`FrameAlloc::add_free_memory`). Subsequently, whenever an OSTD client requests a new `Frame` (or `Segment`), OSTD redirects the request to the injected allocator (`FrameAlloc::alloc`), which returns the address of the allocated memory. Conversely, when a `Frame` (or `Segment`) is dropped and its reference count is reduced to zero, the underlying frames will be returned to the injected allocator (`FrameAlloc::dealloc`).

A `Frame` (or `Segment`) must be created out of a *valid* and *unused* range of physical memory. But this safety precondition may be violated by an injected frame allocator due to potential logical bugs. To guard against such bugs, OSTD *only* turns memory ranges obtained from the injected allocator into `Frame`s through a safe constructor method, `Frame::from_unused(addr, size)`, which enforces Inv. 1 by leveraging the frame metadata system (§4.2).

4.4.3 Slab Allocator

We now describe how OSTD supports a custom slab allocator [14, 15] and its injection as the heap allocator. A **slab** is one or more contiguous pages partitioned into an array of fixed-size **slots** [14]. Each slot can hold a single object of a particular type or size. A **slab cache** pools these slots for rapid allocation and release. Typically, a per-CPU free list tracks empty slots, refilled from a global pool of slabs when needed. If all slabs are full, new slabs are allocated from free pages. Conversely, the allocator can free unused slabs to reclaim memory. An OS typically manages multiple slab caches for different slot sizes, all governed by a **slab allocator**.

We introduce two new abstractions in OSTD: `Slab` and `HeapSlot`, whose APIs are summarized in Table 6. These APIs perform type conversions critical to memory safety: from an unused memory page to a slab (`Slab::new`), then to a free slot (`Slab::alloc`), and ultimately to a heap object (`HeapSlot::into_box`). With these abstractions, developers can implement slab caches and the slab allocator in ASTERINAS using only safe Rust.

These abstractions maintain some key invariants. For example, a `Slab` owns its underlying pages, so dropping the `Slab` should free those pages – unless some slots are still occupied by active objects. To avoid use-after-free, each `Slab` tracks the number of active `HeapSlot`s it spawned. A panic is triggered if a `Slab` is dropped while any slot remains active:

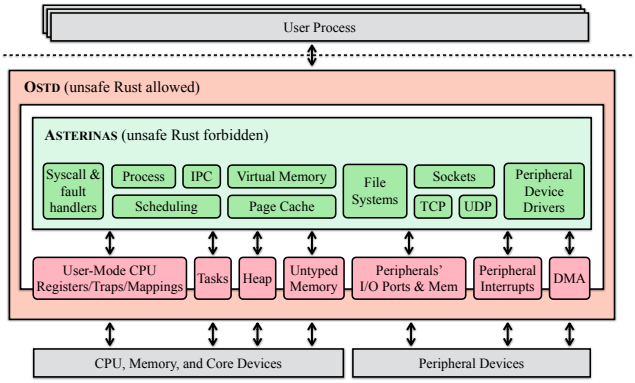

Figure 4: An overview of Asterinas.

Inv. 9: *A `HeapSlot` or any object derived from it must not outlive its parent `Slab`.*

Additionally, when `HeapSlot::into_box` is called, the method checks cheaply whether the slot's address and size can fit a requested object of type `T`:

Inv. 10: *An object is created from a `HeapSlot` only if the slot meets the object's size and alignment requirements.*

In practice, many kernel components rely on a global heap rather than creating their own slab caches. OSTD allows injecting a slab-based, global heap allocator, which can dispatch each heap allocation to the appropriate slab cache.

Overall, the safe policy injection technique allows OSTD to enjoy the performance advantage of advanced implementations without bloating its TCB size.

5 ASTERINAS

We develop ASTERINAS (see Figure 4), a framekernel-based OS built on top of OSTD. ASTERINAS implements a substantial subset of Linux features, including virtual memory, user processes, preemptive scheduling, IPC, a page cache, a virtual file system, and sockets, providing over 210 system calls. It supports various file systems (e.g., Ext2, exFAT32, OverlayFS, RamFS, ProcFS, and SysFS), socket types (e.g., TCP, UDP, Unix, and Netlink), and devices (e.g., Virtio Block, Virtio Network, Virtio Vsock, USB controller, and USB HID). Two CPU architectures are supported: x86-64 (tier-1) and RISC-V (tier-2). All the functionality is written in safe Rust by leveraging OSTD's APIs. ASTERINAS has been under development for three years (see Figure 7). The repository of ASTERINAS and OSTD is open-sourced [1, 2], contains over 100K lines of Rust contributed by over 50 individuals.

Towards smaller TCB. In pursuit of a smaller TCB, ASTERINAS (rather than OSTD) implements much of the OS infrastructure that Linux considers part of its core. For instance, ASTERINAS manages all interrupt bottom halves, such as softirq, tasklets, and work queues, by using an interrupt han-

dling hook provided by OSTD. OSTD enforces "atomic mode" to prevent client-provided callbacks from sleeping in interrupt context. ASTERINAS also maintains system time, monotonic time, and wall clocks by registering timer interrupts and reading the timestamp counter (TSC) through OSTD.

ASTERINAS takes advantage of OSTD's safe policy injection feature. It incorporates a Linux-style task scheduler with multiple scheduling classes—including a real-time scheduler and a rudimentary CFS [5]. ASTERINAS provides an efficient and scalable buddy system frame allocator, with per-CPU caching. ASTERINAS also features a slab allocator following the original design [14]. Our primary focus has been establishing the injection mechanism rather than extensively refining each scheduling or allocation policy; we plan to continue improving these components for greater maturity.

Performance optimization. Many performance bottlenecks in ASTERINAS and OSTD have been identified and addressed. Due to space constraints, we cannot cover every optimization in detail. In many instances, we have adapted strategies from Linux's optimized C implementations to align with the framekernel philosophy and the constraints of safe Rust.

One optimization in ASTERINAS is a pooling mechanism for DMA-able memory regions (akin to persistent mapping [61]), which may be requested frequently by device drivers. This approach minimizes the need for DMA mapping setup, requiring it only during initialization, thereby preserving IOTLB entries and enhancing the hit rates for IOMMU. In contrast, a dynamic mechanism would necessitate frequent unmaps, leading to IOTLB invalidation and a subsequent performance decline.

Thus far, our optimization efforts have been concentrated on single-core systems. Ongoing work is focused on improving SMP scalability through the use of SMP-friendly locks (e.g., RCU [45], MCS locks [35]) and the application of more fine-grained locking mechanisms. In this paper, our evaluation compares ASTERINAS directly with Linux in a single-core environment, with a comprehensive multi-core analysis planned for future work.

6 Evaluation

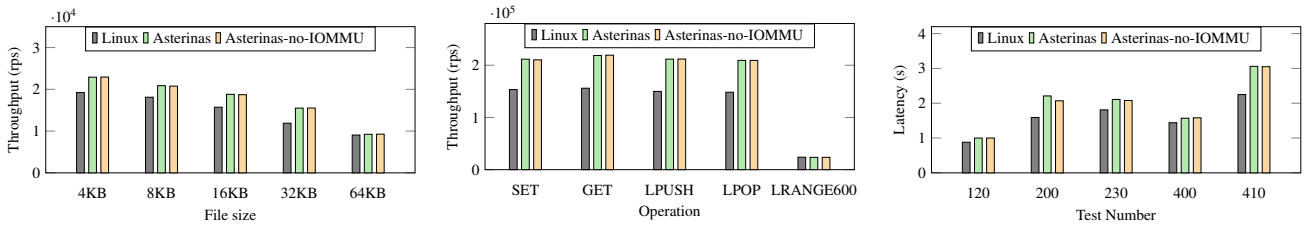
6.1 Performance Evaluation

We evaluate the performance of ASTERINAS. The experiments are performed on a machine with an Intel i7-10700 processor, 32GB of memory, and an Intel SSDPEKNW512GB solid state drive. The system software on the machine includes Ubuntu 22.04 (Linux version 6.8.0) and QEMU 9.1.0.

For comparison with ASTERINAS, we use Linux kernel version 5.15 as the baseline. Some Linux features that are missing in ASTERINAS, including CPU mitigations (`mitigations=off`) and huge pages (`hugepages=0`), are disabled to ensure fairness. Without disabling CPU mitigations, Linux's performance would be affected considerably.

Both the Linux and ASTERINAS kernels are tested within QEMU virtual machines (VMs) configured as follows: SMP set to 1, machine type set to q35 with the kernel IRQ chip in split mode, CPU specified as Icelake-Server, PCID disabled, and x2APIC and KVM enabled. Each VM is attached with a virtio-blk device (having a single queue with a length of 64) and a virtio-net device (a tap device with vhost support enabled), which will be used for block and network I/O benchmarks, respectively.

6.1.1 Micro-benchmarks



We run LMbench [46], a series of system call-intensive microbenchmarks. Specifically, the benchmarks are classified into five categories: process-related (Proc), memory-related (Mem), Inter-process communication-related (IPC), filesystem-related (FS), and network-related benchmarks (Net). The last column (Norm) of Table 7 shows the normalized performance—for throughput it shows results of Asterinas/Linux; for latency it shows results of Linux/Asterinas—and hence higher results suggest better performance of ASTERINAS. ASTERINAS is evaluated with IOMMU enabled and all reported results are averaged over ten runs of the benchmarks.

As shown in Table 7, the geometric mean of the normalized performance is 1.08, which means ASTERINAS slightly outperforms Linux in more benchmarks. This result suggests that ASTERINAS is comparable to Linux in performance, but does not necessarily mean ASTERINAS is better optimized. As a newly developed Rust kernel, ASTERINAS misses some of the advanced features and configurations in Linux. For example, in the network TCP tests, ASTERINAS uses the smoltcp [22] library, which lacks congestion control, enabling TCP to operate at full speed and resulting in faster performance compared to Linux. In the FS-related open and stat tests, Linux employs RCU-walk to achieve faster filename lookup, an optimization not implemented in ASTERINAS.

6.1.2 Macro-benchmarks

We evaluate ASTERINAS's performance with popular I/O-intensive applications, including Nginx (1.26.2), Redis (7.0.15), and SQLite (3.46.1). The results in Figure 5 report ASTERINAS's performance with IOMMU enabled (default) and disabled (for comparison).

- **Nginx.** We evaluate the throughput of Nginx using ApacheBench [26] with a concurrency level of 32 and a total of 200,000 requests. The results shown in Figure 5(a) indicate that the throughput of Nginx is higher on ASTERINAS (22,912 rps) than Linux (19,227 rps) when the requested file size is 4096 bytes (19% higher). When the file size is 64 KiB, ASTERINAS's throughput drops to 9,234 RPS, which is close to Linux's result. This drop may happen because ASTERINAS 's `sendfile` implementation is less optimized—it

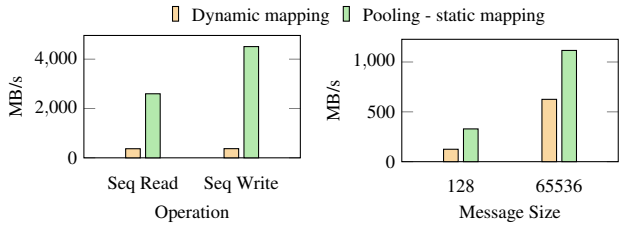
[1] Normalized performance. For throughput, use Asterinas/Linux; for latency, use Linux/Asterinas. The higher the better.
[2] With mmap_only.
[3] With io_only.



requires an extra copy to an intermediate buffer. For small files (4 KiB), ASTERINAS performs better than Linux because it lacks congestion control (using the smoltcp crate). However, as the file size increases, the overhead of redundant copying outweighs this advantage, causing ASTERINAS 's performance to fall behind Linux. The geometric mean of all the normalized performances (ASTERINAS/ Linux) is 1.17.

- **Redis.** We use the official Redis benchmark tool [53], which measures performance by executing a series of Redis commands and recording the throughput. Figure 5(b) shows a subset of representative commands, and the complete results can be found in Appendix B. The results indicate that ASTERINAS outperforms Linux. For instance, the throughput for GET operation on ASTERINAS is 218,670 rps, 40.2% higher compared to 155,994 rps on Linux. This result aligns with our LMbench findings, where ASTERINAS outperforms Linux for smaller packet sizes, as the Redis benchmark involves small message sizes in its operations. The geometric mean of all the normalized performance results is 1.31.
- **SQLite.** We utilize SQLite's speedtest1 [51] as the benchmarking tool. In the test, we set the base size to 1000 to ensure data is written to the device (default is 100) and run the tests on an Ext2 mount over a virtio-blk device. Due to space limits, we only show representative results in Figure 5(c), whose test numbers are 120 (500000 unordered INSERTS with one index/PK), 200 (VACUUM), 230 (100000 UPDATES, numeric BETWEEN, indexed), 400 (700000 REPLACE ops on an IPK), and 410 (700000 SELECTS on an IPK). The complete results are shown in Appendix C. The geometric mean of all the normalized performances (Linux / ASTERINAS) is 0.85.

  In all these tests, ASTERINAS performs worse than Linux. The Vacuum test (200) shows the worst case, reaching only 72% of Linux's performance with IOMMU enabled. Once the IOMMU is disabled, the ratio will become 77%. To understand the root causes of Vacuum test, we used Strace [58] for performance diagnosis. The analysis revealed that Vacuum frequently makes `pwrite64` calls for writing 4-byte data. When disabling the SQLite journal, `pwrite64` with small data writes disappears, and ASTERINAS' performance increases to 80% and 83% of Linux's performance with IOMMU enabled and disabled, respectively. This analysis shows that ASTERINAS could benefit from optimization for both `pwrite64` operations with small data writes and IOMMU.

Table 8: Overhead due to OSTD's safety mechanism.

Operations	Sources of Safety Overheads	CPU Cycles Overhead / Total
Segment::read_bytes (4KB)	Boundary check	3/125(2.4%)
Segment::write_bytes (4KB)	Boundary check	2/239(0.8%)
IoMem::read_once (4 bytes)	Boundary check	170/10988(1.5%)
IoMem::write_once (4 bytes)	Boundary check	166/10666(1.6%)
KernelStack::new	Guard page creation	25/2950(0.8%)
Task::yield_now	Running flag check	1/167(0.6%)
FrameAlloc::alloc (1 frame)	Ownership check	12/180(6.7%)
Box::new (48 bytes)	Ownership check	1/148(0.7%)

(a) Block device bandwidth (b) Network device bandwidth

Figure 6: IOMMU overhead with different mechanism

6.1.3 Overhead due to Safety Checks

The overhead introduced by the OSTD's safety mechanisms does not prevent ASTERINAS's performance from being comparable to a monolithic kernel. ASTERINAS has integrated several safety mechanisms into its OSTD to ensure system safety. To evaluate the cost of safety mechanisms, we directly invoke the interfaces corresponding to these safety mechanisms at the API level, measuring the CPU cycles required with and without the safety checks. The results are presented in Table 8. The "Allocate frame" test, which is related to the Frame allocator injection, exhibits the highest overhead at 6.7%, while the overhead of all other tests remains below 3%.

6.1.4 IOMMU Optimization

One optimization of IOMMU using the pooling mechanism leads to a significant performance gain. As shown in Figure 5, the results indicate that ASTERINAS does not introduce significant overhead for Nginx, Redis, and SQLite (in most cases). Both Nginx and Redis show almost no overhead, with the largest overhead observed in the SPOP test of Redis at 2.3%.

However, SQLite exhibits higher overhead in some cases (8.3%), primarily due to the incomplete pooling mechanism in the block device driver compared to the network device driver. Figure 6 further highlights the significance of pooling. We evaluate the bandwidth of block devices using FIO [13] and network devices using bw_tcp. Upon switching from polling to a dynamic mechanism, both network and block devices experienced considerable performance degradation.

6.2 TCB Evaluation

In this section, we evaluate the current TCB size of ASTERINAS and estimate its growth as the codebase evolves.

6.2.1 TCB Comparison

To assess the efficacy of ASTERINAS's implementation of the minimality principle, we compare the TCB size of ASTERINAS with RedLeaf [49], Theseus [16], and Tock [38].

Methodology. We employ a crate-level classification approach to evaluate the run-time TCBs of Rust-based OSes. In Rust, crates serve as the primary units for organizing and distributing code, with no additional isolation mechanisms within a crate. Consequently, a crate's interface naturally forms a trust boundary. So we consider a crate either belongs to the TCB, implying it must be trusted for security, or is excluded from the TCB, indicating it is secured by the Rust compiler. We adhere to the following rules to determine whether a crate is within the run-time TCB or not:

- **Rule 1**: The Rust toolchain is trusted. Consequently, crates provided by the Rust toolchain itself, like `alloc` and `core`, are *not* considered part of the run-time TCB.
- **Rule 2**: Crates containing `unsafe` code may potentially introduce soundness bugs, and as a result, they are considered part of the TCB.
- **Rule 3**: Crates that are dependencies of TCB crates should also be part of the TCB. This is because even if a crate doesn't use `unsafe` at all and thus doesn't introduce soundness issues on its own, the correctness of its APIs can still impact the soundness of the TCB crate that relies on it.

Since crates vary in size, evaluating the TCB size by counting the number of crates would be too simplistic and inaccurate. Therefore, a more refined metric is needed. However, directly comparing lines of code across crates is not ideal, as not all code within a crate is necessarily utilized during runtime. This is especially true for third-party dependencies, where often only a small fraction of the code is actually used at runtime.

To address this, we introduce a metric called **Linked Code Size (LCS)**, which measures the number of lines of code that are ultimately compiled and linked during the OS build.

We leverage the LLVM toolchain [42] to estimate the LCS for each OS. Specifically, we measure the number of source code lines that have corresponding statements in the generated LLVM IRs after link-time optimization. The content of the LLVM IR is closer to that of a binary file, primarily retaining the IR corresponding to executable statements within functions. It does not trace back to statements used for imports or struct definitions, which are not directly executable during runtime. This focus on executable IR provides a more accurate measure of the code that is relevant to the TCB during runtime operations.

Results. As illustrated in Table 9, the relative TCB size of ASTERINAS is a mere 14.0%, which is notably lower than that of other Rust-based OSes. While some OSes, such as RedLeaf, enforce restrictions that permit only safe Rust in specific crates, they still depend on numerous self-maintained crates that utilize `unsafe`, leading to a substantial portion of their code being part of the TCB (i.e., 66.1%).

Tock OS, being an embedded OS, is relatively lightweight, and thus its TCB size is slightly better than the other two. However, its TCB size (i.e., 43.8%) is still more than double of ASTERINAS. These results clearly underscore the effectiveness of the minimality principle that we adhere to.

Table 9: Comparison of TCB size

	RedLeaf	Theseus	Tock[1]	**Asterinas**
Total (LoC)	25992	70468	6628	**75285**
TCB (LoC)	17182	43978	2903	**10571**
Relative TCB	66.1%	62.4%	43.8%	**14.0%**

[1] Tock implementation of board `nrf52840dk`.

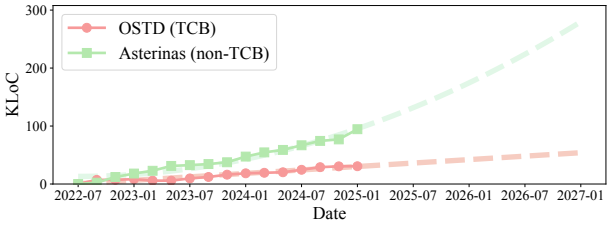


Figure 7: The codebase of ASTERINAS (non-TCB) has grown faster than OSTD (TCB) and is expected to remain so.

6.2.2 TCB Evolution

ASTERINAS has been under development for three years. We analyze and visualize the growth of its codebase (in KLoC). As shown in Figure 7, ASTERINAS (non-TCB) has experienced significant growth, while OSTD (TCB) has maintained a slower, steadier expansion. Curve fitting indicates that the TCB portion of the kernel will continue to grow in a controlled manner. This aligns with prior research on Linux codebase development [27, 57], which suggests that while overall codebases grow super-linearly with increasing complexity, core kernel functionality—excluding drivers—grows sub-linearly [34].

6.3 Safety Evaluation

To evaluate the soundness of OSTD, we develop a testing tool named KERNMIRI. This tool extends the official Rust UB detection tool, Miri [48], to support core OS concepts such as physical memory, page tables, etc. The overall architecture of KERNMIRI is depicted in Figure 8. It retains Miri's original UB detection logic (represented by grey boxes and lines) while introducing an additional 1,200 LoC to implement new components (indicated by green boxes and lines).

As illustrated in Figure 8, KERNMIRI enhances Miri by simulating physical memory and implementing a basic paging system. These improvements enable KERNMIRI to accurately interpret OS operations that demand fine-grained memory management. Moreover, KERNMIRI introduces additional shims to synchronize the OS state, which can be leveraged to direct KERNMIRI to activate a page table at a specific address or to inform KERNMIRI of changes in the state of a physical page, such as transitions between typed and untyped states.

KERNMIRI interprets the execution of OSTD and all its test cases. Following the workflow of OSTD's unit testing, KERNMIRI first interprets the initialization phase of OSTD to synchronize the system's initial memory state, and then

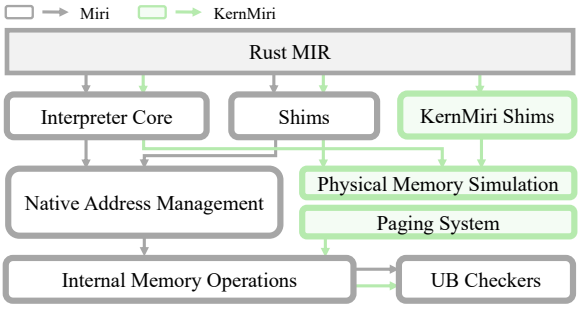

Figure 8: KERNMIRI, a UB detection tool for Rust OSes

Table 10: Coverage and efficiency of KERNMIRI on OSTD.

Modules	# Tests	Lines	Unsafe	Execution	
		Covered / Total	Covered / Total	Native	KernMiri
dma	12	385/443 (87%)	8/8 (100%)	0.25s	1.22s
frame	28	634/649 (98%)	41/41 (100%)	0.21s	3.14s
heap	6	278/319 (87%)	6/6 (100%)	0.01s	0.31s
kspace	8	287/323 (89%)	9/9 (100%)	0.04s	0.93s
page_table	34	931/1032 (90%)	46/46 (100%)	1.23s	34.83s
io	29	358/371 (97%)	23/23 (100%)	0.16s	3.12s
vm_space	17	662/672 (99%)	10/10 (100%)	0.28s	6.95s
All	**134**	**3535/3809** (93%)	**145/145**(100%)	**2.18s**	**50.50s**

executes each unit test of OSTD via interpretation. As such, the coverage of KERNMIRI depends on the unit test cases that have been developed for OSTD.

6.3.1 Coverage of KERNMIRI

We primarily use KERNMIRI to test and validate the `mm` module of OSTD, which is closely related to memory safety. This module also contains the majority of `unsafe` code in OSTD. Table 10 summarizes the measured metrics for each submodule of `mm` module separately, including the coverage of lines of code (Column `Line`), coverage of unsafe blocks (Column `Unsafe`) and interpreted execution time compared to native execution (Column `Execution`).

The results suggest that, with in total 134 unit tests, KERNMIRI covers all instances of `unsafe` code and over 90% on average of lines in all submodules. This confirms that the majority of the OSTD's memory operations is free of UBs. Furthermore, the few detected instances of UB have been addressed, with a detailed discussion provided in Section 6.3.2.

In addition, as shown in the last column of Table 10, KERNMIRI's interpreted execution takes approximately 25 times longer than normal execution. While significantly higher, this overhead is reasonable as a one-time cost for soundness evaluation. Thus, we conclude that KERNMIRI is a practical and effective tool for validating the soundness of Rust-based operating systems.

6.3.2 Case Studies

KERNMIRI has helped us detect several UBs that we would not be able to catch using other methods, significantly im-

```
/// Overview: 1 and 2 execute concurrently with 2 executing first. This
/// allows 1 to exchange successfully, leading to a race condition in
/// subsequent metadata modifications.

impl<M: FrameMeta> Frame<M> {
    pub fn from_unused(paddr: Paddr, metadata: M) -> Self {
        ...
① ---- ref_count.compare_exchange(0, 1, Acquire, Relaxed).expect(...);
        // Modify metadata.
    }
}

impl<M: FrameMeta> Drop for Frame<M> {
    fn drop(&mut self) {
② ---- let last_ref_cnt = self.ref_count().fetch_sub(1, Release);
        if last_ref_cnt == 1 {// Modify metadata.}
    }
}
```

(a) Data Race UB

```
/// Overview: The reference to the heap array is converted into a const
/// pointer for its first time pointer transition, yet the heap region
/// will be mutated later which results in mutability UB.

pub unsafe fn init() {
    static mut HEAP_SPACE: InitHeapSpace = InitHeapSpace([0; HEAP_SIZE]);
    HEAP_ALLOCATOR.init(HEAP_SPACE.0.as_ptr(), HEAP_SIZE);
}                                   └─ read-only transition
```

(b) Mutability UB

Figure 9: UB cases detected by KERNMIRI.

proves the soundness of our implementation of OSTD. We outline two representative UB cases in OSTD detected by KERNMIRI, as illustrated in Figure 9.

The first case involves a data race UB (Figure 9(a)). When creating a `Frame` using `from_unused` (see 4.4.2), if the `ref_count` corresponding to the physical address has just been decremented by a `drop` operation that has not yet completed, these two operations may concurrently modify the metadata, leading to data race UB.

The second case pertains to mutability UB (Figure 9(b)), where the code overlooks Rust's rules regarding the conversion of references to pointers. Specifically, when a reference is first converted into a pointer, the type of pointer determines the mutability constraints of the memory region. In this case a reference to the `HEAP_SPACE` is incorrectly converted into an immutable pointer during initialization. This conversion conflicts with subsequent mutable operations, resulting in UB.

7 Related Work

Safe language-based OSes. The development of operating systems using safe programming languages has been steadily increasing. Examples include Biscuit [19], implemented in Go; JX [28], developed in Java; MirageOS [43], built with OCaml; Verve [62], written in C#; and Singularity [33], which utilizes Sing# (an extension of C#). Rust has also become a popular choice for system development, as seen in projects like Theseus [16], Tock [38], RustyHermit [37], Redox [21], and rCore [52]. ASTERINAS is also implemented in Rust but goes further by leveraging Rust's type and memory safety features to achieve a minimal and sound TCB.

Intra-kernel privileged separation. Various mechanisms have been proposed to achieve privilege separation within the kernel. PerspicuOS [20] enforces separation using page table write protection and static analysis. RustyHermit-MPK [59], CubicleOS [56], and KDPM [36] employ Intel MPK for isolation. Lightweight Virtualized Domains [50] achieve separation through EPT and VMFUNC. RedLeaf [49], Tock [38], and Theseus [16] utilize Rust's safety features to create a new privilege level within the kernel. ASTERINAS achieves both soundness and minimality of intra-kernel privilege separation through a redefinition of the essential TCB functions.

Scheduler Injection. ghOSt [32] modifies Linux to delegate scheduling to userspace, incurring non-trivial overhead, while Enoki [47] adapts ghOSt's architecture but moves scheduler back to the kernel. In contrast, ASTERINAS offers (i) a smaller TCB—ghOSt relies on C-based run-queues, and Enoki can't catch all semantic bugs—and (ii) more flexible APIs, as Enoki schedulers must coordinate with Linux to avoid inconsistencies when managing run-queues, limiting independence.

8 Conclusions

This paper presents ASTERINAS, a Linux ABI-compatible OS kernel based on our novel *framekernel* architecture. By harnessing Rust's ownership and type-safety guarantees, a framekernel enforces *intra-kernel privilege separation* to achieve a small TCB in terms of memory safety. Using the APIs of OSTD (TCB), ASTERINAS (non-TCB) is implemented entirely in safe Rust, supporting over 210 Linux system calls. Our comprehensive evaluation shows that ASTERINAS delivers performance on par with Linux, demonstrating that a fully-featured, general-purpose OS can be both memory-safe and highly efficient.

Abstract

Safe kernel extensions have gained significant traction, evolving from simple packet filters to large, complex programs that customize storage, networking, and scheduling. Existing kernel extension mechanisms like eBPF rely on in-kernel verifiers to ensure safety of kernel extensions by static verification using symbolic execution. We identify significant usability issues—safe extensions being rejected by the verifier—due to the *language-verifier gap*, a mismatch between developers' expectation of program safety provided by a contract with the programming language, and the verifier's expectation.

We present Rex, a new kernel extension framework that closes the language-verifier gap and improves the usability of kernel extensions in terms of programming experience and maintainability. Rex builds upon language-based safety to provide safety properties desired by kernel extensions, along with a lightweight extralingual runtime for properties that are unsuitable for static analysis, including safe exception handling, stack safety, and termination. With Rex, kernel extensions are written in *safe* Rust and interact with the kernel via a safe interface provided by Rex's kernel crate. No separate static verification is needed. Rex addresses usability issues of eBPF kernel extensions without compromising performance.

1 Introduction

Kernel extensibility is an essential capability of modern Operating Systems (OSes). Kernel extensions allow users with diverse needs to customize the OS without adding complexity to core kernel code or introducing disruptive kernel reboots.

In Linux, kernel extensibility has traditionally taken the form of loadable kernel modules. However, kernel modules are inherently *unsafe*—simple programming errors can crash the kernel. Despite the support of safe languages like Rust [23], there is no systematic support to ensure the safety of kernel modules—*unsafe* Rust code is allowed in kernel modules wherein checks to prevent errors are non-existent. Moreover, the vast, arbitrary interface exposed to kernel modules creates significant challenges in providing a safe Rust kernel abstraction to enforce safe Rust code [48, 76].

Recently, eBPF extensions have gained significant traction and become the *de facto* kernel extensions [5, 10]. Core to eBPF's value proposition is a promise of *safety* of kernel extensions, enforced by the in-kernel verifier. The verifier statically analyzes extension programs in eBPF bytecode, compiled from high-level languages (C and Rust). It performs symbolic execution against every possible code path in the bytecode to check safety properties (e.g., memory safety, type safety, termination, etc). The kernel rejects any extension the verifier fails to verify. Today, eBPF extensions have evolved far beyond simple packet filters (its original use cases [75, 77]) and are increasingly being used to construct large, complex programs that customize storage [40, 55, 102, 106], networking [107, 108], CPU scheduling [11, 60, 87], etc.

However, we observe that eBPF's static verifier introduces significant usability issues, making eBPF extensions hard to develop and maintain, especially for large, complex programs. For example, the eBPF verifier often incorrectly rejects *safe* extension code due to fundamental limitations of static verification and defects in the verifier implementation. When such false rejections happen, developers have no choice but to refactor or rewrite extension programs in ways that "please" the verifier. Such efforts range from breaking an extension program into multiple small ones, nudging compilers to generate verifier-friendly code, tweaking code to assist verification, etc (see §3). Some of the efforts also involve reinventing wheels and hacking eBPF bytecode, which creates significant cognitive overheads and makes maintenance difficult.

We argue that these usability issues are rooted in the gap between the programming language and the eBPF verifier, which we term the *language-verifier gap*. When writing eBPF programs, developers interact with the high-level language and naturally obey a *language contract* to align with the safety requirements of the language. The compiler also adheres to the language contract. Unfortunately, the verifier is not part of the language contract and has different expectations. As a result, verifier rejections may be surprising; the feedback (verifier log) is at the bytecode level and is hard to map to source code. As a result, developing eBPF extensions requires not only a deep knowledge of the high-level language and safety properties of kernel extensions but also a deep understanding of implementation details and quirks of the verifier.

Unfortunately, recent efforts to improve the eBPF verifier (e.g., via testing and verification [35, 97]) cannot fundamentally close the language-verifier gap because (1) they do not

address scalability issues of symbolic execution, so extension programs have to ill-fit the verifier's internal limits, and (2) it is unlikely that the language compiler (e.g., LLVM) and the eBPF verifier are always in synchronization, given their independent developments. Recent efforts to improve extension expressiveness via techniques like software fault isolation (e.g., KFlex [52]) largely inherit the eBPF verifier and, therefore, do not address the language-verifier gap.

We present Rex, a new kernel extension framework that closes the language-verifier gap and effectively improves the usability of kernel extensions, in terms of programming experience and maintainability. Rex builds up safety guarantees for kernel extensions based on safe language features. With Rex, safety properties are checked by the language compiler within the language contract. Rex drops the need for an extra verification layer and closes the language-verifier gap. We choose Rust as the safe language, as it is already supported by Linux [23] and offers desired language-based safety for practical systems programming [33, 36, 76, 82].

Rex kernel extensions are strictly written in *safe* Rust with selected features (unsafe Rust code is forbidden in Rex extensions). Rex transforms the promises of Rust into safety guarantees for extension programs with the following endeavors. First, to enable Rex extensions to be written entirely in safe Rust in the context of kernel extension, Rex develops a kernel crate and offers a safe kernel interface that wraps the existing eBPF kernel interface (eBPF helper functions and data types) with safe Rust wrappers and bindings. The kernel crate enforces memory safety, extends type safety, and ensures safe interactions with the kernel. Rex further enforces only safe Rust features through its compiler toolchains.

Moreover, Rex employs a lightweight extralingual runtime for safety properties that are hard to guarantee by static analysis. Specifically, Rex supports safe stack unwinding and resource cleanup upon Rust panics at runtime. Rex also checks kernel stack usage and uses watchdog timers to ensure termination with a safe mechanism. The Rex runtime is engineered with minimal overhead to achieve high performance.

We evaluate Rex on both its usability and performance. We show that by closing the language-verifier gap and offering Rust's rich built-in functionality, Rex effectively rules out the usability issues in eBPF. We further evaluate the usability by implementing the BPF Memcached Cache (BMC) [55] (a complex, performance-critical program written in eBPF) using Rex and show that Rex leads to cleaner, simpler extension code. We also conduct extensive macro and micro benchmarks. Rex extensions deliver the same level of performance as eBPF extensions—the enhanced usability does not come with a performance penalty.

Limitations. Rex's design comes with tradeoffs. To close the language-verifier gap and improve usability, Rex requires kernel extensions to be written in Rust, though its design principles apply to other safe languages. Rex brings the Rust toolchain into the Trusted Computing Base (TCB) and adds additional runtime complexity. Note that Rex extensions and eBPF extensions can co-exist—Rex and eBPF represent different tradeoffs. Rex targets large, complex kernel extensions for which usability and maintainability are critical, while small, simple extensions (e.g., packet filters) can still be written in eBPF, as their small amount of code and simple logic makes them less susceptible to the language-verifier gap.

Contributions. We make the following main contributions:

- A discussion of the language-verifier gap and its impact on the usability and maintainability of safe kernel extensions;
- Design and implementation of the Rex kernel extension framework, which closes the language-verifier gap by realizing safe kernel extensions upon language-based safety, together with efficient runtime techniques;
- The Rex project is at `https://github.com/rex-rs`.

2 Safety of Kernel Extensions

Safety is critical to OS kernel extensions—extension code runs directly in kernel space, and bugs can directly crash a running kernel. The eBPF verifier checks safety properties of extension programs in bytecode before loading them into the kernel to prevent programming errors such as illegal memory access. The verifier also checks the extension's interactions with the kernel via a bounded interface, defined by eBPF *helper functions*, to prevent resource leaks and deadlocks. We summarize the safety properties targeted by eBPF as follows:

- **Memory safety.** Kernel extensions can only access preallocated memory via explicit context arguments or kernel interface (helper functions), preventing NULL pointer dereferencing and corruption of kernel data structures. The eBPF verifier tracks the category of each value in the program to prevent dereference of invalid pointers (e.g., an arbitrary scalar value) as well as the size of the pointed memory to avoid out-of-bounds accesses.
- **Type safety.** When accessing data in memory, kernel extensions must use the correct types of data, avoiding misinterpretation of the data and memory corruption. The eBPF verifier checks the offset and size of memory accesses and ensures that they always match the underlying object.
- **Resource safety.** When acquiring kernel resources (e.g., locks, memory objects, etc.) through helper functions, kernel extensions must eventually invoke the appropriate interface to release the resources, preventing memory leaks or deadlocks that can crash or hang the kernel. In eBPF, the release of resources is checked by the verifier on all code paths. Since doing so is not enough to prevent deadlocks due to the possibility of circular wait, eBPF additionally restricts extensions to only hold one lock at a time.
- **Runtime safety.** Kernel extensions must terminate, with no infinite loops that can hang the kernel indefinitely. The verifier checks presence of backedges in the program and sets

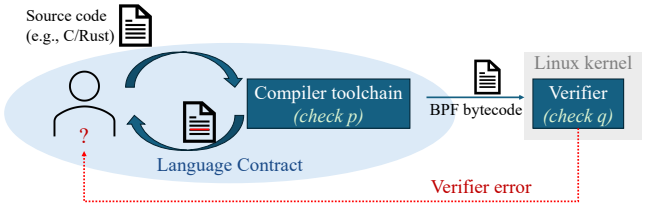

Figure 1: The language-verifier gap

a verification complexity limit on the number of bytecode instructions [92] it would explore to ensure termination.

- **Stack safety.** Kernel extensions must not overflow the limited and fixed-size kernel stack, avoiding kernel crashes or kernel memory corruptions. The verifier tracks stack usage of the program across function calls and rejects programs that use excessive amount of stack.

The eBPF verifier is complemented by the eBPF helper functions acting as the kernel interface, which allows interactions between the extension and the kernel. The helper function interface only contains around 200 routines, which is much more restrictive than that of the loadable kernel modules. The interface is designed to be high-level: helper functions are typically self-contained and encapsulate many low-level kernel operations, which in most cases eliminates the need of a protocol between extensions and the kernel. The simple and high-level nature of the interface makes it easy to reason about its safety—the eBPF verifier only needs to check value categories of the arguments passed for most helper functions. Helper functions are also the only means for extensions to acquire kernel resources. The interface defines both the acquisition and release routines for each resource, with the verifier ensuring the release routine is called before program exits.

Note that the above notion of safety in eBPF focuses on preventing programming errors that may crash or hang the kernel. Despite the discussions on whether security is a reasonable target [65, 73], in practice, eBPF and other extension frameworks (e.g., KFlex [52]) no longer pursue unprivileged use cases due to their inherent limitations (see detailed discussion in §4) [47, 53, 58]. Our work follows this safety model.

3 The Language-Verifier Gap

A fundamental problem of eBPF's safety verification mechanism is the *language-verifier gap* (illustrated in Figure 1). Developers mainly implement and maintain eBPF extensions in high-level languages (e.g., C and Rust) and compile them to eBPF bytecode; they agree to a contract with the high-level language (code has property p), which is enforced by the compiler. When a program fails to compile, developers receive feedback about how they violate the language contract. However, in eBPF, the compiled extension code will be further checked by the verifier. If correctly compiling code fails to pass the verifier (e.g., the code lacks property q, which is not part of the contract), it is difficult for developers to understand why the extension program fails despite obeying the contract.

Table 1: Patterns of common verifier workarounds

Category	Count
Refactoring extension programs into small ones	27
Hinting LLVM to generate verifier-friendly code	22
Changing code to assist verification	15
Dealing with verifier bugs	9
Reinventing the wheels	1

The language-verifier gap is further exacerbated when the verifier incorrectly rejects *safe* extension programs due to (1) scalability limitations of the symbolic execution used by the verifier, (2) conflicting analyses between the compiler and the verifier, and (3) the verifier's implementation defects. Today, the language-verifier gap forces developers to understand the verifier's internal implementation and its limitations and defects, and to revise extension code in ways that can pass the verifier at the bytecode level. Many such revisions are workarounds solely to please the verifier. Fundamentally, the language-verifier gap breaks the language abstractions and artificially forces extension programs in a high-level language to tightly couple with the low-level verifier implementation.

3.1 Verifier Workarounds

To understand the impact of the language-verifier gap, we analyzed commits related to revising eBPF programs to resolve verifier issues in popular eBPF projects, including Cilium [6], Aya [3], and Katran [16]. The commits were collected by searching through the commit logs of each project using keywords and manually inspected. In total, we collected 72 commits related to verifier issues. We also included two issues raised by BMC [55] and Electrode [107] in the discussion.

In all 72 commits, we confirmed that the original eBPF programs were safe but were rejected by the verifier due to defective or overly conservative safety checks. When the verifier rejects a safe program, the developer must find a *workaround*. Table 1 summarizes the workaround patterns.

Refactoring extension programs into small ones. The most common pattern (27 out of 72) is refactoring a large eBPF program, which the verifier rejects due to exceeding the verifier's internal limits into smaller ones. Since symbolic execution is hard to scale, the eBPF verifier imposes a series of limits on the complexity of extension programs (e.g., the number of bytecode instructions and branches [92]) to ensure verification completes at load time. The eBPF extension will be rejected if it exceeds any of these limits. Such rejections have no implication on the safety of the extension; rather, they are artifacts of scalability limitations of static verification.

We observe two standard practices of refactoring eBPF programs to work around verifier limits: (1) splitting eBPF

```
; return (void *)(unsigned long)ctx->data;
; LLVM generates a 32-bit load on ctx->data
2: (61) r9 = *(u32 *)(r7 +76)
; LLVM generates a 32-bit assignment, prompting
; the verifier to discard the pointer value type
3: (bc) w6 = w9
...
; now verifier treats it as an untrusted scalar
7: r2 = *(u8 *)(r6 +22)
Error: R6 invalid mem access 'inv'
```

(a) Verifier log showing an invalid memory access, which is hard to diagnose and does not directly map to the source code in C

```
static __always_inline void *
ctx_data (const struct __sk_buff *ctx) {
  void *ptr;
  /* prevent LLVM from generating 32-bit move */
  asm volatile (
    "%0 = *(u32 *)(%1 + %2)"
    : "=r"(ptr)
    : "r"(ctx),
      "i"(offsetof(struct __sk_buff, data))
  );
  return ptr;
}
```

(b) Inline assembly code created to work around the verification failure by preventing the compiler optimization

Figure 2: An example of the language-verifier gap from Cilium [41], where a safe eBPF extension is incorrectly rejected by the verifier (2a) and developers had to work around the problem by creating inline assembly code (2b).

programs into smaller ones and (2) rewriting eBPF programs with reduced complexity the verifier can handle.

We use BMC [55] as an example to explain these practices. BMC uses eBPF to implement in-kernel caches to accelerate Memcached. Conceptually, only two extension programs are needed (at ingress and egress, respectively). However, to satisfy the verifier limit, BMC developers had to split BMC code into *seven* eBPF programs connected via tail calls.[1] Such splitting creates an unnecessary burden on the implementation and maintenance of BMC; it also creates performance issues when states need to pass across tail calls (using maps).

Despite the smaller size of each program after splitting, BMC programs that iterate over the packet payload in a loop cannot easily pass the verifier. While the programs correctly check for the bounds of the payload, the programs result in an excessive number of jump instructions and exceed the verifier's complexity limit. As a workaround, developers must bind the size of the data BMC can handle further to pass the verifier. §7.1 revisits this example in more depth.

