      updateContext(e.context.total_credit, credit);
      e.eventType = Send;
    }else{
      e.eventType = LoopBack;
    }
    postEvent(&e);  /* Write the event to CSR */
  }
}
/* Program running in the RX CC cores*/
int recv(){
  Event e;
  int credit;
  while(true){
    pollEventSync(&e);
    /* Update the credit when receiving an ACK */
    if(e.packet.opcode == ACK){
      credit = e.context.total_credit + e.packet.returned_credit;
      updateContext(e.context.total_credit, credit);
      e.eventType = Done;
    /* Send a ACK when receiving a WRITE_REQ or READ_RESP */
    }else{
      updatePkt(e.packet.returned_credit, e.packet.pktLength);
      updatePkt(e.packet.opcode, ACK);
      e.eventType = GenTxEvent;
    }
    postEvent(&e);
  }
}
```

Listing 1: An example of programming with SwCC.

Next, we show how to implement the CCA using the provided programming interfaces. Before writing CC controller logic, the developer has to complete three definitions. First, the developer has to define the variable `TracedPkts`

Function	Parameters	Description
pollEventSync (`&Event`)	The `Event` containing the `PKTHeader`, `QPContext` and `EventType`	Busy polling for the arrival of new packet, then read the `PKTHeader` and `QPContext` from the CSR into the `Event`.
updatePkt (`packet.item`, `item`)	An item in the `PKTHeader` (`packet.item`), A variable (`item`) to update the item in the `PKTHeader`	Update the `packet.item` in the `PKTHeader` using `item`
updateContext (`context.item`, `item`)	An item in the `QPContext` (`context.item`), A variable (`item`) to update the item in the `QPContext`	Update the `context.item` in the `QPContext` using `item`
postEvent (`&Event`)	The `Event` containing the `PKTHeader`, `QPContext` and `EventType`	Write the `Event` into the CSR, then notify the hardware engine that packet processing is complete

Table 2: SwCC programming APIs for implementing CCAs.

(Line 2), and this value can tell the "Packet Filter" hardware to only generate RX events when receiving ACK-/RDMA_WRITE_REQ/RDMA_READ_RESP packets. Second, the developer has to define the `returned_credits` field as an extensible CC header in the structure `PktHeader` (Line 9), and this field is used to store the returned credits in the ACK packets. Third, the developer has to define the field `total_credit` field in the QP context table (Line 13), and this field is used to store the remaining credits of each QP. After that, the developer can write the RX function and TX function.

In the TX path, the TX CC core first polls send packet requests in the send request FIFO (Line 21). After polling a request, the TX CC core checks whether the remaining credit is larger than the requested packet size (Line 23). If so, the TX CC core decreases the total credit accordingly (Lines 24-25) and marks the request with `Send`, indicating that this send packet request is granted (Line 26). Otherwise, the TX CC core marks the request with `LOOPBACK` which indicates that the request should be pushed back into the send request FIFO (Lines 28). At last, the TX CC core posts the event and notifies the NIC hardware (Line 30).

In the RX path, the RX CC core polls the event FIFO (Line 38). After polling an event, the RX CC core checks whether the received packet is an ACK packet (Line 40). If so, the RX CC core increases the total credits by the value of the `returned_credit` field in the extensible CC header (Lines 41-42), and then marks the event with `Done` (Line 43), indicating that NIC hardware does not need to do extra work. Otherwise, we should generate an ACK for the received packet (`RDMA WRITE_REQ` or `RDMA READ_RESP`). In this case, the RX CC core marks the event with `GenTxEvent` (Line 48) and sets the `returned_credit` field in the extensible QP context as the received packet length (Line 46). At last, the RX CC core posts the event and notifies the NIC hardware.

In summary, SwCC provides programmers with easy-to-use programming abstractions. As such, SwCC allows developers to focus on the CCA logic instead of dealing with low-level NIC hardware interactions.

5 Evaluations

Our evaluations aim to answer the following questions:

- How does the control loop delay of SwCC compare to that of RoCE and Soft-RoCE (§5.2)?
- How much frequency can the TX/RX separated multi-core increase (§5.3)?
- How effective is the QP-aware memory subsystem (§5.4)?
- How are the flexibility and programmability of SwCC (§5.5)?
- How many resources do the SwCC use (§5.6)?
- How does the end-to-end performance of SwCC compare to that of ASIC-based NIC CC solutions (§5.7.1) and CPU-based CC solutions (§5.7.2)?

5.1 Experimental Setup

Experimental platform. The experimental platform consists of three servers, connected with a Wedge100BF-32X P4 reconfigurable switch. Each server is equipped with two Intel Xeon Silver 4214 CPUs @2.20GHz, 256GiB 2400MHz DDR4 memory, a Xilinx U280 FPGA, and a Mellanox ConnectX-5 NIC.

SwCC implementations. We prototype "SwCC" in Xilinx Alveo U280 FPGA (6K LoCs of Chisel3). SwCC mainly reuses the PCIe and CMAC modules of FpgaNIC [77]. There are mainly three extensions. First, we replace FpgaNIC's TCP/IP transport with our RoCEv2 implementation. Second, we place several RISC-V cores in the NIC, which are positioned between the transport layer and the PCIe module. The RISC-V cores use the open-source *riscvmini* core [15], features a simple 3-stage pipeline. We mainly modify the cache/memory subsystem and the interface to the hardware. Third, we propose a QP-aware memory subsystem and related hardware logic that serves the RISC-V cores to minimize data/packet access time during CCA processing.

The SwCC logic runs at 250 MHz. We implement five CCAs (DCQCN [88], TIMELY [55], HPCC [42], Swift [40], Homa [57]) in the SwCC.

RoCE Baseline. The ASIC-based NIC CC solution baseline, labeled "RoCE", runs traffic on the Mellanox ConnectX-5 NIC. We use MLNX_OFED 23.1 driver and enable DCQCN in the server.

Soft-RoCE Baseline. We implement CPU-based CC solution baseline, labeled "Soft-RoCE", based on Soft-RoCE [62]. We implement DCQCN (100 LoCs of C++), TIMELY (70 LoCs of C++) and HPCC (110 LoCs of C++) by referring to [42, 55, 88].

RDMA-HLS Baseline. The FPGA-based 100Gb RoCEv2 stack [74] baseline used in [68–70], labeled "RDMA-HLS", runs traffic on the Xilinx Alveo U280 FPGA. We implement DCQCN in the stack using HDL.

BF3 Baseline. We implement baseline "BF3" that uses PCC

in SoC SmartNIC Bluefield-3 [60] to implement DCQCN.

Parameter Setting. We implement DCQCN, TIMELY, and HPCC using SwCC and Soft-RoCE. In the two implementations, we use the same parameters except those related to RTT, which we configure according to the actual measurements from SwCC and Soft-RoCE. For DCQCN, we set K_{min} = $5KB$, K_{max} = $200KB$, P_{max} = 1% and $g = 1/256$ following the default parameter setting in [88]. For TIMELY, we set α = 0.875 and β = 0.8, as suggested in [55]. For HPCC, we set η = 0.95 and *maxStage* = 5, as suggested in [42].