Hinting LLVM to generate verifier-friendly code Another common pattern is to change source code in ways that nudge the compiler (LLVM) to generate verifier-friendly bytecode. In several cases, LLVM generates eBPF bytecode that fails the verifier due to complex, often undocumented expectations of the verifier. Figure 2a shows a case from Cilium [41] that accesses a pointer field (`ctx->data`) in a socket buffer, defined as a 32-bit integer in the kernel `uapi` interface. LLVM generates a 32-bit load on `data` and assigns its value to another 32-bit register. While `data` is defined as 32-bit, under the hood it represents a pointer to the start of the packet payload. The 32-bit assignment made the verifier interpret the pointer as a scalar and incorrectly reject the program when it tries to access memory through the scalar. As a workaround, developers encapsulated access to `data` in inline assembly (Figure 2b) to prevent LLVM from generating 32-bit move as an optimization (LLVM does not optimize inlined assembly). The verifier then treats the register as a pointer rather than a scalar.

In another case [38], developers were forced to use `volatile` when loading from a 32-bit integer pointer and only using its upper 16 bits. Without `volatile`, LLVM optimized the code to only load the upper 16 bits from the pointer, which the verifier perceives as a size mismatch violation.

In fact, many eBPF programs today can only pass the verifier if compiled with `-O2` optimization—the verifier has a hardwired view of eBPF extension bytecode, which the compiler cannot generate with other levels, including `-O0`.

Changing code to assist verification. In this pattern, developers had to assist the verifier manually. A common pattern is refactoring the code into new functions when the verifier loses track of values in eBPF programs. It is often unclear what code needs to be refactored to pass the verifier, which significantly burdens developers. In a case from Cilium [86], developers had to refactor a network policy check into a separate function to change the program control flow that caused verifier to lose track of certain values in the program. We discuss examples of this category in more details in §A.

Dealing with verifier bugs. The language-verifier gap is further exacerbated by verifier bugs [35, 63, 72, 85], as developers need to acquire knowledge of the verifier's expectations and deficiencies. Moreover, different kernel versions can have different verifier bugs. Dealing with verifier bugs and maintaining compatibility across kernel versions is non-trivial. In a Cilium case [57], the verifier rejected a correct program with valid access to the context pointer due to the verifier's incorrect handling of constant pointer offsets. The verifier bug was known, but the fix was not present in all kernel versions. Cilium developers had to tweak their program to avoid the bug-triggering, yet correct, context pointer access so the code could verify on all kernel versions.

Reinventing the wheels. Developers may need to reimplement existing functions to pass the verifier. In Aya, the default definition of the `memset` and `memcpy` intrinsics provided by the language toolchain failed to pass the verifier [50]. Aya eventually implemented its own version for both intrinsics, using a simple loop to iterate over the data to avoid ever tripping the verifier. This case reflects a key challenge of using eBPF for large, complex extension programs, as developers may need to re-implement many standard, nontrivial library functions.

[1] Since BMC, the limit has increased, but the fundamental gap remains.

3.2 Implications

Our analysis shows that the language-verifier gap causes severe usability issues in developing and maintaining eBPF kernel extensions. eBPF developers have to implement arcane fixes and change their mental model to meet the verifier's constraints. If an eBPF extension fails to verify, the verifier log rarely pinpoints the root causes and cannot help trace back to the source code. Since it is hard to require compilers like LLVM to follow the eBPF verifier's implementations, we expect the language-verifier gap will continue to exist, especially for large, complex extension programs.

4 Key Idea and Safety Model

The key idea of Rex is to realize *safe* kernel extensions without a separate layer of static verification. Our insight is that the desired safety properties of kernel extensions can be built on the foundation of language-based properties of a safe programming language like Rust, together with extralingual runtime checks. In this way, the in-kernel verifier can be dropped, and the language-verifier gap can be closed. Rex extensions are strictly written in a *safe* subset of Rust. We choose Rust as the safe language for kernel extensions (instead of other languages like Modula-3 [34] and Sing# [54]) because Rust is already supported by Linux [45] and offers desired language features for practical kernel code [36,71,82]. Rex enforces the same set of safety properties eBPF enforces (§2). Hence, Rex extensions fundamentally differ from unsafe kernel modules.

Safety Model. Rex follows eBPF's non-adversarial safety model—the safety properties focus on preventing programming errors from crashing/hanging the kernel instead of malicious attacks. Like eBPF, Rex extensions are installed from a trusted context with root privileges on the system. Rex extensions can only be written in safe Rust with selected features and language-based safety is enforced by a trusted Rust compiler (§5.1). Unlike Rust kernel modules that can use unsafe Rust, the language-based safety of Rex extensions is strictly enforced. Other safety properties that are not covered by language-based safety (e.g., termination) are checked and enforced by the lightweight Rex runtime.

While historically eBPF supported unprivileged mode [47] and there are research efforts in supporting unprivileged use cases for kernel extensions [64, 65, 73], in practice, eBPF and other frameworks (e.g., KFlex [52]) no longer pursue it [53, 58]. The reasons come from inherent limitations of securing eBPF or kernel extensions in general.

First, it is hard for the eBPF verifier to prevent transient execution attacks like Spectre attacks completely, without major performance and compatibility overheads (see [53]). Specifically, new Spectre variants are being discovered; though many of them are bugs in hardware, they cannot be easily detected and fixed by static analysis [68]. Sandboxing techniques cannot completely prevent Spectre attacks either, e.g., SafeBPF [73] only prevents memory vulnerabilities, while

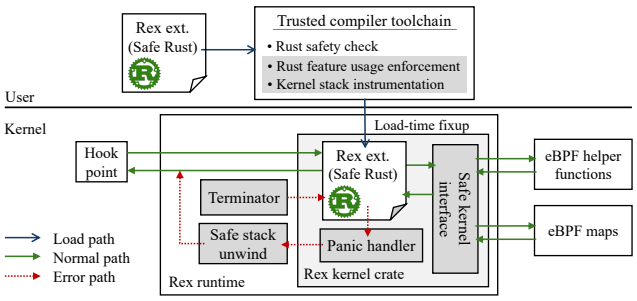

Figure 3: Overview of the Rex kernel extension framework. The gray boxes are Rex components.

BeeBox [65] only focuses on two Spectre variants and requires manual instrumentation of helper functions. For these reasons, the Linux kernel and major distributions also have moved away from unprivileged eBPF [25, 58, 80].

Second, eBPF chose not to be a sandbox environment (like WebAssembly or JavaScript) that does not know what code will be run [53]. Instead, the development of eBPF assumes that "*the intent of a BPF program is known* [53]."

Lastly, the constantly reported verifier vulnerabilities [63, 88, 91] indicate that a bug-free verifier is hard in practice.

Trusted Computing Base (TCB). With Rex's safety model, the TCB consists of the Rust toolchain, the Rex kernel crate, and the Rex runtime. Rex has to trust the Rust toolchain for its correctness to deliver language-based safety. We believe the need to trust the Rust toolchain is acceptable and does not come with high risks with our safety model. Recent work on safe OS kernels [36, 76, 82] makes the same decision to establish language-based safety by trusting the Rust toolchains. The active effort on extensive fuzzing and formal verification of the Rust compiler [12, 24, 66, 67, 69, 70] may further reduce the risk. Certainly, we acknowledge that the existing Rust compiler, such as rustc [30], is larger than the eBPF verifier.

5 Rex Design

The key challenge of the Rex design is to provide safety guarantees of kernel extensions (listed in §2) on top of Rust's safe language features (adopting a safe language alone is insufficient, as in Rust kernel modules).

Figure 3 gives an overview of the Rex framework. To realize language-based safety, Rex enforces kernel extensions to be strictly written in *safe* Rust with selected features. The Rex compiler toolchain rejects any Rex program that uses unsafe language features. Although this safe subset of Rust already provides inherent language-based safety within Rex extensions, eliminating undefined behaviors, safety of extensions is only achieved with the presence of safe kernel interactions provided by the *Rex kernel crate*. The kernel crate is trusted and bridges Rex extensions with unsafe kernel code. Rex builds on top of the eBPF helper function interface to provide a safe kernel interface for Rex extensions to interact with the

kernel using safe Rust wrappers and bindings. The safe interface encapsulates the interaction across the foreign function interface in the kernel crate. We reuse the eBPF helper interface, because it is designed for kernel extensions with a clearly defined programming contract and separates extensions from the kernel's internal housekeeping (e.g., RCU [32]).

Rex employs a lightweight extralingual in-kernel runtime that checks safety properties that are hard for static analysis. The runtime enforces program termination, kernel stack safety, and safe handling of runtime exceptions (e.g., Rust panics).

Although Rex reuses the existing hook points of eBPF, it assumes no nesting of extension programs, where another program executes on top of an existing program (e.g., by kprobing a helper function). This simplifies the reasoning of shared states and data races. At the same time, we note that uncontrolled program nesting is also unsafe in existing eBPF.

5.1 Safe Rust in Rex

Rex only allows language features that are safe in the context of kernel extensions. First, Rex excludes any *unsafe* Rust code as it misses important safety checks from the Rust compiler and can violate various safety properties (§2). Second, Rex forbids Rust features that interfere with Rust's automatic management of object lifetimes, which include `core::mem::{forget,ManuallyDrop}` and the `forget` intrinsic. These features are considered safe in Rust but violate resource safety of kernel extensions by facilitating resource leakage. Third, language features that cannot be supported in the kernel extension context are excluded by Rex. This group contains the `std` [26] crate and dynamic allocation support (not available in `no_std` build [20]), the floating point and SIMD support (generally cannot be used in kernel space), and the `abort` intrinsic (triggers an invalid instruction). Note that dynamic allocation may be supported by hooking the `alloc` [1] crate to the kernel allocator. We plan to explore the use of dynamic allocation in extensions in future works (§8).

To enforce the restrictions, Rex configures the Rust compiler and linter to reject the use of prohibited features. Specifically, we set compiler flags [17] to forbid unsafe code and unstable Rust features, which include SIMD and intrinsics. For individual langauge items such as `core::mem::forget`, we configure the Rust linter [7] to detect and deny their usage. We further remove floating point support by setting the target features [8] in Rex compilation. The `std` library and dynamic allocation are already unavailable in `no_std` environment used by Rex and therefore warrant no further enforcement.

5.2 Memory safety

Rex enforces that extensions access kernel memory safely. There are two common memory access patterns, depending on the ownership of the memory region: (1) memory owned by the extension (e.g., a stack buffer) is sent to the kernel through helper functions, and (2) memory owned by the kernel (e.g., a kernel struct) is accessed by the extension.

Memory owned by extensions. A Rex extension can allocate memory on the stack and send it to the kernel (e.g., asking the kernel to fill a stack buffer with data) via existing eBPF helper functions. Rex ensures no unsafe memory access and thus prevents stack buffer overflow and kernel crash (e.g., corruption of the return address on the stack).

Unlike eBPF, which checks a memory region with its size on every invocation of a helper function, in Rex, the strict type system of Rust already prevents unsafe access. Rex leverages the generic programming feature of Rust [13] to ensure that the size sent through the helper function interface is always valid. For helper functions that take in pointer and size as inputs, the Rex kernel crate creates an adaptor interface that parametrizes the pointer type as a generic type parameter. The interface queries the size of the generic type from the compiler and invokes the kernel interface with this size as an argument. Since Rust uses *monomorphization* [18], the concrete type and its size are resolved at compile time, adding no runtime overhead. In this way, the size is guaranteed to match the type statically and the kernel will never make an out-of-bound access. This works for both scalar types and array types. We use Rust's *const generics* to allow a constant to be used as a generic parameter [13] to encode array lengths.

Memory owned by the kernel. The kernel can provide extensions with a pointer to kernel memory (e.g., map value pointers and packet pointers). The extension must not have out-of-bound memory accesses. In eBPF, the verifier checks uses of kernel pointers with a static size, e.g. map value pointers (maps store the size of values); for pointers without a static size, like packet data pointers, the verifier requires extensions to explicitly check memory boundaries.

In Rex, pointers with static sizes are handled through the Rust type system. The kernel map interface of Rex encodes the key and value types through generics and returns such pointers to extension programs as safe Rust references. To manage pointers referring to dynamically sized memory regions, the Rex kernel crate abstracts such pointers into a Rust *slice* with dynamic size. Rust slices provide runtime bounds checks (§5.5), which allow the checking to happen without explicit handling by the extension.

Rust slices are in principle similar to `dynptr` in eBPF [96], but provide more flexibility. eBPF `dynptr`s are pointers to dynamically sized data regions with metadata (size, type, etc); however, access to the `dynptr`'s referred memory must be of a static size. Rust slices allow dynamically sized access to the underlying memory, benefiting from its runtime bounds checks. Moreover, the `bpf_dynptr_{read,write}` helpers do not implement a zero-copy interface like that available in Rust slices. While `bpf_dynptr_{data,slice}` helpers allow extensions to obtain data slices without copying, they again require explicit checks of the bound of the slice. As a tradeoff, eBPF `dynptr`s avoid runtime overheads of dynamic bounds checks, which we find negligible in our evaluation (§7.2).

5.3 Extended type safety

Rex extends Rust's type safety to allow extension programs to safely convert a byte stream into typed data. This pattern is notably found in networking use cases, where extensions need to extract the protocol header from a byte buffer in the packet as a struct. Safety of such transformations is beyond Rust's native type safety because they inevitably involve unsafe type casting. eBPF allows pointer casting; the verifier ensures: (1) the program does not make a pointer from a scalar value, and (2) the new type fits the memory boundary.

Rex also enforces the above two properties so that the reinterpreting cast (dubbed "transmute" in Rust) is safe. Rex extends Rust's type safety to cover such casts. To satisfy (1), Rex ensures the target Rust type of casting does not contain raw pointers or safe references in any transitively reachable fields. Rex introduces a Rust *auto trait* [2], `rex::NoRef`. The Rust compiler automatically implements an auto trait on a type unless the type is explicitly opted out via a *negative implementation* [19] or the type contains a field on whose type the trait is not implemented. We negatively implement `rex::NoRef` on the raw pointer and safe reference types of Rust, which ensures any type transitively containing a pointer or a reference will not have an implementation of the trait generated by the Rust compiler. Note that polymorphic types without statically known fields are not a problem because they take the form of *trait objects* [31] in Rust and can only exist behind pointers that already do not have an implementation of `rex::NoRef`. By requiring the target type of casting to implement `rex::NoRef` via trait bounds [4], (1) is effectively satisfied. To satisfy (2), Rex performs explicit bound checking in the transmute interface to ensure the target type always fits.

5.4 Safe resource management

Rex extensions are ensured to acquire and release resources properly to avoid leaks of kernel resources (e.g., refcounts and spinlocks). Different from eBPF where the verifier checks all possible code paths to ensure the release of acquired resources, Rex uses Rust's Resource-Acquisition-Is-Initialization (RAII) pattern [21]—for every kernel resource a Rex extension may acquire, the Rex kernel crate defines an RAII wrapper type that ties the resource to the lifetime of the wrapper object.

For example, when the program obtains a spinlock from the kernel, the Rex kernel crate constructs and returns a *lock guard*. The lock guard implements the RAII semantics through the `Drop` trait [9] in Rust, which defines the operation to perform when the object is destroyed. In the case of the lock guard, its `drop` handler releases the lock. Rex uses compiler-inserted `drop` calls at the end of object lifetime during normal execution, and implements its own resource cleanup mechanism (§5.5) for exception handling. The use of RAII automatically manages kernel resources to ensure safe acquisition and release. Extension programs do not need to explicitly release the lock or drop the lock guard.

5.5 Safe exception handling

While certain Rust safety properties are enforced statically by the compiler, the others are checked at runtime and their violations trigger exceptions (i.e., Rust panics). To handle exceptions in userspace, Rust uses the Itanium exception handling ABI [14] to unwind the stack. A Rust panic transfers the control flow to the stack unwinding library (e.g., llvm-libunwind), which backtracks the call stack and executes cleanup code and catch clauses for each call frame. Unfortunately, this ABI is unsuitable for kernel extensions:

- Unlike in userspace where failures during stack unwinding crash the program,[2] stack unwinding in kernel extensions cannot fail—kernel extensions must not crash the kernel and must not leak kernel resources.
- Unwinding generally executes destructors for all existing objects on the stack, but executing untrusted, user-defined destructors (via the `Drop` trait [9] in Rust) is unsafe.

Rex implements its own exception handling framework with two main components: (1) graceful exit upon exceptions, which resets the context, and (2) resource cleanup to ensure release of kernel resources (e.g., reference counts and locks).

Graceful exit. Rust invokes the panic handler upon a panic, which diverges the control flow from normal execution path. To gracefully exit the program upon a panic, the control flow must be redirected back to the normal execution path and with the correct context (e.g., stack pointer). To ensure such a graceful exit, Rex implements a small runtime (Figure 4), which consists of a program dispatcher and a landingpad in the kernel, as well as a panic handler in the Rex kernel crate. The dispatcher takes the duty of executing the extension program (like the eBPF dispatcher). It saves the stack pointer of the current context into per-CPU memory, switches to a dedicated program stack (§5.6), sets the termination state (§5.7), and then calls into the program. If the program exits normally, it returns to the dispatcher, which switches the stack back and clears the termination state. Under exceptional cases where a Rust panic is triggered, the panic handler releases kernel resources currently allocated by the extension, and transfer control to the in-kernel landingpad to print debug information to the kernel ring buffer and return a default error code to the kernel. Then, the landingpad redirects control flow to a predefined label in the middle of the dispatcher, where it restores the old value of the stack pointer from the per-CPU storage. This effectively unwinds the stack and resets the context as if the extension returned successfully.

Resource cleanup. Correct handling of Rust panics requires cleaning up resources acquired by the extension. However, static approaches that rely on the verifier to pre-compute resources to be released during verification (e.g., object table in [52]) do not apply to Rex due to the language-verifier gap.

[2] Theseus [36] implements stack unwinding in the kernel. But, it assumes that unwinding never fails; faults in unwinding result in kernel failures.

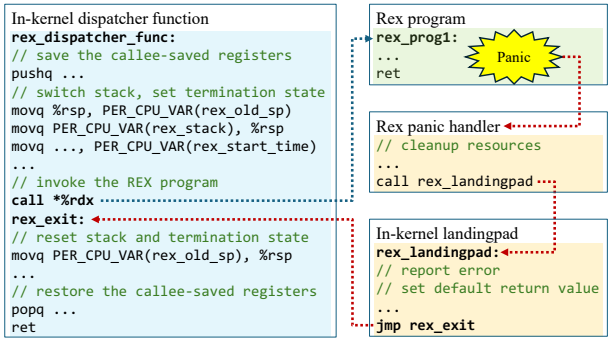

Figure 4: Exception handling control flow in Rex

Our insight is that extensions can only obtain resources by explicitly invoking helper functions. So, Rex records the allocated kernel resources during execution in a per-CPU buffer, which is in principle like the global heap registry in [82]. Upon a panic, the panic handler takes the responsibility to correctly release kernel resources, which involves traversing the buffer and dropping recorded resources.

We implement the cleanup code as part of the panic handler in the Rex kernel crate, as it is responsible for coordinating helper function calls that obtain kernel resources. Implementing the cleanup mechanism in the kernel crate ensures safety: as the code is called upon panic, it must not trigger deadlocks or yet another Rust panic to fail panic handling. To this end, we avoid using functions that may panic as much as possible and explicitly ensure the panic conditions cannot be met in case their usage is inevitable. This careful design of the Rex kernel crate frees the cleanup code and `drop` handlers of locks and panic-triggering code. Kernel functions invoked by such code may still hold locks internally, but they are self-contained and do not propagate to Rex (deadlocks in kernel functions is out of the scope of Rex). Rex does not execute user-supplied `drop` handlers upon panic, as they are not guaranteed to be safe (i.e., free of a nested panic) under panic handling context.

Rex implements a crash-stop failure model—a panicked extension is removed from the kernel. Any used maps and other Rex extensions sharing the maps will also be removed recursively. This prevents extensions sharing the maps from running in a potentially inconsistent state—exception handling in Rex already ensures the kernel is left in a good state.

5.6 Kernel stack safety

Kernel extensions should never overflow the kernel stack. Unlike userspace stacks which grow on demand with a large maximum size, the stack in kernel space has a fixed size (4 pages on x86-64). The eBPF verifier checks stack safety by calculating stack size via symbolic execution. However, it is reported that stack safety is broken in eBPF due to the difficulties of statically analyzing indirect tail calls [91] and uncontrolled program nestings [43].

Our insight is that stack safety can be enforced at compile time to avoid runtime overhead if the extension program has no indirect or recursive calls, as the stack usage can be statically computed. Otherwise, it is easy to check stack safety at runtime. Rex, therefore, takes a hybrid approach and selects between static and dynamic checks based on the situation.

Static check. The static check is done by a Rex-specific compiler pass (§6). If the extension has no indirect or recursive calls, its total stack usage can be calculated by traversing its global static callgraph and sum up the size of each call frame. We turn on fat LTO and use a single Rust codegen unit [8] for Rex programs to ensure the compiler always has a global view across all translation units.

Runtime check. For extensions with indirect or recursive calls, it is hard to calculate the stack usage from the callgraph due to the presence of unknown edges (indirect calls) and cycles (recursive calls). Under these cases, Rex performs runtime checks. The Rex compiler pass first ensures each function in the program takes less than one page (4K) of stack. This is more relaxed than the frame size warning threshold (2K) in Linux and ensures enough stack to handle Rust panics. Before each function call in the extension, the compiler inserts a call to the `rex_check_stack` function from the kernel crate to check the current stack usage: if the stack usage exceeds the threshold, it will trigger a Rust panic and terminate the program safely (§5.5).

To manage stack usage of Rex extensions effectively, Rex implements a dedicated kernel stack for each extension. The dedicated stacks are allocated per-CPU and virtually mapped at kernel boot time with a size of eight pages. Before executing a Rex extension, the dispatcher (Figure 4) saves the stack pointer of the current context, and then sets the stack and the frame pointer (already saved with other callee-saved registers) to the top of the dedicated stack. When the extension exits, the original stack and frame pointers are restored.

Rex sets the stack usage threshold to be four pages for extension code; it reserves the next four pages with following considerations: (1) helper functions are not visible at compile time but they also account for stack usage during execution; we use four pages as the de facto stack size used by the kernel itself, and (2) since stack usage of each function is limited to one page of stack, in the worse case, the remaining stack space is at least three pages when `rex_check_stack` triggers a Rust panic. Since the panic handler is implemented in the kernel crate and does not change with programs, this worse-case guarantee empirically leaves enough space for panic handling and stack unwinding. Rex's dynamic approach achieves stronger stack safety than that of eBPF.

5.7 Termination

Termination is an important property of kernel extensions. In eBPF, an extension with a back edge or exceeds the instruction limit will be rejected, regardless whether it eventually terminates. Since it is challenging to statically reason about termination of an arbitrary program, the eBPF termination

semantic creates many false positives and greatly contributes to the language-verifier gap. KFlex [52] lifts the back edge restriction by inserting cancellation points in eBPF bytecode on all back edges during verification, which triggers termination at runtime. However, back edge analysis is non-trivial outside eBPF bytecode and is unreliable for general Rust programs.

Instead of following eBPF's termination semantic that contributes to the language-verifier gap, Rex employs a termination semantic based on extension execution time. Rex implements termination support in its runtime, which interrupts and terminates extensions that run for too long. Rex limits the run time of extensions by leveraging kernel timers as watchdogs. Rex builds the runtime on the high resolution timer (`hrtimer`) subsystem in Linux [56]. Since `hrtimer` callbacks execute in hardware timer interrupts, they are capable of interrupting the contexts in which most extensions execute (soft interrupts and task context [42]). Since hardware timer interrupts are periodically raised by the processor, regardless whether an `hrtimer` is present, executing timer callbacks in this existing hardware timer interrupt adds no extra interrupt or context switch, keeping the watchdog overhead minimal.

Rex sets one timer for each CPU to avoid inter-core communication, in contrast to using a single, global timer to handle programs from all CPUs. Each timer only needs to monitor extensions running on the core. Rex arms the timers at kernel boot time, which are triggered periodically with a constant timeout, and re-armed each time after firing.[3]

Rex implements its watchdog logic in the timer handlers. When a timer fires, its handler suspends any soft interrupt or task context, and saves its registers. The handler then checks the current CPU on whether the termination timeout of the Rex extension in the stopped context has been reached. This is done by comparing the extension start time (stored as a per-CPU state as shown in Figure 4) with the current time. If the extension exceeds the threshold, the timer handler overwrites the saved instruction pointer register to the panic handler (§5.5). After returning from the timer interrupt, the extension executes its panic handler, which cleans up kernel resources and gracefully exits. Rex sets both the timer period and runtime threshold to the default RCU CPU stall timeout (Rex extensions run in RCU locks as they use eBPF hook points).

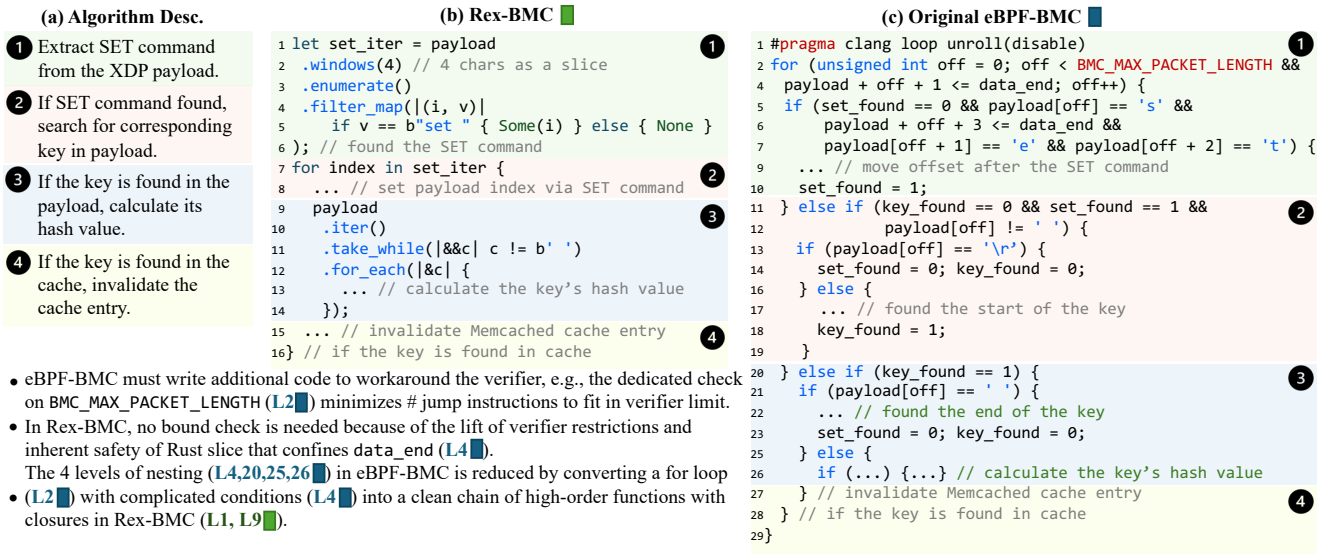
Rex defers termination when the extension is running kernel helper functions to avoid disrupting the kernel's internal resource bookkeeping; it also does not terminate an extension if it is in the panic handler. Rex uses a per-CPU tristate flag to track the state of an extension: (1) executing extension code, (2) executing kernel helpers or panic handlers, and (3) termination requested. A helper call changes the state from 1 to 2. When executing the timer handler, if the flag is at state 2, the termination handler modifies it to state 3 without changing the instruction pointer. When a helper returns, if the flag is at state 3, the panic handler is called to gracefully exit.

A corner case of this design is deadlock. Since spinlock acquisition in Rex is implemented by a kernel helper function, a deadlocked program will never return from the helper, and therefore will never be terminated properly. Rex follows eBPF's solution toward deadlocks, where a program can only take one lock at a time. This is achieved by using a per-CPU variable to track whether the program currently holds a lock—a program trying to acquire a second lock will trigger a Rust panic. We note that if the ability of holding multiple locks at the same time is desired, the kernel spinlock logic can be modified to check the termination state of Rex programs during spinning and terminate a deadlocked program accordingly.

Limitation. Rex uses hard interrupts, and thus cannot interrupt extensions that are already executing in hard or non-maskable interrupts [42] (e.g., hardware perf-event programs). Such extensions are not targeted by Rex, as they are supposed to be small, simple, and less likely to encounter the language-verifier gap. Note that Rex extensions and eBPF extensions are not mutually exclusive and can co-exist.

Moreover, the termination of a timed-out Rex extension may be delayed if the extension is already interrupted by another event when the timer triggers (the extension registers will not be available to the timer handler). Rex needs to wait for a triggering of the timer that directly interrupts the extension. However, to date, we have never encountered such delayed termination in our experiments (§7).

6 Implementation



We implement Rex on Linux v6.11. Rex currently supports five eBPF program types (tracepoint, kprobe, perf-event, XDP, and TC) and shares their in-kernel hookpoints. Rex only includes helpers for kernel interactions. Helpers introduced due to contraints posed by the eBPF verifier (e.g., `bpf_loop`, `bpf_strtol`, and `bpf_strncmp`) are entirely excluded by Rex.

Kernel crate. The Rex kernel crate is implemented in 3.5K lines of Rust code, among which 360 lines are unsafe Rust code. The kernel crate contains the following components:

- *Helper function interface* in Rex is implemented on top of eBPF helpers, with wrapping code that allows Rex extensions to invoke helpers with safe Rust types.
- *Kernel data-type bindings* are generated for the extension to access kernel data types defined in C. Rex uses rust-bindgen [22] to automatically generate kernel bindings and integrates it into the build process of extensions. Rex programs need to be rebuilt for each kernel they target to account for ABI differences in kernel data types.
- *Program context* in Rex is wrapped in a Rust struct, which marks the context as private and implements getter methods for its public fields.

Kernel support. Rex implements the extension load code and the runtime in the kernel in 2.2K lines of C code on

[3] Disarming the timer when no extension is running saves CPU cycles, but incurs high overhead due to timer setup on the hot path of extension execution, especially for frequently triggered extensions (e.g., XDP extensions [5]).

- eBPF-BMC must write additional code to workaround the verifier, e.g., the dedicated check on `BMC_MAX_PACKET_LENGTH` (L2) minimizes # jump instructions to fit in verifier limit.
- In Rex-BMC, no bound check is needed because of the lift of verifier restrictions and inherent safety of Rust slice that confines `data_end` (L4). The 4 levels of nesting (L4,20,25,26) in eBPF-BMC is reduced by converting a for loop
- (L2) with complicated conditions (L4) into a clean chain of high-order functions with closures in Rex-BMC (L1, L9).

Figure 5: Cache invalidation implementation of Rex-BMC and eBPF-BMC; Rex leads to cleaner, simpler code.

vanilla Linux. To load an extension, the kernel parses the ELF executable of the extension and locates all the `LOAD` segments in the executable. It then allocates new pages and maps the `LOAD` segments into the kernel address space based on the size and permissions of the segments. The load function is responsible for fixups on the program code to resolve referenced kernel helpers and eBPF maps. The Rex runtime in the kernel consists of the stack unwinding mechanisms (§5.5), support for dedicated kernel stack (§5.6) and termination (§5.7).

Compiler support. Rex implements a compiler pass for Rex-specific compile-time instrumentations on the stack (§5.6). We take advantage of Rust's use of LLVM [29] as its default code generation backend and implement the pass in LLVM. A Rex-specific compiler switch is also added to the Rust compiler frontend (rustc [30]) to gate the Rex compiler pass.

7 Evaluation

We evaluate Rex in terms of its usability and performance (with both macro and micro benchmarking).

7.1 Usability

Measuring usability is challenging. We evaluate Rex in two ways: (1) heuristic evaluation on whether it saves workarounds to the language-verifier gap, and (2) our dog-fooding experience of using Rex to implement a large, complex extension (BMC [55]). Overall, we find that Rex enables developers to write simpler and cleaner code.

Eliminating workarounds. Because Rex introduces no language-verifier gap, none of the workarounds in §3 is needed in writing Rex extensions.

- Rex extensions have no limit on program size and complexity. There is no need to artificially refactor extension programs into smaller or simpler ones (§3.1).
- There is no need to artificially make Rex extensions verifier-friendly (§3.1). In fact, by decoupling static analysis from the kernel, Rex can enable new analysis (e.g., by allowing compilers to optimize for extra analysis/verification [99]).
- For the same reason, developers no longer need to tweak code to assist verification (§3.1).
- Developers no longer need to manage different verifier bugs across kernel versions (§3.1). The Rust compiler can have bugs and break safety guarantees, but it is arguably easier to upgrade than the kernel for fixes.
- Rex enables developers to use rich builtin intrinsics defined by the Rex toolchain without reinventing wheels (§3.1).

Case study: Rex-BMC We rewrite BMC [55] as a Rex kernel extension (Rex-BMC), which was originally written in eBPF extensions (eBPF-BMC). Rex-BMC is not a line-by-line translation of eBPF-BMC, because Rex provides a more friendly programming experience (e.g., no need to split programs due to the verifier limit; see §3.1). Rex-BMC covers all safety aspects discussed in §5. The extension accesses packet payloads as Rust slices that provide memory safety (§5.2) and safe exception handling (§5.5), leverages extended type safety (§5.3) from Rex to reinterpret payload bytes into Memcached headers, and uses spinlocks that are safely managed via RAII (§5.4). Kernel stack checks (§5.6) and termination support (§5.7) are also covered by Rex-BMC as they are not bound to specific program implementations. Rex-BMC does not contain indirect calls, and thus does not invoke runtime stack checks. Additionally, Rex-BMC uses four helper functions from the Rex kernel crate to perform map accesses and packet manipulations. In this section, we discuss Rex-BMC from the usability perspective and measure its performance in §7.2.

Our experience shows that Rex enables cleaner and simpler extension code, compared to eBPF. Essentially, Rex enables

us to focus on key program logic without the overhead of passing the verifier. For example, we no longer need to divide code into in parts, add auxiliary code to help the verifier, dealing with tail calls and state transfer, etc. In addition, we can directly use Rust's builtin language features and libraries (e.g., iterators and closures). As one metric, Rex-BMC is written in 326 lines of Rust code. In comparison, eBPF-BMC is written in 513 lines of C code (splitting into seven programs).

Figure 5 compares the code snippets of eBPF-BMC and Rex-BMC that implement cache invalidation, respectively, as a qualitative example. The checks in eBPF-BMC code, required by the eBPF verifier, including these for offset and `data_end` limits, are now being enforced via the inherent language features of Rust, such as slices with bound checks in Rex (L2 and L10). The check on `BMC_MAX_PACKET_LENGTH`, which serves as a constraint to minimize the number of jump instructions to circumvent the eBPF verifier, is no longer needed. Other checks for identified SET commands and loops states can be implemented with built-in functions and closures in an easy and clean way (L4–L6 and L11).

Moreover, with the elimination of program size and complexity limits in Rex-BMC, developers no longer have to save the computation state in a map across tail calls, which leads to a clearer and more efficient implementation.

Note that the usability benefit does not come from the expressiveness difference between Rust and C, but from closing the language-verifier gap via Rex. Evidently, the cleaner code of Rex-BMC would fail the verifier if it were to be compiled into eBPF (e.g., via Aya [3]): the compiler is unable to generate verifier-friendly code for convenient language features such as slices, and the verifier complexity limits will always be an issue. Rex allows us to fully leverage Rust's expressiveness without being constrained by verification issues.

7.2 Macro benchmark

Rex's usability benefits do not come with a performance cost. We show that Rex extensions deliver comparable performance as eBPF extensions. Rex-BMC achieves a throughput of 1.98M requests per second (RPS) on 8 cores, which is slightly higher than eBPF-BMC (1.92M).

Our setup consists of a server machine and a client machine. The server machine runs the Rex custom kernel based on Linux v6.11.0 on an AMD EPYC 7551P 32-Core processor with 112 GB memory without SMT and Turbo. The client machine runs a vanilla v6.11.0 Linux kernel on an AMD Ryzen 9 9950X processor with 96 GB memory. Both machines are equipped with Mellanox ConnectX-3 Pro 40GbE NICs and are connected back-to-back using a single port.

We evaluate the throughput of (1) Memcached which binds multiple UDP sockets to the same port [55], (2) Memcached with eBPF-BMC, and (3) Memcached with Rex-BMC. For each setup, we vary the number of CPU cores for Memcached server and NIC IRQs and pin one Memcached thread onto each available core. We use the same workloads as in BMC [55], albeit with a smaller number of Memcached keys.

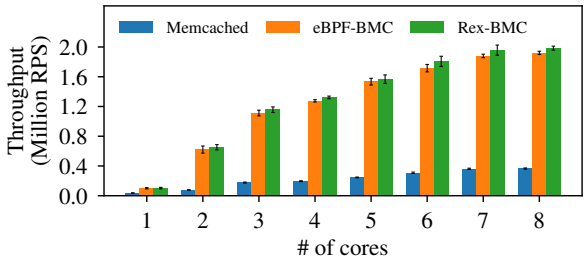


Figure 6: Throughput of Memcached, with eBPF-BMC, and with Rex-BMC under different number of cores.

Figure 6 shows the throughput of the three setups under different numbers of CPU cores. Memcached processes all requests in userspace with the overhead of the kernel network stack, achieving only 37K RPS on a single core and 365K RPS on 8 cores. Both eBPF-BMC and Rex-BMC achieve a much higher throughput as they process a large fraction of requests at NIC driver level without going through the kernel network stack. With 8 cores, eBPF-BMC and Rex-BMC achieve a throughput of 1.92M and 1.98M, and a performance benefit of 5.26x and 5.43x, respectively. The slight performance improvement over eBPF is attributable to the elimination of overheads of tail calls and associated state-passing via maps, along with optimizations in the rustc frontend and x86 backend, despite the overhead of additional runtime checks.

7.3 Micro benchmark

Several of Rex's design decisions could introduce overheads, despite being invisible in the Rex-BMC evaluation. We use specially designed microbenchmarks to stress our design and measure overheads. We show that overheads exist in some pessimistic cases, but have negligible impact in real-world scenarios. All experiments are performed on the same server machine in the Rex-BMC experiments (§7.2).

Setup and teardown. Entering and exiting a Rex program requires Rex-specific operations (Figure 4). Rex's use of a dedicated stack requires saving the stack pointer and setting the new stack and frame pointer to the dedicated stack (and restoring to the saved values after the extension exits). Rex also needs to set up the per-CPU state used by its termination mechanism (§5.7). In total, these operations add eight instructions on the execution path in Rex. To measure the overhead, we implement an empty extension program in both eBPF and Rex and record their execution time (including the program dispatcher). As shown in Table 2, the measured execution time of the empty Rex and eBPF programs only differ in around a nanosecond on average.

Exception handling Rex's safe cleanup for exception handling requires recording allocated resource at runtime (§5.5), which, compared to eBPF, adds overhead. We measure the overhead using a program that acquires and then immediately releases an eBPF spinlock. Since the acquired spinlock needs

Table 2: Time to execute an empty extension program and to acquire and release a spinlock in eBPF and Rex (nanosecond)

Extension	Empty prog runtime	Spinlock runtime
eBPF	42.1 ± 4.1 ns	130.4 ± 20.3 ns
Rex	42.6 ± 5.8 ns	183.1 ± 27.5 ns

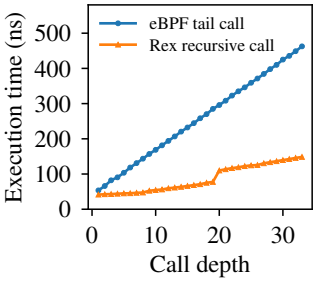

Figure 7: eBPF tail call and Rex recursive call time

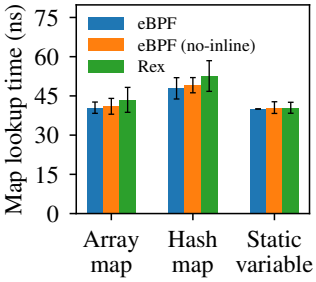

Figure 8: Map lookup time under various setups

to be released upon Rust panics, Rex's cleanup mechanism records it in its per-CPU buffer. Additionally, Rex sets up a per-CPU state flag to indicate execution of a helper function (§5.7). The program is implemented in both eBPF and Rex and the time used to acquire and release the spinlocks are measured. Table 2 shows that the runtime difference between eBPF and Rex is roughly 50 nanoseconds. We argue that such runtime difference is negligible in real world use cases, as exemplified by Rex-BMC (§7.2) that uses fine-grained locking (one spinlock per map entry).

Stack check. Stack checks are added before function calls in Rex extensions that contain indirect or recursive calls (§5.6). We implement recursive extension programs in both eBPF and Rex to measure the overhead. The recursive function calls itself for a controlled number of times. In Rex, we pass the call depth as the argument to the recursive function; since eBPF does not support recursive functions, we use eBPF tail calls to implement the logic—since it is inconvenient to pass arguments to tail-called programs (§3.1), we use a static variable to set the call depth. Figure 7 plots execution time of the recursive programs with call depths from 1 to 33 (eBPF cannot do more than 33 tail calls). Rex is roughly 3x faster than eBPF. The overhead of eBPF is due to its runtime check on tail-call count limit and accessing the static variable, which is a map in eBPF (not a register as in Rex's normal calls).

Map access Map access in Rex is expected to have more overhead than in eBPF. First, Rex implements wrapping code to enforce safety of helper function calls (§6). Moreover, the eBPF JIT compiler inlines the helper function for map lookup at load time as a performance optimization; however, inlining is not available in Rex (no JIT in Rex). We measure map lookup time of Rex, compared with eBPF, with and without inlining, including array maps, hash maps, and static variables. In eBPF, static variables are converted into maps; we use a static Rust atomic variable in Rex, as the counterpart of a static variable map in eBPF. Figure 8 shows the lookup time of different maps in eBPF and Rex, respectively. We find that inlining map lookups in eBPF are $\sim$0.5*ns* faster on array maps and $\sim$1.2*ns* faster on hash maps. An additional slowdown of 2*ns*–4*ns* is present in Rex over non-inlined eBPF, due to the wrapping code. Static variables in eBPF are always accessed via direct load without invoking a helper. Hence, their access latency is almost the same to accessing Rust atomic variables.

8 Discussion

Verification without language-verifier gaps. Rex currently uses language features of Rust to ensure safety of kernel extensions. This approach defers the checking of some safety properties to the runtime (e.g., termination, integer errors). It may be possible to minimize the amount of runtime errors by incorporating Rust-based verification techniques, e.g., ensuring freedom of panics [15, 24, 69, 70, 105]. Certainly, push-button verification techniques that use symbolic execution such as PanicCheck [105] are likely to re-introduce the language-verifier gap. We suspect that using verification techniques that combine proofs and programming [27, 28, 69, 70], such as Verus for Rust may allow Rex to reduce runtime errors *without* the language-verifier gap.

Dynamic memory allocation. eBPF has recently supported dynamic allocation [51] that allows extension programs to request memory from the kernel using allocation kfuncs [46]. Rex currently does not support dynamic memory allocation. We plan to integrate memory allocation [1] of Rust with the eBPF all-context allocator [44], granting Rex dynamic allocation. Dynamic allocation enhances programmability of extension programs and opens up more advanced use cases [52]. It also makes more components of the Rust standard library available, notably the collection and smart pointer types with automatic memory management.

Kernel crate maintenance. The Rex kernel crate inevitably needs to use unsafe Rust, as it directly interacts with kernel functions and variables defined in C. As a principle, unsafe Rust code must not be used for escaping safety checks but only when it is the last resort (mostly for foreign function interface, FFI). This keeps the scope of unsafe Rust at its minimum—the Rex kernel crate only leverages unsafe Rust necessary for FFI interaction and contributes to about 10% (360 lines) of kernel crate code. We explicitly check and ensure the preconditions of unsafe code blocks (e.g., argument requirements of eBPF helper functions) for the soundness of the Rex crate. As unsafe code is isolated from extension programs and managed at a central location by trusted maintainers, we are not particularly concerned about its maintainability.

9 Related Work

Aya-rs [3] provides an infrastructure that allows developers to write eBPF programs in Rust and compile to eBPF bytecode.

Aya is fundamentally different from Rex in that it does not rely on the Rust language for safety properties, but relies on the in-kernel eBPF verifier. Programming in Aya ignores the safety aspect of Rust and only treats it as a frontend language for eBPF—unsafe code blocks that directly use raw pointers are common. Differently, in Rex, one can safely use the high-level language features of Rust exposed by Rex. These features are important to write more intuitive, cleaner, and more optimized code for large, complex kernel extensions.

Improving eBPF. eBPF has evolved from simple use cases like packet filtering [75, 77] into a general-purpose kernel extension language and programming framework that enables many innovative projects [11, 40, 55, 59, 60, 79, 87, 90, 106–108]. Recent work is making active progress to improve the correctness and security of the eBPF infrastructure, including fuzzing and bug finding [61,78,94,95], formal verification [84, 85, 98, 100], sandboxing [65, 72, 73], and integrating with hardware protection mechanisms [74, 104]. eBPF's design, which relies on an in-kernel static verifier for extension safety, inevitably creates the language-verifier gap (§3). In contrast, Rex provides an alternative to develop and maintain large, complex kernel extensions directly with high-level language safety, avoiding the language-verifier gap.

Other frameworks. The idea of building safe OS extensibility using safe languages was proposed by SPIN [34] and revisited by Singularity [62], Tock [71], and a few recent discussions [39, 63, 76]. However, adopting them in practice is challenging as they are based on clean-slate OS designs. Rex develops a practical kernel extension framework for Linux, taking the opportunity of recent support of Rust as a safe language for OS code. It addresses the key challenges of enforcing safe code only, interfacing with unsafe C code, and providing safety guarantees beyond language-based safety.

Prior works such as VINO [89] explore extension safety through Software Fault Isolation (SFI) with unsafe languages. SFI is in principle implemented as runtime checks, which not only causes programming errors to be completely uncaught before deployment but also leads to non-trivial overhead. While recent works [81, 103] have demonstrated low-overhead SFI techniques, we note that Rex represents a different design tradeoff and complements SFI. By leveraging language-based safety, Rex pushes a good set of safety checks into compile time, allowing programming errors to be detected before execution. It strikes a balance between static checks and runtime protection to close the language-verifier gap.

Similar to SFI, hardware-based isolation mechanisms such as Intel MPK [49] offer alternative paths toward extension safety [74, 104]. However, such mechanisms alone usually do not satisfy all the safety requirements of kernel extensions, e.g., Intel MPK does not handle safety of kernel interactions as it cannot ensure a lock acquired will be properly released.

KFlex [52] is a recent kernel extension framework built on top of eBPF. KFlex aims to improve the flexibility of eBPF to let developers express diverse functionality in extensions. It employs an efficient runtime by co-designing it with the existing eBPF verifier: (1) its SFI elides checks already done by the verifier for efficiency, and (2) its termination mechanism uses the verifier to statically compute the kernel resources acquired by the extension. Rex made the same design choice as KFlex to use a lightweight runtime for safety properties that are hard to check statically. Unlike KFlex, which is co-designed with the eBPF verifier, Rex eliminates the verifier to close the language-verifier gap.

BCF [93] is a recent proposal to enhance eBPF's in-kernel verification with help from user space, asking for proof when the verifier fails to reason about certain program properties. The idea echoes proof-carrying code [83] which asks a program to attach a formal proof that its code obeys the safety policy. BCF leverages the eBPF verifier's range analysis and symbolic execution for proof generation but still requires developers to specify safety conditions to aid the generation. Its uses of the verifier still lead to the language-verifier gap.

Rust for OS kernels. Rust has been embraced by modern OSes [23, 101] as practical language which leads to safer code. Recent work shows the promises to build new OS kernels using Rust [36, 39, 71, 82]. We claim no novelty of using Rust as a language. In fact, a safe language alone does not lead to system safety, as exemplified by Rust kernel modules [48]. Rex shows an example of how to build upon language-based safety to enable and enforce safe kernel extension programs.

10 Conclusion

We build Rex, a new kernel extension framework that closes the language-verifier gap. We believe that closing the gap is essential to the programming experience and maintainability of kernel extensions, especially those that embody large, complex programs for advanced features. Rex provides a solution that allows kernel extensions to be developed and maintained in a high-level language, while providing desired safety guarantees as in existing frameworks like eBPF.

Acknowledgement

We appreciate the help from our shepherd Diyu Zhou, as well as the anonymous reviewers, on improving this paper. We thank Zhenyu Huang, Manvik Nanda, Quan Hao Ng, Raj Sahu, Wentao Zhang, and Md Sayeedul Islam for their participation in the project. We also thank Jiyuan Zhang, Di Jin, Hao Lin, James Bottomley, and Darko Marinov for their feedback and discussion. We used Rex to develop Machine Problems (MPs) for CS 423 (Operating System Design) at the University of Illinois Urbana-Champaign in Fall 2022, 2023, and 2024. We thank students in CS 423 for being the beta users of Rex, which provides valuable feedback for us to improve the usability of Rex. This work was funded in part by NSF CNS-1956007, NSF CNS-2236966, and an IBM-Illinois Discovery Accelerator Institute (IIDAI) grant.

A Appendix

We discuss more details of the example mentioned in §3.1 where developers have to change their code to assist the eBPF verifier. Figure 9a shows a code example from Cilium [86], which originally used a `goto` statement to combine the code path of `policy` and `l4policy` to avoid duplicated code. However, the combined code, which assigns `l4policy` to `policy`, later causes the verifier to incorrectly believe that `policy`, which is a pointer variable, is instead a scalar and reject the program. As a workaround, developers had to refactor the policy check code into an inlined function to separate the code path to pass the verifier.

Developers also have to teach the verifier by providing additional information. Figure 9b shows an example in Cilium [37] where the verifier lost track of `nh_params.nh_family`, a 32-bit scalar value on the stack, and mistakenly treated it as a spilled 64-bit pointer, leading to an invalid size error on the load. As a workaround, developers passed `fib_params->l.family` directly instead of going through `nh_params.nh_family` to let the verifier know the scalar value.

```
1    if (likely(l4policy && !l4policy->wildcard_dport)) {
2      *match_type = POLICY_MATCH_L4_ONLY;
3  -   policy = l4policy;
4  -   goto policy_check_entry;
5  +   return __account_and_check(ctx, l4policy, ...);
6    }
7
8    if (likely(policy && !policy->wildcard_protocol)) {
9      *match_type = POLICY_MATCH_L3_PROTO;
10 -   goto policy_check_entry;
11 +   return __account_and_check(ctx, policy, ...);
12   }
```

(a) The assignment of `policy` to `l4policy` (L3) and the `goto` (L4) causes the verifier to misinterpret the `policy` pointer as a scalar, requiring the policy check logic to be refactored into its own function.

```
1    #ifndef ENABLE_SKIP_FIB
2    ...
3    if (likely(ret == BPF_FIB_LKUP_RET_NO_NEIGH)) {
4      nh_params.nh_family = fib_params->l.family;
5      ...
6    } else {
7      return DROP_NO_FIB;
8    } ...
9    skip_oif:
10   #else
11   *oif = DIRECT_ROUTING_DEV_IFINDEX;
12 - nh_params.nh_family = fib_params->l.family;
13   #endif /* ENABLE_SKIP_FIB */
14   ...
15 - dmac = nh_params.nh_family == AF_INET ? ...;
16 + dmac = fib_params->l.family == AF_INET ? ...;
```

(b) The verifier mistakenly treats the 32-bit on-stack scalar `nh_params.nh_family` as a pointer. Developers are forced to refactor the code and avoid its use (L12 and L15).

Figure 9: Examples that developers had to work around the language-verifier gap by refactoring already safe extensions

Barre: Empowering Simplified and Versatile Programmable Congestion Control in High-Speed AI Clusters

Abstract

Network interface cards (NICs) and switches have entered the 400 Gbps era. RoCEv2 networks face significant challenges in congestion management, particularly under high-throughput workloads. While advanced congestion control algorithms have been proposed, their deployment in large-scale data centers remains hindered by complex parameter tuning and dependency on sophisticated hardware features. In this paper, we present Barre, a simple yet highly effective congestion control scheme designed for modern AI/HPC clusters operating at 400 Gbps. By leveraging commodity hardware and standard network functionalities, Barre achieves near-optimal performance in fairness, congestion responsiveness, and scalability with minimal overhead. Deployed in our 400 Gbps RoCE cluster for over a year and supporting up to 10,000 GPUs, Barre improves AI training task throughput by an average of 9.6%. Furthermore, we demonstrate that Barre's core principles can be seamlessly applied to enhance DCQCN, a widely deployed congestion control algorithm, underscoring its practicality and versatility.

1 Introduction

The leading tech companies are building new data centers to support current and next-generation high-performance computing and AI models. The networks in these data centers play a crucial role in interconnecting thousands of GPUs, providing the infrastructure to train large models with hundreds of billions of parameters, e.g. LLAMA 3.1 405B. These cutting-edge large-scale network infrastructures have utilized high-performance switches with 51.2 Tbps of throughput capacity and network interface cards (NICs) with 400Gbps interconnect capabilities [14, 27, 44].

Despite the widespread adoption of high-bandwidth networking infrastructure, the Machine FLOP Utilization (MFU) in large-scale LLM training remains suboptimal. This limitation arises primarily due to network congestion during the transmission of vast amounts of data across multiple compute nodes, which causes long delays for the parameter updates and gradient exchanges required in the training process. In current AI clusters, RoCEv2 (RDMA over Converged Ethernet v2) is widely applied for inter-node communication transport. Data Center Quantized Congestion Notification (DCQCN) [60] is the de facto congestion control algorithm for RDMA NICs. However, DCQCN faces significant challenges in achieving low-latency performance under dynamic traffic patterns due to its intricate parameter tuning requirements [6, 35, 51]. A key limitation of DCQCN is its sluggish congestion response, stemming from prolonged control loops, which perpetuates dependence on Priority Flow Control (PFC) for backpressure mitigation. In high-bandwidth networks, relaxed DCQCN configurations exacerbate congestion, increasing PFC pauses by 2–3 times while aggressive tuning yields marginal improvements in flow completion time (FCT) at the cost of degraded throughput under collective communication patterns [14].

Although many advanced congestion control (CC) algorithms have been proposed, their adoption in production AI clusters remains limited across industry deployments [10]. For the hardware dependency, HPCC [31] mandates In-band Network Telemetry (INT) support in NICs and switches, creating deployment barriers in heterogeneous environments. Swift [28] requires computationally intensive operations (e.g., square root calculations) for congestion signal processing, introducing non-trivial overhead. Poseidon [52] also identified the performance issues when deploying these algorithms. For example, HPCC may still react to congestion at any hop with high inflight bytes, even if the flow itself is not a major contributor to the congestion. For Swift, the estimation of end-to-end latency is easily affected by link length. Notably, though numerous CC algorithms have been proposed [1, 2, 4, 13, 16, 23, 34, 48, 57], these algorithms need more effort to enhance the compatibility with commercial off-the-shelf hardware environments of 400Gbps and beyond.

In this paper, we investigate the new performance require-

*Equal contribution.
†Corresponding author: Huichen Dai, email: daihuichen@bytedance.com and Xiaoming Fu, email: fu@ieee.org

ments and challenges for congestion control introduced by emerging AI clusters. Then we characterize the support for customized CC algorithms provided by the state-of-the-art AI network infrastructures, along with their inherent limitations. Instead of introducing a new congestion control algorithm, we aim to propose a new framework called Barre, which guides the design of congestion control that is simple and flexible to support the continuous rapid growth of network capacity (400Gbps and 800 Gbps) and the fast-evolving traffic patterns in new models. Barre fully leverages the capabilities provided by modern NICs, addressing the challenges posed by their limitations to achieve effective integration of hardware, software, and algorithms.

To meet the demand for designing customized protocols in cloud operators, a new trend has emerged that introduces programmability into the hardware. The emergence of programmable smartNICs has enabled new paradigms in congestion control for AI-optimized networks. NICs offer Programmable Congestion Control (PCC) capabilities [45], providing hardware-accelerated event APIs that enable customized congestion management solutions for mission-critical AI workloads. Building on these advancements, Barre implements a rate-based congestion control that adheres to the AIMD principles, utilizes the NIC's hardware-accelerated 1μs CNP feedback and dynamically adjust its rate update with built-in RTT probing: (1) *Fast Increase* ensures optimal bandwidth utilization while sustaining low queue length of switches both in mice flows and elephant flows; (2) *Dual-lock* addresses the issue of delayed congestion signal feedback in congested scenarios, ensuring timely congestion responses; (3) *Inflight Monitor* serves as a defensive mechanism against extreme congestion, preemptively reducing the sending rate based on inflight byte control, akin to window-based control. Additionally, we propose RTT-based enhancement to the implementation, which obtained lower latency and improvement of average throughput in end-to-end testing. This tight hardware-software co-design enables precise congestion response while maintaining network stability.

We evaluate Barre on a 256-GPU cluster equipped with 400 Gbps Bluefield-3 SuperNICs. Experimental results show that under NCCL AlltoAll test, Barre reduces the queue length in switches by 16.45% on average (up to 21.79%), and improves the overall throughput of AI training task at an average of 9.6%. Under large-scale test, compared to DCQCN, Barre reduced latency by an average of 55.89%, and improved bandwidth utilization by 15%. Compared to InfiniBand (IB), Barre is able to achieve almost the same latency and throughput. Additionally, we apply insights from Barre to optimize DCQCN, resulting in an enhanced variant that achieves faster convergence while improving fairness and stability under Incast traffic scenarios. Barre has been deployed in our production environment for over 10K GPUs equipped with 400G BlueFiled-3 SuperNICs, with communication across four levels of switches (S3). Over one year of monitoring, Barre achieves maximal throughput with no PFC triggered, and achieves comparable performance with IB for training tasks.

In summary, we make the following contributions:

- We re-examine the performance requirements and challenges that emerging workloads and AI network infrastructures pose for CC algorithms, characterize the merits and limitations of various CC design choices within the context of current NICs and switches, and provide design guidance to realize precise congestion control and fully leverage hardware capacity in modern high-speed AI clusters.
- By leveraging the programmable congestion control capabilities and CC event interfaces provided by BlueField-3 SuperNIC, we propose a CC scheme named Barre. Bare is an event-based algorithm that primarily relies on TX Event, CNP events, and RTT events of the NIC, rather than using ACK events and Timer events. This approach results in low overhead and is more suitable for software and hardware processing in high-speed AI clusters.
- We evaluated Barre on a 256-GPU 400 Gbps cluster with NCCL AlltoAll test, and demonstrated that Barre achieves performance comparable to InfiniBand while utilizing commercially available RoCE NICs (RNICs). Its innovative technique improves flexibility, compatibility, and performance. Inspired by the idea we can guide and enhance the performance of existing congestion controls, e.g. DCQCN, with low deployment complexity.

2 Background

2.1 Dilemma of Advanced CC Algorithms

Congestion control (CC) is one of the most critical techniques for network performance and fair bandwidth allocations. In our investigation, we have observed that despite the proliferation of advanced congestion control algorithms, HPC and AI data centers continue to predominantly employ DCQCN [15, 61], a protocol introduced over a decade ago. The design of DCQCN is grounded in the hardware capabilities and network characteristics prevalent around 2015, rendering it particularly challenging and inefficient to fine-tune for today's high-speed AI training clusters [15, 59]. This leads to the question, *why advanced CC algorithms are not widely adopted in modern data centers?*

Current state-of-the-art CC algorithms generally achieve near-maximal throughput on bottleneck links during congestion [28,31,33,52]. These algorithms employ different congestion signals and leverage diverse process mechanisms, which results in a great disparity in the cost of algorithm implementation (§7). Nonetheless, the majority of CC algorithms require functionalities that are either incompatible with commercial hardware or impose a high computational complexity that exceeds the capability of commercial NICs. This mismatch brings significant challenges for practical deployment and

Table 1: Collective Communication in Parallel Modes

Collectives	Parallel Patterns	Traffic pattern	Network congestion	Incast Scale	Key Requirement
AllReduce	Data Parallel	Tree or Ring	1 to 1, or many to 1	<20	Full bisection bandwidth
AllGather		Ring	1 to 1	=1	Bandwidth
AlltoAll	Expert Parallel	Fullmesh	N to N, N is very large	>500	
SendRecv	Pipeline Parallel	Point to Point	1 to 1, or many to 1	<20	Strict latency

scalability of these advanced CC mechanisms in industrial network environments. Taking HPCC [31] as an example, its deployment necessitates support for In-band Network Telemetry (INT) across all NICs and switches, a capability that remains generally unmet by most commercial NICs and switches. Furthermore, the computationally intensive operations, including square root calculations and complex multiplicative/division operations [28], can significantly prolong congestion signal processing latency and consequently reduce the maximum number of concurrent flows supportable by the congestion control mechanism under fixed hardware constraints.

2.2 Demand for Effective Congestion Control in Modern HPC/AI Clusters

Large-scale distributed training such as generative AI jobs introduces multi-dimension and stringent performance requirements to network infrastructure that are different from general cloud computing [43]. Table 1 illustrates the communication patterns associated with various parallelization methods in LLM training. The parameter configurations for flows to achieve fast convergence differ significantly across different collectives in practice. For example, mice flows such as AllReduce involve small-scale incast, which demand a more aggressive increase in per-flow rate to reach full bandwidth with minimal convergence time. In contrast, elephant flows such as AlltoAll generate high-concurrency, uniformly distributed traffic, require more conservative rate adaptation to prevent network oscillations and transient congestion caused by synchronized rate increases across multiple flows. Diverse traffic patterns and performance requirements pose challenges to the design of CC algorithms with comprehensive coverage. Current approaches struggle to establish universally optimal parameter settings, and transitions between traffic patterns frequently trigger severe congestion events due to suboptimal adaptation dynamics.

In large-scale HPC/AI network, e.g. Meta's statistical analysis of collective communication data from approximately 30K training tasks, AlltoAll communication has dominated total collectives, comprising approximately 60% of total collective traffic volume [14]. Its full-mesh traffic mode can cause ephemeral buffer buildup and severe congestion even with fine-grained flow management. The growing adoption of Mixture-of-Experts (MoE) architectures in large language model development has brought renewed attention to the network congestion challenges posed by AlltoAll collective operations [32]. These communication patterns create intense all-to-all traffic that stresses modern data center networks. In contrast, optimized AllReduce implementations employing multi-rail topologies and Ring algorithms can mitigate the risk of congestion [27], highlighting the importance of communication pattern-aware network optimization.

Consequently, an effective congestion control design must fully leverage the capabilities of modern commodity NICs and switches while satisfying stringent performance requirements in high-speed networks. The architecture should emphasize three key principles: (1) algorithmic simplicity to ensure high performance, (2) deployment flexibility for seamless integration, and (3) implementation practicality to maintain compatibility with existing hardware infrastructure. This balanced approach enables optimal performance without requiring costly hardware upgrades or complex configuration.

3 Motivation

3.1 Design Rationale of Congestion Control in High-speed HPC/AI Cluster

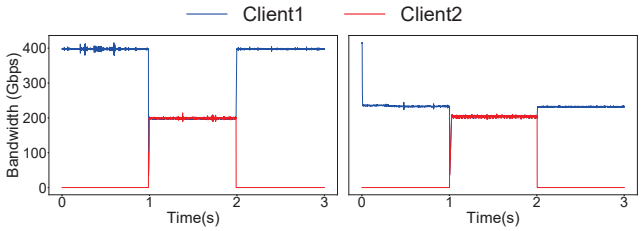
The design of algorithms must be compatible with available hardware, necessitating careful consideration of the costs and efficiency associated with exploring various combinations of hardware, software, and algorithmic approaches.

– Sara Hooker in the hardware lottery [21]

Modern HPC/AI data centers employ cutting-edge network infrastructures featuring 400 Gbps NIC ports and approach to emerging 800 Gbps transmission rate. In large-scale LLM training clusters, the network infrastructure alone constitutes over 20% of total hardware costs (excluding NVSwitch) [7]. On the other hand, the rapid evolution of LLM training has posed significant challenges for the deployment of AI infrastructure, particularly in scaling to clusters comprising tens of thousands of GPUs. With both high-speed network infrastructure and large-scale inter-connection GPUs, the configuration of parameters for CC algorithms has become increasingly challenging. Relaxed thresholds are more prone to trigger Priority-based Flow Control (PFC), whereas more aggressive thresholds can substantially reduce overall throughput, leading to performance degradation [14].

In summary, there is a need for practical CC algorithms

designed for advanced high-speed AI cluster networks, that not only fulfill emerging performance requirements but also align with and leverage the capabilities of the hardware infrastructure. We observe that the new CC algorithms must satisfy the following fundamental requirements:



- **Broad Applicability.** CC algorithms should be able to adapt rapidly to traffic bursts while keeping both high bandwidth utilization and low switch buffer occupancy across varying traffic patterns.
- **Simplified Logic.** The algorithm should feature a minimal set of parameters and straightforward threshold selection, avoiding difficult trade-off decisions between strict congestion control and high resource utilization.
- **Implementation Practicality.** The components of the algorithm, e.g. congestion signal, should be widely supported by commercial hardware to avoid customized modifications to NICs and switches. The algorithm should also impose low computational and storage demands for maintaining intermediate congestion handling contexts to achieve fast response.

3.2 Re-examine the CC Design

The evolution of CC algorithms has yielded diverse design paradigms. Nevertheless, our studies have identified incompatibilities between certain approaches and the operational demands of high-speed RoCE networks, presenting significant deployment obstacles. With contemporary NICs delivering 400Gbps inter-GPU server connectivity, CC algorithm design must holistically incorporate both specialized hardware attributes and associated cost constraints. Therefore, this section presents a comprehensive analysis of AI-optimized network hardware characteristics. We re-examine: (1) hardware-informed congestion signal selection criteria, (2) rate adaptation mechanisms optimized for high-bandwidth environments, and (3) co-design methodologies that exploit hardware capabilities while mitigating intrinsic limitations.

Congestion Signals. CC algorithms are based on different congestion signals to detect and feedback congestion information in the network. The widely used signals involves:

• **ECN** (Explicit Congestion Notification) [3] is embedded in the IP header of packets widely supported by unmodified switches to inform endpoints about congestion without dropping packets [3, 16, 60]. ECN provides early feedback by monitoring buffer levels or queue length without awaiting packet loss. However, in the case of multiple queues, a single bit ECN signal may not be sufficient to accurately convey the congestion level or effectively express the status of multiple priority queues. In practice, ECN is coupled with CNP (Congestion Notification Packet). CNP, associated with RoCE connections, offers per-connection congestion notifications with fine-grained information [36]. The combination introduces a simple and efficient congestion notification mechanism that has been extensively adopted in modern data center networks.

(a) Short path (Hop=1) **(b) Long path (Hop=5)**

Figure 1: Improper RTT baseline setting causes inefficient utilization

• **INT** (In-band Network Telemetry) provides near real-time information about the network status, including latency, queue length and packet loss of each hop, which helps CC algorithms to respond correctly to congestion throughout the paths [31, 52]. However, INT is heavily dependent on specialized switch hardware support, and the parsing of INT metadata is computationally demanding, making it difficult to deploy in existing network infrastructure [56]. Further more, the INT header is not yet able to be combined with RoCEv2 packets, and requires the sender to send probe packets with the same five-tuple as the QP traffic through middleware, which increases the end-side latency and CPU overhead. Nonetheless, when congestion arises at a hop that lacks support of INT, particularly in cases of congestion on the reverse path or across multiple hops, the system may fail to accurately identify and react to congestion. As a result, congested flows might persist in transmitting packets at elevated rates, thereby causing more severe congestion or unfair bandwidth allocation [47, 52].

• **RTT** (Round-Trip Time) provides a direct measure of end-to-end delay and an indication of overall network congestion. Modern NICs are capable of measuring RTT within a few microsecond [5, 9, 28], which causes RTT-based algorithms extremely sensitive to slight variation. However, RTT-based measurements exhibit significant dependency on path stability, where dynamic routing changes, fluctuating network device loads, and variable link quality can all introduce substantial measurement jitter. This instability frequently leads to erroneous congestion state estimation and subsequent misapplication of congestion control strategies. The temporal fluctuations in RTT measurements would be disproportionately amplified, triggering excessive rate reductions that significantly degrade overall network utilization. Specifically in multi-tier leaf-spine topologies, conventional congestion control algorithms cannot effectively distinguish between latency variations caused by variation of path length or network congestion. To clearly demonstrate this phenomenon, we implemented a basic RTT-based congestion control algorithm in a testbed comprising three 400Gbps NICs configured with two client nodes and one server node.

Figure 1 presents comparative throughput measurements

for two NICs of the server with different network topologies: (a) short distance communication in a single switch (Hop = 1, baseline RTT of 5μs); (b) an extended path traversing five switches in CLOS topology (Hop=5, measured RTT of 15μs). If the algorithm's baseline RTT is set inappropriately to 10μs for the long-distance communication, compared to short path (Figure 1 a), long path (Figure 1 b) transmission experienced inadequate bandwidth utilization even with no congestion. This experimental result demonstrates the practical challenge of defining a single RTT baseline suitable for all possible network paths and operating conditions in production deployments. While existing solutions attempt to address this through auxiliary mechanisms - such as queue delay extraction for INT header updates [52] or TTL-based hop count estimation [28] - these approaches incur non-trivial computational overhead that may offset their benefits in high-speed networks.

Rate Adjustment. Different types of rate adjustment mechanisms are employed in CC algorithms, such as window-based, rate-based, and credit-based approaches, each of which has raised several challenges in large-scale deployments.

• **Credit-based control** regulates the transmission rate by exchanging credits between the sender and the receiver. By detecting congestion in advance and estimating the link resources available to each node, it allows data transmission to be guaranteed with bounded delay and fast convergence. InfiniBand (IB) leverages the credit mechanism to ensure reliable data transmission at the hardware level and provides exceptionally low end-to-end latency [49]. However, deploying a private network with IB necessitates specialized NICs and switches, which typically incur hardware costs that are 5 to 10 times higher than those of conventional network equipment [8]. Moreover, IB faces scalability limitations due to its port count constraints and fabric complexity, making large-scale deployments challenging [12]. Due to its high performance, IB remains the gold-standard baseline in comparative evaluations. The primary design goal of our CC scheme is to achieve comparable performance of IB while overcoming its scalability barriers.

• **Window-based control** is a conventional technique extensively employed in traditional congestion control mechanisms (e.g. TCP). The transmission rate is regulated through the maintenance of congestion windows at both the sender and receiver, and the window size is adjusted based on the number of ACK packets returned by the receiver, ensuring a fine-grained response to congestion management. Window-based control depends on high-frequency ACK response (e.g. per-packet ACKs [28, 31]) and sequence headers that convey packet lengths to achieve precise control and accurate inflight byte statistics. Inflight byte control helps to monitor the amount of unacknowledged data and prevent sender from injecting excess packets to avoid network overload or receiver buffer overflow. Implementing this mechanism requires complex logic to maintain window sizes and acknowledgment information [53], along with supplementary algorithm to achieve accurate control in extremely congestion (e.g. window<1) under high-speed network. RDMA leverages ACK coalescing and Packet Sequence Number (PSN) [24,26], which precludes the direct implementation of a byte-oriented window. RNICs support only per-flow control, lacking the per-packet granularity necessary for precise window-based CC. Moreover, window-based congestion control mechanisms inherently depend on transport-layer state information to ensure reliable data delivery. This architectural design creates tight coupling between the congestion control implementation and the underlying transport protocol stack. Consequently, any algorithmic modification or enhancement necessitates corresponding hardware updates to the NIC's transport offload engines, significantly constraining the flexibility and evolvability of congestion control schemes in production environments [46].

• **Rate-based control** calculates the transmission rate directly based on network conditions and implements through a rate limiter or pacing module. The sender autonomously sends packets based on CC algorithm, and avoids complex calculation of ACK association, which leads to cumulative ACK in implementation [24, 26]. On the other hand, rate-based control decouples CC and reliable delivery, and makes the implementation of the transport layer less complicated. Therefore current RNICs predominantly support congestion control only at a rate-based per-flow granularity [18,55]. Rate-based congestion control exhibits inherent limitations compared with window-based approaches, e.g. its inability to explicitly bound the amount of inflight bytes. When congestion occurs, before receiving congestion signals, the transmitter continues injecting packets at pre-determined rates. In addition, rate-based control typically adopts the Additive Increase Multiplicative Decrease (AIMD) algorithm (such as DCQCN). The coexistence of dynamically changed traffic patterns and ultra-high-bandwidth NICs introduces fundamental challenges in parameter optimization. For instance, in the high-speed network of 400Gbps bandwidth, CC algorithms should adopt a large rate increase step to ensure rapid convergence. But if large-scale burst congestion occurs, an aggressive aggregate increment can lead to severe network oscillation and instantaneous congestion. These intrinsic limitations demand new congestion control designs.

3.3 Customized CC Design over RNICs

The rise of proprietary LLMs has driven demand for customizable networking, prompting NIC vendors to expose programmable interfaces that enable tailored solutions in data centers. Programmable NICs allow users to define customized congestion control algorithms to address variable network conditions and application demands.

Now SmartNICs have been widely deployed in current data centers (e.g. Nvidia ConnectX-6 DX [38] and BlueField-3 DPU [40]). These equipment provides programmable congestion control (PCC) platforms [37] and support multiple RoCE CC algorithms compatible with existing network protocol stacks. PCC provides hardware-based proactive network probes that are independent with transport layer [50], and automatically generates CC events when sending data or receiving ACK/ NACK/ CNP/ RTT packets. The embedded event APIs streamline the design of CC algorithms and reduce implementation overhead. For instance, PCC leverages dedicated RTT probe packet instead of add additional header to the data packets, mitigating the processing overhead associated with frequent RTT measurements. Upon sending a fixed amount of packets within a session, a TX event is generated which facilitates the measurement of accumulated sending byte within the current RTT and leverages the carried timestamp for timer functionality.

The design of CC algorithms leveraging the PCC capabilities provided by SmartNICs represents a cost-effective and efficient approach. This method ensures compatibility with mainstream commercial switches and NICs, thereby facilitating easier deployment in various network environments. With the iterative enhancement of NIC capabilities, e.g. the BlueField-3 SuperNIC now achieving CNP packets responses within 1 μs interval, CC algorithms can implement fine-grained rate control. Furthermore, implementing congestion control algorithms on RISC-V-based NIC architectures significantly reduces development cycles compared to conventional approaches, enabling tighter co-evolution with rapidly advancing hardware capabilities and application requirements.

Nevertheless, PCC has certain limitations that require compensation through CC algorithms. For instance, PCC supports only a per-flow granularity for rate adjustment, meaning that PCC-based CC algorithm also face the challenges of the poor responsiveness during severe congestion and the lack of inflight byte control. Specifically, the CC controller's trigger interval exhibits higher latency compared to FPGA-based SmartNICs, which achieve per-packet processing at granularity of several hundred nanoseconds, potentially resulting in delayed congestion responses and subsequent over-transmission. Additionally, PCC implementations typically operate on resource-constrained embedded CPUs, necessitating low-complexity CC algorithms to maintain both rapid response times and support for large quantities of queue pairs.

4 Barre Design

Based on the analysis of the characteristics and inherent limitations of RNICs, we propose Barre, a practical and scalable CC solution tailored for high-speed AI cluster networks. Barre ingeniously leverages the PCC capabilities and flexible event interfaces provided by RNICs to address the challenges and ensure compatibility with existing network infrastructure. Owing to its simple design, this solution can be easily deployed and utilized in any AI/HPC data center equipped with modern commercial RNICs.

4.1 Adaptive Adjustment Interval

Barre implements a rate-based congestion control architecture grounded in the widely-adopted AIMD framework. To address the issue of late responses introduced by timer-triggered rate adjustments under dynamically varying loads, Barre implements adaptive rate adjustment intervals based on CNP and RTT signals. We adopt CNP rather than RTT as the congestion signal because selecting an appropriate RTT baseline is challenging in large-scale deployments, which can lead to inadequate bandwidth utilization and unfair network allocation (as shown in Figure 1).

Delay-based increase: if the sender does not receive any CNP packets within a real-time RTT, the transmission rate (R) is updated with an additive increase according to the formula $R = R + \alpha$ (α refers to increment step). As RTT provides a straightforward indication of end-to-end latency across the network link, our approach employs real-time RTT monitoring to dynamically adapt the rate increase interval, enabling microsecond-scale adjustments that precisely track network conditions. When the link is idle, the frequency of rate increases is determined by the RTT baseline. During congestion, the frequency drops off as the end-to-end delay increases.

Per-CNP-based decrease: whenever the sender receives a CNP signal, the transmission rate is reduced according to the formula $R = R \times \beta$ immediately ($0.95<\beta<0.99$). The congestion indication in the IP header of CNP is widely employed by congestion control of RoCEv2 [39], where switches and routers will embed an indication for congestion once congestion is detected. Upon congestion detection, a CNP Packet is generated and routed back to the source, triggering precise rate limitation for the specified Queue Pair (QP). This closed-loop control mechanism enables microsecond-scale reaction to network congestion events. By monitoring switch buffer levels, ECN and CNP provide early congestion awareness. With modern NICs capable of generating CNP packets at the time granularity of 1 μs, Barre combines high-frequency rate reductions triggered per CNP with smaller reduction magnitudes. By adopting a slight but high frequency adjustment approach, the system can respond more precisely to congestion signals, while maintaining smooth network performance and avoiding significant fluctuations in transmission rates.

Dynamic self-constraint fairness: we find that DCQCN struggles with ensuring fairness between flows and adaptively allocating bandwidth in high-speed networks (as shown in Figure 12 a). In Barre design, per-CNP-based rate decrease auto-

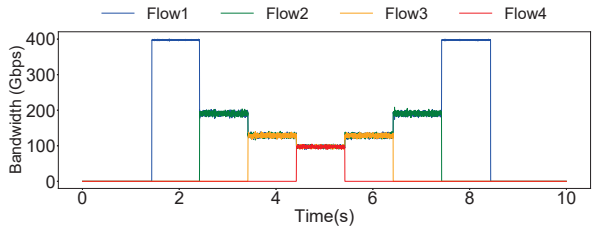


Figure 2: Throughput of 4 flows shows Barre fairness

matically achieves dynamic fairness between high-speed and low-speed flows within the same link. As link bandwidth approaches its bottleneck, high-speed flows, due to transmitting more data packets, receive a proportionally higher number of CNPs, thereby triggering a rate decrease more frequently. Consequently, this mechanism enables high-speed and low-speed flows to rapidly converge toward fair bandwidth allocation. Figure 2 illustrates the fairness achieved by Barre among four flows. The results indicate equitable allocation of bandwidth, maintaining full utilization without significant network oscillation or underutilization. Furthermore, we utilize a fluid model to analyze the theoretical stable point and stability of Barre. The analytical conclusions are verified by simulation experiments (refer to Appendix B).

4.2 Barre Functional Components

To address the limitations of RNIC and rate-based control, we propose three functional components: **Fast Increase**, **Dual-lock** and **Inflight Monitor**. These components are designed to be lightweight and decoupled from one another, enabling seamless integration into existing rate-based algorithms. The design philosophy underlying these features reflects the essence implied by the name "Barre", as a portable handle to make the trunk easier to use.

4.2.1 Fast Increase

The traditional AIMD algorithm applies fixed increase parameter α, which faces the dilemma between inadequate bandwidth utilization and burst transient congestion. When there is ample bandwidth available and the number of flows is relatively small (e.g. SendRecv collective), the rate increase should be more aggressive to improve network utilization. On the contrary, when the number of flows is very large (e.g. AlltoAll collective) or congestion has already occurred, rate increases must be more conservative to prevent excessive queue buildup and buffer overflow at switches. While dynamic increasing factors have been widely adopted as a solution, we attempt to explore a simple and easily implemented approach.

We propose Fast Increase as a solution to address this issue. To distinguish between aggressive and conservative rate increases, we use experienced rate increases over multiple RTTs as an accurate indicator of inadequate link bandwidth. When a flow experiences K times consecutive rate increases without receiving any CNP messages, it indicates substantial available bandwidth on the link. In this scenario, the increasing factor is set to a significantly large value, denoted as A, (e.g. 1/1000 of the bandwidth of NIC port), allowing for fast convergence. During the Fast Increase phase, if the sender receives a CNP signal, the increasing factor resets to its initial value α, and a rate decrease is triggered to mitigate potential congestion.

Integrating with Barre's technique of using real-time RTT for dynamic rate increase intervals, Fast Increase can achieve rapid algorithmic convergence within a very short period by large value A for mice flows, while keeping stability by small value α for elephant flows.

4.2.2 Dual-lock

Barre detects link congestion status via CNP signals received at the sender. Under severe congestion scenarios where BDP is less than MTU, the transmission rate becomes very low, requiring multiple RTTs to send a single data packet. Consequently, it also takes multiple RTTs to generate a CNP packet. This delay can result in several rounds of rate increase operation before the CNP reaches the sender, leading to an influx of additional packets into an already congested path. Currently, there are no effective solutions to address this issue. So we introduce a Dual-lock mechanism.

In QCN and DCQCN, the reaction points use both "ByteCounter" and "Timer" to control rate increase. For example, if the ByteCounter of an RP (reaction point, sender NIC) shows that the RP has transmitted 150 KB data or the Timer has passed 15 ms, RP will increase the sending rate. Generally, the RPs with larger sending rates will increase their rates more quickly, which are defined as the *QCN unfariness*. To solve this problem, the ByteCounter employed in QCN is modified to an adaptive ByteCounter [20]. DCQCN employs the relationship of ByteCounter "or" Timer as the condition of rate increase, which will cause high-speed flows (i.e. flow rate > 1.45 Gbps in DCQCN) to increase more frequently than low-speed flow (i.e. flow rate < 1.45 Gbps), leading to unfair bandwidth allocation.

Dual-lock optimizes rate increase conditions under severe congestion by modifying the relationship between the ByteCounter and Timer from "OR" to "AND", i.e. both conditions must be satisfied simultaneously to trigger a rate increase. As a result, the rate increase condition of high-speed flow is determined by Timer instead of Bytecounter, mitigating the unfairness issue. In practice, the Timer is generally set to one RTT. Therefore, for high-speed flows, the frequency of rate increase remains controlled by RTT, ensuring dynamic response to network conditions. Meanwhile, for low-speed flows, the rate increase is decided by the ByteCounter, preventing aggressive rate increases that could lead to congestion. This dual-lock approach effectively mitigates rapid rate increases during congestion while addressing fairness issues between high-speed and low-speed flows.

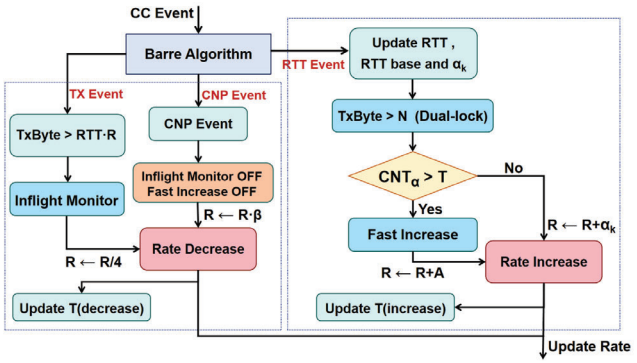

Figure 3: Process of CC module

4.2.3 Inflight Monitor

Due to the lack of fine-grained ACK responses and Seq packet headers that carry payload sizes, RNICs cannot effectively track and limit the amount of inflight bytes that have been sent but not yet acknowledged. During severe congestion, delayed CNP feedback can prevent the CC algorithm from fast respond, causing the sender to continue injecting packets and exacerbating congestion.

PCC periodically generates TX events that include information on the volume of data transmitted each time. Based on this new functionality, we propose an Inflight Monitor mechanism as a safeguard to manage in-flight data during congestion. Inflight Monitor tracks the accumulated sending bytes within the current RTT, denoted as S_{now}. Based on the current transmission rate R and the real-time RTT value, we can estimate the maximum allowable data volume for the current RTT, denoted as $\gamma = R \times RTT$. If S_{now} exceeds the estimated threshold γ, it indicates potential network congestion, even though no CNP signal or RTT probe packet is returned to the sender. Then inflight byte control is triggered, and the current transmission rate is immediately reduced to one-quarter of its original value. The rate remains at this reduced level until a CNP signal is received, at which point the transmission rate is restored to its initial value.

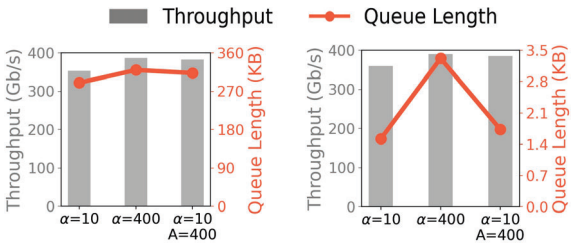
4.3 Effect Improvement of Barre System

The control flow in Barre, as illustrated in Figure 3, is driven by TX/RTT/CNP event provided by PCC. These events trigger corresponding actions such as rate increase, rate decrease, or optimized features operations, ensuring efficient and adaptive management of network traffic under varying conditions. The main function of Barre and the conditions for the functional component are presented in Algorithm 1.

The three components of Barre can be utilized independently, while the coupling yields significantly enhanced performance benefits. To evaluate the effectiveness, we start from Fast Increase and enable them one by one gradually, and compare with the default set as basic Barre algorithm.