5.2 Comparison of Control Loop Delay

We first measure the RTT control loop delay of `RDMA WRITE` with a packet size of 1 KB. Figure 7 illustrates the results. We have two observations.

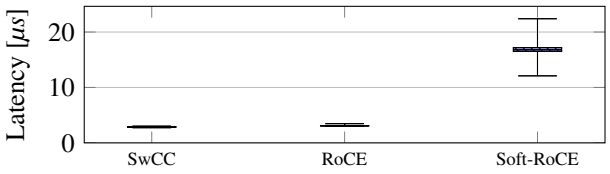

Figure 7: Control loop delay comparison. Whiskers show the 1st and 99th percentile.

First, both SwCC and RoCE achieve a similar average control loop delay of approximately 3.1 μs. This is because both approaches offload the CC controller to the NIC, avoiding additional PCIe traversals and software overhead. Second, Soft-RoCE exhibits significantly higher and more variable latency compared to SwCC and RoCE. Soft-RoCE runs the CC controller on the CPU software, which introduces PCIe traversals along with overheads from data copying, and kernel switching, resulting in a longer and less stable control loop delay. The SwCC design would not increase the control loop delay and can have nearly the same control loop delay as the ASIC-based solution.

5.3 Effect of TX/RX Separated Multi-Core

We then validate the effectiveness of TX/RX Separated Multi-Core by measuring the maximum frequency and the throughput of SwCC.

Figure 8 shows the FPGA routing with/without the TX/RX separated multi-core (two cores for both implementations). We observe that the TX/RX separated multi-core has much less (50%) routing wire from/to the CC cores. This is because the TX/RX separated multi-core allows a single core to connect to only a subset of NIC resources as a core only needs to process TX or RX logic.

The reduced routing wire can help to increase the achieved design frequency. Figure 9 shows the achieved frequency with/without TX/RX separated multi-core, under different numbers of RISC-V cores[3] with Vivado default implementation strategy. We observe that TX/RX separated multi-core can increase the achieved frequency by up to 16%. This is because TX/RX separated multi-core reduces the routing wire to/from the CC cores.

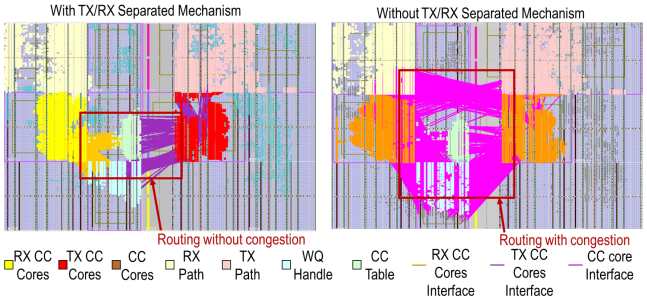

Figure 8: Comparison of routing with/without functional separation mechanism. "congestion" indicates the routing resource contention for circuits as the number of required routing wires increases.

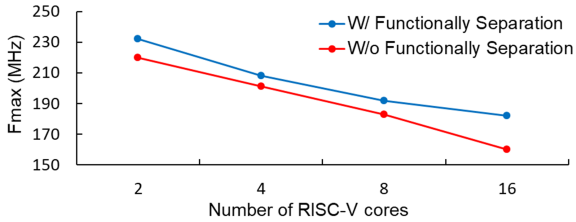

Figure 9: Comparison of the assessed F_{max} with/without TX/RX separation mechanism.

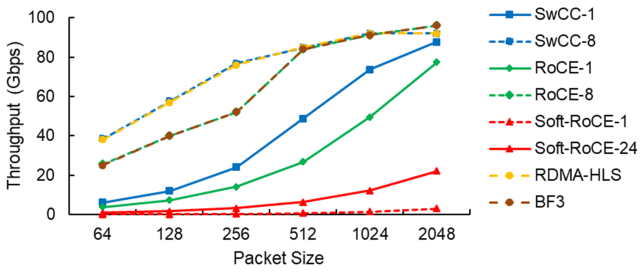
Effect of Core Number. We evaluate the effect of core number, by comparing the throughput of `RDMA WRITE`.

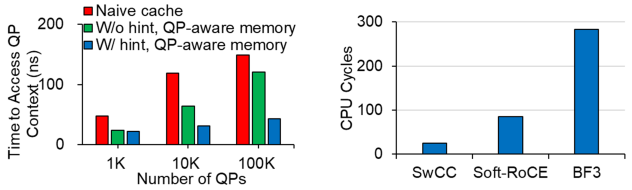
Figure 10 demonstrates the throughput of different RDMA implementations under different packet sizes.[4] The "SwCC-n" means that SwCC instantiates *n* "RX CC" cores and n "TX CC" cores. The "RoCE-n" means the utilization of n PUs in the CX-5 NIC. There are only 8 PUs in the CX-5 NIC, so "RoCE-8" has reached the maximum throughput of the CX-5 NIC [65]. The "Soft-RoCE-n" means the use of n threads in the CPU to run Soft-RoCE. The CPU in our testbed supports up to 24 hardware threads and we use up to 24 threads in Soft-RoCE.

We have three observations. First, SwCC can achieve comparable throughput to that of commercial NICs. "SwCC-8" and "RoCE-8" both achieve line rates with packet sizes above 512B. The throughput of "SwCC-1" is 1.1-1.5 times that of "RoCE-1". This is because SwCC uses two RISC-V cores (a "TX CC" and a "RX CC") to handle a single flow, while the CX-5 NIC uses only one PU to process a flow. Second, the throughput of Soft-RoCE is much lower than the other two implementations. Even with 24 threads in "Soft-RoCE-24", Soft-RoCE only achieves around 24Gbps throughput. This

[3]The calculation method is: F_{max} (MHz) = max(1000/(T - WNS)), where T is the target clock period (ns) and WNS is the worst negative slack (ns) of the target clock [3].

[4]Except for "RoCE-1", which uses a single QP, all other approaches utilize 24 QPs. This is because the CX5 NIC can only control the number of PUs (processing units) used by adjusting the number of QPs. Additionally, all approaches, except RDMA-HLS, enable DCQCN for CC.





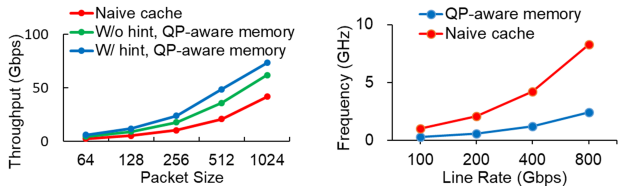


Figure 10: Comparison of throughput for various approaches using different numbers of cores/units/threads.

(a) Average time to access QP context.

(b) The cycles of CC controller.

(c) The `RDMA WRITE` throughput of SwCC.