Algorithm 1: Barre Main Function

function `OnTransmitPacket(`Tx_Pkt`)`**:**
- $R_{prev} \leftarrow R_{cur}$ `// update sending rate`
- **Update** $TxBytes$;
- **if** $TxBytes_{incre} > N$ ***and*** $Timer > RTT$ **then**
  - `// Exceed Dual-lock threshold, rate increase`
  - **if** $CNP_{RECV} = 0$ **then**
    - **if** $CNT_\alpha > T$ **then**
      - $R_{cur} \leftarrow R_{prev} + A$ `// Fast increase`
    - **else**
      - $R_{cur} \leftarrow R_{prev} + \alpha$
    - CNT_α ++ `// Counter of Fast increase`
  - $CNP_{RECV} \leftarrow 0$, $TxBytes \leftarrow 0$
- **if** $TxBytes_{Inflight} > R_{cur} \times RTT$ ***and*** $FN_{Inflight} == 0$ **then**
  - $FN_{Inflight} \leftarrow 1$; $R_{cur} \leftarrow R_{prev} \times \frac{1}{4}$
  - `// Enable Inflight Monitor`



function `OnRecvRTTResponse(`RTT_Pkt`)`**:**
- **Update** RTT
- **if** $RTT < RTT_{base}$ **then**
  - $RTT_{base} \leftarrow RTT$
  - `// Update RTT base for each flow`

function `OnRecvCNP(`CNP_Pkt`)`**:**
- $R_{cur} \leftarrow R_{prev} \times \beta$ `// β: ratio`
- $CNP_{RECV} \leftarrow 1$, $CNT_\alpha \leftarrow 0$
- $TxBytes_{inflight} = 0$
- $TxBytes_{incre} = 0$
- **if** $FN_{Inflight} = 1$ **then**
  - $R_{cur} \leftarrow R_{prev} \times 4$, $FN_{Inflight} \leftarrow 0$
  - `// Disable Inflight Monitor, recover original rate`

First, we evaluate Fast Increase with experiments of two distinct scenarios: mice flow (less connections as QP=4) and elephant flow (large-scale incast as QP=1000). Compared with fixed rate increase magnitude as α=10 or α=400, we employ both the base increase factor (α=10) and the aggressive increase factor (A=400 MB) in Fast Increase. The results are illustrated in Figure 4.

Communication of mice flow (QP=4) has almost no congestion, resulting in negligible differences in switch queue lengths among the three methods, as indicated by the yellow line in Figure 4 (a). Fast Increase achieves higher throughput than the set of small α=10 (an increase of 8.5%) for mice flow in QP=4, and keeps lower queue lengths compared with the aggressive α=400 (an improvement of 48%) for elephant flow in QP=1000. The experimental results demonstrate that Fast Increase effectively balances rapid convergence and low latency. It adapts dynamically to varying traffic conditions, ensuring optimal bandwidth utilization without compromising stability.

Then we enable Dual-lock function and evaluate the average queue occupancy at the switch under varying levels

(a) QP=4 (b) QP=1000

Figure 4: Performance comparison of different increasing factors in mice flow and elephant flow. Fast Increase achieves optimal bandwidth utilization while keeping low queue length in different traffic patterns.

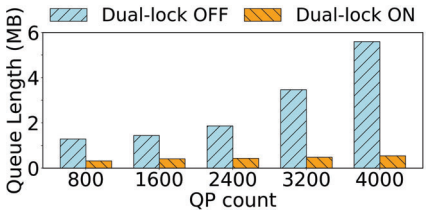


Figure 5: Dual-lock maintains extremely low switch queue length in large-scale Incast.

of congestion. In this experiment, four clients are connected to a single server through a ToR switch, and we continuously increase the number of flows involved in the traffic to simulate an Incast scenario. The ByteCounter threshold for Dual-lock is set to 8KB. As illustrated in Figure 5, across five experimental setups, enabling Dual-lock consistently reduces the average switch queue length while maintaining the same throughput, achieving an overall reduction of 79.9% (with a maximum reduction of 90.25% when QP=4000). This significant decrease in queue length indicates a substantial alleviation of congestion. Moreover, Fast Increase maintains a relatively small increment factor α during congestion, which can lead to high switch buffer occupancy. The combination with Dual-lock achieves higher throughput while keeping low buffer occupying.

We enable the Inflight Monitor function in the last step. Figure 6 illustrates the performance improvements achieved by coupling of the three components. To emulate real training workloads, we conducted NCCL AlltoAll test on a cluster composed of 256 Nvidia BlueField-3 400 Gbps NICs, recording the total bus bandwidth for varying message sizes. The results indicate that when Inflight Monitor is enabled, the throughput is improved on average by 16.45%, with a maximum increase of 21.79%. These findings demonstrate that Inflight Monitor can significantly enhance network performance of large-scale incast congestion scenarios.

Barre is an event-driven algorithm that leverages TX Event, CNP event and RTT event provided by the PCC functionality for its design. These events incur lower overhead compared to ACK events and Timer events, making them more suitable for

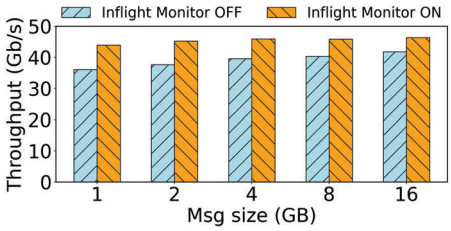

Figure 6: Average throughput in NCCL AlltoAll test. The inflight Monitor function significantly improves the throughput in large-scale congestion.

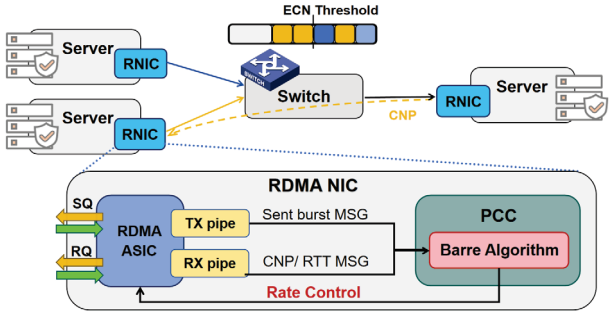

Figure 7: System architecture

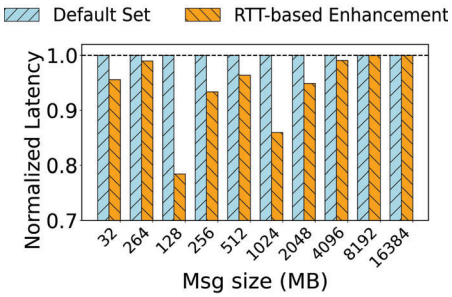
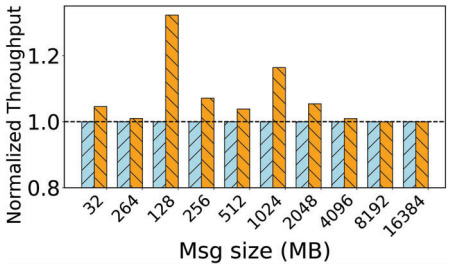
efficient processing by both software and hardware. TX Event, serving as the most critical event for Barre, offers accumulated sending byte and timestamp information. Coupled with the application of Barre's three components, this significantly reduces the number of events processed by CC algorithm.



5 Implementation

Barre is implemented on BlueField-3 SuperNICs, and is designed to leverage the maximal potential of the event interface provided by PCC, achieving integration of software, hardware and algorithm. As illustrated in Figure 7, PCC-based software-programmable CC operates directly on the network layer of a dedicated RISC processor embedded within the NIC. This setup facilitates the utilization of transmission (TX) event and reception (RX) events for synchronizing communication operations between applications and the NIC, ensuring reliable and efficient data transmission and reception.

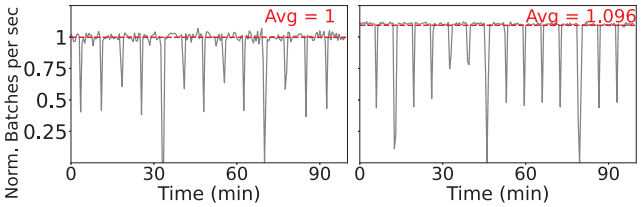


5.1 RTT-based Enhancement

Barre dynamically adjusts rate increase interval based on real-time RTT to adaptively respond to network state. We find several challenges to leveraging RTT as an indicator in deployment and propose two mechanisms to address the problems.

RTT Probe Modification. Barre dynamically adjusts rate increase interval based on real-time RTT to adaptively respond to the network state. PCC provides a dedicated RTT probe packet, while SP (Sender NIC) generates an RTT_Req packet

(a) Normalized Latency



(b) Normalized Throughput

Figure 8: The normalized latency and throughput of RTT-based enhancement in 128-GPU NCCL AlltoAll test.

at the beginning of an RTT, and RP (Receiver NIC) generates an RTT_Rsp packet. Thus Barre executes a rate increase at the time RP receives RTT_Rsp packet. However, due to limitations of hardware NIC (e.g. packet loss or delay), RTT probe packets may be lost, leading to missed rate increases for Barre. In a test using NCCL AlltoAll across a three-layer Clos network cluster of 128 GPUs, we find that the loss rate of RTT probe packets can achieve as high as **8.9%**.

To address this issue, we implement an RTT probe modification by leveraging the head carried in RTT probe packets. We add a sequence header into the RTT probe packet to avoid mismatching. As an RTT packet involves timestamp information, we make each RTT_Rsp packet carry both the sending time of RTT_Req and the receiving time of RTT_Rsp. Thus the sender could accurately calculate the real-time RTT by simply computing the difference between the timestamps. This method prevents mismatching of RTT probe packets from different batches, thereby avoiding errors in the calculation of real-time RTT. Thus, we modify Barre's rate increase logic to update the last $real-timeRTT$ whenever an RTT probe packet returns. A rate increase is triggered if no CNP signal is received by RP within a period equivalent to the $real-timeRTT$.

RTT-based per-flow Increase Factor. Additionally, we find that RTT-based rate increases may lead to unfairness among flows with different path lengths, causing lower frequency of rate increases for longer-distance transmissions. Therefore, we adjust the rate increase magnitude for different flows, correlating the value of the increase factor α with the baseline RTT of each flow, as $\alpha_k = RTT_k \cdot \alpha / C$. While C denotes a

(a) Default set **(b) RTT-based enhancement**

Figure 9: The throughput log from real training tasks (normalized to average throughput of default set). The red dashed line represents the average throughput under the default settings.

constant set to 1us or 2us depending on the network infrastructure. For flow k, Barre continuously measures and updates the minimum real-time RTT value observed during actual communication, and denoted as RTT_k. Therefore, the increasing factor α_k of long-distance transmission is larger due to longer RTT, which makes up for the unfairness leveraged by a lower increase frequency.

We evaluated RTT-based enhancement on a 128-GPU cluster, contrasting it with the default set with an increase factor uniformly applied to all flows and without RTT probe timestamp. The latency and bandwidth of the NCCL AlltoAll test were recorded for various message sizes, with performance normalized to the uniform increase factor, as illustrated in Figure 8. Utilizing the RTT-based enhancement resulted in an average reduction of 5.71% in latency and a corresponding increase of 7.13% in throughput.

As AlltoAll messages in AI training workloads typically do not exceed 1GB, actual tasks are more sensitive to loss of rate increase operation and RTT probe packets compared to NCCL tests. As shown in Figure 9, in end-to-end testing, we observed that employing RTT-based enhancement effectively reduced the latency of AlltoAll communication by up to 50%, and improved the overall throughput of AI training task at an average of 9.6%.

5.2 In-production Deployment

Barre can be fully deployed on hardware NIC, maintaining complete transparency to the application layer without modifications to RoCEv2 protocol. For instance, with Nvidia BlueField-3 SuperNIC, CC algorithm can be compiled into a binary file, flashed onto the NIC firmware, and executed on the RISC-V cores embedded within the NIC. This design allows the entire CC process to bypass the PCIe channel, eliminating the need for host CPU involvement, which significantly improves network efficiency and congestion response speed. Three functional components of Barre address the limitations proposed by RNIC and rate-based control and achieve the fundamental requirements as discussed in Section 3.2. Practical tests have demonstrated that Barre can leverage the four RISC-V cores on the NIC to manage congestion events

at a rate of 10 million events per second, showcasing excellent responsiveness to network congestion.

Our production cluster workloads consist of two types: LLM training and inference. In LLM training tasks spanning thousands of GPUs, collective communications consist of ReduceScatter, AllGather, AlltoAll, and SendRecv operations. In most scenarios, AllGather and ReduceScatter operations dominate, accounting for over 50% of the total communication volume, with message sizes typically at the gigabyte level. MoE models exhibit particularly heavy AlltoAll traffic, where message sizes can expand to 10^8 bytes with increasing batch sizes. For inference tasks operating at smaller scales, typically hundreds of GPUs, AlltoAll communications account for more than 50% of traffic with generally smaller messages (<1 GB). AllReduce operations form the second most significant portion of communications. Notably, execution alternates between AlltoAll full-mesh traffic and ReduceScatter ring-based traffic, causing the network to frequently switch between large-scale incast and uncongested states. This variation requires the CC algorithm rapidly adapting to dynamic traffic pattern, while mitigating congestion caused by elephant flows and also ensuring fast convergence of mice flows.

6 Evaluation

In this section, we evaluate the effectiveness of Barre on large-scale NCCL AlltoAll test (Section 6.2) in comparison with InfiniBand and DCQCN. In addition, we modify a few parameter settings of DCQCN based on the idea of adaptive adjustment interval achieved in Barre (Section 6.3) to demonstrate flexibility and versatility of Barre.

6.1 Network Topology

Barre has been deployed in a AI production cluster for nearly one year. The network architecture employs a three-layer switch topology similar to CLOS to interconnect over 10K GPUs, each equipped with a BlueField-3 SuperNIC supporting 400Gbps port bandwidth. For switches at each layer, the bandwidth ratio between downlink and uplink is 1:1. For the ToR switches, a specific Active Optical Cable (AOC) is used to split an 800 Gbps downlink port into two 400 Gbps downlink ports. Each server involves eight 400 Gbps NICs, and is connected to eight different ToR switches with multi-rail topology. A total of 64 GPU servers are interconnected through this set of ToR switches.

6.2 Large-scale Collective Communication

We conducted the congestion control test on a 256-GPU cluster to test Barre's performance. The experimental setting is the same as that in section 6.1. Each GPU was equipped with an Nvidia BlueField-3 400Gbps NIC. As discussed in Section 2.2, the distributed parallel approach for LLM training

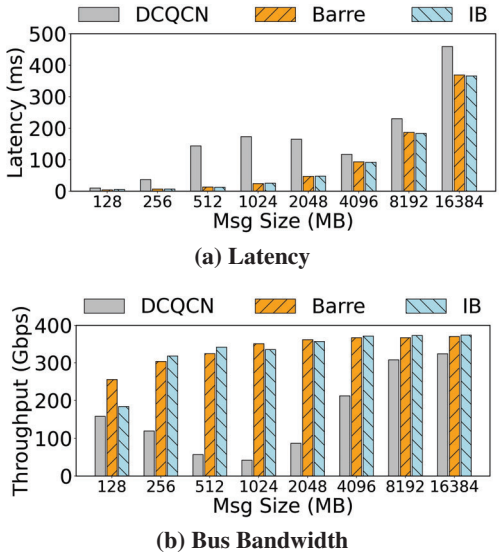


Figure 10: NCCL AlltoAll test in 256-GPU cluster

involves a significant amount of collective communication traffic. Among 3D parallelisms, AlltoAll dominates and is more likely to cause high ephemeral congestion due to its full-mesh communication mode.

To validate the superior performance of Barre, we conducted comparative experiments using DCQCN [60] and InfiniBand (IB), two commonly employed CC mechanisms in AI networks. In NCCL AlltoAll test, the overall communication volume (message size) was incrementally expanded from 128 MB to 16 GB (2^{14} MB), with corresponding network latency and average bandwidth (message size divided by flow completion time) recorded. The experimental results are illustrated in Figure 10. Observations indicate that Barre achieves superior latency and throughput comparable to IB while significantly outperforming DCQCN. Compared to IB, Barre exhibits substantially lower hardware deployment costs and implementation complexity, along with enhanced scalability in large-scale clusters. Therefore Barre offers a simple, high-performance, and cost-effective CC solution.

In contrast, DCQCN displayed a pattern where latency initially increased and then decreased as message sizes grew. The complexity of DCQCN's parameter takes a long time to complete multiple iterations, which leads to a fluctuation of latency and throughput during smaller message sizes (128 MB to 1024 MB). As message sizes further increase, DCQCN gradually converges and improves bandwidth utilization. Throughout the experiment, both Barre and IB demonstrated excellent convergence properties, maintaining high throughput and low latency even under full mesh traffic conditions in large-scale environments.

Figure 11 illustrates switch traffic logs collected over a period from the production environment. Barre has enhanced communication across a four-layer switch architecture (S3). It achieves near-optimal utilization without triggering PFC

Table 2: DCQCN Parameter Tuning Settings

Parameter	Default Value	Tuned Value	Explanation
min_time_between_cnps	4	0~2	Interval for Receiver Responding with CNP (us)
rpg_min_dec_fac	50	80~98	The minimum reduction at each rate decrease
rate_reduce_monitor_period	4	1~4	Minimum deceleration interval (us)
rpg_alpha_rate	5	8~20	Rate increase magnitude
rpg_time_reset	300	20~100	Rate increase interval (us)

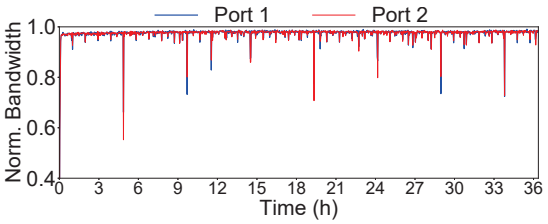

Figure 11: Switch traffic in production

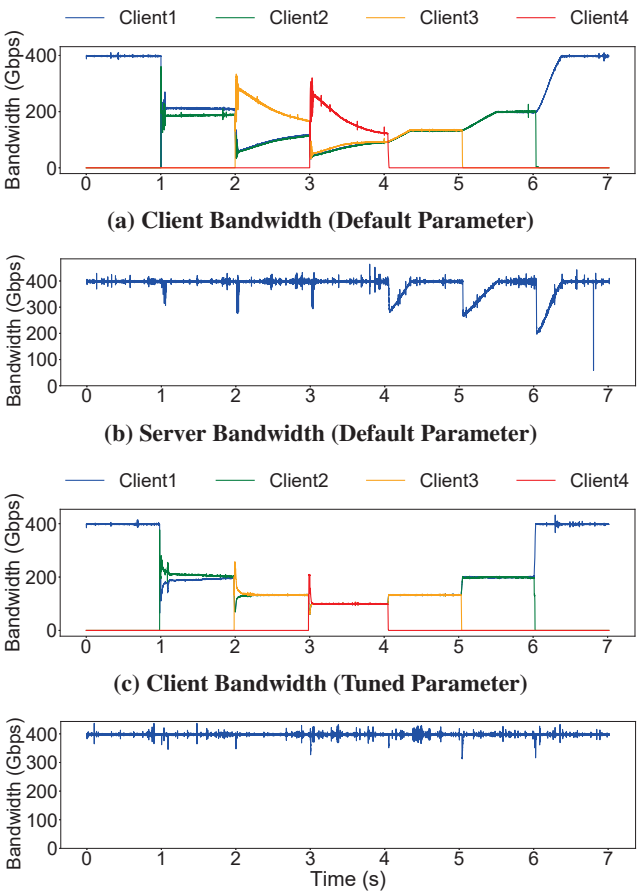
event. Moreover, Barre exhibits robust convergence and fairness under varying traffic loads. Its capability ensures that the network remains stable and efficient, effectively supporting the demanding requirements of large-scale AI workloads.

Given that most CC algorithm are not well-aligned with the characteristics of current mainstream hardware, implementing them in AI/HPC clusters poses significant challenges. We provide a qualitative analysis to compare against other CC protocols (e.g. Swift [28], PowerTCP [1] and HPCC [31]) in Appendix A.1.

Since ring-based collective communications (e.g. AllReduce, AllGather, and ReduceScatter) rarely cause congestion compared to AlltoAll, we present Barre's performance of these operations in Appendix A.2 (Figure 14). Experimental results show that Barre achieves near-full bandwidth for both ReduceScatter and AllGather communications with NVLink disabled to enforce RDMA routing. We also conduct experiments on extreme incast scenarios in Appendix A.3 (with results shown in Figure 15).

6.3 Barre-inspired Optimization on DCQCN

To demonstrate the flexibility and versatility of Barre, we apply its design ideas to optimize DCQCN by adjusting certain parameters. DCQCN, originally developed in 2014, was tailored to leverage the hardware characteristics of Mellanox NICs. Given the technological limitations a decade ago, NIC capabilities were relatively constrained, leading to the implementation of a CNP response interval set at 55 us. The algorithm adjusts the transmission rate based on the number of consecutive CNPs received by the sender over fixed intervals, i.e. as the count of CNPs increased across multiple periods, parameter α would increase while parameter β would decrease accordingly.



As modern NIC technology has significantly advanced, currently the BF-3 SuperNIC is capable of responding with CNP messages for every 0 to 2 us. We applied the principles of Barre to optimize the DCQCN parameter. The modified parameter settings are shown in Table 2. The CNP packet generation interval is set a smaller value to fit modern NICs, and each CNP will trigger a rate decrease operation with a small decrease step. We recommend setting the increase interval to a range of 20~100 ms, depending on the maximum number of incast flows and the base RTT in the network. A larger number of concurrent incast flows necessitates a longer interval to avoid congestion. For α, we suggest a higher value between 8 and 20 in 400G networks to enable faster rate increases and convergence.

We selected four nodes as clients (Client 1 to Client 4), and the other one as the server, all connected to a single ToR switch. During the experiment, each client established connections with the server according to a predefined schedule, and then gradually terminated the connection one by one.

Figures 12(a) and (b) illustrate bandwidth utilization of the four clients and the server under unmodified DCQCN parameter (Default value in Table 2). As clients progressively joined the network and established connections, the link bandwidth was dynamically reallocated, leading to oscillations in network bandwidth, and low utilization (e.g. 197.7 Gbps at 6s). Despite gradual convergence towards a more balanced bandwidth distribution, the allocations remained unfair throughout the experiment.

Figures 12(c) and (d) present the results following parameter modification to DCQCN based on Barre (Tuned value in Table 2). The observation indicates that the system rapidly becomes stable and achieves fair bandwidth sharing across different flows. Moreover, as connections are progressively terminated, the network quickly converges to a stable bandwidth allocation condition. Specifically, Figure 12(d) shows that during the experimenting period, the server NIC bandwidth remains close to full utilization and exhibits stability. The frequency and magnitude of network oscillations are significantly reduced compared to Figure 12(b). These results demonstrate the effectiveness of the Barre-inspired parameter adjustments in enhancing the responsiveness and fairness of DCQCN, thereby ensuring efficient and stable network operation for dynamically changed traffic loads.

Additionally, we conducted NCCL AllReduce test on a 1024-GPU cluster to evaluate the effect of Barre's inspired op-

(b) Server Bandwidth (Default Parameter)

(c) Client Bandwidth (Tuned Parameter)

(d) Sever Bandwidth (Tuned Parameter)

Figure 12: Barre-inspired optimization on DCQCN

timization. Employing multi-rail optimized network topology with a ring algorithm significantly mitigates ECMP hashing conflicts, which could prevent most congestion during AllReduce communication [27]. However, we notice that numerous data centers have not upgraded to multi-rail topologies, which means AllReduce remains a performance problem. Figure 13 illustrates the normalized bus bandwidth across various message sizes of both default and tuned parameters of DCQCN. Following optimization with Barre, an average improvement of 19.54% of throughput was achieved. In addition, the resource allocation among different flows has become fairer. As AlltoAll and AllReduce communication account for the dominant proportion in large-scale AI training tasks, Barre-inspired optimization on DCQCN could achieve significant end-to-end revenue, with only a few modifications of parameter.

7 Related Work

Congestion control is critical for optimizing network performance and ensuring reliable communication.

Host-driven Congestion Control: Host-driven CC can be further divided into sender-driven CC and receiver-driven CC. Currently, sender-driven CC is widely deployed in data center

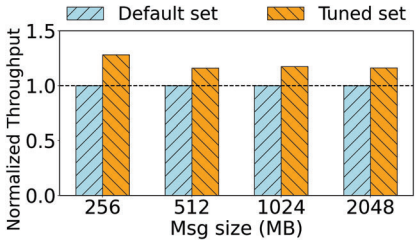

Figure 13: NCCL AllReduce test

networks. DCQCN [60] uses ECN as the congestion signal [3, 41]. Another widely used congestion control signal is Delay or RTT [5,9,28–30,33]. TIMELY [33] and Swift [28] utilize RTT and RTT gradient to ensure network transmission efficiency without the involvement of switches [61]. INT signal has been proposed to provide more detailed congestion information [1, 31]. PowerTCP [1] calculates the congestion status based on the bandwidth-window product. Receiver-driven CC aims at maintaining near-zero queues in switches [11, 19, 22, 23, 25, 34, 42]. ExpressPass [54] uses credits to probe bandwidth, and the receiver regulates the transmission rate based on the credit loss rate. HOMA [34] prioritizes small flows to ensure low latency for short messages.

Switch-driven Congestion Control: The switches make appropriate rate adjustment decisions instead of announcing congestion status. RoCC [48] utilizes queue length as a congestion signal and follows the Proportional Integral Control method to compute the fair rate. It relies on the switches to generate CNPs containing the fair rate to directly control the rate decrease of the senders. HierCC [58] employs virtual queue length as a congestion signal and divides congestion into two types: the congestion between ToR and NICs, and the congestion between ToR. It implements direct rate allocation to adjust sending rates and limit queue lengths. ACCurate [17] makes use of Flow Rate Packets (FRPs) injected by the senders as congestion information. When the switch detects an FRP, it allocates the minimum flow rate based on the number of flows on the egress port.

8 Conclusion

Barre exploits recent trends including programmable congestion control and proposes a decoupled design of congestion control atop the transport layer stack. By careful design to efficiently use the advanced features of TX event based byte-counter and timestamp, Barre introduces an adaptive rate decrease per CNP and dynamic rate increase based on RTT probing, which meets the demand for fast response to traffic variance and low software and hardware overhead. Barre has been implemented in 400Gbps Bluefield-3 NICs as part of our production data center. Barre exhibits not only superior performance in terms of fairness and congestion response but is able to enhance DCQCN, which converges faster and maintains better fairness and stability.

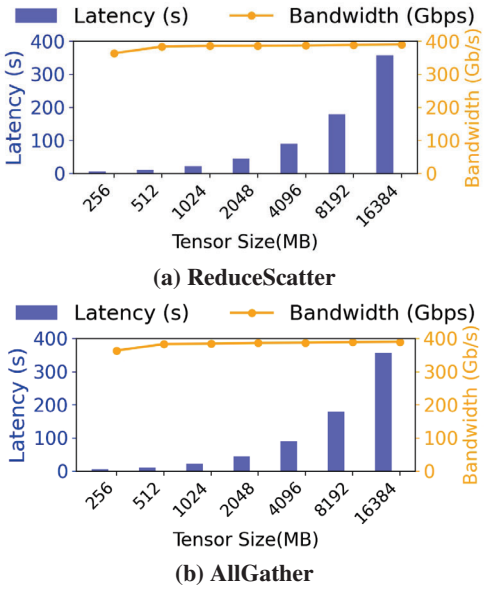
Appendix

A Extended Evaluation

A.1 Qualitative Comparison Against other CC Protocols

We provide a qualitative analysis to compare against other CC protocols. Swift [28] relies on per-packet RTT measurements for congestion control. However, standard RDMA-packet does not carry RTT information, necessitating individual RTT probe packets. In high-speed AI networks, this requirement can result in significant overhead, with probe packet rates reaching up to 12.5 MPPS. Additionally, because AI training networks adopt a multi-tier ToR network topology, it becomes challenging to establish an appropriate RTT baseline for flows with different path lengths, which can lead to inefficient network utilization (as shown in Figure 1). Protocols like PowerTCP [1] and HPCC [31] rely on INT-metadata carried in per-packet ACKs, which are incompatible with the current ROCEv2 UDP packet format. Moreover, RNICs do not support per-packet ACKs and lack the capacity to handle the enormous volume of ACK packets and INT-metadata.



Therefore, we compare with the most widely used DCQCN and IB protocols. It is notable that our experiments are conducted on the real-world system, as simulation results lack practical significance due to their omission of hardware capabilities.

A.2 The Performance of Other Collectives

In practice, ring-based collective communications, e.g. AllReduce, AllGather, and ReduceScatter, rarely cause congestion compared to AlltoAll operations. We evaluated ReduceScatter and AllGather operations in a 64-GPU, 400 Gbps CLOS cluster with NVLink disabled to enforce RDMA routing, the results are shown in Figure 14. The x-axis indicates the message size of the tensor involved in the collective communication. The blue bar represents the total communication delay, and the orange line represents the average NIC throughput. By testing tensor sizes from 256 MB to 16,384 MB, we observed that the average bandwidth rapidly increased to 390.35 Gb/s, achieving near-full bandwidth utilization. Although congestion hardly triggers in these collectives, it can occur during traffic transitions, such as switching from AllReduce to AlltoAll, where Barre demonstrates good performance.

A.3 The Performance of Extreme Incast Scenarios

We evaluated Barre's performance under extreme incast scenarios, with the results presented in Figure 15. We gradually increase the number of incast flows from 16 to 4096, and

(a) ReduceScatter

(b) AllGather

Figure 14: Performance of NCCL ReduceScatter and AllGather in 64-GPU cluster

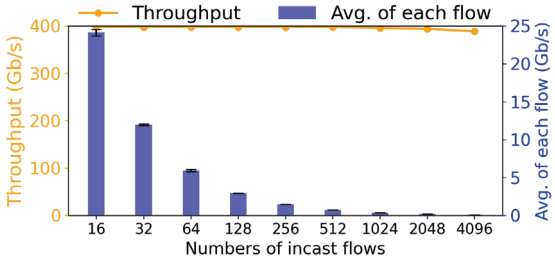


Figure 15: Performance of extreme incast scenarios

record throughput of each flows. The x-axis denotes the number of flows participating in the incast. The orange line represents the total network throughput, the blue bars indicate the average throughput per flow, and the black error bars depict the difference in throughput across each flows. The results demonstrate that as the number of incast flows grows, the total throughput remains consistently within the range of 390–400 Gbps. Furthermore, the stdev of the average throughput across all flows rapidly decreases from 0.35 to 0.002. The results indicate that even under large-scale extreme incast, Barre is capable of maintaining relative fairness and stability while achieving high throughput.

B Model Analysis and Derivation

We utilize the classical fluid model to analyze the stability and steady state of Barre. The parameters and variables used in the fluid model are detailed in Table 3. In this model, for every $D(t)$R increases by α such that $R = R + \alpha$. Conversely, for every Congestion Notification Packet (CNP) event, the sending rate R is adjusted by a multiplicative factor β, resulting in $R = R \cdot \beta$. The fluid model is represented by Equations (1)-(5).

Table 3: Symbols in Barre fluid model

Symbol	Explanation
α	Increase parameter
β	Decrease parameter
C	Link capacity
U	Maximum Transmission Unit (MTU)
d	Baremetal round-trip delay
K_{min}, K_{max}	ECN parameter
P_{max}	ECN parameter
$D(t)$	Real-time Round Trip Delay
$R(t)$	Sending Rate of current CC session (per-QP, per-DestIP)
N	Number of flows over the bottleneck link
n	Number of CNPs in one RTT
$q(t)$	Real-time queue size
$p(t)$	ECN marking probability

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \frac{\alpha}{D(t)} - \frac{\left(1-\beta^{p(t)R(t)D(t)/U}\right)R(t)}{D(t)} \tag{1}$$

$$n(t) = p(t)\frac{CD(t)}{U}) \tag{2}$$

$$p(t) = \frac{q(t)-K_{\min}}{K_{\max}-K_{\min}}P_{\max} \tag{3}$$

$$\frac{\mathrm{d}q}{\mathrm{d}t} = NR(t) - C \tag{4}$$

$$D(t) = d + \frac{q(t)}{C} \tag{5}$$

B.1 Stable Point Analyses

The stable point of the system is defined as the solution of the equations $\frac{\mathrm{d}R}{\mathrm{d}t}=0$ and $\frac{\mathrm{d}q}{\mathrm{d}t}=0$, denoted by ($R^*$, q^*, p^*, n^*). From this condition, we can get:

$$n^* = P^*\frac{CD^*}{U}$$

$$R^* = \frac{C}{N}$$

Combined with Equation (2) (3) and (5), n^* could be translated in to Equation (6):

$$\begin{aligned} n^* &= \frac{N\ln\left(1-\frac{\alpha N}{C}\right)}{\ln\beta} \\ &= (q-K_{\min})(q+Cd)\frac{P_{\max}}{(K_{\max}-K_{\min})U} \end{aligned} \tag{6}$$

Thus, we obtain a quadratic equation in terms of q:

$$q^2 + (Cd-K_{\min})q - K_{\min}Cd - \frac{N\ln\left(1-\frac{\alpha N}{C}\right)(K_{\max}-K_{\min})U}{P_{\max}\ln\beta} = 0$$

And the discriminant of this equation in terms of q is:

$$\Delta = (Cd-K_{\min})^2 + 4\left(K_{\min}Cd + \frac{N\ln\left(1-\frac{\alpha N}{C}\right)(K_{\max}-K_{\min})U}{P_{\max}\ln\beta}\right)$$

Since the rate increment of all flows within one RTT will definitely be less than C, $\ln\left(1-\frac{\alpha N}{C}\right)<0$. Because of $0<\beta<1$, we can get $\delta>0$ and $\sqrt{\Delta} > Cd - K_{\min}$, so the solution $q_1>0$, as shown in Equation (7).

$$q_1 = \frac{-(Cd-K_{\min})+\sqrt{\Delta}}{2} \tag{7}$$

Therefore, the stable point for the queue length $q^* = q$, and the stable point p^* for the ECN marking probability is:

$$p^* = \frac{q^*-K_{\min}}{K_{\max}-K_{\min}}$$

In conclusion, we can derive that a stable point must exist, and it is given by (R^*, q^*, p^*, n^*).

B.2 Stability Analyses

Near the stable point, the feedback delay of the control system is assumed to be constant D^*. The right halves of Equations (1) and (4) are represented by functions $f()$ and $g()$ respectively as follows:

$$f(R,p,q) = \frac{\alpha}{D(t)} - \frac{\left(1-\beta^{p(t)R(t)D(t)/U}\right)R(t)}{D(t)} \tag{8}$$

$$g(R) = NR(t) - C \tag{9}$$

The partial derivatives near the equilibrium point (R^*, q^*, p^*) are:

$$\begin{aligned} \left.\frac{\partial f}{\partial R}\right|_{\substack{R=R^*\\q=q^*\\p=p^*}} &= \left.-\frac{1-\beta^{p(t)R(t)D(t)/U}\left(\frac{p(t)R(t)D(t)}{U}\ln\beta+1\right)}{D(t)}\right|_{\substack{R=R^*\\q=q^*\\p=p^*}} \\ &= -\frac{1-\beta^{n^*/N}(n^*\ln\beta/N+1)}{D^*} \end{aligned}$$

$$\begin{aligned} \left.\frac{\partial f}{\partial p}\right|_{\substack{R=R^*\\q=q^*\\p=p^*}} &= \left.\frac{R(t)}{D(t)}\beta^{p(t)R(t)D(t)/U}\ln\beta\cdot\frac{R(t)D(t)}{U}\right|_{\substack{R=R^*\\q=q^*\\p=p^*}} \\ &= \frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N} \end{aligned}$$

$$\begin{aligned} \left.\frac{\partial f}{\partial q}\right|_{\substack{R=R^*\\q=q^*\\p=p^*}} &= -\frac{\alpha}{CD(t)^2} + \frac{R(t)}{CD(t)^2}\left(1-\beta^{p(t)R(t)D(t)/U}\left(1-\frac{p(t)R(t)D(t)}{U}\ln\beta\right)\right) \\ &= -\frac{\alpha}{CD^{*2}} + \frac{R^*}{CD^{*2}}\left(1-\beta^{n^*/N}\left(1-\frac{n^*}{N}\ln\beta\right)\right) \\ &= -\frac{\alpha}{CD^{*2}} + \frac{R^*}{CD^{*2}}\left(1-\beta^{n^*/N}\left(1-\ln\left(1-\frac{\alpha}{R^*}\right)\right)\right) \end{aligned}$$

$$\left.\frac{\partial g}{\partial R}\right|_{R=R^*} = N$$

According to the analysis at the stable point, it can be known that $-\frac{\alpha}{CD^{*2}} + \frac{R^*}{CD^{*2}}(1-\beta^{n^*/N}) = 0$. Therefore, the partial derivative of f with respect to q can be expressed as

$\frac{\partial f}{\partial q}\Big|_{\substack{R=R^*\\q=q^*\\p=p^*}} = \frac{R^*}{CD^{*2}}\beta^{n^*/N}\ln(1-\frac{\alpha}{R^*})$. So, the condition for the partial derivative of f with respect to q to be zero is restricted by whether $\ln(1-\frac{\alpha}{R^*})$ is 0. Only when $R^* >> \alpha$, can $\frac{\partial f}{\partial q}$ be approximated as zero.

Condition 1: $\frac{\partial f}{\partial q}\Big|_{\substack{R=R^*\\q=q^*\\p=p^*}} \neq 0$**.** At the equilibrium point (R^*, q^*, p^*), find the partial derivatives of $f()$ with respect to r, p, q. Then apply the Taylor series expansion near the equilibrium point to obtain:

$$\begin{aligned}\frac{d\delta R}{dt} \approx &-\frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}\delta R(t)\\ &+\frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}\delta p(t-D^*)\\ &+\left(\frac{R^*}{CD^{*2}}\beta^{n^*/N}\ln\left(1-\frac{\alpha}{R^*}\right)\right)\delta q(t)\end{aligned} \tag{10}$$

$$\frac{d\delta q}{dt} \approx N\delta R(t) \tag{11}$$

In equations (10) and (11), $\delta R(t) = R(t) - R^*$, and $\delta p(t) = p(t) - p^*$. Applying the Laplace transform to both sides of the equation, we could get:

$$\begin{aligned}s\tilde{R}(s) - \delta R(0) = &-\frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}\tilde{R}(s)\\ &+\frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}\tilde{p}(s)e^{-sD^*}\\ &+\left(\frac{R^*}{CD^{*2}}\beta^{n^*/N}\ln\left(1-\frac{\alpha}{R^*}\right)\right)\tilde{q}(s)\end{aligned}$$

$$s\tilde{q}(s) - \delta q(0) = N\tilde{R}(s)$$

Here, $\tilde{R}(s)$ and $\tilde{q}(s)$ represent the Laplace transforms of $\delta R(t)$ and $\delta q(t)$, respectively. The transfer function from $\tilde{p}(s)$ to $\tilde{R}(s)$ is:

$$G_{p\to R}(s) = \frac{\frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}}{s+\frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}-\frac{N}{s}\left(\frac{R^*}{CD^{*2}}\beta^{n^*/N}\ln\left(1-\frac{\alpha}{R^*}\right)\right)}e^{-sD^*}$$

The transforms of $\tilde{R}(s)$ to $\tilde{q}(s)$ is $G_{R\to q}(s) = \frac{N}{s}$. Similarly, we define $\delta p(t) = p(t) - p^*$. Based on Equation (4), $\delta p(t)$ could be translated into:

$$\delta p(t) = p(t) - p^* \quad = \frac{\delta q(t)}{K_{\max} - K_{\min}}P_{\max}$$

The transforms of $\tilde{q}(s)$ to $\tilde{p}(s)$ is :

$$G_{q\to p}(s) = \frac{\tilde{p}(s)}{\tilde{q}(s)} = \frac{P_{\max}}{K_{\max} - K_{\min}}$$

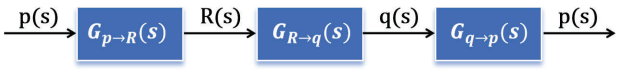

Figure 16: The equivalent open-loop system

Thus, the transfer function for the closed-loop system is:

$$G(s) = G_{p\to R}(s)G_{R\to q}(s)G_{q\to p}(s) = \frac{a}{s(s+b+\frac{c}{s})}e^{-sD^*} \tag{12}$$

In Equation (12), a, b and c can be expressed as:

$$a = \frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}N\frac{P_{max}}{K_{max}-K_{min}}$$

$$b = \frac{1-\beta^{n^*/N}(n^*\ln\beta/N+1)}{D^*}$$

$$c = -N(\frac{R^*}{CD^{*2}}\beta^{n^*/N}\ln(1-\frac{\alpha}{R^*}))$$

The equivalent open-loop system to the closed-loop system is shown in Figure 16. The frequency response of the system is denoted by $G(j\omega)$, with the magnitude and phase angle denoted by $r(\omega) = |G(j\omega)|$ and $\theta(\omega) = \angle G(j\omega)$, respectively. Thus, we have:

$$r(\omega) = \frac{a}{\sqrt{b^2\omega^2 + (c-w^2)^2}}$$

$$\theta(\omega) = -\omega D^* - \arctan\frac{b\omega}{c-w^2}$$

Let ω_g denote the 0-dB crossover frequency on the Bode plot, where $r(\omega_g) = 1$. In accordance with the Bode stability criterion to find the stability conditions, if within the frequency range $(0, \omega_g)$, the phase angle $\theta(\omega)$ is greater than $-\pi$, then the phase margin is greater than 0, ensuring the system is stable. Since $\theta(\omega)$ is monotonically decreasing and given that $\theta(0) = -\frac{\pi}{2}$, the stability condition is $\theta(\omega_g) > -\pi$, as $-\omega_g D^* - \arctan\frac{b\omega_g}{c-w_g^2} > -\pi$. The stability condition is:

$$-\omega_g D^* - \arctan\frac{b\omega_g}{c-w_g^2} > -\pi \tag{13}$$

Condition 2: $\frac{\partial f}{\partial q}\Big|_{\substack{R=R^*\\q=q^*\\p=p^*}} = 0$**.** Given that parameter β is set close to 1 in the Barre algorithm, $\ln\beta$ can be approximated as 0, thus $\frac{\partial f}{\partial q}\Big|_{\substack{R=R^*\\q=q^*\\p=p^*}} \approx 0$. Performing a Taylor series expansion around the equilibrium point yields the following:

$$\frac{d\delta R}{dt} \approx -\frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}\delta R(t) + \frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}\delta p(t) \tag{14}$$

$$\frac{d\delta q}{dt} \approx N\delta R(t) \tag{15}$$

In Equation (14) and (15), $\delta R(t) = R(t) - R^*$, and $\delta p(t) = p(t) - p^*$. Applying the Laplace transform to both sides of the equation, we could get:

$$s\tilde{R}(s) - \delta R(0) = -\frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}\tilde{R}(s) + \frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}\tilde{p}(s)$$

$$s\tilde{q}(s) - \delta q(0) = N\tilde{R}(s)$$

Here, $\tilde{R}(s)$ and $\tilde{q}(s)$ represent the Laplace transforms of $\delta R(t)$ and $\delta q(t)$, respectively. The transfer function from $\tilde{p}(s)$ to $\tilde{R}(s)$ is:

$$G_{p\to R}(s) = \frac{\frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}}{s + \frac{1-\beta^{n^*/N}\left(\frac{n^*\ln\beta}{N}+1\right)}{D^*}}$$

The transforms of $\tilde{R}(s)$ to $\tilde{q}(s)$ is $G_{R\to q}(s) = \frac{N}{s}$. Similarly, we define $\delta p(t) = p(t) - p^*$. Based on Equation (4), $\delta p(t)$ could be translated into:

$$\delta p(t) = p(t) - p^* \quad = \frac{\delta q(t)}{K_{\max} - K_{\min}} P_{\max}$$

The transforms of $\tilde{q}(s)$ to $\tilde{p}(s)$ is :

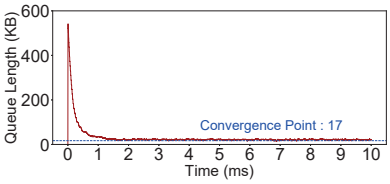
$$G_{q\to p}(s) = \frac{\tilde{p}(s)}{\tilde{q}(s)} = \frac{P_{\max}}{K_{\max} - K_{\min}}$$

Thus, the transfer function for the closed-loop system is:

$$G(s) = G_{p\to R}(s)G_{R\to q}(s)G_{q\to p}(s) = \frac{a}{s(s+b)} \tag{16}$$

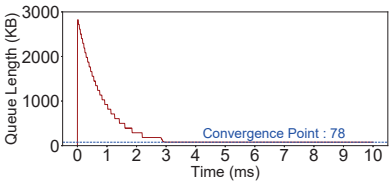
In Equation (16), a and b can be expressed as:

$$a = \frac{(R^*)^2\ln\beta}{U}\beta^{n^*/N}N\frac{P_{max}}{K_{max} - K_{min}}$$



$$b = \frac{1-\beta^{n^*/N}(n^*\ln\beta/N+1)}{D^*}$$

The equivalent open-loop system to the closed-loop system is the same as in Figure 16. The frequency response of the system is denoted by $G(j\omega)$, with the magnitude and phase angle denoted by $r(\omega) = |G(j\omega)|$ and $\theta(\omega) = \angle G(j\omega)$, respectively. Thus, we have:



$$r(\omega) = \frac{a}{\sqrt{\omega^2 + b^2}}\ ,\ \theta(\omega) = -\frac{\pi}{2} - \arctan\frac{\omega}{b}$$

Let ω_g denote the 0-dB crossover frequency on the Bode plot, where $r(\omega_g) = 1$. In accordance with the Bode stability criterion to find the stability conditions, if within the frequency range $(0, \omega_g)$, the phase angle $\theta(\omega)$ is greater than $-\pi$, then the phase margin is greater than 0, ensuring the system is stable. Since $\theta(\omega)$ is monotonically decreasing and given that $\theta(0) = -\frac{\pi}{2}$, the stability condition is $\theta(\omega_g) > -\pi$, as $-\frac{\pi}{2} - \arctan\frac{\omega_g}{b} > -\pi$. The stability condition is:

$$\arctan\frac{\omega_g}{b} < \frac{\pi}{2} \tag{17}$$

(a) 20:1 Incast

(b) 100:1 Incast

Figure 17: Convergence of Barre's fluid model

B.3 Simulation Verification

We utilize NS3 simulations to evaluate the convergence of Barre. The network topology consists of 10 servers connected to a single ToR switch, with each server equipped with a 100Gbps NIC linked to the switch. The baseline RTT is set to 2us. The increase factor and decrease factor for CC algorithm are configured at 10Mbps and 0.99, respectively. For ECN threshold, we configure K_{min}=10KB, K_{max}=200KB, and P_{max}=1 KB. We test different scale of AlltoAll traffic for 20:1 Incast (Figure 17 (a)) and 100:1 Incast (Figure 17 (b)).