(d) The frequency required to achieve various line rates.

Figure 11: The effect of QP-aware memory subsystem.

is because of the inefficiencies in the kernel network stack caused by data copying from the kernel to application buffers, kernel switching, etc [10]. Third, "SwCC" and "RDMA-HLS" achieve nearly identical performance as both run on FPGA-based SmartNICs. Likewise, "BF3" and "RoCE" deliver comparable performance because they use the same hardware network card.

5.4 Effect of QP-aware Memory Subsystem

We examine the effect of the QP-aware memory subsystem by comparing the CC core's access time to the QP context, CC controller execution cycles and throughput of `RDMA WRITE`. The size of QP context table is 128 KB, "w/o hint" and "w/ hint" indicate whether the QPN hint interface is used for the QP-aware memory subsystem. We also implement a naive memory subsystem, which includes a 4-way associative cache with a cache line size of 64B, and the size of cache is 128 KB, labeled "naive cache".

Time to Access QP Context. We establish 1K, 10K, and 100K QPs on two servers. The sender randomly selects a QP from these QPs with a uniform probability of initiating an `RDMA WRITE` request. We send 100M requests with each carrying a 1KB message and measure the time to access the QP context on the RISC-V core.

Figure 11a illustrates the average QP context access time for different approaches with different numbers of network flows. We observe that, regardless of the number of network flows running, QP-aware memory reduces memory access time by at least 50% compared to naive cache. When the number of QPs is 1K, the QP context is fully cached, the naive cache requires multiple load/store instructions to move the QP context into the registers, leading to additional delays. When the QP context is not fully cached, QP-aware memory can leverage its hint interface to prefetch the QP context, further reducing access time. As the number of QPs increases, the performance of SwCC remains nearly constant.

Execution Cycles. Figure 11b shows the cycles of different baselines for the CC controller running DCQCN. We have two observations. First, "Soft-RoCE" runs on the CPU and uses a naive memory system, and thus requires approximately 3× the cycles of "SwCC". Second, "BF3", significantly increases the total execution cycles, reaching 11.4× that of "SwCC". It is mainly due to BlueField-3's poor DPA memory subsystem.

Throughput. We compare the network throughput with naive cache and QP-aware memory under different packet sizes. We instantiated 1 pair of CC cores in SwCC, and we set the number of network flows to 100K. Each flow sends 1K `RDMA WRITE` requests with each carrying a 1 KB message.

As shown in Figure 11c, when one pair of CC cores is instantiated in SwCC, the QP-aware memory significantly impacts throughput. The throughput of the naive cache is approximately 40% of that of the QP-aware memory with small packets. This is because, in this case, the throughput bottleneck of the SwCC core lies in the CC core, where excessive CPU cycles are required to process each event, resulting in low throughput. Therefore, reducing the number of CPU cycles required by the CC core to process events can effectively increase the throughput of SwCC.

Potential ASIC Design. SwCC currently targets an FPGA-based SmartNIC, however, because it comprises fixed components and RISC-V cores, it readily supports an ASIC design, which offers higher clock frequencies and more efficient hardware resource utilization. We use simulations to estimate the processor frequency required to achieve line rate under a single QP with different memory subsystems, setting the RDMA message size to 1 KB. As shown in Figure 11d, naive cache requires up to 8 GHz to reach an 800 Gbps line rate, whereas QP-aware memory needs only 2.4 GHz, which is more realistic to achieve. This outcome demonstrates SwCC's potential for ultra-high-speed networks.

Regarding the power consumption of the ASIC design, we can compare SwCC with RISC-V cores in commercial SmartNICs. The BlueField-3 SmartNIC features a 1.8 GHz, 16-core/256-thread RISC-V core, with total NIC power consumption at 66 W. Since SwCC employs only a simple in-order, 3-stage 2-core RISC-V design at 2.4 GHz, we believe its projected power consumption to be reasonable for a NIC.

Table 3: C code lines for implementing various CCAs in SwCC.

CCA	CC Signal	Triggering Event	Adjustment Strategy	C code (lines)
DCQCN	ECN	CNP, DATA, Timer	rate	140
TIMELY	timestamp	ACK	rate	102
HPCC	INT	ACK	wnd	148
Swift	timestamp	ACK	wnd	164
Homa	token	DATA, GRANT, RESEND, BUSY	credit	95

Table 4: FPGA resource consumption.

Name	LUTs (K)	REGs (K)	BRAMs	URAMs
RDMA-HLS	26 (2%)	65(2.5%)	130 (6.4%)	0 (0%)
SwCC-1	51 (3.9%)	62 (2.4%)	220 (11%)	4 (0.4%)
SwCC-8	112 (8.6%)	124 (4.8%)	220 (11%)	32 (3.3%)
CC Core	8 (0.6%)	4 (0.2%)	0 (0%)	2 (0.2%)
QP-aware Memory	2.5 (0.2%)	0.5 (0.1%)	114 (5.6%)	0 (0%)

5.5 Flexible User-Defined CC Framework

Based on SwCC, we implement five representative CCAs that 1) use different CC signals, 2) trigger the CC controller at different times, and 3) adjust data transmission differently. Table 3 shows 1) what CC signals these CCAs use, 2) what types of packets trigger the CC controller when received by these CCAs, 3) which kind of data transmission strategies these CCAs use, and 4) lines of C code to implement these CCAs. We have two observations. First, SwCC supports a broad range of CCAs. SwCC achieves its design goal of high flexibility. Second, regardless of the algorithm, each can be implemented in less than 200 lines of code. This is because SwCC allows developers to focus on the CCA logic without dealing with complex hardware details. SwCC achieves its design goal of high programmability.

5.6 Hardware Resource Usage

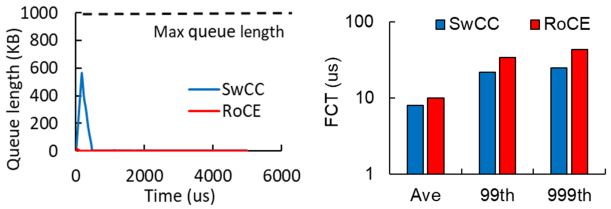

Table 4 shows the FPGA resource consumption of "RDMA-HLS" and "SwCC". "SwCC-1" requires the instantiation of RISC-V cores and supports extended CC headers of various lengths. Consequently, it utilizes slightly more resources compared to "RDMA-HLS". "SwCC-8", which instantiates 16 RISC-V cores, consumes approximately twice the hardware resources of "SwCC-1". Despite the increased resource usage, it only occupies under 10% resources, leaving ample capacity for other functionality.

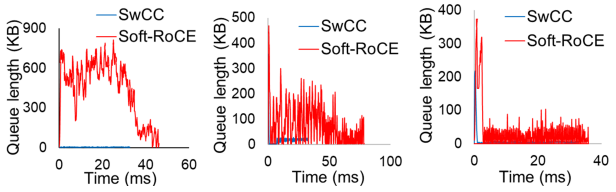
5.7 End-to-End Performance

We compare "SwCC", "RoCE", and "SoftRoCE" to evaluate the end-to-end performance of "SwCC". We compare "SwCC" and "RoCE" on a 100Gbps network. The comparison between "SwCC" and "Soft-RoCE" is conducted on a 10Gbps network because "Soft-RoCE" cannot reach a line rate of 100Gbps.



5.7.1 SwCC vs. RoCE

In the experiment, we use three servers, two as senders and one as a receiver. Each of two senders starts 5 flows to the receiver, where each flow sends 2K messages, each with a size of 2 KB. We implement the DCQCN algorithm in SwCC,

(a) Queue length (b) FCT

Figure 12: The end-to-end performance comparison of SwCC and RoCE.

(a) TIMELY (b) DCQCN (c) HPCC

Figure 13: Comparison of buffer occupancy at the congested port of the switch under various CCAs.

labeled "SwCC". We set the period of CNP generation in DCQCN as 50 μs, and the period of updating α as 55 μs, which follows the parameter setting in [88].

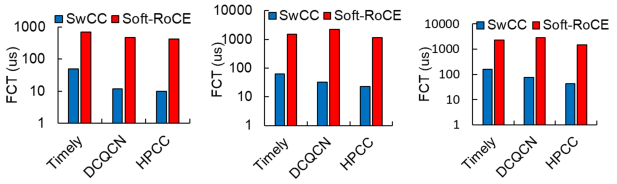


Figure 12 shows the buffer occupancy comparison and flow completion time. We observe that when the CX-5 NIC detects congestion in the "RoCE" baseline, it halts data transmission for approximately 90 μs. In contrast, SwCC's implementation of the DCQCN algorithm adjusts the transmission rate based on work [88]. Consequently, the buffer occupancy of "RoCE" drains more quickly than that of "SwCC", but it still remains significantly below the switch's maximum queue length. Additionally, the halt in transmission results in a slightly longer FCT for "RoCE" compared to "SwCC". In the absence of publicly available details of the NIC's CCAs, we can not devise an identical algorithm. In sum, "SwCC" delivers slightly better performance than "RoCE".

5.7.2 SwCC vs. Soft-RoCE

We implement the DCQCN, TIMELY, and HPCC in SwCC and Soft-RoCE, with the same settings as Section 5.7.1. In our testbed, the RTT is approximately 5 µs for SwCC and 30 µs for Soft-RoCE, respectively.

Figure 13 shows the switch buffer occupancy comparison under different algorithms for SwCC and Soft-RoCE during congestion. We observe that SwCC alleviates congestion more rapidly under different levels of network congestion. This is due to SwCC's shorter control loop, which increases its sensitivity to congestion, allowing it to respond more quickly and effectively mitigate network congestion.

Figure 14 shows the comparison of FCT under different algorithms for SwCC and Soft-RoCE during congestion. We observe that when implementing the TIMELY, DCQCN, and HPCC CCAs, the FCT of Soft-RoCE is 14×, 39×, and 42× higher than that of SwCC respectively. This is mainly because

(a) Average (b) 99th percentile (c) 999th percentile

Figure 14: Comparing of FCT statistics for SwCC and Soft-RoCE under various CCAs.

SwCC has a much lower control loop delay than Soft-RoCE.

6 Related Work

ASIC-based NIC CC solution. Some NICs offload the network stacks with hard-wired transport protocols [9, 35, 53]. However, they only implement at most two types of congestion control, including PFC [32] and DCQCN [61], and can only be modified by their vendor.

CPU-based CC solution. The "pluggable TCP" API [37] and QUIC [41] support user-space programming of congestion control. However, they do not bypass the kernel, resulting in poor performance. Kernel bypass libraries such as DPDK [16], netmap [67] and Snap [46] allow programs to send packets from userspace to the NIC. The mTCP [38] implements NewReno [18] on DPDK. Google deploys Swift [40] and 1RMA [71] on Snap. However, Snap's RTT latency for a single-sided operation is 8.8 µs, which is 2.8 × higher than the control loop latency of ASIC-based NICs.

FPGA-based SmartNIC CC solution. The emergence of FPGA-based SmartNICs [12, 30, 31, 70, 84, 85, 89] has made programmable CC on NICs feasible. Prior works [4, 5] enable programmers to implement a variety of transport protocols in hardware by Verilog or P4 language. However, the HDL offers low programmability. Some works [26, 64] implement rate-based CCAs using packet pacing, but they do not provide a programmable interface.

SoC-based SmartNIC system. Prior works [17, 23, 39, 43, 45, 72, 78, 79, 83] propose the frameworks or systems on SoC-based SmartNIC to alleviate the host CPU pressure. None of these works address the issue of a programmable CC controller. Many vendors [36, 58, 60, 80] have developed SoC-based SmartNICs that incorporate CPUs and network acceleration hardware. However, only a few of these SmartNICs [63] feature dedicated programmable congestion control interfaces, and their flexibility remains limited.

7 Conclusion

This paper presents SwCC, an RDMA engine integrated with a RISC-V processor that enables the execution of a wide range of CCAs directly on the RISC-V core, while keeping high performance. SwCC achieves an end-to-end control loop delay of 3 µs, which is comparable to that of leading commercial NICs while providing high flexibility and programmability for CCA development. The ASIC design of SwCC can easily scale to higher network bandwidth.

A Artifact Appendix

A.1 Abstract

This artifact provides the source code of SwCC and scripts to reproduce the main experimental results. The experiments are run on two 4U AMAX servers, each equipped with two Intel Xeon Silver 4214 CPUs@2.2GHz, 256GB DDR4 memory, a Xilinx U280 FPGA, a ConnectX-5 NIC. SwCC is implemented on Xilinx Alveo cards U280 with Vivado 2020.1.

A.2 Artifact check-list

- **Program:** C/C++
- **Compilation:** g++-11.3.0, gcc-11.3.30
- **Run-time environment:** QDMA driver installed
- **Hardware:** Xilinx Alveo U280
- **Execution:** Running commands as root with sudo
- **Metrics:** control loop delay and the throughput for various approaches using different numbers of cores/units/threads
- **Output:** Experiments produce outputs in the console or bin files
- **Experiments:** a) Control loop delay comparison between SwCC, RoCE and Soft-RoCE, b) Throughput comparisons between SwCC-1, SwCC-8, RoCE-1, RoCE-8, Soft-RoCE-1 and Soft-RoCE-24
- **Disk space required:** 1GB
- **Time needed to prepare workflow:** 1 hour
- **Time needed to complete the experiments:** 3 hours
- **Publicly available:** Yes
- **Code licenses:** MIT
- **Data licenses:** MIT

A.3 Description

A.3.1 How to access

The codebase can be accessed from GitHub https://github.com/RC4ML/SwCC.git.

A.4 Installation

Use the following commands to clone the SwCC repository, install the necessary tools and build binary programs.