In Figure 17 (a), 20 flows start at the same time, and keep going until each flow finished sending 100MB message. The simulation result shows that, the switch queue length of the congestion point is bounded by 17 KB when the flows are converged at approximately 1.5 ms. We use can get theoretical steady state q given by Equation (7) in fluid model analysis is 9.6 KB. Similarly, Figure 17 (b) shows the simulation result of 100 Incast flows, as each flow sends 10 MB message. The switch queue length converged to 79 KB at about 3ms. And the computational steady point is 78.27KB.

The simulation results and theoretical analysis demonstrate a consistent convergence point, validating the accuracy of Barre's convergence analysis. More importantly, Barre exhibits robust convergence properties even with large-scale incast traffic. This consistency underscores the reliability of Barre's design principles and its effectiveness in maintaining stable performance under dynamic traffic conditions.

FLB: Fine-grained Load Balancing for Lossless Datacenter Networks

Abstract

Remote Direct Memory Access (RDMA) over Converged Ethernet (RoCE) cooperating with Priority Flow Control (PFC) has been widely deployed in production datacenters to enable low latency, lossless transmission. At the same time, modern datacenters typically offer parallel transmission paths between any pair of end-hosts, underscoring the importance of load balancing. However, the well-studied load balancing mechanisms designed for lossy datacenter networks (DCNs) are ill-suited for such lossless environments.

Through extensive experiments, we are among the first to comprehensively inspect the interactions between PFC and load balancing, and uncover that existing fine-grained rerouting schemes can be *counterproductive* to spread the congested flows among more paths, further aggravating PFC's head-of-line (HoL) blocking. Motivated by this, we present FLB, a *F*ine-grained *L*oad *B*alancing scheme for lossless DCNs. At its core, FLB employs threshold-free rerouting to effectively balance traffic load and improve link utilization during normal conditions and leverages timely congested flow isolation to eliminate HoL blocking on non-congested flows when congestion occurs. We have fully implemented a FLB prototype, and our evaluation results show that FLB reduces PFC PAUSE rate by up to 96% and avoids HoL blocking, translating to up to 45% improvement in goodput over CONGA+DCQCN and 40%, 36%, 29% and 18% reduction in average flow completion time (FCT) over LetFlow+Swift, MP-RDMA, Proteus+DCQCN and LetFlow+PCN, respectively.

1 Introduction

Lossless network switching fabric is crucial and increasingly deployed in Converged Enhanced Ethernet (CEE) datacenters [1–15], e.g., Microsoft Azure [16], Alibaba Cloud [17] and Google cloud [18]. Remote Direct Memory Access (RDMA) over Converged Ethernet (RoCE) [4, 5, 19] is a widely deployed transport protocol in CEE datacenters. To guarantee lossless transmission, CEE employs priority flow control (PFC) [20] to prevent buffer overflow.[1] However, PFC PAUSE/RESUME mechanisms may lead to HoL blocking and congestion spreading [2, 4, 21–25], etc., causing severe performance degradation up to 10× for individual flows [2]. Worse still, a local PFC pausing may propagate backward hop by hop and eventually to the sources, turning into a global network paralysis! At the same time, load balancing (i.e., transmitting packets via multiple paths) is crucial because relying on a single path cannot fully leverage the rich parallel paths available in modern datacenters [7, 26–30].

In this paper, we point out that despite the great effort, the well-studied load balancing schemes [28, 29, 31–39] designed for lossy DCNs are ill-suited for PFC-enabled lossless DCNs for reasons experimentally demonstrated in §2.

On one hand, existing load balancing (LB) solutions cannot effectively split traffic among parallel paths in lossless DCN, even if they work well for the lossy network (§2.1). The reason is that in the current RDMA deployment, the forwarding rate is usually smoothed by a rate-shaper, flowlets rarely appear under the same fixed flowlet timeout as in lossy DCN to ensure no out-of-order packets [7]. Thus, the advanced flowlet-based load balancing schemes such as CONGA [28] and LetFlow [31] cannot flexibly reroute traffic in lossless DCN, resulting in unbalanced load and low link utilization.

On the other hand, fine-grained load balancing schemes (*e.g.*, flowlet-based [28, 31–33], flowcell-based [34], packet-level [7, 29, 35, 36, 40]) make the HoL blocking and congestion spreading more severe under PFC-triggered scenarios compared to single-path approaches (§2.2). Specifically, once PFC is triggered, if the congested flows that really responsible for congestion are sprayed across multiple paths, the number of PFC paused ports increases significantly, resulting in more blocked victim flows. In brief, the existing multipath schemes can be counterproductive in PFC-enabled lossless DCNs, as they spread the congested flows among more paths, aggravat-

[*] Equal contribution.

[1] With PFC, the downstream switch sends a PAUSE frame to its upstream switch once the ingress queue length exceeds the PFC threshold, and sends a RESUME frame when the queue drains below another threshold [4, 7].

ing the HoL blocking.

Furthermore, the above problems cannot be completely addressed even combined with sophisticated end-to-end congestion control protocols such as DCQCN [4], TIMELY [10], Swift [12], HPCC [11], and PCN [2] (§2.3). This is because current congestion control protocols cannot entirely prevent PFC from being triggered, particularly in bursty scenarios, thereby failing to avoid the counterproductive interaction between PFC and load balancing mechanisms.

Given the limitations of existing solutions, we ask: *can we design a load balancing scheme for PFC-enabled lossless DCNs that achieves high link utilization while eliminating PFC side effects?* This translates to three design goals:

- Flexibly rerouting the traffic to effectively balance load and enhance link utilization in normal conditions.
- Eliminating the HoL blocking and congestion spreading during congestion and PFC triggering.
- Reducing dependency on complex congestion control.

To this end, we present FLB, a PFC-aware fine-grained load balancing scheme for lossless DCNs that achieves all the above design goals (§3). First of all, to flexibly balance the load in normal conditions, FLB reroutes flows without a preset threshold, while still effectively adapting to varying packet intervals (§3.1). To avoid packet reordering, FLB reroutes the arrival packets from current slow path to another one only when the time interval between the arrival packet and the previous one in the same flow is larger than the delay difference of the two paths. Meanwhile, to ensure low latency, the path with minimum delay among all feasible paths is selected for rerouting.

Second, to mitigate the side effects of PFC during congestion, FLB leverages a traffic isolation scheme (§3.2) that consolidates, rather than spreads, the congested flows into a minimized set of isolation paths, while rerouting the uncongested flows through the remaining parallel paths. Specifically, when the egress queue exceeds a preset isolation threshold, a congestion notification message (CNM) is generated and sent to the source edge switch. Based on the CNM, the source edge switch identifies the congested flows and consolidates them from original paths into a minimized set of isolation paths. In this way, FLB maintains the efficiency of multipath transmission for uncongested flows while effectively eliminating HoL blocking and preventing congestion from spreading caused by congested flows.

Theoretically, FLB can be integrated with any end-host congestion control mechanisms. Moreover, by effectively balancing traffic and limiting the side effects of PFC, FLB reduces the need for complex congestion control algorithms. To validate this, we come up with a minimal end-host rate control (§3.3) where the sender starts transmission at line rate and pauses only when receiving a CNM. We show that even with this simple rate control, FLB achieves superior performance compared to other combinations of load balancing and congestion control (§4.3).

We have implemented a FLB prototype (§3.4) using P4 programming language [41], and quantified the hardware resource usage of FLB. We evaluate FLB on a testbed including 20 Dell servers equipped with Mellanox ConnectX-5 100GbE Network Interface Cards (NICs) and 100Gbps programmable switches. The experimental results show that FLB reduces the average flow completion time (AFCT) by up to 30% compared to MP-RDMA under realistic datacenter workloads. FLB also improves link utilization by 78%, 144% and 28% in Web Search workload over LetFlow, LetFlow+DCQCN and MP-RDMA, respectively (§4.1). We also analyzed various design components of FLB and demonstrated their contributions to its superior performance (§4.2).

To complement the small-scale testbed experiments, we conducted large-scale NS3 simulations. The results show that FLB with minimal rate control (FLB+RC) outperforms state-of-the-art multipath transmission schemes, even when integrated with congestion controls, reducing the AFCT by up to 70%, 36% and 29% compared to LetFlow+DCQCN, MP-RDMA and Proteus+DCQCN, respectively (§4.3).

Finally, we note that there emerges a thread of research on lossy fabric without PFC [8, 42]. However, as reported in [1], lossless fabric is still the most-deployed infrastructure in production datacenters. FLB targets a practical solution for these lossless FPC-enabled datacenter fabrics.

2 Problem Demonstration

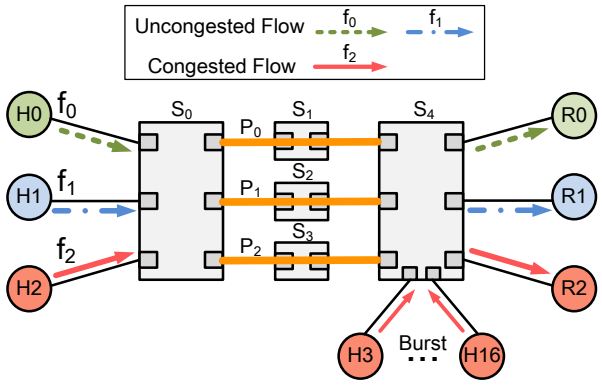
This section experimentally demonstrates the problems of existing fine-grained load balancing schemes (designed for lossy DCNs) in PFC-enabled lossless DCNs, motivating our design of FLB.

2.1 Inflexible rerouting leads to load imbalance and link under-utilization

As many prior studies have noted, flow-based load balancing, such as ECMP [43], is ineffective in distributing the load in modern datacenters [44, 45]. Therefore, spreading traffic across multiple paths with finer granularity is essential to achieving higher network utilization.

Both industry and academia have proposed various fine-grained load balancing mechanisms [7, 28, 29, 31–36]. However, these mechanisms are typically designed for lossy DCNs. State-of-the-art flowlet-based schemes, such as CONGA [28] and LetFlow [31], are also unable to flexibly reroute traffic in lossless DCNs due to the rare occurrence of flowlet gaps. This is because hardware-accelerated data transmission with rate shapers in RDMA networks minimizes packet intervals. Furthermore, RDMA bypasses the operating system, eliminating interruptions that might otherwise create gaps.

Small-scale Testbed Experiments. We investigate how the typical flowlet-based schemes work in Leaf-spine [28] topol-



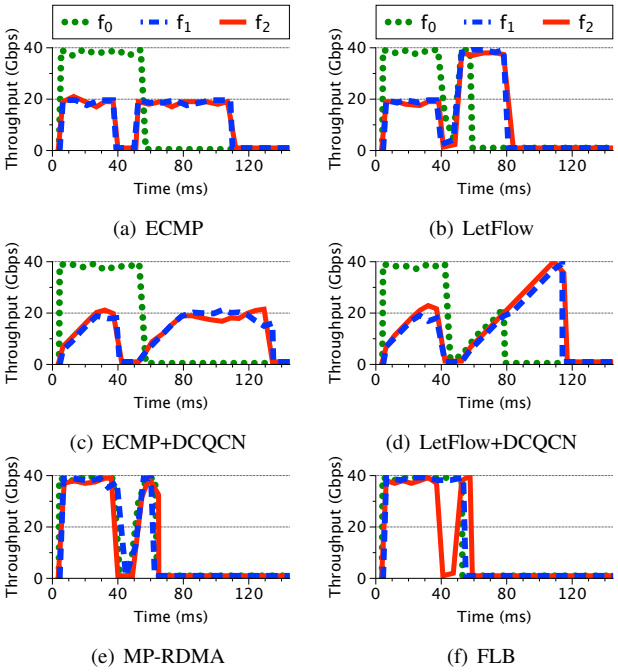


Figure 1: Typical network scenarios. Under flow-based LB such as ECMP, f_0 takes the path P_0 {S0, S1, S4}, f_1 and f_2 hash collide on the path P_2 {S0, S3, S4}. Under flowlet-based LB such as LetFlow, f_0, f_1 and f_2 are spread across three paths P_0 {S0, S1, S4}, P_1 {S0, S2, S4} and P_2 {S0, S3, S4}.

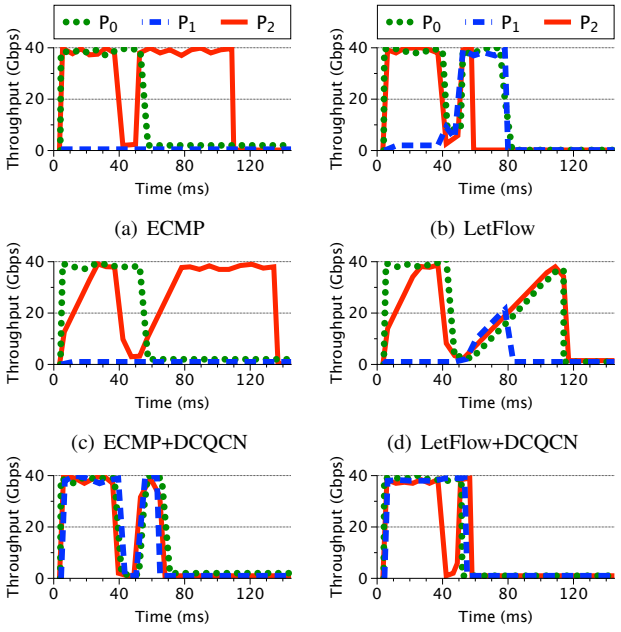
ogy as used in prior work [2,3]. As shown in Fig. 1, 3 senders (H0, H1, H2) and 3 receivers (R0, R1, R2) connect to the corresponding edge switches (S0, S4), respectively. There are 3 equal-cost paths between the two edge switches passing through core switches (S1, S2, S3) and represented by P_0 {S0, S1, S4}, P_1 {S0, S2, S4} and P_2 {S0, S3, S4}, respectively. In addition, 14 senders (H3∼H16) connect to the switch S4.

We conduct experiments to explore the issues of load balancing schemes including ECMP, LetFlow, ECMP+DCQCN, LetFlow+DCQCN, and MP-RDMA, which are implemented by using DPDK [46] and P4 hardware switch [41,47]. The testbed consists of 20 servers connected to two P4 switches with 3 parallel paths of 40Gbps. Each switch has 22MB shared buffer and 32 full duplex ports enabling PFC with dynamic threshold[2]. The flowlet timeout is set to 50μs. We set all parameters to the default values recommended in [4,7,31]. The bursty scenarios follow the prior work [2,3]. At time 0ms, H0, H1 and H2 start a long flow with 250MB to R0, R1 and R2, respectively, named f_0, f_1 and f_2. At time 40ms, each sender of H3∼H16 generates 40 short flows to R2 at line rate, and the size of each short flow is 64KB. These bursty flows last about 8ms.

At the beginning, we configure f_0 takes the path P_0 {S0, S1, S4}, while f_1 and f_2 share the path P_2 {S0, S3, S4} under both ECMP and LetFlow. The results are shown in Fig. 2. Since f_2 and all bursty short flows arrive at the same receiver R2, the egress port from S4 to R2 is congested during the duration of bursty flows. Once PFC is triggered at the ingress ports in S4, the PAUSE frames from these ingress ports pause their upstream ports. As previously configured, both f_1 and f_2 are routed to the same path P_2 under ECMP, LetFlow and MP-RDMA. An ideal load balancing scheme should timely switch f_1 to the idle path P_1. However, as shown in Fig. 2, none of them can flexibly distribute traffic. They fail to reroute

[2]We implement PFC based on the IEEE Standard 802.1Qbb [20].



(a) ECMP (b) LetFlow (c) ECMP+DCQCN (d) LetFlow+DCQCN (e) MP-RDMA (f) FLB

Figure 2: Throughput of flows under various schemes. Under ECMP and ECMP+DCQCN, the uncongested flow f_1 is blocked. Under LetFlow, LetFlow+DCQCN and MP-RDMA, both the uncongested flows f_0 and f_1 are blocked. The blocked victim flows cannot be rerouted to other paths. There are no victim flows in FLB.

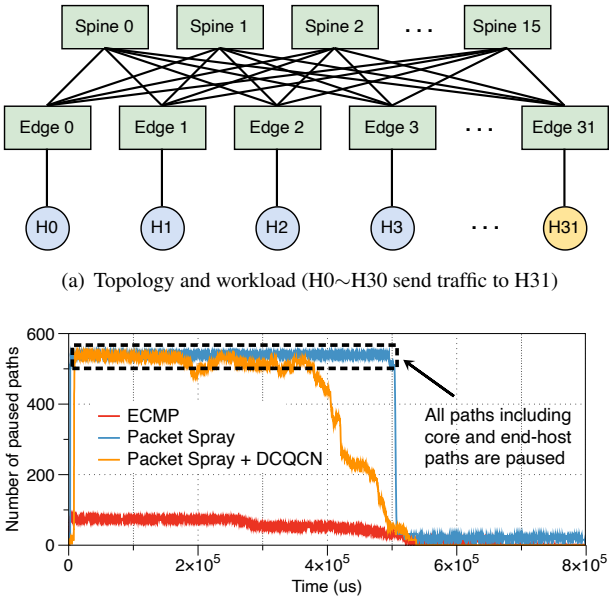
the uncongested flow f_1 from the congested path $P2$ to an uncongested path. This is because the flowlet-based switching cannot reroute packets unless flowlets emerge, which is prevented by inappropriate fixed timeouts for avoiding packet reordering. As a result, available link bandwidth is wasted.

2.2 Multi-path spreading expands the influence scope of PFC's HoL blocking

We repeat the above experiment in Fig. 1 but *manually* configured the congested flow f_2 to utilize all three paths (P_0, P_1, and P_2) under LetFlow and MP-RDMA. The throughput for these three paths is shown in Fig. 3, and we make the following observations: (1) single-path transmission: under the ECMP and ECMP+DCQCN schemes, since f_2 follows a single path, P_2, *only* P_2 *is paused by PFC*. As a result, only the uncongested flow f_1 on the same path is blocked, while flow f_0 on the other path remains unaffected by PFC's HoL blocking; (2) multi-path spreading: under LetFlow and MP-RDMA schemes, *all three paths* (P_0, P_1, *and* P_2) *are paused by PFC* during the bursty flows. This occurs because the congested flow f_2 is routed across all three paths, causing PFC PAUSE frames to be sent to all upstream ports of S4. This leads to more severe congestion spreading, where all paths (P_0 and P_1) and flows (f_0 and f_1) are blocked.

(a) ECMP (b) LetFlow

(c) ECMP+DCQCN (d) LetFlow+DCQCN



(e) MP-RDMA (f) FLB

Figure 3: Throughput of paths under various schemes. Under ECMP and ECMP+DCQCN, one path P_2 is paused by PFC due to the congested flow f_2 transmitting on P_2. Under LetFlow, LetFlow+DCQCN and MP-RDMA, three paths P_0, P_1 and P_2 are paused since the congested flow f_2 is spread on all three paths.

Large-scale Simulations. To further show the problem, we construct a larger-scale Clos topology with 16 spine and 32 leaf switches using NS3 (Fig. 4(a)). The switch configuration is the same as in the preceding testbed experiments. The end-hosts H0∼H30 simultaneously transmit 200MB of traffic to H31, creating a long-living 31-to-1 incast pattern.

We investigate the extent of congestion spreading during multi-path transmission (using packet spraying as an example) in lossless DCNs. We compare the number of paused paths (*i.e.*, paths receiving PFC PAUSE frames during a given time interval) under packet spraying and ECMP. The results are presented in Fig. 4(b). As the results show, ECMP causes only the passing paths of 31 flows to pause (about 70 paths in total). In contrast, packet spraying results in all paths (about 340 paths) being paused. This is because data is sprayed across all paths, causing the PFC PAUSE frames to back-propagate throughout the network hop by hop.

In summary, with fine-grained rerouting, packets from congested flows are counterproductive spread across multiple paths, causing more paths to be paused by PFC, which aggravates to more victim flows and reduced link utilization. Therefore, an ideal load balancing scheme should prevent congested flows from using multiple paths and minimize the number of paused paths.

(a) Topology and workload (H0∼H30 send traffic to H31)

(b) The number of paused paths of three configurations.

Figure 4: Difference in congestion spreading between packet spraying and ECMP under large-scale topology.

2.3 Congestion control does not help

We envision that the above problems cannot be solved with congestion control as it cannot entirely prevent PFC from being triggered. To illustrate this issue, we observe again the results in Fig. 2 and Fig. 3. The performance is even worse when the existing LB schemes work with congestion control (*e.g.*, LetFlow+DCQCN). Although the congestion control effectively regulates the rates of f_1 and f_2 before 40ms, PFC is still triggered when the bursty flows start, because each bursty flow lasts less than 1 RTT and cannot be controlled by DCQCN. In this case, after the uncontrollable bursty flows finish transmissions, the remaining flows cannot utilize the available bandwidth immediately due to the slow evolution-based rate increasing of end-to-end congestion control. For MP-RDMA, the throughput of flows f_0, f_1 and f_2 are further reduced by congestion control due to the slow convergence.

We also evaluate the impact of end-host congestion controls (using DCQCN as an example) on the congestion spreading caused by packet spraying. As shown in Fig. 4(b), DCQCN only slowly reduces the number of paused paths, it cannot quickly eliminate congestion and stop the PFC pausing.

3 FLB

Building on the preceding observations and analysis, we pose the question: Can we design a fine-grained load balancing scheme for PFC-enabled lossless DCNs that achieves (1) efficient rerouting with high link utilization, (2) elimination of PFC side effects such as congestion spreading and aggravated

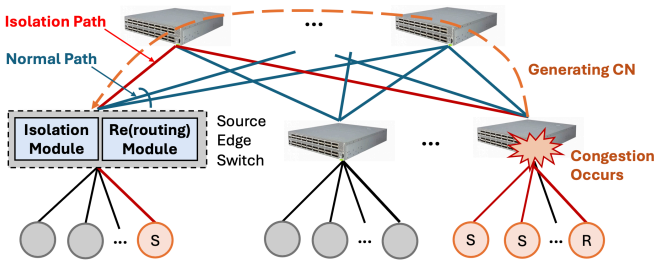


Figure 5: FLB overview. S, R and CN stand for sender, receiver and congestion notification, respectively.

HoL blocking, and (3) reduced reliance on congestion control mechanisms? We address this question with FLB.

The design of FLB mainly consists of two modules, as illustrated in Fig. 5. In normal conditions, FLB employs a flexible rerouting scheme (*i.e.*, the Rerouting Module) to effectively balance the traffic across multiple paths without causing packet reordering. Upon congestion, FLB quickly consolidates congested flows from their original multi-spread paths onto a minimized set of paths (*i.e.*, the Isolation Module), thereby eliminating the impact of PFC's HoL blocking on non-congested flows.

FLB can be integrated with any end-host congestion control schemes, including the existing lossless DCN congestion control algorithms [2, 4, 10, 48]. Moreover, since well-balanced traffic reduces congestion and congested flows are isolated, FLB minimizes the reliance on complex congestion control. To validate this, we design a minimal rate control at end hosts (§3.3), with a simplified algorithm that the senders start transmission at line rate and pause only when notified.

3.1 Flexible Rerouting

FLB employs flexible rerouting without the preset threshold to effectively balance the uncongested traffic and improve link utilization. Instead of switching with coarse granularity or passively waiting for emergence of flowlets, FLB works actively at the packet granularity. When making rerouting decisions, FLB ensures that the subsequent packet with larger sequence number arrives at the receiver later than the previous packets with smaller sequence number in the same flow to avoid reordering.

Algorithm 1 shows the rerouting logic of FLB. When a new active flow arrives, it selects a forwarding path with the minimum delay except the isolated path (lines 3-5). For the packets of existing flows, FLB compares the time interval between the arrival and previous packets in the same flow with the delay difference between the current path and other parallel paths, and selects the fastest path with the delay difference less than the time gap between two packets in order to avoid packet reordering (lines 8-12). Otherwise, the packet remains on its current path (lines 13-14).

Since FLB leverages the path delay differences to make forwarding decisions, the measured one-way delay can be used even if the clock is not synchronized [49]. Specifically, the source edge switch periodically samples packets, embedding their departure timestamps in the packet headers. When these marked packets arrive at the destination edge switch, the system computes precise one-way delay by subtracting the embedded timestamp from the arrival time. This delay measurement is then piggybacked on subsequent packets traversing the same port pair [50], enabling continuous path delay monitoring at the source edge switch without additional overhead. To address the issue of clock asynchrony, FLB calculates the real one-way queueing delay by subtracting the base delay from the measured one-way delay. The base delay is the one-way delay without any queueing delay and is obtained by recording the minimum history delay [50]. By default, FLB measures one-way delay at the edge switches periodically with two base RTT to reduce overhead.

Algorithm 1: Rerouting without Reordering

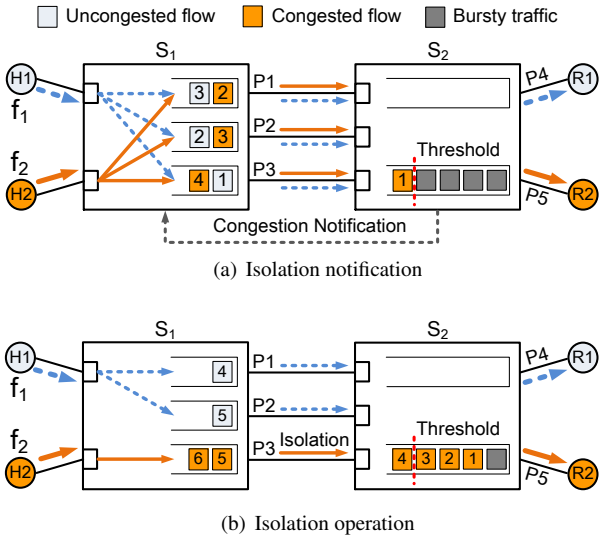
Input:
t_{OWD}: Measured one-way delay of a path;
t_{prev}: The arrival time of previous packet;
t_{cur}: The arrival time of current packet;
Output: p^*: The new routing path;

1 **for** *every packet* **do**
2 Assume its corresponding flow is f;
3 **if** f *is a new flow* **then**
4 $\{P'\}$ = all paths except the isolated paths occupied by the congested flows;
5 $p^* = Argmin_{p \in \{P'\}}(p.t_{OWD})$;
6 **else**
7 Assume f's path is p;
8 $\Delta t = f.t_{cur} - f.t_{prev}$;
9 $\{P'\}$ = all paths with less delay than p and no threat of reordering;
10 /* $\forall p' \in \{P'\},\ 0 < p.t_{OWD} - p'.t_{OWD} < \Delta t$ */
11 **if** $\{P'\} \neq \varnothing$ **then**
12 $p^* = Argmin_{p' \in \{P'\}}(p'.t_{OWD})$;
13 **else**
14 $p^* = p$; /* Do not reroute */
15 **return** p^*

FLB guarantees a better path switching. A flow requires a better path when its original path becomes less efficient than other parallel paths due to congestion. In such cases, end-host PAUSE (if no congestion control is enabled) or congestion control rate adjustments will react accordingly. PFC PAUSE creates a sufficient time interval between consecutive packets, triggering rerouting to a better path. Similarly, congestion control adjustments reduce the sending rate, increasing the time interval between consecutive packets, which also enables rerouting. As a result, FLB can consistently switch to a better path whenever one is available.

FLB works at the finer granularity than flowlet . Instead of switching with coarse flow-level granularity or passively waiting for emergence of flowlets, FLB reroutes flows flexibly without the fixed threshold at the switch to reduce PFC triggering and improve link utilization.

Periodic removal of flow entries. We use timeouts to periodically remove inactive flow table entries. Specifically, flow entries that have not been hit for a certain period (*e.g.*, 1 ms) are removed by periodically checking the age bit of each flow [28, 51]. This logic also applies to the congested flow entries used in the isolation module (detailed in §3.2).



3.2 Flow Isolation

When congestion occurs, FLB aims to shield uncongested flows from being blocked by congested flows (i.e., HoL blocking). Specifically, FLB dynamically isolates congested flows onto a minimal set of paths, rather than all paths, to limit the impact of PFC and reduce buffer and link bandwidth wastage[3]. As a result, uncongested flows are no longer blocked.

Fig. 6 illustrates the flow isolation mechanism of FLB, where one priority class is assumed for each port. In Fig. 6(a), two flows f_1 and f_2 are transferred from source edge switches S1 to S2 via parallel links. With load balancing enabled, the packets of f_1 and f_2 share multiple egress ports of switch S1. Then, traffic bursts from other ingress ports to the egress port P5 at S2. On switch S2, when the queue length of egress port P5 reaches the isolation threshold due to the burst, a congestion notification message (CNM) with congestion flag, containing the flow identifier (ID) and the number of congested flows (n), is immediately generated and sent to S1 before PFC is triggered.

Upon receiving the CNM from downstream switch S2, as shown in Fig. 6(b), FLB stores the flow ID in a flow table (called isolation table) and isolates the congested flow f_2 onto a minimized set of isolated paths (for illustration, Fig. 6(b) shows one path) where the last packet in f_2 is pending, while rerouting subsequent packets of the uncongested flow f_1 to another path. Uncongested flows are not allowed to use the isolated path. When multiple isolation paths are available, the source edge switch randomly assigns the congested flows to one of these paths.

Determining the number of isolation paths. The source edge switch determines this number based on the total converged rate of all congested flows. Assuming the link bandwidth (C) is uniform across the entire cluster, the converged sending rate for each congested flow can be calculated as C/n, where n is the number of congested flows reported in the CNM. The total converged rate of all congested flows, partitioned by the single link bandwidth, determines the number of isolation paths. Maintaining multiple isolation paths with a comparable bandwidth ensures that the source edge switch does not introduce more severe congestion on these congested flows. This further ensures that the congestion root remains constant and does not shift to the source edge switch.

(a) Isolation notification

(b) Isolation operation

Figure 6: FLB isolation mechanism.

Releasing congested flows when congestion subsides. When the queue length of the previously congested port falls below the isolation threshold, a CNM with a non-congestion flag is generated and sent to the corresponding source edge switch. Upon receiving the CNM with the non-congestion flag, the associated congested flow is removed from the isolation table. FLB periodically checks the isolation table to recalculate the required number of isolation paths, releasing one or more paths as necessary. Once the isolation table is empty, all isolation paths are released. In scenarios where the CNM with the non-congestion flag is lost, we rely on timeouts to release inactive congested flow entries.

Determining isolation threshold. One challenge is to determine the isolation threshold for isolating congested flows at switch. If we use a large isolation threshold, PFC may be triggered at a high risk, resulting in more serious congestion spreading. In contrast, a small isolation threshold may prematurely pause the congested flow, resulting in throughput degradation. The detailed analysis of optimizing isolation threshold is leaved in §A and the corresponding experiments are shown in §4.2.

CNM construction. FLB utilizes the direct signal CNM of existing QCN mechanism [48], which is commonly available in commodity switches [52]. However, QCN forwards packets based on L2 addresses and does not preserve the original sender's Ethernet/IP address. To solve it, FLB records flow ID and the source MAC address of the previous hop in the flow

[3] Since the ingress port must reserve buffer space for each priority to absorb inflight packets during the transmission of PFC PAUSE to the upstream switch, the shallow buffer (*e.g.*, 9MB or 12MB) of the commodity switch has no enough space to support PFC on all of the class-of-service queues [5]. As reported in [5], PFC can be enabled on only 2 priorities in practice even though the switches typically support 8 traffic classes.

table at switches. The switch can then propagate the CNM to all the corresponding source edge switches by looking up the flow table hop by hop in IP-routed networks.

3.3 Minimal Rate Control

Enabled by the limited impacts of PFC (achieved by the flow isolation in §3.2), and the well-balanced traffic (achieved by the flexible rerouting in §3.1), FLB reduces the need for and dependency on complex congestion control algorithms. To validate this, we design a minimal rate control, which works as follows:

- All flows start at line rate by sending a bandwidth-delay product (BDP) worth of data packets.
- The source edge switch forwards the CNM to notify the end-hosts of the congested flows. Upon receiving a CNM with a congestion flag, the source host pauses its data transmission for each congested flow and directly sets the future sending rate as $r = \frac{C}{n}$, where C is the line rate and n is the maximum number of congested flows indicated in the CNM. The congested flows resume transmission at the rate r upon a CNM with a non-congestion flag is received. The rate varies with the change of n in the received CNM.

This minimal rate control approach bypasses the iterative convergence process, directly adjusting the sending rate based on CNM information, which significantly reduces the complexity of end-host congestion control.

3.4 Implementation

We implement FLB based on the Wedge 100BF-32X programmable switch [47]. The ingress pipeline with multiple match-action tables for data packets is shown in Fig. 7. Specifically, the metadata $flow.isolation.flag$ is set to 1 to trigger the isolation operation when the queue length exceeds the isolation threshold K. Since the egress queue cannot be read from the ingress intrinsic metadata on P4 hardware platform, we implement the queue-size SRAM with a similar function by counting the packets enqueueing and dequeueing the egress port. In the *Forwardport* tables, for an uncongested flow, FLB selects an egress port according to the rerouting Algorithm 1 in §3.1. For a congested flow, FLB randomly forwards the packet to an isolated port. For a new flow, the packet is routed on the path with minimal delay.

Flow table is maintained at the edge switch. Each flow entry consists of a 16-bit flow ID, a 8-bit selected path ID, a 8-bit aging metric and 48-bit MAC address. Flow ID is calculated based on a CRC16 hash function over the unique 5 tuples of a flow. Aging metric (similar to CONGA [28]) is used to measure packet interval without recording timestamps. Specifically, each incoming packet resets the aging metric of its flow, while a timer periodically increases the metric by one. In this way, the memory consumption is reduced significantly, *e.g.*, only 0.1MB SRAM is used. While in a 3-tier Fat-tree

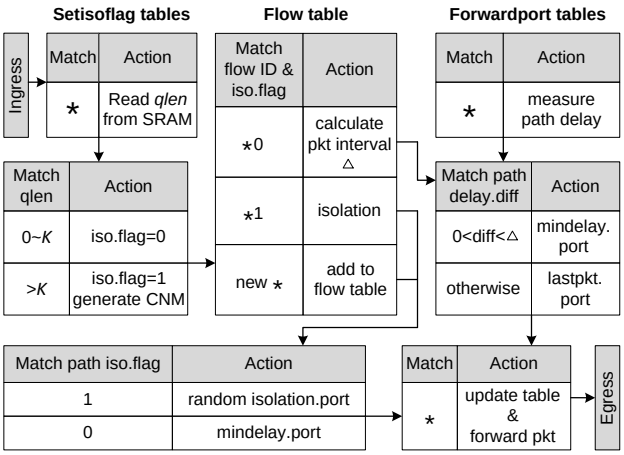


Figure 7: Ingress pipeline for data packets.

topology [53], SRAM consumption increases to 0.12MB due to the increase of path ID to 24bit.

Resource consumption: Table 1 lists the resource consumption of ECMP, LetFlow and FLB under 100K concurrent flows. While the resource consumed by FLB is higher than the others, it occupies no more than 10% of the total switch resource in general. The reason of higher resource consumption is that FLB needs more pipeline stages to isolate congested flows, reroute uncongested flows and flexibly select paths. FLB performs the pipelining of each packet through visiting the match-action tables without violating the access restriction, resulting in more overhead such as Gateway. Meanwhile, FLB needs more SRAM and stateful ALUs to store and update selected path ID and age bits of the last packet. Nonetheless, the overall resources consumption for FLB remains low, meaning that FLB can be deployed in high-speed switch with reasonable resources consumption.

Table 1: Resource consumption of different schemes.

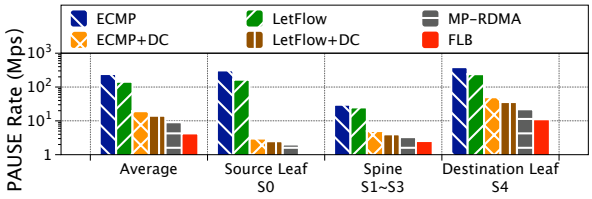
Resource	ECMP	LetFlow	FLB
Match Crossbar	2.41%	4.82%	5.82%
Hash Bits	3.08%	5.67%	5.87%
Gateway	1.39%	2.96%	9.56%
SRAM	1.56%	3.33%	4.12%
VLIW Actions	1.56%	2.34%	3.34%
ALU Instruction	2.6%	5.2%	8.2%

Practical deployment: To reduce deployment overhead in multi-tier topologies, FLB is deployed only on the edge switches while still maintaining comprehensive control over the routing decisions. (1) If FLB is deployed in the two-level topologies (e.g., Leaf-Spine), rerouting is determined solely at the leaf layer. Once the spine switch is selected, the routing to the destination leaf is automatically decided, as there is only a single path from the spine to the destination leaf. (2) If FLB is deployed in the multi-level topologies (e.g., three-layer Fat-Tree), the edge switches maintain the flow table and the delay information of each end-to-end path specified by a

unique path ID [54]. When a packet arrives at an edge switch, it selects the appropriate path based on this information and is forwarded using explicit source routing techniques, such as XPath [54].

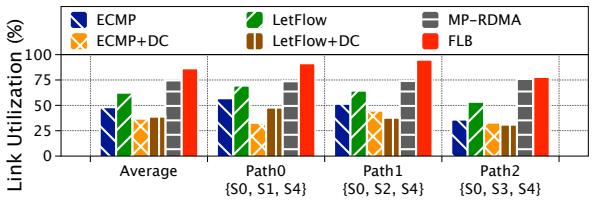
4 Evaluation

We evaluate FLB using both testbed experiments and NS3 simulations. Our evaluation centers around the following key questions:



- **How does FLB perform in practice?** Testbed experiments (§4.1) demonstrate the superior performance of FLB. Specifically, FLB reduces the AFCT by 48%, 42% and 30% compared to ECMP+DCQCN, LetFlow+DCQCN and MP-RDMA, respectively.
- **How sensitive is FLB to traffic patterns and parameters, and how effective are the design components?** Deep-dive experiments (§4.2) show that FLB achieves persistent good performance under various traffic patterns and parameter settings, and validate the effectiveness of its design components.
- **How does FLB with minimal rate control (§3.3) (FLB+RC) perform in large-scale DCNs?** Using large-scale NS3 simulations (§4.3), we show that FLB+RC scales well to large and multi-tier network topologies, and performs better than various load balancing mechanisms.

4.1 Testbed Experiments



Testbed and parameter settings: We use the same topology as prior work [2, 3] (see Fig. 1) and the testbed settings are the same as in §2. Each server (Dell PRECISION TOWER 5820 server) is equipped with 10 cores Intel Xeon W-2255 CPU, 64GB memory, Mellanox ConnectX-5 100GbE NICs that support DPDK 20.08 and Ubuntu 20.04.1. By default, the link capacity is set to 40Gbps. All parameters in DCQCN [4] and MP-RDMA [7] are set to the recommended values. FLB and FLB+RC respectively indicate without minimal rate control (§3.3) and with minimal rate control (RC).

Results with realistic workload: For this experiment, hosts H0∼H16 generate dynamic traffic according to the realistic Web Search workload [55] with heavy-tailed distribution. The average flow size is 1.6MB. The flows generated from hosts H3∼H16 are concurrent bursty flows. The target load at the bottleneck link is set to 0.6. We measure the flow completion time (FCT), pause rate and link utilization to compare the performance of FLB with the other five schemes.

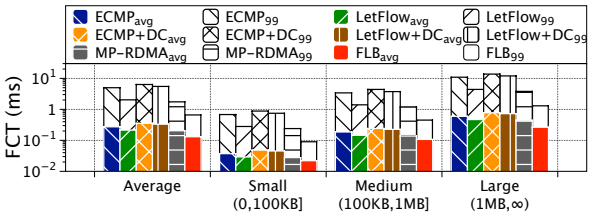


Fig. 8 (a) shows the generating rates of PFC PAUSE from different switch layers. Although the traffic changes dynamically, FLB effectively reduces PFC PAUSEs and suppresses congestion spreading. For FLB, the PAUSE rates at the core and source edge switches are smaller than that at the destination edge switch. Due to lacking of congestion control, the

(a) Generating rate of PAUSEs on different switches.