```
git clone --recursive https://github.com/RC4ML/SwCC.git

## Install QDMA driver
cd qdma_driver
make
sudo insmod /path/to/qdma_driver/src/qdma-pf.ko
echo '1024' | sudo tee -a
     /sys/bus/pci/devices/0000:1a:00.0/qdma/qmax
sudo dma-ctl qdma1a000 q add idx 0 mode st dir bi
sudo dma-ctl qdma1a000 q start idx 0 dir bi desc_bypass_en
     pfetch_bypass_en

## Install MLNX_OFED
wget https://content.mellanox.com/ofed/MLNX_OFED
```

```
-23.04-1.1.3.0/MLNX_OFED_LINUX-23.04-1.1.3.0
-ubuntu18.04-x86_64.tgz -O mlnx.tgz
tar -zxvf ./mlnx.tgz
cd mlnx && sudo ./ofedinstall

## build SwCC programs
mkdir SwCC/build
cd SwCC/build
cmake ..
make

## Build baseline software
mkdir Baseline/libr/build
cd Baseline/libr/build
cmake ..
make

## After completing the RoCE experiments, follow these steps to
     prepare for the Soft-RoCE experiments
### Uninstall MLNX_OFED
cd ~/MLNX_OFED_LINUX-23.04-1.1.3.0-ubuntu18.04-x86_64/
sudo ./uninstall.sh
sudo reboot

### Load kernel modules and install required libs
sudo modprobe ib_core
sudo modprobe ip6_udp_tunnel
sudo modprobe udp_tunnel
sudo modprobe ib_uverbs
sudo depmod -a
cd ~/SwCC/Baseline/rxe/
make -j
sudo insmod ./rdma_rxe.ko
sudo apt install librdmacm-dev libibverbs-dev libibumad-dev
     libpci-dev

### Environment setup in atc25@r4:
sudo rdma link add sr4 type rxe netdev enp62s0np0
sudo ifconfig enp62s0np0 mtu 9000 up
sudo service irqbalance stop

### Environment setup in atc25@r3:
sudo rdma link add sr3 type rxe netdev enp28s0np0
sudo ifconfig enp28s0np0 mtu 9000 up
sudo service irqbalance stop
```

A.5 Experiment workflow

We provide three machines for artifact evaluation: a **Sender**(atc@r4), a **Receiver**(atc@r3), and a **Vivado machine**(atc@max). Both the **Sender** and the **Receiver** are equiped with a Xilinx U280 FPGA and a ConnectX-5 NIC machine. The **Sender** and the **Receiver** are used for the experiment, and the **Vivado machine** is used for deploying bitstream.

You can refer to our GitHub repo to see how to connect and deploy bitstream on FPGA. Please reboot the FPGA machine after programming the FPGA. And then you can run the SwCC experiment on the FPGA machine.

A.6 Evaluation and expected results

We use the control loop delay experiment of SwCC as an example, you can find other evaluations in our GitHub repo.

A.6.1 Run the control loop delay experiment

Program **bistream/SwCC-1.bit** to the FPGA on both the sender and receiver, and after reboot the machines, run the following command to start the experiment:

```
## On the Receiver:
sudo SwCC/build/example/latency_receiver
## On the Sender:
sudo SwCC/build/example/latency_sender
```

Then the Receiver and Sender display the messages.

```
## On the Receiver:
After both the sender and receiver programs are started, enter
     any value to launch the receiver:
## On the Sender:
After the receiver is launched, enter any value to begin the
     latency test.
```

Entering any value in the Receiver, then entering any value in the Sender. The output will be like this:

```
5th percentile: 3096 ns
25th percentile: 3168 ns
50th percentile (median): 3168 ns
75th percentile: 3168 ns
95th percentile: 3168 ns
```

A.7 Notes

Before running Soft-RoCE experiments, it is necessary to uninstall MLNX_OFED and configure the Soft-RoCE environment. Therefore, we strongly recommend completing all RoCE-related experiments before proceeding with Soft-RoCE experiments.

DRack: A CXL-Disaggregated Rack Architecture to Boost Inter-Rack Communication

Abstract

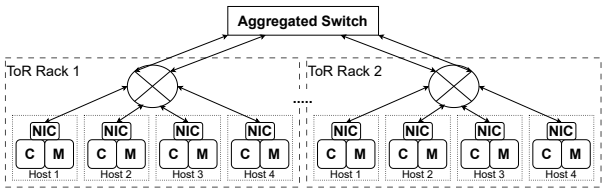
Data-intensive applications are scaling out across more and more racks, and boosted with advanced computing units with enhanced throughput, which necessitates increased NIC capacity and network bandwidth to transport inter-rack traffic. As a result, when running them over ToR-centric racks, inter-rack traffic can be bottlenecked at host NICs and core network due to oversubscription. However, we observe that, although a large volume of inter-rack traffic exists, the utilization of the host's NICs within a rack remains low. If those underutilized NICs within a rack can be utilized by any host, inter-rack communication can be accelerated. Therefore, we propose DRack. At its core, DRack disaggregates all NICs within a rack from their hosts, forming a shared NIC pool. As the local memory bandwidth or the PCIe link at a host is much smaller than the NIC pool capacity, the host cannot fully utilize the NIC pool. DRack also disaggregates memory devices within a rack from their hosts, so that data from the NIC pool can be written and read from multiple memory with full capacity, while host processors can directly access the memory pool with memory semantics. We realize DRack with CXL as it supports device pooling and memory semantics, which is well-suited to our designs. We have implemented DRack prototype and evaluated it with real applications, such as DNN training and graph processing. The result shows that DRack can reduce the communication stage by an average of 37.3% compared to ToR-centric rack.

1 Introduction

Today's production clouds organize hosts in ToR-centric racks. Each rack hosts tens of hosts connected via a Top-of-Rack (ToR) switch and is linked to the network core. Data-intensive applications running in those clouds, such as graph computing [1], data analytics [2], and deep neural network (DNN) training [3] often operate with Bulk Synchronous Parallel (BSP) [4] or MapReduce paradigms [2], generally involving computation stage and communication stages (*e.g.*, data shuffling and synchronization). They tend to scale the job out across more and more racks for acceleration, resulting in a large volume of across-rack traffic. As measured by Facebook during 24 hours [5], an average of 87.1% of network traffic in their datacenter needs to go out of the rack. Moreover, recent innovations on processors and domain-specific accelerators, such as GPUs [6, 7], and FPGAs [8], have significantly enhanced computing throughput, which necessitates increased NIC capacity and network bandwidth to accommodate. Thus, the two trends result in communication bottlenecks for inter-rack communication, including NIC egress/ingress port, and core network bottleneck due to oversubscription that is predominant in datacenter networks (DCN) (§2.1) .

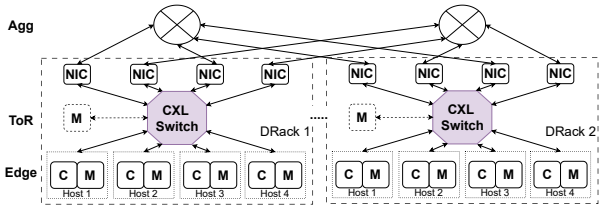
We can address these bottlenecks intuitively with a brute-force approach, by overprovisioning NICs for every hosts [9–11], or switching equipments [10]. It is cost-prohibitive in terms of power consumption and hardware expenses. Another line [12–14] adds reconfigurable hardware to provide extra bandwidth between the intensively communicating racks, or to enable a reconfigurable network that changes its topology to adapt dynamic inter-rack traffic volume. However, they are limited by reconfiguration delay and complexity, and face challenges in predicting inter-rack traffic pattern that is bursty and highly dynamic [5]. Last, some job schedulers [15–20] reduce inter-rack traffic by scheduling jobs based on predictable features, *e.g.*, the data volume to send, which is hard to predict for existing data-intensive applications (see §2.3).

By studying the traffic trace from Facebook [5] and running real-world applications in our cluster, we find, *although a large volume of inter-rack traffic prevails [12], the hosts NIC utilization within a rack remains low (for both ingress and egress)*. The reason can be two-fold: 1) there is no network traffic during job computing stages and the traffic volume to send/receive during communication is highly skewed between hosts; 2) each job has its resource requirement and emphasis, resulting in resource fragmentation, *e.g.*, non-distributed DNN training jobs leave the NICs unused [21].



Inspired, a natural direction to explore is, *if those underutilized NICs from other hosts within a rack can be borrowed, could inter-rack communication be accelerated?* Therefore, we propose Disaggregated Rack (DRack), a new rack architec-

ture concept with the following three key designs. ① DRack disaggregates all the NICs of existing hosts to form a rack-level NIC pool which can be used by any host to accelerate its inter-rack traffic. However, maximizing the utilization of NIC pool capacity poses a challenge. This is because, when writing the data from the NIC pool to the memory of destined hosts, the NIC pool's capacity can surpass the bandwidth of the PCIe links at the destined hosts, or the total memory bandwidth of their local memory, given the number of communicating hosts is small. Thus, ② DRack also disaggregates local memory from hosts, forming a rack-level memory pool with an aggregated bandwidth exceeding the capacity of the NIC pool, so that data can be written/read to/from multiple memory devices from the NIC pool with the full capacity. ③ DRack allows host processors or accelerators (*e.g.*, CPU) to load and store the memory pool with memory semantics during computation, without moving data to their local memory first with DMA. This approach contrasts with prior works that relied on PCIe for device pooling [22–24].



To realize the above three key designs, we find that CXL is a perfect fit due to the following facts: 1) CXL 2.0 [25] supports memory and IO device pooling with CXL switches which are responsible for routing and address remapping when the host is accessing any device attached to it. Consequently, CXL 3.0 enhances it by proposing CXL fabric, which is an interconnect that supports rack-level resource polling (designs ① and ②). 2) CXL supports memory semantics (CXL.mem), which enables hosts to load and store the memory pool directly throughout the computation stage (③).

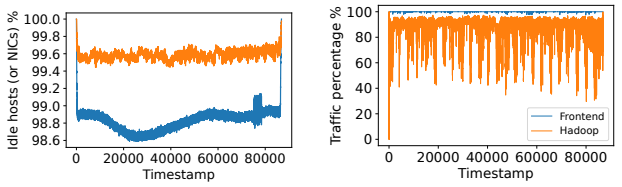
By doing so, DRack alleviates the bottlenecks in the inter-rack communication when running over the ToR-centric architecture, and its new architecture complements existing job scheduling algorithms with a better communication efficiency [26, 27]. Compared to prior architectures, DRack is static without the complexity of reconfigurability and traffic prediction, and does not add more hardware for more bandwidth across racks, while DRack can be flexible and scalable by simply attaching more memory/NIC devices to the CXL interconnect.

We still face several challenges in porting real applications/jobs and ensuring DRack efficiency (see §2.4). For example, CXL.mem load/store to remote memory (in other hosts) exhibits higher latency than accessing the local memory, which could impact the computation efficiency. We solved them and implemented a full functional DRack prototype with 8 customized MPSoC FPGAs and one server connected by optical fibers, instead of using simulator and NUMA nodes in prior works [28–31], enabling running different applications transparently on DRack with various (CXL) bandwidth and latency configurations. We realized CXL 3.0-like memory protocols, such as CXL.mem and CXL.io, atop an academia lightweight conceptual hardware protocol stack [32]. We evaluated DRack with both microbenchmarks, real data-intensive applications, such as DNN training, graph processing, and KV store, and user cases like job scheduling, and show that DRack reduces the communication time by an average of 37.3% compared to the conventional ToR-based rack. DRack also achieves 62.2% lower p99 tail latency when running latency-sensitive applications, *e.g.*, Redis.

(a) Conventional Rack-centric architecture.

(b) DRack: a logical shared memory and NIC pool

Figure 1: The architectural comparison between two racks. CPU (c), Memory (M).



2 Background and Motivations

In this section, we first elucidate the reason why inter-rack communication is prevalent and inevitable in conventional rack-centric datacenter networks (DCN), and why it is critical to the performance of data-intensive applications. Second, we review prior approaches aimed at enhancing inter-rack communication efficiency. Third, we reveal a unique insight resulting from workload execution paradigms (*e.g.*, BSP) and job placements – the utilization of existing NICs' full-duplex bandwidth is low, *e.g.*, 20%-45% reported in [21]. This insight motivates the DRack strawman design, which decouples NICs from their physical hosts and pools them to form a rack-level NIC pool. Last, we discuss the use cases that can benefit from DRack and the challenges that must be addressed to realize DRack in practical.

2.1 Inter-rack Communication in DCNs

Although conventional DCNs, such as public clouds in Amazon [33] and Tencent [34], can vary from one deployment to another. They have one property in common – they arrange hosts in racks as the basic unit. As shown in Figure 1(a), a ToR switch interconnects tens of hosts via Ethernet links, all of which are stacked within a physical rack. Racks connect to the aggregation layer with oversubscribed uplinks. This *ToR-based rack architecture* streamlines the management process, while aiming to offer high throughput and low latency for application traffic with a high degree of rack locality.

Inter-rack traffic is rising and inevitable. We conducted an analysis of a public dataset from Facebook [5], which en-

(a) The percentage of hosts (or NICs) are not communicating.

(b) The percentage of the volume of inter-rack traffic.

Figure 2: The network traffic patterns motivating DRack.