(b) Link utilization of different parallel paths.

(c) FCT with different flow sizes.

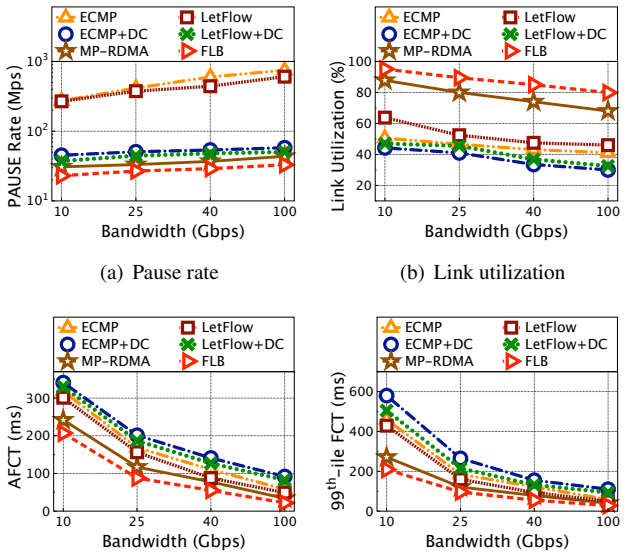

Figure 8: Results with realistic workload.

PAUSE rates of ECMP and LetFlow are larger than those of ECMP+DCQCN and LetFlow+DCQCN, respectively.

Fig. 8 (b) shows the link utilizations of different parallel paths. By balancing traffic among parallel paths, FLB and MP-RDMA achieve higher link utilization on different paths than the other schemes. In addition, since FLB reduces the number of ports affected by PFC PAUSEs through isolating the congested flows, FLB obtains the highest average link utilization over the other schemes.

Fig. 8 (c) shows the FCTs of small (0,100KB], medium (100KB,1MB] and large (1MB, ∞) flows in Web Search [56]. Since FLB can rapidly isolate and pause the congested flows, the uncongested flows are not blocked by PFC PAUSEs and complete quickly. FLB achieves the lowest average and 99^{th} percentile FCTs of all flows. Compared to ECMP+DCQCN, LetFlow+DCQCN and MP-RDMA, FLB reduces the AFCT of all flows by 48%, 42% and 30%, respectively. The improvement of FLB over ECMP+DCQCN and LetFlow+DCQCN in the 99^{th} percentile FCT is even up to 88% due to successfully avoiding HoL blocking and congestion spreading.

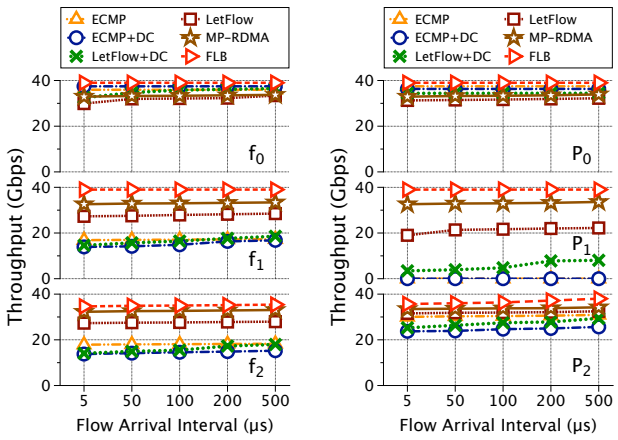
Results with bursty flows: We evaluate the performance of FLB under bursty flows following the same settings as described in §2. Fig. 2 and Fig. 3 show the throughput results of various schemes. We find that FLB effectively avoids the HoL blocking and congestion spreading problems. Specifically, with FLB, (1) uncongested flows f_0 and f_1 no longer suffer

(a) Pause rate (b) Link utilization

(c) AFCT (d) 99^{th} percentile FCT

Figure 9: Results with bursty flows under various link speeds. DC stands for the DCQCN congestion control.

from HoL blocking due to the congested flow f_2 (shown in Fig. 2 (f)); (2) two paths P_0 and P_1 in FLB are no longer affected by the PFC PAUSEs (shown in Fig. 3 (f)).



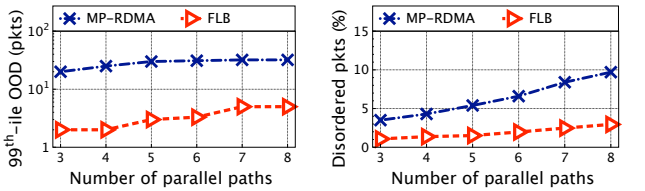
We then vary the link capacity from 10Gbps to 100Gbps, and repeat the same experiments. Fig. 9 (a) shows FLB reduces the rate of PFC PAUSE by up to 96% through isolating the culpable flows. Since the data transmission at line rate leads to fast queueing buildup especially under high-speed links (*e.g.*, 40Gbps, 100Gbps), ECMP and LetFlow trigger significantly more PAUSEs than the other schemes. With employing congestion control, ECMP+DCQCN, LetFlow+DCQCN and MP-RDMA trigger small number of PFC PAUSEs. However, as shown in Fig. 9 (b) and Fig. 9 (d), slow convergence to the target rate under DCQCN results in increments in utilization loss and tail latency, respectively.

Fig. 9 (b) shows that FLB improves link utilization by up to 95%, 78%, 166%, 144% and 28% compared to ECMP, LetFlow, ECMP+DCQCN, LetFlow+DCQCN and MP-RDMA, respectively. Fig. 9 (c) and Fig. 9 (d) show the average and 99^{th} percentile FCTs. Because FLB mitigates PFC triggering between switches and isolates the culpable flows to protect victim flows, FLB achieves lower FCT than the other schemes under various bandwidth of the bottleneck link.

4.2 FLB Deep Dive

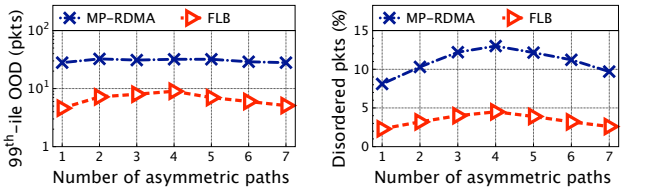
We further conduct the testbed experiments to answer the following three questions:

- **How sensitive is FLB to bursty flows?** As traffic demand varies across time and space in DCN, FLB should be robust to dynamic traffic. We find that, even with only 5μs flow arrival interval, FLB still effectively avoids PFC's HoL blocking and achieves high link utilization.
- **How effective is the rerouting mechanism in avoiding packet reordering?** In both symmetric and asymmetric scenarios, FLB effectively avoids reordering problem, and the out-of-order degree is lower than MP-RDMA.
- **What is the effect of the optimized isolation threshold?** Compared to FLB with fixed isolation threshold, FLB with the optimized threshold reduces the PAUSE rate by up to 89% and increases the link utilization by up to 40%.
- **How effective is FLB integrated with rate control?** FLB+RC achieves the lowest flow completion time.



(a) Throughput of flows (b) Throughput of paths

Figure 10: Performance under bursty traffic.



Impact of bursty flow: To explore how FLB performs in bursty scenario, we vary the arrival interval of concurrent flows [2, 57]. Each long flow is 250MB and bursty flows from H3∼H16 to R2 start at different intervals, varying from 5μs to 500μs. We measure the throughputs of each flow and each path. The results are shown in Fig. 10.

We make the following three observations: First, for the uncongested flows f_0 and f_1, FLB maintains high throughput with different arrival intervals of bursty flows. This is because FLB timely isolates the culpable flow f_2 on one path to avoid HoL blocking for uncongested flows. Compared to MP-RDMA, FLB improves the throughputs of f_0 and f_1 by 24% and 20%, respectively. Second, for the congested flow f_2, FLB also achieves higher throughput than other schemes, since f_2 resumes its transmission at line rate, rather than slowly converging to the target rate like DCQCN. In addition, f_2 can flexibly transfer packets among parallel paths when congestion does not occur. Third, FLB and MP-RDMA balance traffic across 3 parallel paths well and achieve high path throughput with varying arrival interval of bursty flows. However, since MP-RDMA splits the congested flow f_2 to all paths, all paths are paused by PFC, resulting in link utilization degradation. FLB achieves up to 19% higher throughput of paths.

Effect of rerouting under symmetric and asymmetric sce-

(a) OOD in symmetric topology (b) Disorder in symmetric topology

(c) OOD in asymmetric topology (d) Disorder in asymmetric topology

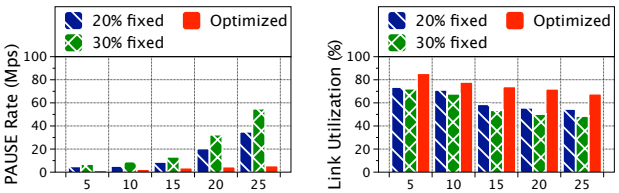


Figure 11: Out-of-order control.

narios: To show rerouting mechanism in FLB is able to well address the out-of-order issue, we conduct experiments in both symmetric and asymmetric topologies and measure the 99^{th} percentile of out-of-order degree (OOD), which is defined as the difference between the sequence numbers of an out-of-order packet and the expected one.

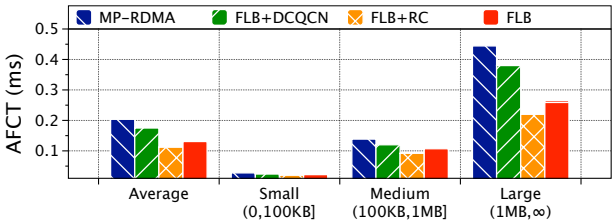
We first vary the number of parallel paths in the symmetric topology. Fig. 11 (a) and Fig. 11 (b) show that FLB effectively reduces the 99^{th} percentile of OOD and disordered packets ratio compared to MP-RDMA. This is because the delay difference between the new rerouting path and the current path is less than the interval between two consecutive packets in the same flow. For MP-RDMA, it can control the OOD to a preset range. Next, in the symmetric topology with 8 equal-cost paths, we change the default 40Gbps bandwidth of some parallel paths to 25Gbps to create bandwidth asymmetry. Fig. 11 (c) and Fig. 11 (d) show FLB achieves low OOD and disordered packets ratio even under the highest asymmetric degree (*i.e.*, the number of asymmetric paths is 4).

Sensitivity to isolation threshold: To validate the effectiveness of the optimized isolation threshold based on Equation (4) in §A, we compare the optimized isolation threshold with the small fixed ones to avoid PFC triggering. We test the fixed thresholds of 20% and 30% of the shared buffer size. We increase the number of concurrent flows for each burst and measure the rate of PFC PAUSE frames from the switch S4 and the average link utilization of the three parallel paths. As shown in Fig. 12, FLB with the optimized threshold achieves 82% and 89% lower PAUSE rates than those of 20% and 30% fixed thresholds, respectively.

Integrated with rate control: To validate the effectiveness of integrating FLB with rate control, we compared the AFCT of four mechanisms, i.e., FLB, FLB+RC, FLB +DCQCN and MP-RDMA under the same experimental setup and Web Search workload as in §4.1. Due to the ability to isolate congested flows and effectively suppress congestion spreading, FLB both with and without rate control is superior to that of MP-RDMA, as shown in Fig. 13. Since the minimal rate control with pause/resume mechanism at the end-host rapidly converges congested flows to the target rate, FLB+RC further reduces the AFCT by 15% compared to pure FLB. In contrast to the end-to-end congestion control protocol DCQCN, which converges the congested flow rate more slowly to the target rate, both FLB and FLB+RC outperform FLB +DCQCN.

(a) PAUSE rate (b) Link utilization

Figure 12: Sensitivity to isolation threshold.



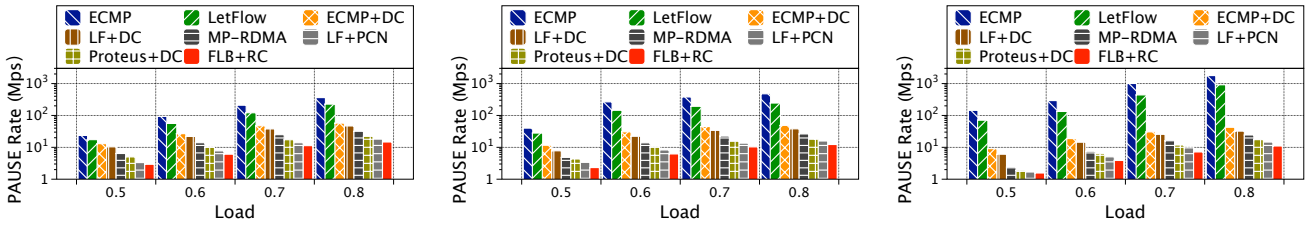


Figure 13: Performance of FLB integrated rate control.

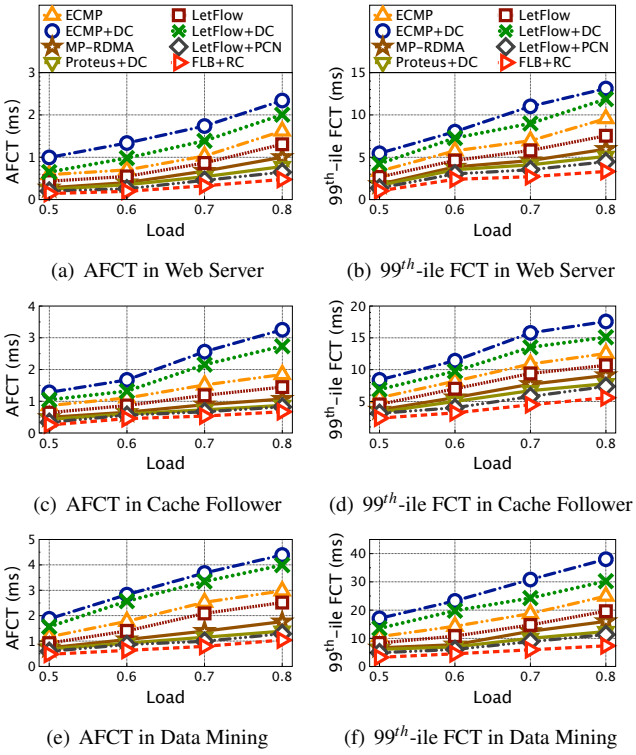
4.3 Large-scale NS3 Simulations

We run NS3 simulations to answer the following questions.



- **How does FLB+RC perform compared to other load balancing schemes with realistic workloads?** FLB+RC outperforms ECMP [43] and LetFlow [31], reducing the AFCT by 65% and 58%, respectively. Furthermore, the AFCT of FLB+RC is respectively 76%, 70%, 36%, 29% and 18% lower than those of ECMP+DCQCN [4], LetFlow+DCQCN, MP-RDMA [7], Proteus+DCQCN [26] and LetFlow+PCN [2] in large-scale scenarios.
- **How does FLB+RC perform with incast workload under the over-subscribed network?** In the incast scenario under a 3:1 over-subscribed topology, FLB+RC delivers persistently higher goodput (up to 27%) compared to other solutions.
- **How does FLB+RC perform under the multi-tier topology?** In a 12-pod Fat-tree topology, FLB+RC achieves lower PAUSE rate and FCT (up to 71% and 92%, respectively) under realistic workloads.

Simulation settings: We evaluate FLB on a leaf-spine topology with 10 leaf switches and 10 spine switches. Each leaf switch is connected to 30 hosts and 10 spine switches with 40Gbps links. The over-subscription ratio is 3:1 at the leaf

Figure 15: FCT under realistic workloads.

switch layer. The link delay is 5μs. The switch buffer size is set to 9MB. PFC is enabled to guarantee lossless transmission and the PFC threshold at each ingress port is set to 256KB. To explore the scalability of FLB, we further evaluate its performance under a multi-tier 12-pod Fat-tree topology [51, 53]. Each pod consists of 6 edge switches, 6 aggregation switches, and 84 end-hosts, and communicates with other pods through 36 core switches. So there are 36 equal-cost paths between any pair of edge switches across pods.

Realistic workloads: We use various realistic workloads including Web Server, Cache Follower, Hadoop Cluster and Data Mining [2, 55, 56, 58] with the average flow sizes ranging from 64KB to 7.41MB. In the Web Server workload, all flows are less than 1MB, while in the Data Mining scenario there are around 9% flows larger than 1MB. Each flow is generated between random pair of source and destination hosts. The traffic ratio between intra-ToR and inter-ToR is 1:3. The traffic load is changed from 0.5 to 0.8. We compare the performance of FLB+RC with ECMP, LetFlow, ECMP+DCQCN, LetFlow+DCQCN, LetFlow+PCN, MP-RDMA and Proteus+DCQCN.

Fig. 14 shows the generating rates of PFC PAUSEs from leaf and spine switches. Results validate that FLB suppresses PFC PAUSEs better than the other schemes. This is because FLB pauses the congested flows accurately to drain out the backlog packets, and balances traffic among multiple paths to avoid congestion spreading. Since ECMP and LetFlow start and resume flows at the line rate, they trigger more PFC PAUSEs. In contrast, ECMP+DCQCN, LetFlow+DCQCN, LetFlow+PCN, MP-RDMA and Proteus+DCQCN employ the sophisticated rate adjustment mechanisms to effectively reduce PFC PAUSEs, especially under the Data Mining workload containing more heavy-tailed flows.

Fig. 15 shows the average and 99^{th} percentile FCTs under different realistic workloads and load levels. FLB+RC achieves the best performance across all applications. Taking the Data Mining as an example, FLB+RC reduces the AFCT by 65%, 58%, 76%, 70%, 36%, 29% and 18% under 0.8 load over ECMP, LetFlow, ECMP+DCQCN, LetFlow+DCQCN, MP-RDMA, Proteus+DCQCN and LetFlow+PCN, respectively. This is because FLB isolates the culpable flows timely to avoid the side effects of PFC and flexibly reroutes flows to ensure high link utilization. Due to the slow convergence after resuming, the FCTs of ECMP+DCQCN and LetFlow+DCQCN are larger than ECMP and LetFlow with line-rate resuming, respectively. Since distributing traffic in a congestion-aware manner, MP-RDMA significantly outperforms ECMP and LetFlow. Although multiple paths are potentially paused by PFC in LetFlow+PCN, PCN can identify and throttle the congested flows, effectively reducing PFC triggering and outperforming MP-RDMA.

Incast workload: Next, we evaluate the network performance in the incast scenario where a client initiates concurrent requests to fetch responses from a large number of servers [4, 7, 28]. Simultaneous arrival of the response flows imposes great buffer pressure at the switches, potentially resulting in

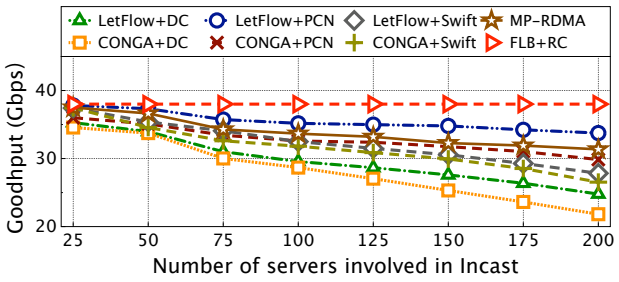

Figure 16: Incast performance vs. number of servers

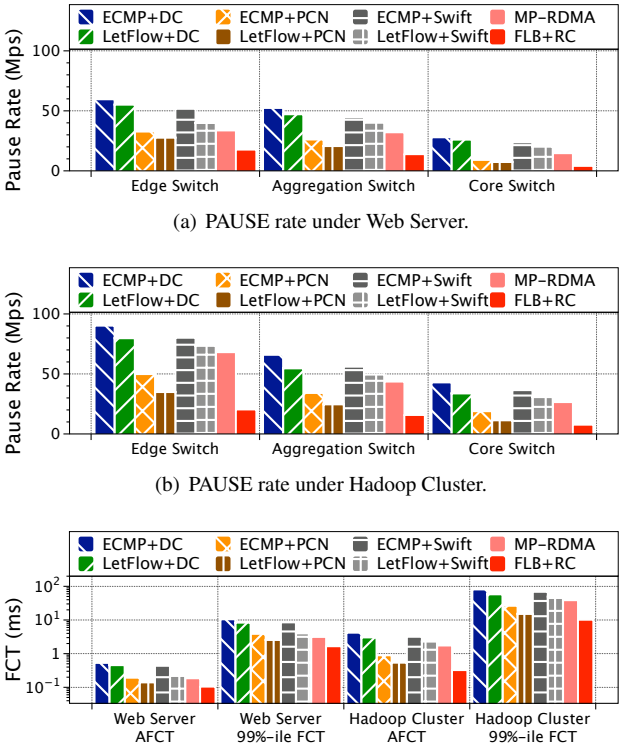

continuous PFC PAUSEs in lossless DCN.

In this test, there are N flows concurrently transmitting a fixed total amount of data from N servers under randomly selected leaf switches to one client. We set the total data size as 100MB and vary the number of servers N from 25 to 200. Each response is $\frac{1}{N}$MB. We measure the goodput at the client and repeat the test for 100 requests to get the average result.

As shown in Fig. 16, although more PFC PAUSE messages are generated with more servers, the throughput of FLB+RC is almost independent of the number of servers. The reason is that FLB pauses and resumes congested flows at a fair rate when the sender receives the CNM with congestion or non-congestion flag, respectively. Compared with other schemes, the incast throughputs in CONGA+DCQCN, LetFlow+DCQCN, CONGA+Swift and LetFlow+Swift are degraded due to the slow convergence of the sending rate. Moreover, CONGA incorrectly reroutes packets to the paused paths with lower link utilization, resulting in a larger throughput loss of up to 45%. Since PCN and MP-RDMA increase the sending rate rapidly after receiving the RESUME messages, they can obtain higher throughput under highly concurrent flows compared with DCQCN.

Multi-tier topology: In this experiment, the workloads are generated among randomly selected host pairs in the aforementioned Fat-tree topology with an exponentially distributed inter-arrival time and targeted load of 0.6.

Fig. 17 (a) and Fig. 17 (b) show the generating rates of PFC PAUSEs from edge, aggregation and core switches. PFC triggers most at the edge switches due to many-to-one communication at the destination end-hosts. Fig. 17 (c) shows the average and 99^{th} percentile FCTs. For Web Server workload, about 80% of short flows less than 10KB and about 10% flows larger than 100KB, resulting in dramatically burst in network congestion. In addition, most short-lived flows have no chance to switch path, resulting in very small difference in performance between deploying ECMP and LetFlow. Since FLB can rapidly detect and isolate the congested flows, the innocent flows complete quickly without suffering from PFC's HoL blocking. Compared with LetFlow+DCQCN, LetFlow+Swift, MP-RDMA and LetFlow+PCN, FLB+RC suppresses 71%,55%, 45% and 37% PFC PAUSEs, reduces 76%, 40%, 32% and 28% average FCT and 81%, 56%, 45%

(a) PAUSE rate under Web Server.

(b) PAUSE rate under Hadoop Cluster.

(c) Average and 99^{th} percentile FCTs.

Figure 17: Performance under Fat-tree topology.

and 32% 99^{th}-ile FCT, respectively. For heavy-tailed Hadoop Cluster workload, about 96% of traffic is provided by only 9% of long flows larger than 1MB, and around 86% short flows less than 100KB. Since FLB effectively avoids PFC's HoL blocking caused by congested long flows, the average and 99^{th}-ile FCTs are reduced by up to 92% and 83% compared with other solutions, respectively.

5 Related Work

We classify previous work on balancing traffic in DCNs into two categories: load-balance routing solutions (*e.g.*, [26–29, 31–39, 43, 59]) and multipath transport solutions (*e.g.*, [7, 30]). Most of them are designed for lossy DCNs and cannot be directly used in lossless Ethernet DCNs.

Load-balance routing solutions [28, 29, 31–39, 43, 59] generally improve link utilization by splitting traffic evenly across multiple paths. ECMP [43], FlowBender [39], Hedera [37], MicroTE [38] schedule flows at flow level, but may obtain suboptimal link utilization due to coarse routing granularity. Presto [34] spreads traffic at fixed flowcell-level granularity. RPS [35], DRILL [36], Hermes [29] and DRB [59] work at packet level and unavoidably suffer from packet reordering problem. CONGA [28], LetFlow [31], HULA [32] and CLOVE [33] employ flowlet-level switching to avoid out-of-order delivery. Proteus [26] and ConWeave [27] effectively balance traffic in the RDMA networks. However, these fine-grained solutions make more ports affected by the side effects

of PFC because they spread the congested flows among more parallel paths. Instead, FLB isolates congested flows timely to eliminate HoL blocking and reroutes uncongested flows by utilizing rich multiple paths to improve link utilization.

Multipath transport solutions [7, 30] divide a flow into multiple subflows for multipath transmission, resulting in potentially more ports to get paused by PFC. There are also efforts [2–4, 8, 10, 12, 22, 48, 60–62] targeting at minimizing FCTs for RDMA. On the one hand, for lossless RDMA, QCN [48] works at Layer 2 to alleviate congestion. IEEE P802.1Qcz [60] supports the isolation of flows from different applications. DCQCN [4] and DCQCN+ [22] are rate-based congestion control for RoCEv2 [61]. TIMELY [10] and Swift [12] use RTT as the congestion signal to adjust sending rate. PCN [2] recognizes the congested flows and employs a receiver-driven rate control algorithm to achieve fast convergence. TCD [3] defines ternary states of switch ports to detect congested ports. BFC [62] uses a per-hop per-flow control scheme to reduce HoL blocking. While the above end-to-end transmission schemes effectively alleviate congestion, they still cannot completely avoid HoL blocking especially under bursty traffic. On the other hand, for lossy RDMA, some works [8, 42, 63] explore the possibility of running RDMA without PFC. However, further efforts are still needed for large-scale deployment in production DCNs.

6 Conclusion

This paper presented FLB, a fine-grained load balancing solution for PFC-enabled lossless DCNs. The core of FLB contains: (i) a flexible rerouting scheme to improve link utilization in normal conditions; and (ii) an isolation mechanism to avoid PFC spreading upon congestion. The testbed experiments as well as large-scale NS3 simulations show that FLB is a viable solution that achieves all our design goals.

A Optimizing Isolation Threshold

In this section, we theoretically analyze the isolation threshold K to simultaneously avoid PFC triggering and link underutilization. We assume a typical multi-tier DCN topology, like Fat-tree [53] or 3-stage Clos [64], in which n senders send flows to n receivers via multiple equal-cost paths between the source and destination edge switches. The one-way delay between the sender S_i and the destination edge switch DS is d_i. The instantaneous queue length of DS's egress port is $Q(t)$ at time t. The sending rate of each sender is $v_i(t)$ and the link capacity of DS's egress port is C.

Note however, the isolation notification is generated from the egress queue while PFC PAUSE is from the ingress queue of DS. Thus, the isolation threshold K and PFC threshold Q_{PFC} are for the egress and ingress queues, respectively. The worst case in the above network model is that packets coming from a single ingress queue of DS are sent to all n egress

queues. To guarantee that PFC is not triggered on this corresponding ingress queue before isolation is triggered on the egress queue, the condition $K < \frac{Q_{PFC}}{n}$ should be satisfied. However, an isolation notification (CNM) will take some time to arrive at the sender. To avoid PFC triggering, the egress queue must reserve enough buffer to accommodate the in-flight packets. Therefore, we analyze the reasonable range of K with considering the above worst case.

Specifically, we assume that, when the egress queue length increases to $Q(t_P)$ at time t_P, the isolation notification CNM is generated and sent to the sender S_i for pausing the congested flow. Due to the transmission delay of CNM, the sending rate $v_i(t)$ of S_i cannot be reduced to zero immediately and the egress queue length continues to increase for a short time $2d_i$. The maximum egress queue length $Q(t_P + 2d)$ ($d = \max d_i$) can be given by

$$Q(t_P + 2d) = Q(t_P) + \sum_{i=1}^{n} \int_{t_P}^{t_P+2d} v_i(t)dt - 2d \times C. \quad (1)$$

To ensure that PFC is not triggered, the condition $Q(t_P + 2d) < \frac{Q_{PFC}}{n}$ needs to be satisfied. Thus, we obtain

$$Q(t_P) < \frac{Q_{PFC}}{n} - \sum_{i=1}^{n} \int_{t_P}^{t_P+2d} v_i(t)dt + 2d \times C. \quad (2)$$

On the other hand, we assume that when the egress queue length drains to $Q(t_R)$ at time t_R, a non-congestion notification message is sent to the sender S_i for resuming the transmission of the congested flow. Similarly, the egress queue length will keep on decreasing for a short time of $2d_i$. To avoid the link under-utilization, the isolation threshold $Q(t_R)$ should satisfy the following condition.

$$Q(t_R) \geq 2d \times C - \sum_{i=1}^{n} \int_{t_R}^{t_R+2d} v_i(t)dt. \quad (3)$$

Hence, to ensure that the isolation for congested flows is always triggered before PFC and the congested flows resume transmission before the egress queue becomes empty, the isolation threshold K is set in the range

$$\begin{aligned} K \in [&2d \times C - \sum_{i=1}^{n} \int_{t_R}^{t_R+2d} v_i(t)dt, \\ &\frac{Q_{PFC}}{n} - \sum_{i=1}^{n} \int_{t_P}^{t_P+2d} v_i(t)dt + 2d \times C). \end{aligned} \quad (4)$$

In our implementation, we set a conservative isolation threshold K in the range of $[2d \times C, \frac{Q_{PFC}}{n} - 2d \times C \times (n-1))$. Our experiments show that such isolation threshold is effective and robust to a wide range of traffic variations (§4).

SNARY: A High-Performance and Generic SmartNIC-accelerated Retrieval System

Abstract

Industrial large-scale recommendation systems mostly follow a two-stage paradigm: retrieval and ranking stages. The retrieval stage aims to select thousands of relevant candidates from a vast corpus with millions or more items, and thus often becomes the performance bottleneck. Offloading the retrieval stage to hardware is a promising solution. Nevertheless, previous solutions either fail to achieve optimal performance or lack the sufficient generality to support fuzzy search, which has been widely used in modern retrieval systems to improve their scalability and efficiency.

In this paper, we present SNARY, a generic SmartNIC-accelerated retrieval system, to facilitate both exact and fuzzy search. Specifically, SNARY utilizes High-Bandwidth Memory (HBM) for corpus storing and scanning and designs two types of search engines: a data parallelism exact search, and a Locality-Sensitive Hashing (LSH)-based fuzzy search. Furthermore, SNARY employs a pipeline-based approach to select Top-K items and streams the data flow of the whole system. We have implemented SNARY on Xilinx commercial SmartNICs. Experimental results show SNARY achieves a 20.91%-83.88% lower latency and a 1.26×-18.27× higher latency-bounded throughput in exact search scenarios, and achieves a 85.13%-87.40%lower latency and a 20.18×-23.81× higher latency-bounded throughput in fuzzy search scenarios in comparison with the state-of-the-art hardware-based solutions.

1 Introduction

Due to the rapid growth in the amount of information, recommendation systems have been widely applied in many web-scale applications (e.g., Amazon and ByteDance) to assist users in finding their preferred items. A typical industrial recommendation system often consists of two sequential stages [20, 36]: matching (a.k.a retrieval) and ranking[1] (see Figure 1). The retrieval stage selects thousands of relevant items from a very large-scale corpus (e.g., millions of items) while the ranking stage further filters out the top dozens of items from the selected small-scale candidates with high precision and recall. In this paper, we mainly focus on the retrieval stage.

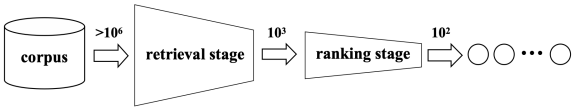

Figure 1: Hierarchical structure of the recommendation systems. Recommendation systems are composed of two distinct stages: retrieval and ranking.

With advancements in deep learning, neural retrieval models are being extensively applied in the retrieval stage, with progressively better results [5, 36]. Among them, representation learning [1], which is also called *embedding*, has become the mainstream trend to facilitate deep retrieval in practice [15, 20, 27]. Specifically, in an embedding-based retrieval (EBR) system, all corpus items and user queries are represented with semantic embedding vectors via two parallel deep neural networks. The retrieval process of the EBR system can be regarded as a Nearest Neighbor (NN) algorithm: given one user query, a matching function is then used to calculate the similarity (a.k.a distance) in the embedding space for each corpus item with the query. Each retrieval operation is associated with a recall count, K, indicating the number of embeddings that require final retrieval. After similarity calculation, a sorting algorithm is deployed to efficiently select Top-K items based on their similarity to the query. That is to say, the retrieval problem is finally converted into a similarity search problem.

According to the retrieval scenario requirements and specific algorithm implementations, retrieval methods are further divided into exact search and fuzzy search. Exact search is based on the K-Nearest Neighbor (KNN) algorithm, and the retrieval results are the top K embeddings that are closest to the user query, which are strictly sorted according to the distances between embeddings, while fuzzy search is based on

[1]Recent works further divide the ranking into three phases: pre-ranking, ranking and re-ranking [27, 28].

Approximate Nearest Neighbor (ANN) algorithms, and the retrieval results are embeddings with relatively high similarity to the user query, but not necessarily exact, which usually sacrifices a certain degree of precision to improve the retrieval speed [20]. Due to the high precision of retrieval results, exact search is very popular in various fields [25, 51]. It is worth noting that fuzzy retrieval can provide more effective solutions in scenarios where exact results are not required and lower latency is needed, such as video recommendation [5], product search [27, 47], and information retrieval [15]. At the same time, there are some scenarios where the combination of exact search and fuzzy search is required to improve the stability of the system's response time. For example, a specific recommendation system has significant traffic differences at different times of the day. Appropriately using fuzzy search during high-traffic periods and exact search during relatively stable traffic periods can effectively balance the system's response time and enhance the user experience.

However, existing EBR systems usually have some deficiencies in two aspects: (*i*) the growing corpus sizes have brought about serious performance problems; (*ii*) the requirements of different scenarios for retrieval methods bring about the issue of generality. For the performace issue, the EBR systems are required to fetch all corpus items, calculate their similarity, and choose Top-K items as long as they receive one user query. Consequently, the corpus size determines the scale of the problem. Low retrieval performance (high response delay) indeed degrades user experience and satisfaction. Therefore, the recent interest in the community has moved to the implementation of high-performance EBR systems, especially with hardware accelerators. For example, some works exploit GPUs (Graphics Processing Units) to accelerate those computation-intensive tasks in EBR, such as similarity computation [49]. There are already mature GPU retrieval system frameworks that support both exact search and fuzzy search simultaneously [25]. However, GPUs are not optimized for pipeline parallelism that is required by the data flow of the whole EBR system, especially at the Top-K selection stage due to the cost of external memory communication. To this end, the community has turned to another popular hardware accelerator, FPGA (Field Programmable Gate Array), which does not have the inherent limitations of GPUs. Unfortunately, the state-of-the-art FPGA-based EBR system [51] only works with exact search and falls short for fuzzy search, lacking support for both types of retrieval methods which brings limited generality.

In this paper, we design SNARY, a **S**mart**N**IC-**A**ccelerated **R**etrieval s**Y**stem, which can achieve high performance and generality for both exact and fuzzy search. We choose SmartNICs for two reasons: (*i*) modern SmartNICs are often equipped with FPGAs; (*ii*) SmartNICs are the nearest devices to user queries in servers because queries are often from remote users in practice. That is to say, SNARY can directly process user queries when the NIC receives them. Overall, SNARY is integrated with two types of search engines: exact search and fuzzy search. For exact search, SNARY utilizes the FPGA high bandwidth memory (HBM) to store and scan the corpus. With massive fully programmable compute elements on FPGAs, SNARY designs a data-parallelism method to accelerate similarity computation, and a pipeline-parallelism solution to facilitate Top-K item selection. In addition, the whole data flow of SNARY also follows the pipeline parallelism paradigm. For fuzzy search, SNARY proposes a Locality-Sensitive Hashing (LSH)-based [7, 8, 45] search architecture on FPGAs. Specifically, we design multiple LSH hash tables to maintain the corpus on FPGA HBM. With this basis, SNARY can quickly select relevant retrieval results for one query via hash table lookup, which constitutes a small new "corpus". Then, SNARY will further perform a more effective exact search operation on the new corpus for final fuzzy retrieval results.

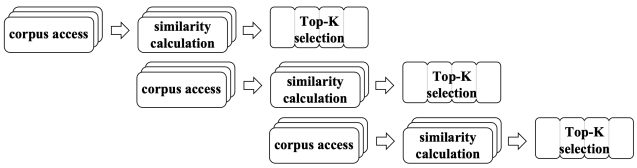
We implement SNARY based on Alveo™ U50 Data Center Accelerator Card, and compare it with Faiss [25], a popular GPU-based EBR system, and FAERY [51], the state-of-the-art FPGA-based solution. Experimental results show that SNARY achieves a 78.75%-83.88% lower query latency than Faiss and a 20.91%-45.19% lower query latency than FAERY, with a 14.12×-18.27× higher latency-bounded throughput than Faiss and a 1.26×-1.64× higher latency-bounded throughput than FAERY in exact search scenarios. It also achieves a 85.13%-87.40% lower query latency than Faiss, with a 20.18×-23.81× higher latency-bounded throughput than Faiss in fuzzy search scenarios, while FAERY does not support fuzzy search. To sum up, this paper makes the following contributions:

- To the best of our knowledge, SNARY is the first SmartNIC-based retrieval system that achieves high performance for both exact and fuzzy searches.
- We utilize large HBM and programmable compute elements on FPGAs to design a data-parallelism similarity computation and a pipeline-parallelism Top-K selection to facilitate exact search. With this basis, we further propose an LSH-based fuzzy search on SmartNICs.
- We implement SNARY on commercial SmartNICs, and evaluate its performance and efficiency. Experimental results show that SNARY outperforms the popular GPU-based approach and the novel FPGA-based approach.

2 Background and Motivation

2.1 Embedding-based Retrieval

Industrial recommendation systems often adopt embedding-based retrieval (EBR) to provide relevant or personalized product candidates [20, 27]. The basic idea of EBR is to translate all corpus items and user queries into embedding vectors via representation learning [1], and convert the retrieval prob-



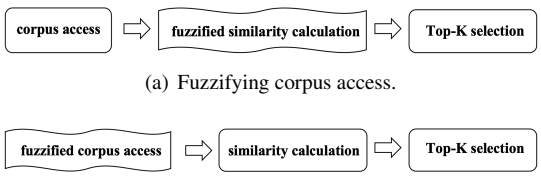


Figure 2: The workflow of an ideal and feasible EBR system.

(a) Fuzzifying corpus access.

(b) Fuzzifying similarity calculation.

Figure 3: Two methods of fuzzy retrieval solutions. Fuzzy retrieval solutions include fuzzifying similarity calculation stage and fuzzifying corpus access stage.

lem into a similarity search problem in the embedding space. It is noteworthy that corpus item embeddings often are precomputed (offline) in practice.

Overall, a typical EBR algorithm mainly consists of three steps: corpus access, similarity computation and Top-K selection. Specifically, given a user query, the algorithm is required to scan the corpus and iterate through its all items (i.e., corpus access) and calculate the similarity between each item and the user query (i.e., similarity computation). After that, the algorithm sorts the items based on their similarity and selects Top-K items (i.e., Top-K selection) as the retrieval results. It is clear that corpus access is a memory-intensive operation while both similarity calculation and Top-K selection are compute-intensive.

Ideal EBR system. With the analysis of the basic EBR algorithm, we then introduce an ideal EBR system architecture that can provide optimal retrieval performance. In summary, it should satisfy the following conditions.

- **Large high-bandwidth memory.** Due to the growing corpus sizes, the EBR system requires a large-capacity external memory to store it. In addition, the memory should provide high bandwidth in order to support the memory-intensive operation (corpus access).
- **Task/Data parallelism.** Logically, the similarity calculations for different item embedding are independent. To match the throughput of corpus access, the ideal EBR system should perform calculations with data parallelism.
- **Pipeline parallelism.** To achieve optimal latency, both inside Top-K selection and the whole EBR data flow should follow the pipeline parallelism paradigm. Otherwise, the accumulation of intermediate results is unacceptable in terms of resource consumption in scenarios with large scale corpus.

Comparison of different hardware. At present, most mainstream EBR systems are implemented on CPUs, GPUs and FPGAs. For CPUs, the relatively low memory bandwidth slows down the reading speed of the corpus, which directly affects the overall performance of the system; at the same time, the relatively small number of CPU cores also poses a challenge to data parallelism. Compared with CPUs, GPUs provide large-capacity and high-bandwidth external memories and have good support for data parallelism. However, due to the overhead of cross-core communication in GPUs and the limitations of single-core memory, GPUs have relatively large defects in supporting the overall pipelining of the system, especially in the Top-K selection stage. Research shows that currently, mature GPU frameworks consume 80% of latency in the Top-K selection stage [51]. Meanwhile, this also limits the maximum supported recall count (e.g., 1024 in [25]). Advanced FPGAs also provide large-capacity and high-bandwidth external memories through HBM. Meanwhile, unlike GPUs, FPGAs provide sufficient on-chip memories that can be directly accessed, and all computing units and interconnects are programmable, which enables FPGAs to better support the implementation of fully pipelined systems.

Performance factors. Figure 2 illustrates the workflow of a pipelined EBR system. Actually, the total latency of the pipelined system is determined by two portions: (*i*) the cost of corpus access; (*ii*) the time for one batch of corpus items to pass through the pipeline, going through similarity calculation and Top-K selection. Thus, we formalize the theoretical latency of the retrieval system in terms of pipeline cycles (denoted by L) as follows:

$$L = \frac{M}{B} + C, \tag{1}$$

where M represents the corpus size, B represents the bandwidth of external memory which determines the throughput in any pipeline cycle, and C is a constant denoting the pipeline cycles needed to process a single batch of corpus items. That is, C is dependent on the specific design and implementation of one EBR system. Since the entire system is pipelined, once the corpus has been fully read, the last batch of the corpus passes through the pipeline, and the entire system completes its operation.

2.2 Accelerating Retrieval with Fuzzy Search

The retrieval phase can be accelerated through fuzzy search, a technique widely employed in industry. It often utilizes ANN algorithms (e.g., LSH [7]) to achieve low response time, but at the cost of slight accuracy degradation. However, such a trade-off is worthwhile in many time-sensitive scenarios, such as search engines and recommendation systems.

Existing fuzzy retrieval solutions mainly focus on fuzzifying the similarity calculation [6, 22, 31] (see Figure 3(a)).

For example, some works employ lexical fuzzification approach [14, 17], synonym expansion technique [39, 43], and machine learning-based methods [29, 48] to enhance the flexibility of matching between user queries and corpus items. These approaches are mainly applied in CPU-based retrieval systems to compensate for the deficiency of data parallelism in CPU-based similarity calculation. However, for those scenarios that involve large-scale corpus, the corpus size often determines the overall latency (see Equation 1). In such cases, fuzzifying similarity calculations has little effect on performance. Instead, fuzzifying corpus access may lead to more improvement (see Figure 3(b)), which means that instead of scanning the entire corpus, only the part of the corpus that is highly relevant to the user's query is selected for retrieval. According to Equation 1, the latency for reading the corpus accounts for the vast majority of the overall system latency. Reducing the size of the corpus can effectively decrease the latency and improve the retrieval speed.