compasses packet-level traces gathered from both Hadoop and Frontend production clusters over one day, sampled at a rate of 1:30k. Each packet sample includes source and destination hosts. As depicted in Figure 2(b), an average of 86.7% and 97.3% of Hadoop and Frontend traffic, respectively, is directed to hosts located in different racks, thereby underscoring the significant demand for inter-rack communication. This observation aligns with prior works [5, 12] and can be attributed to the following factors:

❶ Service-based rack organization: for operation convenience, a rack is typically dedicated to hosts serving a specific (Frontend) service. *e.g.*, cache servers primarily send responses across racks to web servers in other racks, which issued cache read requests. ❷ Resource fragmentation: a Hadoop (Map-Reduce) job may span multiple racks if rack resources are fragmented, thereby resulting in heavy inter-rack traffic for that job. The fragmentation occurs as the scheduler endeavors to localize jobs within a rack [35]; second, dynamic job churns ensure that rack resource is not always neatly packed [36, 37]. ❸ Large scale applications: Data-intensive applications like data analytics [2], iterative graph processing [1] and machine learning [3] (ML), is scaled out across 100 to 1K of hosts [38, 39], *i.e.*, tens or hundreds of racks, to accelerate computation over large input dataset. Their executions follow BSP and Map-Reduce paradigms that require extensive data communication between racks (hosts) after computation, *e.g.*, gradient synchronization.

Inter-rack communication efficiency is crucial for applications. Data-intensive applications are increasingly leveraging advanced computing units such as CPU, GPU and FPGA to execute compute-intensive tasks [6–8]. This trend significantly reduces computation time and generates data at rates exceeding hundreds of GBps, which is several orders of magnitude higher than NIC capacity (*e.g.*, 100 Gbps). Consequently, after the computation phase, each host accumulates a substantial volume of intermediate data, necessitating a bursty transmission and a subsequent reception between racks (or hosts) during the communication phase. When running over ToR-based racks, this communication process traverses the host NIC twice (for egress and ingress) and the potentially oversubscribed uplink of the ToR twice. Therefore, enhancing both the NIC capacity and the capacity of the oversubscribed uplinks of ToRs is crucial for communication efficiency and application performance.

2.2 Existing Approaches

Topology Reconfigurability. One line of prior works [12–14] adds extra bandwidth between the most intensively communicating racks with extra cables, lasers, or antennas to relieve the bottleneck at the uplinks of ToRs, which is usually oversubscribed. Another line does not add bandwidth [12], but builds a flexible network that changes network topology to adapt dynamic workload communication patterns. The efficiency of both approaches highly depends on the predictability of traffic patterns, while it is challenging to identify them due to the *bursty* nature of host- and rack-level outbound traffic (see §2.1). The measurements in production clusters also reveal the presence of a large number of short-lived heavy hitters [5], that is, there is no more than a 50% chance that host- and rack-level heavy hitters will persist in the next 100*ms*.

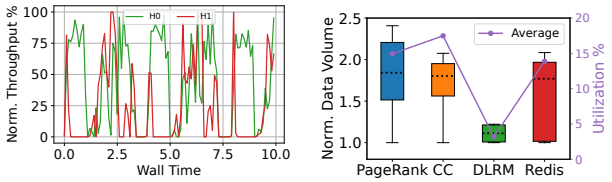
Brute-force hardware upgrade. To relieve the potential bottleneck at the host's egress bandwidth, GRIN [40] leverages multi-port NICs to expand the host egress capacity, but the improvement is constrained by the fact that the number of additional paths is usually limited. Production GPU clusters like EFLOPS [11], vClos [9], and HPN [10] bound each GPU to a single NIC (400 Gbps) to catch the pace with the hardware throughput. They also leverage multi-homed topology to provide a full bisectional network core. However, they exacerbate the link (and NIC) underutilization, given their utilization is already low [5, 41–43]: as measured, 99% of all links are less than 10% loaded. Moreover, this imposes an escalated "scale tax" – power consumption, hardware and operational expenses [44, 45].

Job placement and scheduling. To reduce inter-rack traffic contention, existing cluster schedulers optimize the placement of jobs close to the input data [15, 16] that is spread over the cluster randomly in a distributed file system (*e.g.*, HDFS [46]). Others schedule communication based on the predictable features of tasks [17–20], *e.g.*, the volume of data, start/end time, and source and destination of the communication. However, due to the unpredictability of job traffic as explained in §2.1, job schedulers cannot completely avoid cross-rack traffic contention.

Takeaway. Existing reconfigurable topologies and job schedulers cannot predict the pattern and volume accurately due to the bursty nature of across-rack traffic of distributed workloads, which persists with any frequency [5]. Upgrading switching hardware to meet the peak bandwidth degrades the network utilization. The goal of this work is to seek a cost-effective rack-level architectural design that efficiently handles the inter-rack traffic without extra hardware for more bandwidth or reconfiguration complexity.

2.3 Insights on NIC utilization

By analyzing the same packet-level dataset from [5] and conducting real experiments with data-intensive applications, we observed that *the bandwidth utilization of existing NICs within*



a rack remains low – the insight motivates and carries important implications for the design of DRack. Specifically, we count the number of hosts sending and receiving packet samples within a rack every 1s, respectively, and averaged it over all racks. Figure 2(a) shows over 90% of hosts (NICs) are not sending or receiving in 1s, *i.e.*, remain underutilized, for both Hadoop and Frontend clusters. This observation aligns with prior studies [5,21,41,43], The imbalanced NIC utilization is common and can be attributed to the two factors.

Application semantics. Although all hosts schedule their NICs during the communication stage, the data volume processed by these NICs vary largely due to these factors:

❶ *Compute Irregularity:* Computation tasks are often unevenly distributed across hosts, leading to different computation times [47]. This irregularity results in hosts communicating at different times and NICs handling disparate intermediate data volumes, which are unpredictable and cause imbalanced utilization of NICs. For example, when running graph processing in parallel, each host processes subgraphs with different properties on vertices and edges. This requires varying computation times and produces different amounts of data for synchronization. Moreover, every subgraph evolves iteratively, increasing the unpredictability of communication and computation times. As shown in Figure 3(a) and Figure 3(b), we run a PageRank and CC job over 8 servers and validate data volume and the start time of communication varies significantly. ❷ *Data skewness*: The distribution of data between hosts can be uneven, causing certain NICs to process a disproportionate amount of data compared to others. For example, in DLRM training, input samples of a batch for hosts exhibit heterogeneous access locality on requested embeddings [48–50]. This leads to hosts fetching varying numbers of distinct embeddings from other hosts' embedding tables, and resulting in the uneven generation of gradient data for the embedding layer. In Figure 3(b), the data volume varies substantially for all applications running over 8 hosts, leading to an average NIC utilization less than 20%. We summarize more examples in the Appendix (§A.2), highlighting the generalizability of low NIC utilization across various data-intensive applications.

Resource fragmentation. In datacenters, multiple jobs run concurrently. To schedule them, resource fragmentation is inevitable, as each job has its own resource requirements. If a job can be accommodated by a single host, *i.e.*, a non-distributed job, the NIC of that host remains underutilized. Additionally, BSP paradigm mandates that the NICs can be idle during computation. As observed in production clusters, 20%-45% of machines run non-distributed jobs [21], resulting in underutilized NICs. These NICs could potentially be leveraged by throughput-intensive distributed applications to enhance NIC utilization and performance.