2.3 SmartNIC Opportunities

We have found that accelerating the retrieval system through a SmartNIC implementation has the following advantages:

- SmartNICs are the nearest devices to user queries in servers since queries are often from remote users. SmartNIC-accelerated retrieval systems have the opportunity to achieve optimal performance since they have the shortest data path.
- Accelerating the retrieval system through SmartNICs, i.e., implementing the retrieval phase on FPGA, leverages the hardware advantages of FPGA. It harnesses FPGA's programmability to implement custom data parallelism and pipelining strategies, ultimately achieving a retrieval system with favorable latency.
- FPGAs not only provide ample external storage space for storing large-scale corpus but also allow for preprocessing of the corpus using ANN algorithms. This enables fuzzy search acceleration without compromising the pipeline of the retrieval, thereby simultaneously supporting both exact and fuzzy search scenarios.

3 SNARY Overview

We design SNARY, a high-performance and generic SmartNIC-accelerated retrieval system, that follows the aforementioned ideal EBR system architecture. It is noteworthy that SNARY supports both exact and fuzzy searches. Figure 4 shows its conceptual architecture.

Overall, SNARY utilizes High Bandwidth Memory (HBM) on FPGAs to store a large-scale corpus and enable efficient corpus access. Furthermore, SNARY builds LSH hash tables on HBM in advance to maintain corpus items. Consequently,

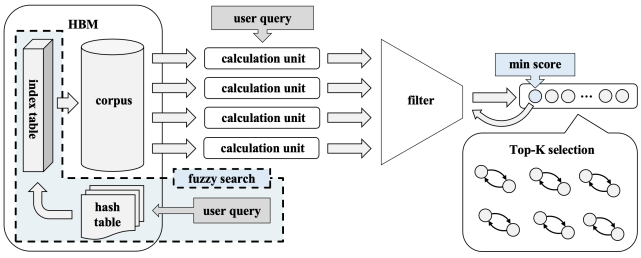

Figure 4: The conceptual architecture of SNARY. SNARY consists of a HBM, multiple similarity computation units, a filter and a pipeline-parallel Top-K selection module.

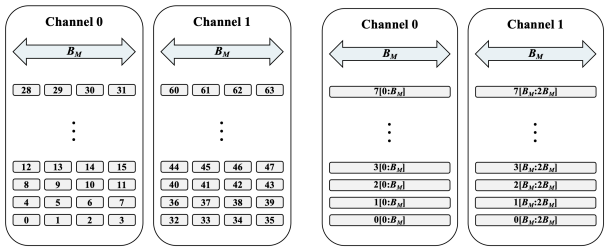
similar items will be inserted into one or neighbor hash buckets[2].

For a query that requires an exact search, SNARY will fetch a batch of items from the corpus, and feed them to multiple similarity calculation instantiations built upon massive fully programmable compute elements of FPGAs. That is, SNARY calculates the similarity between corpus items and the user query in a data-parallel manner. After that, the items will be transmitted to a parallel Top-K selection module which perfectly supports the pipelining framework, selecting the final retrieval results based on their similarity. To balance the throughput between the similarity calculation and the Top-K selection modules, SNARY inserts a filter in-between to drop relatively poor items.

If a user performs a fuzzy retrieval, SNARY will use the user query as a key to look up the LSH hash tables. Those items in the matched hash bucket and its neighbor hash buckets will constitute a new small-scale corpus. Then, SNARY will perform an exact search on the new corpus. That is, SNARY fuzzifies corpus access and significantly reduces the size of the target corpus. This indeed reduces the latency of the overall system.



4 Design and Implementation

In this section, we begin by examining how SNARY achieves efficient exact search, providing a more detailed theoretical proof. Subsequently, we discuss the transition from exact search to fuzzy search and analyze the system design in fuzzy search. After that, we present the theoretical formula for the latency of SNARY. Finally, we elaborate on the implementation details of SNARY.

4.1 Exact Search

SNARY stores the large-scale corpus in HBM. HBM achieves high capacity and bandwidth by stacking multiple DDR chips.

[2]In SNARY, a hash bucket only stores the indexes of corpus items for saving memories.

(a) $E < B_M$. (b) $E > B_M$.

Figure 5: The layout of embeddings in HBM for two situations. According to the relationship between E and B_M, embedding concatenation or embedding splitting is performed.

HBM can be divided into multiple channels, each with a maximum transfer bandwidth B_M, meaning that within one clock cycle, each channel can transfer data of up to B_M bytes. Memory read/write operations in each channel do not interfere with each other, and based on this, HBM allows concurrent reading of multiple candidate objects. Let E represent the size of each embedding; if N channels are used to store embeddings from the corpus, the memory bandwidth in Equation 1 can be expressed as:

$$B = N \cdot B_M. \tag{2}$$

To fully utilize the memory bandwidth, a horizontal storage strategy is employed when storing the corpus. This means that the embeddings in the corpus are evenly divided into N parts, ensuring that the data size within each channel is the same. Consequently, all channels read data synchronously in the vertical direction.

Within one clock cycle, HBM can read a maximum of B_M bytes of data in one channel. As a result, the number of complete embeddings N_E read by HBM in one clock cycle is given by the following equation:

$$N_E = \frac{N \cdot B_M}{E}. \tag{3}$$

As discussed, we expect to read complete embeddings in each clock cycle, enabling the overall system to operate in a pipelined fashion. Generally, both E and B_M are powers of 2, so when they are not equal, embedding concatenation or embedding splitting is performed, as shown in Figure 5.

The similarity calculation stage involves assessing the similarity between user queries and candidate objects, which, in the EBR system, is translated into the distance between two embeddings in the embedding space. Therefore, similarity calculation involves computing the distance (e.g., inner product [42], Cosine distance [2] and Euclidean distance [8], etc.) between the embedding representing the user query and the embedding representing the candidate object to obtain a similarity score. A higher similarity score indicates a greater similarity to the user query.

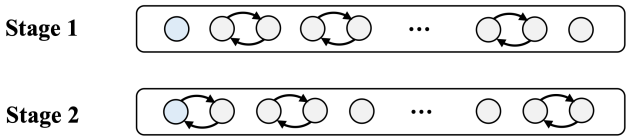


Figure 6: The working principle of the Top-K selection module. It involves two rounds of parallel swaps to maintain the 0th position as the smallest value among the current Top-K elements.

To achieve an efficient processing pipeline, the throughput of the similarity calculation stage needs to match that of the corpus retrieval. In other words, within one clock cycle, the computation of the distance between N_E embeddings and the embedding representing the user query must be completed. As there is no data dependency among these N_E computations, FPGA's data parallelism advantage can be leveraged in the design. N_E similarity computation units are instantiated, with each unit responsible for calculating the similarity score between a candidate object and the user query. Consequently, within one clock cycle, the similarity calculation module receives N_E embeddings and concurrently generates N_E similarity scores.

The Top-K selection stage requires selecting the top K highest scores generated by the similarity calculation module to obtain the final retrieval results. Different retrieval systems may have a varying magnitude of recall quantity [12, 27, 35], so the design of the Top-K selection module needs to satisfy resource constraints and meet performance and scalability goals, when the value of K changes.

The design of the Top-K selection module should support the pipelining of the system. A pipelined retrieval system requires real-time sorting to prevent issues such as pipeline blocking and excessive memory usage. We improved the Top-K sorting algorithm presented in [30] and implemented a Top-K sorting module that maintains pipelined parallelism even with a large number of recall items. We also provide a more detailed and rigorous proof to establish the correctness of the Top-K algorithm. The specific principle is illustrated in Figure 6. The core of the Top-K selection module is an array of size K, which stores the current top K largest values. At any given time, the 0th position of this array holds the smallest value among the current Top-K elements. In each pipeline cycle, a new similarity score is read and compared with the 0th position element. If the new score is larger than the current Top-K's smallest value, a replacement occurs. Subsequently, the array undergoes two rounds of parallel swaps to ensure that the 0th position continues to hold the smallest value in the current Top-K set. The first round of parallel swaps starts from the 1st position and proceeds backward, swapping pairs if they are in reverse order; the second round begins from the 0th position, similarly swapping reverse pairs as necessary. The Top-K selection module generally also needs to ensure

that the results from the retrieval stage are ordered, making them more convenient for processing in the sorting stage. To achieve this, after the final new score is read, we add $K/2$ additional pipeline cycles with empty inputs, during which K rounds of parallel swaps are performed. This guarantees that the scores in the final Top-K array are sorted. The proof of the correctness of the algorithm above can be found in Appendix A.1.

Since the swaps in both Stage 1 and Stage 2 can be performed in parallel, the Top-K selection module can complete its operations with $O(1)$ time complexity for each pipeline cycle. Additionally, each new score is compared with the current smallest value in the Top-K array (i.e., the 0th position), ensuring that the array always contains the top K largest scores at any given time. To maintain the efficiency of parallel swaps when the value of K is large, we partition the Top-K array and distribute it across the on-chip memory to increase the number of read/write ports. In scenarios with limited on-chip resources, we also offer a solution that divides the Top-K array into upstream and downstream segments. This approach splits the array into two sections of size $K/2$, with the first half storing the top $K/2$ values and the second half storing values ranked between $K/2$ and K. The upstream array receives the new scores, determines whether to replace any value and performs parallel swaps. The replaced value (or the non-replaced new score) is then passed to the downstream array, where a similar process is executed.

As stated previously, the performance of the Top-K selection module has a significant impact on the overall performance of the retrieval system. Compared with the Top-K selection module algorithm adopted in [51] (first proposed in [35]), the above-mentioned Top-K selection algorithm based on parallel exchange only occupies $O(K)$ on-chip memory, while the algorithm in [51] requires approximately $O(9K/2)$ of memory. This order-of-magnitude memory footprint optimization yields substantial performance improvements, since under a large recall count, the on-chip resources are almost fully occupied (mainly including the memory occupied by the Top-K module and the filter module). Note that with on-chip memory pressure, the wiring between the memory module and other logic modules will become complicated, which may lead to problems such as wiring congestion and tight logic resources, thereby reducing the working frequency. At the same time, the above-mentioned algorithm only occupies a few (1 or 2) pipeline stages, while the algorithm in [51] has $O(\log K)$ modules and needs to occupy $O(\log K)$ pipeline stages, while each module cannot be reused. Our Top-K selection module is helpful for reducing on-chip memory occupancy, increasing the overall clock frequency, reducing the pipeline depth, and has good scalability at the same time.

Due to the dissimilarity in throughput between the similarity calculation module, which produces N_E scores per clock cycle, and the Top-K selection module, which can only handle one score per clock cycle, a throughput imbalance exists between them. To prevent pipeline blockage, a filter module is introduced between these two modules. The filter module utilizes forward feedback from the Top-K selection module to identify the current minimum score swapped out from the Top-K array and filters out scores that are smaller than the current minimum score. In every pipeline cycle, the filter receives N_E scores, transports the single valid score into the Top-K selection module according to the current minimum Top-K value, and caches or drops other scores.

We provide a detailed analysis of the filtering efficiency and the cache memory usage for other valid scores in the same pipeline cycle in Appendix A.2. Let $\gamma = K/M$ represent the recall rate of the entire retrieval system, the condition under which the filter can be effective is given by:

$$\frac{1}{N_E^2} \geq \gamma - \gamma \ln \gamma, \tag{4}$$

which provides guidance for our system design. For instance, in the case of a recall rate of 1×10^{-3}, we get $N_E \leq 11.25$. Thus, at most 11 candidate objects can be read from the corpus in one clock cycle to make sure the filter works.

4.2 Fuzzy Search

Compared to exact search, fuzzy search reduces search latency by sacrificing accuracy. We implement fuzzy search acceleration in the retrieval process based on the structure of exact search. According to Equation 1, there are three optimization approaches to reduce retrieval system latency and improve performance: (*i*) reducing the size of the corpus, M; (*ii*) increasing the memory bandwidth, B; and (*iii*) decreasing the system's fixed latency, C.

Memory bandwidth is determined by the hardware configuration, while system-fixed latency is a constant related only to system design, accounting for a relatively small portion of the total latency. Therefore, one optional approach is to reduce the size of the corpus, M, to decrease the retrieval system's latency. Specifically, we selected the LSH algorithm, which is more friendly to FPGA, for corpus filtering in the ANN algorithm that accelerates the search by reducing the search scope. Before conducting an exact search, the corpus is filtered to obtain a smaller corpus size, M', and then the exact search is performed on this reduced corpus. This approach maintains the structure of exact search, ensuring high module reusability, and facilitates the flexible switching of system functionality in different scenarios. At this point, according to Equation 1, the theoretical formula for system latency after corpus filtering is:

$$L = \frac{M'}{B} + C. \tag{5}$$

The LSH algorithm achieves dimensionality reduction of target embeddings and partitions the target embedding set into different buckets. In comparison to regular hash algorithms,

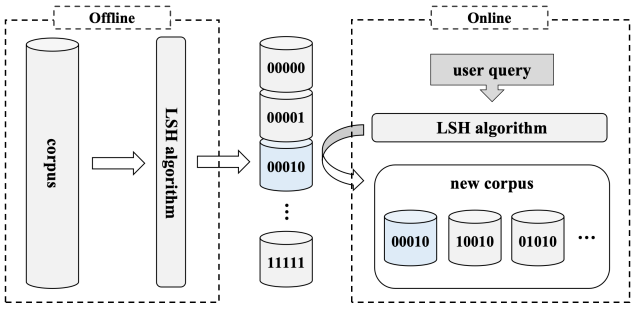

Figure 7: The workflow of corpus filtering. Corpus partitioning happens in the offline phase and the LSH query happens in the online phase.

LSH exhibits a degree of locality sensitivity by locality-sensitive hash functions. Specifically, two embeddings with high similarity in the original space will fall into the same or nearby (Hamming distance) buckets after being mapped by these functions. Conversely, two embeddings with low similarity in the original space will have relatively distant bucket assignments after the LSH mapping. In this way, we can consider the sets of embeddings within the same or nearby buckets as sets of embeddings with high similarity. For embeddings representing user queries, we also employ LSH for dimensionality reduction. We can then treat the bucket where the user queries hit and some neighboring buckets of embeddings in the origin corpus as a new corpus for exact search. This approach allows us to accelerate the search process by filtering out highly similar embeddings in the corpus.

The process of dimensionality reduction and querying through the LSH algorithm involves adjusting three main parameters: K_h, L_h, and T_h, each of which serves a specific purpose:

- K_h represents the number of bits used to represent origin embeddings after dimensionality reduction. In other words, the LSH algorithm maps a high-dimensional embedding to a collection with 2^{K_h} buckets.
- L_h stands for the total number of hash tables in LSH. The LSH algorithm can be configured for multi-table querying, where an embedding can be simultaneously mapped by L_h local sensitive hash functions during a query. This allows searching in L_h tables and identifying L_h buckets where the embedding hits.
- T_h represents the maximum Hamming distance considered when searching for nearby buckets within a single table. To improve search accuracy, LSH can match and hit buckets with Hamming distances smaller than or equal to T_h as a collection of embeddings within the table.

In the case of multi-table querying where $L_h \geq 2$, there is also a choice of query result set intersection or union strategy. The final matching result can either take the intersection or union of the embeddings in the buckets matched in each table.

The necessity of performing intersection (or union) on query results from multiple tables implies that once we have obtained the indices of all matching buckets, we cannot immediately begin pipelined access of embeddings within these buckets, since it is hard to determine whether the current embedding is part of the intersection (or is a duplicate, for the union case). This disrupts the data flow of the system, which will cause performance degradation. Calculating the intersection (or union) before corpus access would introduce significant additional delay and unnecessary memory consumption. Therefore, SNARY adopts a single-table query strategy, meaning $L_h = 1$, adjusting the value of K_h and T_h to control the scale of matched embeddings.

The LSH algorithm we have chosen should approximately distribute the embeddings in the corpus equally among the buckets. Since we expect to search among the bucket where the user queries hit and its neighbors in Hamming distance T_h, we can estimate the size M' of the filtered corpus as follows:

$$M' = \frac{\sum_{i=0}^{T_h} \binom{i}{K_h}}{2^{K_h}} \cdot M. \tag{6}$$

The workflow of our corpus filtering process using the LSH algorithm is illustrated in Figure 7. In the offline phase, we partition the corpus into different buckets based on the LSH algorithm and simultaneously construct hash tables, which is a one-time offline preprocessing phase. That is to say, it does not introduce any extra cost during online queries, since the bucket structure remains static and reusable across all queries, and the execution time of the offline phase remains within a manageable range (approximately 1-2 seconds for a corpus size of 9M). In the online phase, we similarly map user query using LSH and obtain the index of the bucket it falls into. Finally, we use the hit buckets (and neighboring buckets) as the new corpus and perform an exact search within the filtered corpus.

We adopt the widely-used simHash method [3, 34], which reduces a high-dimensional embedding to a low-dimensional signature and the specific process can be divided into the following steps:

- Map each dimension of the high-dimensional embedding to a K_h-bit embedding using a standard hash algorithm.
- Transform the embeddings obtained in the first step based on the weight of each position. Specifically, replace 1 with weight and replace 0 with the additive inverse of weight in each position.
- Accumulate the embeddings in the second step bit-wise.
- Compress the accumulated embedding dimensionally, replacing positive values with 1 and non-positive values with 0.

This process yields a signature representing the bucket number it hits in the hash table. The standard hash function in the first step can be changed to obtain different simHash methods.

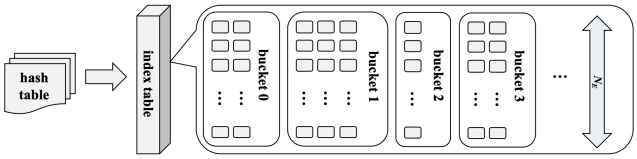

Figure 8: The data structure related to LSH. We store the hash table and index table in HBM, through which we can locate the position of hit embeddings in the corpus.

In this way, we reserve the possibility of constructing different hash tables and performing multi-table querying.

Two available memory channels in HBM are utilized to store data structures related to LSH. Specifically, the hash table and index table are stored in HBM, as illustrated in Figure 8. In the hash table, the starting positions and sizes of each bucket in the index table are recorded, while the index table keeps track of the specific positions of embeddings within each bucket in the corpus. When the bucket where a user query hits is obtained, the hash table is accessed first to mark the regions that need to be accessed in the index table. Afterward, only the elements from the marked buckets in the index table need to be accessed. For each obtained position of an embedding within the corpus, this position can be used to retrieve the specific embedding from the corpus.

During corpus access, we can simultaneously prepare for the next position's retrieval, allowing the system to continue its pipelined operation. However, it's important to note that we still aim to parallelize corpus access, which means accessing N_E embeddings per clock cycle. Due to the uneven distribution of embeddings in the buckets after allocation, it is challenging to determine if N_E continuous embeddings are located in different channels within a bucket. Additionally, it's unclear if accessing N_E positions at once will precisely cover all embeddings within a bucket (since the bucket size may not be a multiple of N_E). To maintain the normal operation of the pipeline, we perform the following steps for each bucket before writing embedding positions to the index table:

- Categorize the embeddings within the bucket into N_E classes based on the channels they are stored in. Let the size of the class with the most embeddings be denoted as S.
- Add paddings to the bucket to reach a size of $S \cdot N_E$ so that, for each class there are S elements including the added paddings.
- Rearrange the elements within the bucket so that, starting from the initial element, every consecutive N_E elements are in different channels. If the elements for a channel have been exhausted, use paddings to fill the gaps.

Through preprocessing, we can achieve parallel access of N_E elements within the current bucket, thereby ensuring a balanced throughput between index table access and corpus access. When we encounter padding elements during the reading, a flagged embedding enters the pipeline. The score generated by this embedding will be filtered out in the filter module, ensuring it doesn't affect the recall results. This optimization strategy increases the pipeline width of fuzzy search to match that of exact search, which significantly improves the efficiency of the fuzzy search process.

4.3 Implementation Details

We implement prototypes of SNARY on the Xilinx AMD Alveo™ U50 Data Center accelerator card of different recall counts K. It features integrated HBM2 (second-generation HBM), which provides up to 400 GB/s of memory bandwidth with 8GB storage and 32 channels for concurrent reads, enabling efficient handling of large datasets and reducing memory bottlenecks. We fully utilize on-chip resources to design SNARY as a completely pipelined structure, supporting seamless switching between exact and fuzzy search modes. We also utilize a 100 Gbps TCP/IP stack [18] to implement corpus uploading, updating, and result transmission on the card. Due to the fact that the FPGA baseline used in our experiment only supports recall counts that are powers of two [51], four systems with recall counts ranging from 512 to 4096 were implemented for comparative experiments.

Corpus access. 16 HBM channels are utilized to store the corpus, providing a total storage capacity of up to 4 GB. Each embedding is stored across 4 contiguous channels, allowing our system to accommodate up to 1024 million embeddings. Since read and write operations among different channels do not interfere with each other, parallel reads are performed in each pipeline cycle to maximize bandwidth. This enables the reading of 4 embeddings at once, which can then proceed to the subsequent computation stages.

Similarity calculation. In the similarity calculation module, the dot product is used to measure the similarity between different embeddings. Data from the contiguous channels belonging to an embedding is computed with the corresponding positions of the user query's embedding, integrating these calculations to form similarity scores. In the computation process, the calculation of similarity scores for different embeddings, as well as the scores for different positions of a single embedding, is fully unrolled, effectively utilizing hardware resources.

Top-K selection. The Top-K selection module adopts the parallel swapping strategy mentioned in Section 4.1 to ensure pipelined parallelism. Specifically, an array of length K is implemented in on-chip memory to store the Top-K scores, with array partitioning used to increase the read/write ports of the Top-K array. For higher recall counts, the array is further divided into upstream and downstream segments to avoid excessive resource consumption within a single pipeline cycle, while maintaining an $O(K)$ byte space usage. After the last score enters the Top-K selection module, additional $K/2$ cycles are added to perform the same parallel swapping and

Table 1: Resource usage and clock frequency of SNARY under different recall counts.

K	resource usage (%)				Freq.(MHz)
	LUT	FF	BRAM	DSP	
512	18.17	12.15	18.42	0.07	302.0
1024	26.41	14.09	18.42	0.07	285.0
2048	34.44	15.97	20.35	0.07	279.0
4096	40.16	24.19	20.35	0.07	235.3

sorting operations to ensure that the final Top-K array is completely ordered.

Filter. The filter is implemented using four FIFO pipelines with a certain depth to balance the throughput between the similarity calculation and Top-K selection modules. These FIFO pipelines receive scores from the similarity calculation and filter out or temporarily cache[3] some scores based on the current Top-K minimum value feedback from the Top-K selection module. They then provide one score to the Top-K selection module. To handle burst scenarios, the depth of each FIFO pipeline is set to accommodate the storage of $2K$ scores according to the analysis in Appendix A.2.

Fuzzy search. Two idle HBM channels are used to store the hash table and index table. Upon the arrival of user queries, the index table, which has already been preprocessed, allows for the parallel reading of the corresponding channels for every 4 indices, with each embedding stored in a different channel. This enables the reading of the corresponding positions in the next pipeline cycle while retrieving the 4 indices without impacting the overall pipelining of the system. The parameters K_h and T_h in the LSH algorithm are set as adjustable parameters, allowing users to control the balance between result accuracy and retrieval speed.

Batch support. SNARY implements batch support through multiple computing units on a single card to further enhance throughput under low-latency conditions. These computing units share the same HBM and possess identical architecture, allowing them to work in parallel coordination. Due to on-chip resource limitations, we achieved a batch size of 3 for systems with recall counts of 512 and 1024, a batch size of 2 for a recall count of 2048, and a batch size of 1 for a recall count of 4096. Furthermore, for increasing batch sizes beyond these values, multi-card coordination may provide additional opportunities for improvement.

Memory Overhead. (*i*) Corpus size. Both exact and fuzzy search operations utilize the HBM external memory to store the corpus. In our experiments, we place up to 9M embeddings in HBM, which occupies about 28% external memories (totaling 32M embeddings). (*ii*) On-chip memory. The hardware implementation for both exact and fuzzy search with the same recall count is the same. We fully utilized the limited 8MB on-chip memory to implement SNARY, and the resource consumption and the clock frequency of SNARY under different recall counts is shown in Table 1.

[3]Caching occurs when multiple scores exceed the current minimum value within one clock cycle.

5 Evaluation

We evaluate the performance of SNARY on both exact and fuzzy search scenarios and compare it with a GPU-based retrieval system Faiss and an FPGA-based retrieval system FAERY. For exact search, we evaluate the delay and the latency-bounded throughput of SNARY, Faiss, and FAERY. For fuzzy search, we first evaluate the efficiency performance of SNARY and Faiss under similar accuracy performance. We also conducted a series of self-comparison experiments to explore the impact of parameter changes on the trade-off between efficiency and accuracy. All error bars in the figures represent the standard error of the mean (SE). Our experimental results show that:

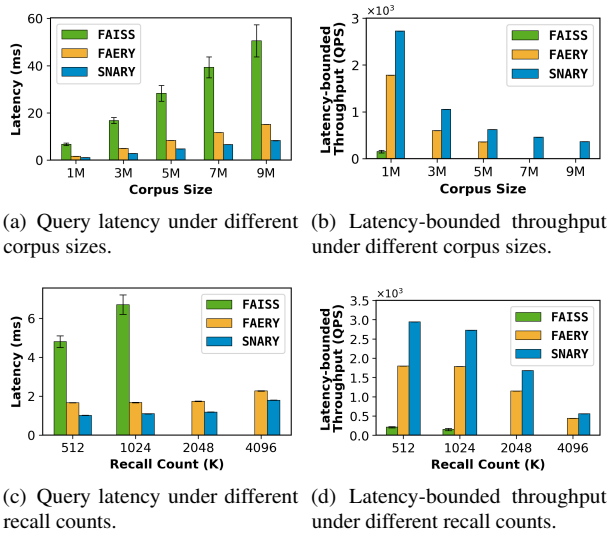
- SNARY achieves a 78.75%-83.88% lower query latency than Faiss and a 20.91%-45.19% lower query latency than FAERY, with a 14.12×-18.27× higher latency-bounded throughput than Faiss and a 1.26×-1.64× higher latency-bounded throughput than FAERY in exact search scenarios.
- SNARY achieves a 85.13%-87.40% lower query latency than Faiss, with a 20.18×-23.81× higher latency-bounded throughput than Faiss in fuzzy search scenarios, while FAERY does not support fuzzy search.
- SNARY allows for the adjustment of relevant parameters to achieve a trade-off between efficiency and accuracy, thereby better meeting various retrieval requirements in fuzzy search scenarios.

5.1 Experimental Setup

Baseline. We use Faiss [25] and FAERY [51] as the GPU-based and FPGA-based baseline in our experiments. Faiss is evaluated on a server equipped with 4 Nvidia A100 GPUs, each with 12GB of VRAM, running CUDA version 12.0. FAERY is implemented and evaluated on the Xilinx AMD Alveo™ U50 Data Center accelerator card, with the same HBM utilization configuration as SNARY. A recall count of 1024 was used as the default configuration in our experiment because FAERY implements a system specifically for this recall count [51], and it also represents the maximum recall count in Faiss. FAERY systems with the same batch size as SNARY under different recall counts were also implemented to conduct comparative experiments with SNARY.

Corpus. SNARY is designed as a generic retrieval system that is not sensitive to any specific workload. Thus, we follow the methodologies of [51] and use synthetic datasets to evaluate the generality and efficiency of SNARY. This is because SNARY focuses on how to improve the retrieval performance

via designing a search engine architecture on SmartNICs. Within this architecture, the retrieval efficiency is mainly decided by the corpus access, which is a hardware-bound process independent of dataset semantics. Specifically, the corpus consists of randomly generated 128-dimensional embeddings with 1 byte each dimension. Since each channel in the HBM provides 32B bandwidth, we utilize 4 consecutive adjacent channels to store a complete embedding.

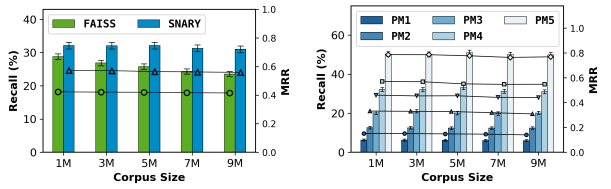


5.2 Evaluation on Exact Search

We measured the query latency and the latency-bounded throughput among different systems in exact search scenarios. Latency-bounded throughput refers to the number of queries a system can process per second (QPS) while maintaining a strict upper limit on response time, or latency. This metric is crucial in real-time retrieval systems, where rapid and efficient data processing is essential to meet user expectations and service requirements. In such systems, high throughput must be achieved without exceeding latency constraints, ensuring both speed and quality of service. In our experiments, we adopted the widely recognized upper latency limit of 10ms as a standard benchmark [4, 10, 27], ensuring the system's ability to handle queries efficiently within this time frame. The experimental results are shown in Figure 9.

We first set the recall count to 1024 and varied the corpus size to compare query latency and latency-bounded throughput among different systems. The experimental results are shown in Figure 9(a) and Figure 9(b). As can be seen, SNARY's latency exhibits a linear relationship with corpus size, which is consistent with the latency formula presented in Equation 1. SNARY achieves a 82.42%-83.63% lower query latency than Faiss and a 34.52%-45.19% lower query latency than FAERY. Under the 10ms latency constraint, SNARY achieves a 18.27× higher throughput than Faiss and a 1.52×-1.76× higher throughput than FAERY, and continues to function even when the other systems fail to meet the latency constraint.

We also fixed the corpus size at 1M and varied the recall count to compare the performance of the different systems. The results are shown in Figure 9(c) and Figure 9(d). As the recall count increases, the performance of all systems decreases, and SNARY obtains more stable performance compared with FAERY as the system architecture is not made more complex. Notably, Faiss was unable to function under higher recall counts due to a recall count limitation of 1024. SNARY achieves a 78.75%-83.88% lower query latency than Faiss and a 20.91%-38.85% lower query latency than FAERY. Under the 10ms latency constraint, SNARY achieves a 14.12× -18.27× higher throughput than Faiss and a 1.26×-1.64× higher throughput than FAERY, and continues to operate under higher recall counts.



The experimental results show that in terms of both the query latency and the latency-bounded throughput, the performance of SNARY is superior to that of Faiss and FAERY. This is because, compared with GPU systems, the inherent hardware advantages of FPGA (mentioned in Section 2.1) enable the retrieval system to be fully pipelined, reducing the retrieval latency, ensuring that the system can still work properly under relatively high recall counts. Meanwhile, since the single-query latency of GPU is relatively high, it is easy to exceed the latency limit on higher batch sizes. However, SNARY adopts a fully parallelized batch support, ensuring high throughput under low latency. Compared with FAERY, the improvements made by SNARY in the Top-K selection module algorithm (mentioned in Section 4.1) are helpful in reducing on-chip resource occupation, increasing the clock frequency, and decreasing the pipeline depth, thus achieving better results.

(a) Query latency under different corpus sizes.
(b) Latency-bounded throughput under different corpus sizes.
(c) Query latency under different recall counts.
(d) Latency-bounded throughput under different recall counts.

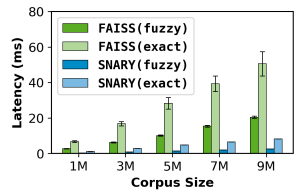


Figure 9: The comparison of query latency and latency-bounded throughput among different systems in exact search as corpus size and recall count varies.

The experimental results also indicate that, compared to Faiss, both SNARY and FAERY, which are FPGA-based implementations, exhibit significantly lower latency jitter. Their latency and latency-bounded throughput remain consistently stable (as seen in Figure 10). This is mainly due to the fact that FPGA can achieve deterministic processing logic through customized hardware circuits, thereby avoiding performance jitter. In contrast, GPUs may experience fluctuations during concurrent processing due to factors such as task scheduling and concurrent memory access. The FPGA's dedicated hardware design ensures stable performance, while the GPU's shared resource architecture introduces variability in execution times. It also can be seen that increasing the recall count results in performance degradation. Because higher recall counts significantly raise the resource occupancy of the Top-K module, which is the bottleneck in GPU-based systems

(discussed in Section 2.1) and dominates the on-chip memory consumption for FPGA-based systems.

5.3 Evaluation on Fuzzy Search

We measured the performance between SNARY and Faiss in fuzzy search scenarios under various corpus with a recall count of 1024 where Faiss functions normally. We used the *IndexIVFFlat* method of Faiss as the baseline, which is the most popular ANN algorithm in Faiss. It accelerates the search by partitioning the dataset into segments, where Voronoi cells are defined in the d-dimensional space, and each database vector is assigned to one cell. During the search, only the vectors in the query's cell and a few neighboring ones are compared to the query vector. It has two tunable parameters, *nlist* and *probe*, which determine the segment number and the search range respectively to balance latency and accuracy. We used the recommended configuration with $nlist = 100$ and $nprobe = 10$.

For the comparison experiment, we first adjusted our own ANN parameters to ensure that the two systems have similar accuracy when comparing latency. We select the parameter combination of $K_h = 4$ and $T_h = 1$ to participate in the comparative experiment. First, we measured the retrieval result accuracy of SNARY and Faiss under different corpus sizes. We use Recall and MRR (Mean Reciprocal Rank) to gauge the accuracy of fuzzy search. In our experimental scenario, Recall represents the ratio of fuzzy retrieval results to exact retrieval results, while MRR refers to the mean of the inverse of the ranking of the first correct result returned in multiple queries. The experimental results are shown in Figure 10(a). It can be seen that when the corpus size changes, the Recall and MRR values of SNARY are similar and slightly higher than those of Faiss. As corpus size increases, the accuracy of SNARY maintains a stable range.

We then measured the query latency and the latency-bounded throughput (with the same upper limit of 10ms) between the two systems and the experimental results are shown in Figure 10(c) and Figure 10(d) with results in exact search scenarios as references. From the experimental results, SNARY successfully reduces query latency in fuzzy search compared with exact search and also outperforms Faiss in terms of latency and latency-bounded throughput under similar accuracy metrics. SNARY achieves a 85.13%-87.40% lower latency and a 20.18×-23.81× higher throughput under the 10ms constraint than Faiss at similar accuracy of searching results. Compared with exact search, SNARY reduces the query latency by 78.05%-78.72%, while Faiss reduces that by 35.41%-39.17%, which also makes the latency-bounded throughput corresponding to the fuzzy search higher than that of the exact search.

The performance advantages of SNARY in fuzzy search come from two aspects: (*i*) high-performance exact search; (*ii*) high-efficiency acceleration effect. Due to the hardware architecture advantages of SNARY, its performance in terms of query latency and latency-bounded throughput in exact search is already better than that of GPU-based systems (mentioned in Section 5.2). Moreover, SNARY adopts the method of directly fuzzifying the reading of the corpus. For a fully pipelined parallel retrieval system, this can directly reduce the delay, and in the scenarios of large-scale corpus, it can very efficiently accelerate the entire retrieval process (mentioned in Section 2.2).

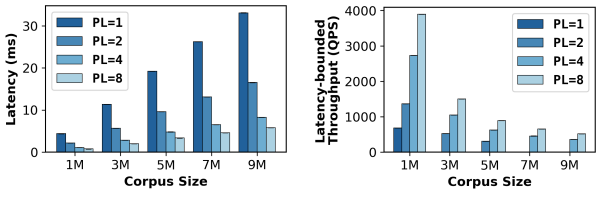
Finally, we investigated the impact of parameter changes on the trade-off between latency and accuracy. As indicated in Equation 6, the reduction in corpus size and consequently, the overall system latency can be controlled by selecting appropriate values of K_h and T_h. We use η to represent the corpus reduction ratio, defined as follows:

$$\eta = \frac{\sum_{i=0}^{T_h} \binom{i}{K_h}}{2^{K_h}}. \tag{7}$$

We selected various parameter combinations, as shown in Table 2, to assess the performance of the fuzzy search. The

Table 2: Performance in fuzzy search of different systems.

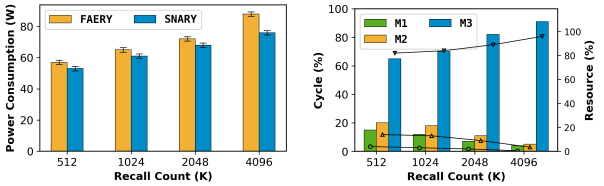
metric	parameter combination				
	param1	param2	param3	param4	param5
K_h	4	3	5	4	3
T_h	0	0	1	1	1
$\eta(\%)$	6.25	12.50	18.75	31.25	50.00



identities of different systems are arranged in ascending order based on the values of η.

We measured the query latency, latency bounded-throughput (with the same upper limit of 10ms), and accuracy of SNARY under different parameter combinations, with a recall count of 1024, the experimental results are shown in Figure 10(b), Figure 10(e) and Figure 10(f). From the experimental results, as the parameter η decreases, the proportion of corpus reduction increases, leading to a decrease in the query latency of SNARY and an improvement in latency-bounded throughput. Conversely, as η increases, the search range expands, resulting in improved precision and higher-quality retrieval results. Additionally, across different corpus sizes, SNARY consistently demonstrates stable acceleration performance, with the latency reduction compared with exact search remaining around $1-\eta$, which is consistent with the corpus reduction ratio in Equation 6.

This also indicates that we can balance retrieval efficiency and accuracy by adjusting the values of K_h and T_h. In scenarios where lower retrieval latency and higher throughput are prioritized over accuracy, a smaller η value can be used, whereas in scenarios requiring higher retrieval accuracy, a larger η value is more appropriate. Additionally, users can directly predict the latency reduction and the increase in latency-bounded throughput in a fuzzy retrieval based on the parameter combination, allowing for more flexible and efficient retrieval in different application contexts.



5.4 Extended System Characterization

Impact of parallel corpus access. As briefly stated in Section 4.1, parallel corpus access improves system efficiency by processing multiple embeddings simultaneously per clock cycle, compared to sequential retrieval. To validate its performance impact, we tested four parallelism levels, using exact search task with recall count 1024 and measured query latency and latency-bounded throughput under different parallelism levels. Experimental results are shown in Figure 11(a) and Figure 11(b). It can be observed that system performance demonstrates significant improvements with increasing parallelism degrees. At the higher parallelism level of 8, the performance gain becomes less pronounced due to the excessive number of embeddings processed per clock cycle. These results confirm that parallel corpus access directly enhances both critical performance metrics of the system.

(a) Query latency among different parallelism levels.

(b) Latency-bounded throughput among different parallelism levels.

(c) Energy consumption between FAERY and SNARY.

(d) Cycle and resource allocation among modules in SNARY.

Figure 11: The experimental results of parallel levels, SmartNIC energy consumption and module performance analysis.

SmartNIC energy consumption. We measured the power consumption of both FAERY and SNARY implemented on identical hardware boards. Experimental results indicate no significant correlation between corpus size and power draw. As depicted in Figure 11(c), increasing Recall Count elevates system complexity, leading to corresponding increases in power consumption. Notably, SNARY demonstrates superior power efficiency compared to FAERY, attributable to its optimized Top-K module design.

Module performance analysis. We measured and analyzed the clock cycle allocation ratios and resource utilization patterns using Vitis across SNARY's modules under varying recall counts, with detailed data presented in Figure 11(d), where corpus access, similarity calculation and Top-K module (with filter) are denoted as M1, M2 and M3, respectively. The results demonstrate that the Top-K module dominates both temporal overhead and hardware resource usage among all components. This finding underscores the critical importance of Top-K module optimization for overall system performance enhancement.

6 Discussion

HBM utilization. Our experiments use 2 channels to store the hash table and index table, and 1 channel for write-back operations. The remaining 29 channels can be fully utilized to store the corpus. This allows for the possibility of reading up to 7 embeddings at once when using 4 contiguous channels per embedding. From inequation 4, we know that the parallelism metric N_E is constrained by the recall rate γ. Under our experimental conditions, the maximum recall rate $\gamma = 1/250$, which yields $N_E \leq 6.19$, indicating that our system can achieve par-

allelism of $N_E = 6$ while utilizing 24 HBM channels. In more general conditions, a recall rate of less than 3×10^{-3} ensures that 7 channels can be simultaneously utilized. Therefore, our system can further reduce latency by utilizing more HBM channels for higher total bandwidth, potentially decreasing it by up to around 43%. When utilizing multiple channels, a limited corpus may result in significant vertical gaps in the HBM. To improve HBM utilization, it is possible to partition HBM vertically into multiple segments, allowing the empty sections to be used for storing additional corpora for other retrieval tasks or to hold a backup corpus for online updates. If fewer channels are used and the corpus involves various data types (such as text, images, and audio), the remaining channels can be allocated for storing multimodal data features.

Early corpus filtering. As discussed in Section 2.1, the performance of SNARY is directly correlated with corpus size, and our fuzzy search solution improves operational efficiency by reducing the corpus size. However, this still requires storing all data on the servers. Future work will focus on implementing early corpus filtering to preemptively remove irrelevant corpus portions based on user requirements or business types. This approach will store only task-related corpora on servers before initiating read operations. Such an implementation is expected to both alleviate server storage burdens and further enhance system efficiency.

Multi-card cooperation. SNARY implements batch support by instantiating multiple on-chip computing units, which will undoubtedly be limited by on-chip resources. For example, when the recall count increases, the batch size supported by the system becomes smaller, and multiple computing units may also bring wiring difficulties, slow timing convergence, and other problems. A feasible approach for higher latency-bounded throughput is multi-card cooperation. This collaborative approach allows for distributing the processing load across several cards, enhancing concurrency and further optimizing performance. The integration of SmartNICs facilitates efficient and low-latency communication between multiple cards, ensuring that the data transfer necessary for batch processing occurs seamlessly and swiftly.

7 Related Work

Deep retrievals. Recently, many different neural models have been proposed to address semantic gap problems, which fall mainly into two categories: representation-based learning [1] and interaction-based learning [9]. For representation-based learning, many DL models (e.g., LSTM-RNN [37], ARC-I [19] and DSSM [21]) are utilized to generate semantic representations of corpus items. Interaction-based approaches learn the complex relevant patterns between the query and items via neural models, such as DRMM [16], Match-SRNN [46], MatchPyramid [38] and K-NRM [50]. SNARY utilizes the semantic representations generated by neural networks to calculate their similarity.

Hardware-accelerated retrieval systems. To improve retrieval performance, some specific hardware accelerators have been integrated into modern retrieval systems. For example, some works utilize GPUs to accelerate similarity calculation [11, 25] or CXL (compute express link) [23] to improve the corpus access. Recently, FPGAs also have been introduced to improve performance [26, 51]. SNARY mitigates the gap and enables both exact and fuzzy search, adapts an optimized Top-K algorithm and involves SmartNIC-centric deployment compared with [51].

Accelerating retrievals with ANN. Besides hardware acceleration, the community also proposes some ANN algorithms to accelerate the retrieval. For example, IVF [44] utilizes an inverted index approach to store vectors in order to reduce the number of accessed items. HNSW [32] employs a hierarchical NSW [33] index graph to conduct an approximate nearest neighbor search. PQ [24] and OPQ [13], using product quantization, reduce the computational cost of distance calculations. For SNARY, it utilizes LSH [7, 8, 45] to reduce the scale of the corpus.

Efficient Top-K algorithms. Although many efficient Top-K methods have been implemented on GPUs [40, 41], the overhead of inter-core communication still presents a bottleneck for these algorithms. [51] introduced a FIFO-based algorithm on FPGA. However, it occupies $O(9K/2)$ memory and exhibits limited scalability with varying recall counts. [30] proposed a parallel swapping algorithm for smaller recall counts with $O(K)$ memory. SNARY presents a strategy for implementing parallel swapping algorithms under larger recall counts while providing detailed theoretical proofs.

8 Conclusion

In this paper, we design and implement SNARY, a high-performance and generic retrieval system. SNARY is built upon SmartNIC and enables both exact and fuzzy retrievals. Specifically, SNARY leverages HBM on FPGAs to store a large-scale corpus. With this basis, it designs a data parallelism exact search engine and an LSH-based fuzzy search engine. To achieve high performance, SNARY further employs a parallel pipelined method to facilitate the Top-K item selection and stream the data flow of the whole system. Experimental results show that SNARY significantly outperforms the popular GPU-based solutions in both exact and fuzzy scenarios and outperforms the novel FPGA-based solutions in exact scenarios which fall short in fuzzy scenarios.

A The Theoretical Proof and Analysis

A.1 Proof of the Correctness of Top-K Module

We now prove that the algorithm in Top-K selection module ensures the 0th position always holds the smallest value in the current Top-K array, and that the entire array can be ordered with at most $K/2$ additional parallel cycles.

- First, when array length $K = 2$, the Stage 1 swap process effectively does nothing, while Stage 2 directly compares the two values in the array and moves the smaller value to the 0th position, confirming that the algorithm works correctly.
- Next, assume that our algorithm holds for an array of length $K = k-1$. We now consider an array of length $K = k$ and divide it into two parts: the 0th position and the remaining $k-1$ elements, denoted as array A. It is important to note that for any pipeline cycle i, Stage 2 of cycle i and Stage 1 of cycle $(i+1)$, when applied to array A, effectively perform the two rounds of parallel swaps for $K = k-1$. In Stage 2 of cycle i, the new score (in the 0th position) is compared and swapped with the 0th position of array A, followed by a parallel sort of array A starting from the 1st position. Stage 1 of cycle $i+1$ then performs a parallel sort starting from the 0th position of array A.

  Since our algorithm holds for array A with length $K = k-1$, after Stage 1 of cycle $(i+1)$, the 0th position of array A contains the smallest value of array A, which means that the 1st position of the original array is the smallest value among the last $(k-1)$ elements. After Stage 2 of cycle $(i+1)$, the 0th and 1st positions of the original array are compared: if the 0th position is smaller, it remains as the minimum value, and no swap occurs; if the 0th position is larger, a swap occurs, making the 1st position the smallest value in the array. As a result, after this process, the 0th position of the original array becomes the smallest value in the entire array.

  Since the array is initialized with negative infinity values at $i = 0$, the induction step holds, and the algorithm is proven to work for $K = k$ in all stages.

From the above proof, it is established that in any pipeline cycle, the 0th position of the array always holds the smallest value in the entire array. At the end of the last clock cycle, we add additional $K/2$ clock cycles to ensure that the array becomes fully ordered. This can be guaranteed because:

- At the end of the last clock cycle, the 0th and 1st positions of the array hold the smallest and second smallest values, respectively.
- Since the swap algorithm can be applied to arrays of any length, after the i-th additional clock cycle, the smallest

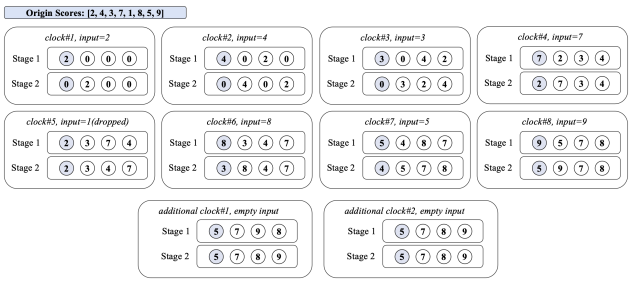

Figure 12: A simplified operational example of the Top-K module with M=8 and K=4.

and second smallest values from position $2i$ to $(K-1)$ are placed in their correct positions, while the first $2i$ elements are already the smallest $2i$ values in the array, and remain unchanged.

- By the end of the $K/2$-th additional clock cycle, the entire array is fully sorted.

We present a simplified operational example in Figure 12 with M=8 and K=4 (note that $M >> K$ in practice) to demonstrate the complete workflow of the Top-K module. It can be observed that the 0th array position consistently maintains the minimum value among all received inputs at every clock cycle termination. Furthermore, the array attains full ordering within at most $K/2$ additional clock cycles.

A.2 Analysis of the Filtering Efficiency

Assuming the total number of embeddings in the corpus is M, i.e., M scores are produced in the similarity calculation module, and the total number of scores that are dropped out by filter is M_f. In order to balance throughput, the total number of filtered scores must not be less than the throughput difference between the two modules, which is given by:

$$M_f \geq M - \frac{M}{N_E}. \tag{8}$$

Considering that the scores generated from similarity calculations are random, for the sake of simplification, let's assume that all scores follow a random uniform distribution within a certain interval. Taking the first input data to the filter as cycle 0, the first output data of the filter and the first input data into the Top-K selection module occur at cycle 1. According to the previous analysis, we know that the first valid smallest Top-K value is produced in cycle $(K+1)$, and it is fed back to the filter in the next cycle. This is because it takes K cycles to fully populate the Top-K array with valid scores. In the subsequent cycles, the current smallest Top-K value based on the valid scores will be replaced. Since the filter requires receiving the valid minimum Top-K value to function properly, it will begin to operate effectively at cycle $C_0 = K+2$ or later:

It is worth noting that the minimum Top-K value is updated every pipeline cycle. In other words, in cycle (C_0+i), the scores input to the filter are compared with the minimum value of the Top-K value of the first $(i+K)$ scores. Since the similarity scores are uniformly random, the probability that a score enters this sequence and is ranked beyond the K-th position after reordering is the probability of being filtered. Therefore, in cycle (C_0+i), the probability of the input score being filtered by the filter is denoted as $P(i)$:

$$P(i) = \frac{(i+K)+1-K}{(i+K)+1} = \frac{i+1}{i+K+1}. \tag{9}$$

In every pipeline cycle, the total number of scores input to the filter is N_E. Since the filter starts inputting scores at cycle 0, the last batch of inputs will arrive at cycle (M/N_E-1), which means:

$$i_{\max} = M/N_E - 1 - C_0. \tag{10}$$

According to Equation 9 and Equation 10, the total number of filtered scores can be expressed by the following equation:

$$\begin{aligned} M_f &= \sum_{i=0}^{i_{\max}} N_E \cdot P(i) \\ &= M - C_0 \cdot N_E - K \cdot N_E \cdot \sum_{i=0}^{i_{\max}} \frac{1}{i+K+1} \end{aligned} \tag{11}$$

Let $j = i+K+1$, we can then obtain:

$$\begin{aligned} \sum_{i=0}^{i_{\max}} \frac{1}{i+1+K} &= \sum_{j=K+1}^{i_{\max}+K+1} \frac{1}{j} \\ &\leq \int_{K}^{i_{\max}+K+1} \frac{1}{x}\,dx \\ &= \ln(\frac{M}{K \cdot N_E} - \frac{2}{K}). \end{aligned} \tag{12}$$

Since we have $M/N_E >> 2$, substituting Inequation 12 into Equation 10, we obtain:

$$M_f > M - C_0 \cdot N_E - K \cdot N_E \cdot \ln(\frac{M}{K \cdot N_E}). \tag{13}$$

Therefore, to ensure the validity of Inequation 8, it is only necessary for the following inequality to be satisfied:

$$M - K \cdot N_E - 2 \cdot N_E - K \cdot N_E \cdot \ln(\frac{M}{K \cdot N_E}) \geq M - \frac{M}{N_E}. \tag{14}$$

Let $\gamma = K/M$ represent the recall rate of the entire retrieval system. Substituting γ into Inequation 14, we obtain:

$$\frac{1}{N_E^2} \geq \gamma - \gamma\ln(\gamma) - \frac{2}{M} - \gamma\ln(N_E) \geq \gamma - \gamma\ln(\gamma), \tag{15}$$

which limits the maximum value of N_E, demonstrating the fact that it becomes increasingly challenging to balance throughput as N_E increases. It is worth noting that $\gamma < 1$, and the

derivative of the inequality's right-hand side $-\ln(\gamma)$ is greater than 0, indicating that the right-hand side of the inequality monotonically increases as γ increases. This suggests that smaller recall values can provide a larger range of possible values for N_E.

The filter can handle throughput imbalance within a certain range, however, additional cache space needs to be set up to avoid losing data that is expected to enter the Top-K selection module. Within one clock cycle, the filter receives N_E scores, and more than one score may be greater than the current minimum value in the Top-K sequence. Therefore, these scores need to be temporarily cached and passed to the Top-K selection module in the following clock cycles. Caching scores happens in two scenarios:

- Before clock C_0, when the current Top-K sequence has not produced the current minimum value yet, all scores need to be cached. In this case, the total number T of scores to be cached is given by:

$$T = C_0 \cdot (N_E - 1) = K \cdot N_E + 2 \cdot N_E - K - 2. \quad (16)$$

- After clock C_0, there may be occasional cases where more than one score is greater than the current minimum Top-K value. The specific design of the filter adopts the following strategies: (*i*) If the filter currently contains scores, it will prioritize outputting scores from the filter and cache any input scores that are greater than the current minimum Top-K value. (*ii*) If the filter is empty, it will output the first input score that is greater than the current Top-K minimum value, and cache any other eligible input scores. (*iii*) If the filter is empty and all input scores are smaller than the current minimum Top-K value, it can randomly output one score to balance throughput, which will not affect the output of the Top-K selection module.

Minos : A Lightweight and Dynamic Defense against Traffic Analysis in Programmable Data Planes

Abstract

Encrypted traffic analysis techniques extract valuable information from encrypted traffic and pose significant threats to user privacy. However, existing defense mechanisms against traffic analysis either incur significant bandwidth overhead and lack scalability, or fail to provide sufficient defense against evolving attacks. The emerging programmable switches provide data plane programmability with line rate packet processing to support advanced defense mechanisms. In this work, we present Minos, a lightweight and scalable programmable switch-based defense mechanism while providing both identity anonymity and traffic anonymity. Minos comprises three key modules: the Proxy Module, the Traffic Morphing Module, and the Schedule Module. In the Proxy Module, we design encryption round compression to take advantage of the match-action pipeline of programmable switches and realize line rate packet header encryption. The Schedule Module incorporates a lightweight dynamic flow scheduling method to interleave packets from different flows, so as to simulate dummy packets without causing bandwidth and delay overhead on the data plane. The Traffic Morphing Module further obfuscates the flows by dummy packet insertion and packet padding. Specifically, we devise a lightweight dummy packet scheduling method using priority dummy queues, minimizing bandwidth and delay overhead within the switch pipeline. We implement our defense on Tofino1 switches and adapt our method to defend Website Fingerprinting and IoT Fingerprinting. The results show that Minos can reduce the accuracy of previous attacks to less than 20% with only one-tenth of the overhead of existing defenses.

1 Introduction

Nowadays, user privacy has become a major concern [54–56], leading to the development of encryption protocols that secure packet payloads and shield user information. Nevertheless, even with encryption protocols, attackers can still compromise user privacy through encrypted traffic analysis techniques [26, 39, 48, 62]. These techniques assume a passive attacker who eavesdrops traffic from the victim by its 5-tuple (Source IP, Destination IP, Source port, Destination port, Protocol) to infer users' intentions–usually the resources they are requesting, such as websites or videos. Attackers can classify encrypted traffic by machine learning classifiers, without actually knowing packet contents, using features extracted from just packet sizes, packet directions, and some statistical features such as the total number of packets and the fraction of incoming or outgoing packets to the total number of packets. By leveraging the aforementioned 5-tuple, attackers can intercept the privacy of specific targets, deducing the content they access. Traffic analysis methods for different kinds of applications have been developed, including Website Fingerprinting (WF) [20, 42, 48] and IoT Fingerprinting [26, 46], posing serious threats to these applications.

The most popular defense methods against traffic analysis are Proxy-based defenses, which obfuscate the 5-tuple of user flows to hinder attackers from capturing pure traffic without background noise, thereby reducing the accuracy of classifiers. For example, IPsec gateways replace the source IP of each flow with its own public IP to create an end-to-end encrypted tunnel between two gateways. Multiple flows from various users are concurrently transmitted through this encrypted tunnel so that attackers can only capture a blend of noisy traffic, making categorizing encrypted traffic considerably more challenging [49]. However, they suffer from several critical weaknesses. First, most IPsec gateways have **limited throughput** [35] and cannot process today's high rate traffic, i.e., 100Gbps. Furthermore, security gateways, being specialized hardware with fixed capabilities, are not designed to incorporate advanced security features. This limitation not only renders them ineffective against new threats but also means they do not offer **traffic anonymity** to protect users' privacy. For example, the attack proposed in [14] applies packet labeling to each packet and successfully infers device types through noisy IoT traffic with per-packet features.

Traffic morphing-based Defenses	×	×	×	✓
Ditto [28]	×	✓	×	✓
Minos	✓	✓	✓	✓

Traffic morphing-based defenses [9, 10, 52, 58] can effectively impede fingerprinting attacks by morphing characteristics of the origin traffic flows through padding, splitting, and inserting packets, reducing the accuracy of WF attacks to random guess [10]. These defense mechanisms obfuscate the metadata of user flows, providing traffic anonymity to defeat traffic analysis attacks. However, traffic morphing-based defenses share a common disadvantage: their practical deployment can be challenging due to high **bandwidth overhead**. For instance, in Tamaraw [10], the bandwidth overhead reaches 199%, resulting in a goodput of less than 40%. Besides, traffic morphing-based defenses, targeted at individual users, lack **scalability** to perform defenses for multiple users due to the escalated overhead. Finally, traffic morphing-based defenses do not offer **identity anonymity** and require a VPN to obfuscate the 5-tuple.

Lately, researchers have explored line rate traffic obfuscation on programmable switches [28] for traffic morphing-based defenses. Programmable switches, with their inherent flexibility, scalability, and customizability, offer line rate processing capability of up to 100Gbps and the ability to adapt to changing network demands. Ditto [28] establishes tunnels between programmable switches and sends packets with a static traffic pattern of fixed intervals and fixed size sequences. Although Ditto has achieved increased throughput compared to its predecessors, it still introduces significant **additional bandwidth overhead** by padding packets to specified sizes, as well as **increased latency** due to passing packets through the switch twice. Besides, Ditto requires the cooperation of IPsec gateways or MACsec gateways to hide user identity, thus fails to provide **identity anonymity**.

In this work, we present Minos, a lightweight and scalable programmable switches-based defense mechanism while providing both *identity anonymity* and *traffic anonymity* at 100Gbps line rate. In Minos, we design three modules as defense primitives in the switch hardware: the Proxy Module, the Schedule Module, and the Traffic Morphing Module. The Proxy Module performs line rate packet header encryption and acts as gateway switches of a trusted entity to realize an end-to-end encrypted tunnel to provide **identity anonymity**. The Traffic Morphing Module enhances the defense performance of Proxy-based defenses by performing lightweight dummy packet insertion and packet padding to provide **traffic anonymity**. In the Schedule Module, we dynamically schedule multiple flows to accommodate multiple end users.

The design and implementation of Minos on programmable switches face three challenges: 1) Ensuring line rate encryption with the Proxy Module is challenging since programmable switches have limited computational resources and cannot accommodate complex calculations or numerous encryption rounds; 2) Managing a multitude of flows from various users concurrently with the Schedule Module is challenging since we need to prevent packet disorder and minimize the overhead associated with traffic morphing. 3) Implementing the Traffic Morphing Module requires inserting dummy packets to obscure flows. However, since packets cannot be directly generated in the data plane and must be injected in advance by the control plane, inserting dummy packets into flows in real-time poses a significant challenge.

We address the above key algorithmic and system design challenges in Minos as follows. To achieve line rate encryption within constrained computations and resources, we devise an *Encryption Round Compression method* to implement the Proxy Module, which realizes implementation on hardware programmable switches equipped with match-action tables, eliminates the necessity for multiple pipeline passes, and ensures line rate encryption. To handle concurrent user traffic in a dynamic and scalable manner, we propose a *Dynamic Flow Scheduling Method* in the Schedule Module, which leverages packets from different flows to act as dummy packets to other flows. We formulate our flow scheduling algorithm to obfuscate flows dynamically according to multiple per-flow states and enable traffic morphing based on active flow numbers. With the scheduling algorithm, Minos is able to obfuscate flows with minimal dummy packets and packet padding. To realize real-time insertion of dummy packets, we design *Priority Queue based Dummy Packet Scheduling* to approximate real-time dummy packet insertions with little bandwidth overhead, thereby enabling the implementation of a lightweight Traffic Morphing Module.

We implement Minos on Tofino1 switches, and the evaluation shows that Minos has better throughput performance than previous defenses. The evaluation results also show that Minos can reduce the accuracy of Website Fingerprinting attacks to less than 20% with lower bandwidth and latency overhead than previous defenses.

The remainder of this paper is organized as follows. We first discuss the related work in Section 2, and then introduce our design goals and Minos system overview in Section 3. Then, we elaborate on the design of the Proxy Module, Schedule Module, Traffic Morphing Module in Section 4, 5 and 6. We evaluate the performance of Minos in Section 7, and adapt Minos to defend against Website Fingerprinting in Section 8. At last, we conclude our work in Section 9. We further expand our defense to defeat IoT Fingerprinting in Appendix A.

2 Background and Motivation

2.1 Encrypted Traffic Analysis

Encrypted traffic analysis is a passive attack in which attackers collect encrypted traffic flows by 5-tuple (Source IP, Destination IP, Source port, Destination port, Protocol) and analyze them through machine learning classifiers to infer whether victims are visiting some specific resources (e.g. websites and videos). Figure.1 shows an example of encrypted traffic analysis attacks, where users use different kinds of applications, e.g., websites, video streams, and IoT applications, inside a local network, and send encrypted traffic through a gateway. A local attacker may eavesdrop on the gateway, while a remote attacker eavesdrops on flows from the untrusted network by the 5-tuple of each flow, thereby locating the user and compromising their privacy. Considering the distinctive characteristics of different target applications, several encrypted traffic analysis attacks have been designed, e.g., Website Fingerprinting (WF) [20, 42, 48] and IoT Fingerprinting [26, 46].

Website Fingerprinting. Website Fingerprinting attacks target victims who use proxies and encrypted protocols to hide their identities and packet contents when browsing. Early works like [16, 48] focus on HTTPS traffic, where attackers are able to utilize the sizes, directions, and intervals of packets. Wang et al. [48] design an attack that utilizes the k-Nearest Neighbour classifier on a feature set including unique packet lengths, bursts, etc., and achieve an accuracy of 0.85 on early defenses like [25, 52]. Recent WF attacks aim at Tor [13], one of the most frequently used anonymous communications tools. Tor conceals clients' packet size by sending packets in fixed size (512-byte) Tor cells, rendering attacks more challenging because Tor traffic only discloses packet directions. Hayes et al. [20] develop a k-fingerprints attack with random forests to extract and represent fingerprints of different traffic traces and achieve 88% TPR in an open-world setting. Recent attacks [6, 37, 42] exploit deep learning against WF defenses, achieving accuracy over 95%.

IoT Fingerprinting. IoT Fingerprinting poses a significant threat to the rapidly growing IoT user base. IoT Fingerprinting attacks have seen success in decrypting IoT device types [30, 43, 44]. For example, [30] identifies device types with over 95% accuracy by passively observing network traffic using a two-fold classification system. Beyond device fingerprinting, [26, 45, 46] even manage to infer user activities from IoT traffic, further exacerbating user privacy concerns. [26] generates sequence profiles from packet sequences and matches them to collected traffic traces to estimate device types and user interactions. [45] develops two polynomial time algorithms to capture IoT devices' activity signatures and full activity sequences.

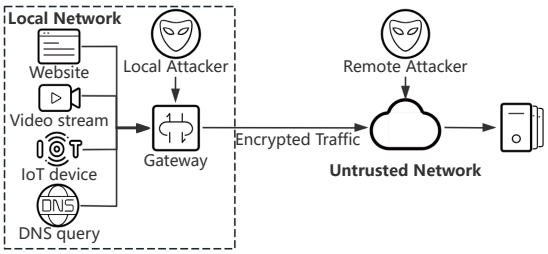

Figure 1: An example of encrypted traffic analysis.

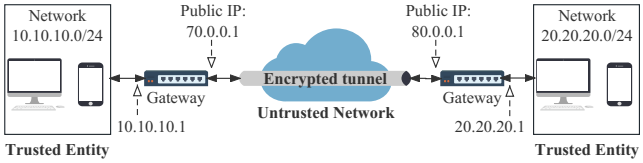

Figure 2: An example of IPsec gateway.

2.2 Defenses against Encrypted Traffic Analysis

Proxy-based defenses. Proxy-based defenses obfuscate the 5-tuple of user flows, preventing passive observers from obtaining clear traffic traces without noise. Popular Socks-based proxies like Shadowsocks [3] and V2Ray [2] break one access to a website into several flows by randomly generating new ports to request different resources in a website. Hence, the attackers can only capture partial access to the website through various 5-tuples. IPsec gateways, commonly used as LAN gateways, establish a secure and encrypted tunnel with aggregated flows by replacing the original IP headers with new IP headers with the same public IP, as illustrated in Figure. 2. In this way, attackers can only capture a noisy flow where multiple flows are actually transmitting, rather than pinpointing any individual user because they cannot capture the user's original IP address.

Proxies are widely deployed because they are lightweight, bringing little bandwidth or latency overhead, and can handle multiple end users. However, these proxies fail to defend against new encrypted traffic analysis. [27] succeeds in recognizing websites through per-flow traffic analysis and breaches socks-based proxies. [14] identifies device types by a LSTM model with per-packet labels, threatening IoT users even with the protection of IPsec gateways. Although proxies provide identity anonymity, emerging studies indicate that traditional Proxy-based defenses are no longer safe, thus traffic morphing-based defenses are necessary.

Traffic morphing-based defenses. Traffic morphing-based defenses obfuscate traffic traces to resist traffic analysis attacks by inserting, delaying, combining, or splitting packets. BuFLO [16] removes all side-channel information by sending fixed-length packets at a fixed interval for at least a fixed amount of time. [21] proposes WTF-PAD, an adaptive

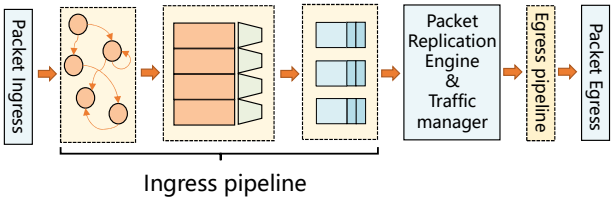

Figure 3: Standard Tofino pipeline.

padding method on top of Tor, which utilizes a finite state machine along with histograms. WTF-PAD is effective against conventional attacks, with half the bandwidth overhead of BuFLO, but fails to resist the more advanced deep learning-based attacks [42]. To defeat deep learning classifiers, researchers have applied adversarial perturbations [32] and patches [23]. [18] designs a lightweight defense that dedicates most of its bandwidth budget to obfuscate the trace front. In IoT Fingerprinting, Alshehri et al. [5] attack tunneled IoT traffic based on packet-size sequences and propose an algorithm to pad packets with uniform random noise to defend against it. According to [5] and [44], it is necessary to hide packet lengths to defend against IoT Fingerprinting.

In summary, traffic morphing-based defenses, despite their effectiveness, face three main challenges. First, their high bandwidth and latency overhead hinder real-world deployment, especially for handling multiple users within a trusted entity. Second, deploying multiple targeted defenses simultaneously is infeasible and laborious due to excessive bandwidth demands. Third, traffic morphing-based defenses can not hide user identity and require the cooperation of proxies. Although recent studies [17] have increased the packet processing speed of end hosts, it is impractical to equip every user with a dedicated network interface card. Moreover, configuring defenses for each user would bring escalated overhead and place a greater burden on the network.

2.3 Traffic Analysis Defense on Programmable Switches

Traditional switches have fixed default functions. Thus network operators have to apply specific middleboxes or upload packets to servers [29] to support customized functions, which bring extra costs with limited throughput [57]. The emerging programmable switches provide data plane programmability with line rate packet processing capability to support customized functions [53, 59, 63]. This advancement presents a valuable opportunity to enhance the throughput of traffic morphing-based defense mechanisms by integrating traffic morphing directly into the programmable pipeline [28]. Our work focuses on PISA (Protocol Independent Switch Architecture) processors, which allow packet processing at line rate (100 Gbps) with flexible modification of packet headers by P4 [8]. A typical Tofino architecture is shown in Figure. 3.

Packets sent to the data plane pass through two programmable pipelines and a Traffic Manager (TM). In the ingress pipeline, packets are first parsed by the ingress parser and mapped into the Packet Header Vector (PHV). After leaving the parser, PHVs are sent into the match-action pipeline where network admins can design their own packet process logic by configuring match-action tables. Packets are then assembled by the deparser and passed to the TM, where packets are replicated, recirculated, or buffered in the Traffic Manager's round-robin queues and then passed forward to the egress pipeline which is identical to the ingress pipeline.

With the help of the programmable pipeline and multi-functional Traffic Manager, programmable switches can potentially deploy proxy-based defense and traffic morphing-based defense at the same time, providing both identity anonymity and traffic anonymity. Several studies have attempted implementing encryption algorithms on programmable switches. [11] and [60] implement standard encryption algorithms, e.g., AES, on programmable switches. However, they must send packets through the pipeline multiple times and thus cannot reach line rate. [12, 19, 33] either lack hardware implementation or require extensive communication with the control plane. [47] implements the two-round Even-Mansour scheme on hardware programmable switches, at the cost of excessive computing resource consumption.

A recent work, Ditto [28], establishes tunnels between programmable switches and obfuscates traffic with packet padding and dummy packets. However, Ditto exhibits a few limitations. First, Ditto relies on IPsec and MACsec gateways for encryption, which will bring additional deployment difficulties and costs. Besides, IPsec gateways have limited throughput compared to programmable switches and may become the bottleneck of the whole system. In Minos, we provide traffic obfuscating primitives along with encryption primitives and no extra devices are required. Second, Ditto realizes complete traffic anonymity by sending packets through a static traffic pattern with fixed intervals and fixed size sequences. Consequently, each packet must be padded to a predetermined size and sent through the pipeline twice for packet scheduling, resulting in significant latency and bandwidth overhead. Third, Ditto cannot adapt to dynamic network environments due to its reliance on a static traffic pattern.

3 Minos Overview

3.1 Design Goals

In this work, we propose Minos, a line rate traffic analysis defense scheme based on programmable switches. Based on the shortcomings of proxy-based and traffic morphing-based defenses, we propose the following design goals.

Lightweight. Minos is lightweight and easy to deploy in the real world. We design each Minos module with minimal

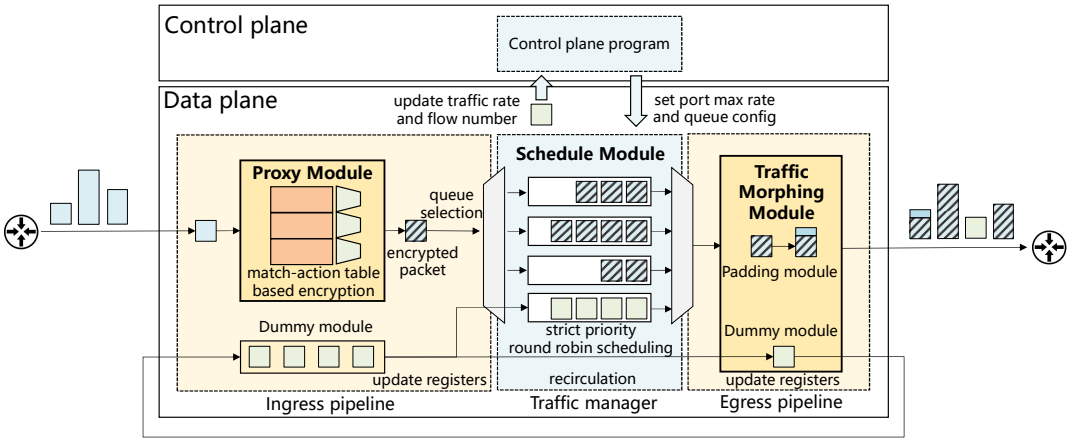

Figure 4: System overview of Minos.

bandwidth overhead and hardware resources.

Scalable. Minos is able to dynamically adjust its defense strategy to accommodate different circumstances and handle concurrent flows from multiple users.

Anonymity. Minos provides both identity anonymity and traffic anonymity. Minos not only hides user identities through encryption but also performs traffic obfuscation, concealing metadata within the traffic.

Like IPsec, Minos establishes an end-to-end tunnel between an obfuscating gateway (e.g., an organization's gateway) and a corresponding de-obfuscating gateway (e.g., ISPs that offer enhanced privacy or IoT operators that secure user data) for traffic obfuscation. We assume a passive attacker [20,48] who collects traffic from any point between Minos gateways and classifies them from their 5-tuples but cannot modify or insert packets.

Unlike Tor, the goal of Minos is not to hide the identities of the endpoints involved, but to establish an encrypted channel between the sender and the receiver and to conceal the metadata and the user identities. This objective is similar to the setup in Ditto. In real-world deployment, for instance, when deploying Minos to defend against IoT Fingerprinting attacks, it is necessary for IoT devices to transmit essential information to the IoT service provider. The objective of Minos is not to conceal the identity of the IoT service provider, but rather to ensure that attackers are unable to infer users' IoT activity from the communication between the IoT device and the service provider. This principle remains consistent when deploying Minos to mitigate other types of attacks.

3.2 System Overview

The main process of Minos runs on the programmable data plane and communicates with the control plane to configure Traffic Manager settings. Packets entering the Minos switch will pass three modules before exit: the Proxy Module, the Schedule Module, and the Traffic Morphing Module.

The **Proxy Module** acts as a gateway switch that replaces the source IP of each packet with the gateway IP and sends packets at line rate. The original source IP and other fields will be encrypted and placed in a new header. Particularly, we design Encryption Round Compression exploiting match-action tables to achieve line rate implementation of packet header encryption on programmable switches.

The **Schedule Module** aggregates different flows to the same destination to obfuscate the original traffic with minimal dummy packets. Packets entering Minos switches will be inserted into specific queues and interleaved by the switch's Traffic Manager. Specifically, we propose a dynamic schedule algorithm to perform flow interleaving and decide whether to enable the Traffic Morphing Module. With the co-action of the Proxy Module and Schedule Module, Minos aggregates each incoming flow with limited overhead.

The **Traffic Morphing Module** provides primitives to implement traffic morphing-based defenses, consisting of the *Dummy Module* and the *Padding Module*. The former module manages dummy packets and the latter module pads and assembles packet headers. We design priority queue-based dummy packet scheduling to realize real-time dummy packet insertion.

Figure. 4 shows the workflow of Minos. When a flow enters a Minos switch, its source IP will be replaced and encrypted by the **Proxy Module** in the ingress pipeline, and scheduled into the Traffic Manager by the **Schedule Module**. Meanwhile, the **Schedule Module** examines the flow state and decides whether the **Traffic Morphing Module** should be applied. When few flows are active, simply interleaving flows is not sufficient to defeat advanced attacks. Thus, the **Traffic Morphing Module** will be activated, and its Dummy module and Padding module will perform dummy packet insertion

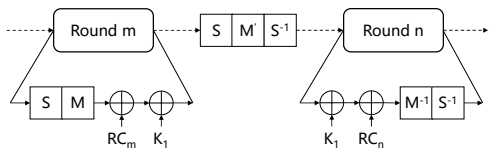

Figure 5: Simplified encryption process of $PRINCE_{core}$.

and packet padding, respectively. When there is a substantial number of active flows, the Traffic Morphing Module is not needed. The control plane periodically adjusts queue configurations and changes the port max rate limitation to perform strict priority round-robin scheduling in the Schedule Module.

4 Proxy Module

The Proxy Module acts as a secure gateway switch and performs line rate packet header encryption. In this section, we introduce how we design and implement the Proxy Module to reach line rate.

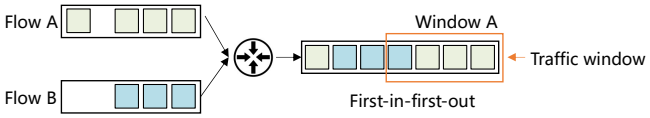
4.1 Choose of cipher

Similar to IPsec gateways, Minos Proxy Module replaces the original source IP of each flow with the public IP of the gateway. Related information (e.g., the original IP header) is encrypted and placed in a new header. Minos is typically used for Website Fingerprinting, IoT Fingerprinting, etc., and the receiver end is often a large service provider. Since these providers commonly deploy technologies such as anycast and CDN with publicly accessible IP addresses, encrypting the destination IP is not necessary. Therefore, Minos encrypts the source IP address and source port to provide identity anonymity.

However, achieving line rate implementation of an encryption algorithm in programmable switches is a challenging task, due to the limited resources and computations of the programmable switches. The selection of cipher should take into account the following aspects. First, the encryption algorithm should exclusively employ computational operations compatible with P4 switches. Asymmetric encryption algorithms that require prime-based computations [22, 38] and resource-intensive symmetric encryption algorithms like IDEA [1] are impractical choices. Second, as Tofino1 programmable switches consist of 12 stages per pipeline and 24 stages in total, the chosen encryption algorithm should be completed within 24 rounds. For instance, implementing a 64-round lightweight cipher TEA [51] on a programmable switch would necessitate multiple pipeline passes, resulting in increased latency overhead. Third, the cipher should utilize as few match action tables as possible to avoid resource contention with other programs.

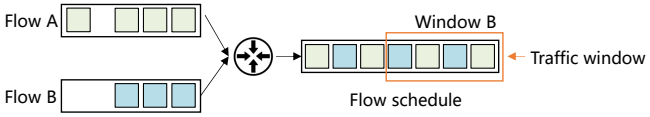
In Minos, we choose PRINCE [7], a low-latency, lightweight SPN-based block cipher as our encryption algorithm on the programmable switch. Figure. 5 shows the basic core encryption process of PRINCE, with one encryption round on each side. PRINCE takes a 64-bit string as input and cuts it into sixteen 4-bit strings. In each encryption round, a 4-bit Sbox maps a 4-bit input to a 4-bit output, which is multiplied with a matrix M and then $XORed$ with a 64-bit RC as well as the key k_1. String-to-string mapping can be easily realized by match-action tables, making Sbox-and-permutation-based ciphers well-suited for programmable switches. Also, PRINCE, with its maximum of 10 encryption rounds (6 or 8 rounds also viable), aligns with typical 12-stage pipelines. Additionally, PRINCE features a α-reflection property, enabling encryption and decryption with the same set of match-action tables.

4.2 Encryption round compression



Although the PRINCE algorithm is well-suited for programmable switches, it cannot be directly implemented on programmable switches due to the limitation of stages. Each encryption round involves a sequence of non-parallelizable operations. Allocating each step of an encryption round to a separate stage would necessitate four stages per round and a total of at least forty stages, exceeding the capacity of a single 12-stage pipeline. To address this limitation, we add k_1 and RC_i together and pre-add the k_1-RC_i to each Sbox in each round to combine the Sbox together with XOR. It's hard to implement the matrix multiplication in the data plane because this computation is not supported in programmable switches. However, we observe that the actual input and output of each 4*4 matrix are four 4-bit strings thus we can combine the matrix multiplication step with the Sbox-xor table by implementing a 4-bit to 4-bit mapping table for each of the 16 4-bit strings.

4.3 Memory Consumption Reduction



The α-reflection feature of PRINCE cipher allows easier implementation on programmable switches. With a 128-bit key k, PRINCE divides it into two 64-bit halves k_0 and k_1, and employs these halves to generate a third 64-bit chunk $k'_0 = (k_0 \ggg 1) \oplus (k_0 \gg 63)$. PRINCE encrypts a packet on the sender switch with k_0, k'_0, k_1 the receiver switch decrypts the packet by encrypting the packet again with $k'_0, k_0, k_1 \oplus \alpha$:

$$D(k_0||k'_0||k_1)(message) = E(k'_0||k_0||k_1 \oplus \alpha)(message), \quad (1)$$

where α is a constant derived from the fraction part of π. Taking advantage of this feature, when implementing Minos on a P4 switch, we employ a single set of keys and match-action tables for both encryption and decryption, effectively reducing the SRAM consumption by half. The match-action tables are determined by key k_1, and the Minos sender switch

(a) An example of IPsec gateways.

(b) An example of Minos flow schedule.

Figure 6: A comparison of IPsec gateway and Minos.

can hold multiple sets of keys to establish encrypted tunnels with different receiver switches by altering k_0, without the need to modify match-action tables. As both ends of the tunnel are trusted, keys can be exchanged and updated by operators through the control plane.

5 Schedule Module

In Minos, the Schedule Module mixes multiple flows by performing dynamic flow scheduling. Figure. 6a illustrates how an IPsec gateway mixes flows. An IPsec gateway mixes packets from multiple flows and sends them out in a first-in-first-out manner, which unavoidably includes consecutive packets from the same flows. Traffic analysis attackers can potentially exploit traffic windows comprising consecutive packets to deduce privacy-related information, such as device types [14,41]. Prior traffic morphing-based defense schemes [9, 10] insert dummy packets between original packets to address this flaw, but at the expense of increased bandwidth and latency overhead.

In Minos, the Schedule Module addresses this with greater efficiency by cleverly exploiting multiple flows, using packets from different flows as dummy packets for one another. As illustrated in Figure 6b, the Schedule Module interleaves packets from flow A and flow B, enabling packets from one flow to act as dummy packets for the other. This innovative scheduling strategy disrupts the attacker's model, significantly reducing its accuracy while providing an effective and lightweight defense mechanism.

The detailed scheduling process of Minos on the data plane is illustrated in Figure. 7. In Minos, our aim is to achieve per-flow scheduling, but the match-action pipeline in a programmable switch typically handles flows on a per-packet basis, lacking consideration for flow states. To enable flow interleaving, maintaining per-flow states becomes essential. In Minos, we address this challenge by utilizing registers within the programmable data plane to store the following flow states:

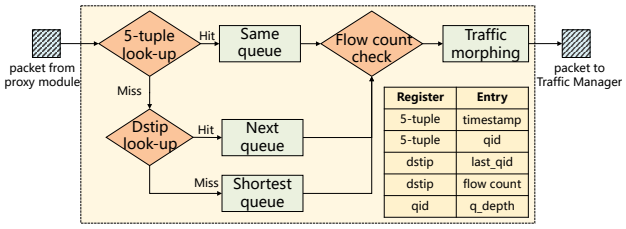


Figure 7: Schedule algorithm of Minos.

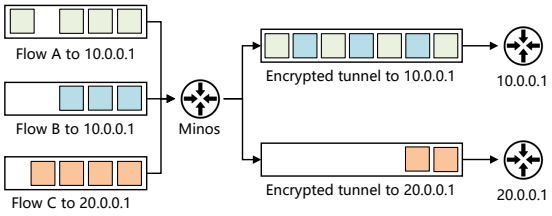

Figure 8: Example of multiple encrypted tunnels.

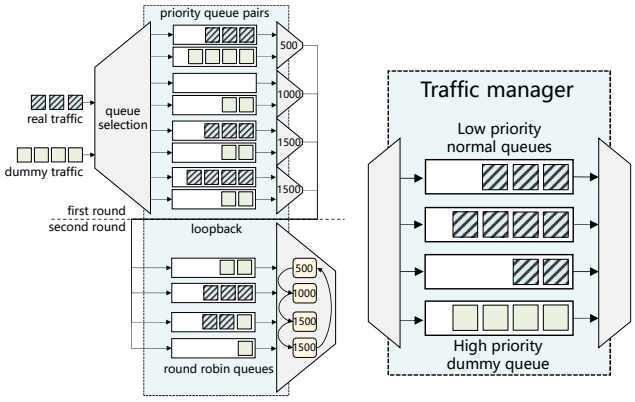
- **Timestamp**. The timestamp for a flow identified by the 5-tuple is stored in the corresponding entry. Upon packet ingress, Minos records the entry timestamp, signifying when the last packet from this flow entered the pipeline. Inactive flow entries are subject to expiration and removal from the register through the recirculation of dummy packets.
- **Queue ID**. The queue ID to which the flow is sent.
- **Flow count**. A Minos sender switch maintains multiple encrypted tunnels with multiple destination IPs, each representing a Minos receiver switch that performs decryption and de-obfuscation. We monitor the number of flows currently transmitting to each destination IP. Figure. 8 shows the scheduling of three flows. Flow A and B are sending to 10.0.0.1, so they will be mixed into an encrypted tunnel to 10.0.0.1. Flow C is sending to 20.0.0.1, so it will be sent into another encrypted tunnel. We assume that passive attackers will eavesdrop on each encrypted tunnel based on sender and receiver Minos switches' IP addresses. Recording flow numbers in each encrypted tunnel helps Minos decide whether traffic morphing is needed.
- The last assignment of the queue ID of each destination IP.

For each packet entering the pipeline, Minos first maps its 5-tuple into the timestamp register and performs a lookup in the queue ID register. If an entry exists, it means that previous packets of this flow have been sent into a specific queue so that the following packets should be sent through the same queue to avoid packet reordering. If no entry is found, it means

the packet is initializing a new flow. Then, the 5-tuple will be matched in the destination IP register. If an entry is found in the destination IP register, the flow will be assigned to the next queue based on the recorded queue ID. This new flow's queue ID will be the origin queue ID plus one. In this way, flows in the same encrypted tunnel will be evenly spread into different queues and scheduled in a round-robin manner, just like Flow A and B in Figure. 8. If the destination IP is not found, it means that we are building a new encrypted tunnel and no restrictions are applied to this flow. In this case, the flow will be sent into the shortest queue to balance queue length.

The flow count table keeps track of the number of flows sent to each destination to decide whether the Traffic Morphing Module should be activated. When the number of flows in an encrypted tunnel is very small, a mixture of these flows is insufficient to conceal their information effectively. Moreover, when only a few flows are active, the Schedule Module may encounter the problem of asymmetric flow interleaving, where one flow sends significantly more packets than others, resulting in consecutive packets from the same flow. This could potentially expose features from the aggregated flow to traffic analysis attackers. In such cases, the Traffic Morphing Module will perform dummy packet insertion to supplement packets for flow mixing. Besides, it will also conduct packet padding to further obfuscate flows. The flow count table is regularly checked to decide whether to invoke the Traffic Morphing Module to make sure sufficient protection is always in place. In the Schedule Module, we only track the target flows that require defenses, rather than recording every incoming flow. For detailed implementation, please refer to Section 7.1.



6 Traffic Morphing Module

The Traffic Morphing Module performs dummy packet insertion and packet padding to implement traffic morphing. In this section, we introduce how we implement the Dummy Module and the Padding Module in a lightweight manner.

6.1 Dummy Module