Implications. Given that inter-rack traffic is predominant (§2.1) and yet NIC utilization remains low and imbalanced, if the underutilized NICs equipped at the hosts were controllable and accessible by a different host within the same rack, inter-rack communication can be accelerated, while the burstiness of the traffic can be alleviated by spreading the traffic between more NICs and paths. Moreover, resource fragmentation due to job scheduler can be reduced if NICs can be scheduled independently, without the need to schedule additional computing resources on the same host.

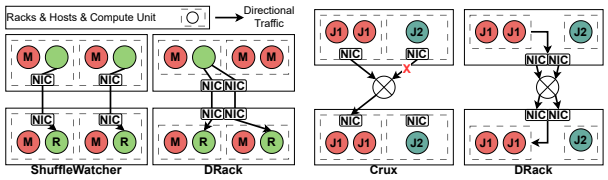
Figure 3: The imbalanced NIC utilization. (testbed see § 7.1)

2.4 The Benefits of DRack



DRack design principle. Driven by the implications of large inter-rack traffic demand and the underutilization of rack NIC ports, we propose a new rack architectural concept – Disaggregated Rack (DRack).

At its core, DRack disaggregates NICs from host boundaries, consolidating them into a rack-level NIC pool accessible by any host to transfer its inter-rack traffic. Maximizing the utilization of the NIC pool's capacity is challenging, as its capacity can exceed the bandwidth of the PCIe links at the destined hosts or the total memory bandwidth of their local memory. For example, in many-to-one across-rack traffic, a NIC pool of 16x200 Gbps NICs (with 16 hosts) can achieve a receiving throughput of 3200 Gbps, which far exceeds the 500 Gbps capacity of a PCIe5x16 link on the destination host. When performing direct memory access (DMA) from/to all NICs, both sending and receiving operations can ultimately be limited by the host's PCIe link or local memory bandwidth.

Thus, the second principle of DRack is to disaggregate system-integrated memories from all host boundaries, forming a rack-level memory pool with an aggregated bandwidth exceeding the capacity of the NIC pool. Hosts can allocate descriptors with referenced address locations spanning all hosts' memory devices, facilitating distributive DMA writing of inter-rack traffic, received from the NIC pool, across all memory devices, not only the local memory of the destined host. Similarly, the NIC pool performs DMA reads from multiple memory devices to achieve full bandwidth transmission.

Last, DRack allows hosts' processors (*e.g.*, CPU) to access the memory pool using memory semantics, This enables them to directly *load* and *store* of data during computation stage, eliminating the need to initially move data to their local memory via DMA.

User cases and benefits. DRack addresses the bottlenecks in inter-rack communication, without the need of additional bandwidth hardware and reconfigurability. Second, DRack is

(a) DRack saves more cores. (b) DRack reduce comm. time.

Figure 4: Workflows of job schedulers on DRack.

not only orthogonal to existing job scheduling and placement strategies, but also unleashes their performance gains.

❶ *Mitigating inter-rack communication bottlenecks.* **1) NIC egress bottleneck**: Recall, during the computation stage, a substantial volume of intermediate data is produced, resulting in a throughput higher than the NIC capacity by several orders. To minimize the idle time of valuable computing resources, DRack allow a host to use underutilized NICs within the same rack to boost its egress capacity like in Figure 1(b), the host then can control multiple NICs to send packets concurrently by passing descriptors to them, thereby mitigating the gap between the compute hardware throughput and the local NIC's egress capacity. **2) Oversubscribed network core**: The NIC pool completes its transmission, as shown in Figure 1(b), acting as the uplinks of tier 2 (ToR), in contrast to Figure 1(a). This is because DRack shifts rack NICs and the above topology components, like ToR switches and aggregated switches, up one tier compared to original ToR-based architecture. The ToR switches effectively take on the role of aggregated switches, while the original aggregated switches can either be eliminated or repurposed to serve as core switches. By appropriately wiring between the NICs and ToR switches in Figure 1(b), DRack achieves a fully bi-sectional bandwidth between any pair of racks, unlike the oversubscribed network core found in ToR-based rack architecture, and does so without the need for additional switching hardware. **3) NIC ingress bottleneck.** Data is received by the NIC pool of the destined rack, as shown in Figure 1(b), and DMA to all rack host' memory devices to fully exploit the NIC pool capacity. In ToR-based racks, incast loss at the ToR switch's egress port can occur due to possible many-to-one traffic and limited capacity of the host's NIC, as the data is only written to a single host.

❷ *User cases.* We show why DRack is orthogonal to existing job scheduler, and can improve them with the following examples: **1) MapReduce jobs schedulers**: We validate how DRack improves ShuffleWatcher [27]. Figure 4(a) shows, upon the mappers of a job running at 4 hosts are done, ShuffleWatcher schedules cross-rack network shuffling with the reducers, This requires each host to schedule the NIC and a compute unit, P, for fetching mappers' output from HDFS and managing data I/O, totally 4P, if little cross-rack traffic exists (assume accurate traffic monitor). Otherwise, ShuffleWatcher schedules mappers of another job to replaces finished mappers. With DRack, it only needs 1P from a host for all shuffling tasks with reducers, as any host can concurrently access all NICs, while leaving the remaining 3P for mappers, thereby enhancing resource efficiency. **2) BSP-based job schedulers**: We validate how DRack improves Crux [26]. Figure 4(b) shows that Crux prioritizes job 1 to use network core bandwidth without contending with other jobs on the same uplink, as it allocates more compute units (4P) than the others (2P). With DRack, job 1 can use 2 NICs (1 from the other host) to send cross-rack traffic, further reducing communication time and minimizing idle time of computing resources.

We validate the DRack benefit in a large scale by evaluating the above two user cases with real experiments (§7.3).

2.5 Realizing DRack

To build DRack, we explore the following techniques and show their suitability for DRack's design.

CXL. The Compute Express Link (CXL) standard [25] enables memory and device pooling, which is a great fit for realizing DRack's memory pool and NIC pool. DRack leverage the fabric topology in CXL 3.0 that supports data-sharing and switch-based pooling: a physical CXL switch can be virtualized into multiple virtual CXL switches (VCS). Each host sees a tree-based virtual hierarchy built with a separate VCS, which handles address remapping for accessing the devices attached in the switch. This maps devices, including memory devices (*e.g.*, local memory and newly-added remote memory in CXL switches) and IO devices (e.g., NICs), along with hosts, into a unified logical address space. CXL memory semantics (CXL.mem) enables hosts to load and store the memory pool directly during the computation stage, unlike prior works using PCIe interconnects for device pooling, which requires moving data to the host's local memory via DMA prior to computation [22–24]. Clearly, CXL is well-suited for DRack design in §2.4. Importantly, DRack only uses CXL hardware (*e.g.*, a CXL switch) without modifications, simplifying future deployment.

SR-IOV. A PCIe device in a PCIe slot (*e.g.*, PCIe NIC) can function as one or multiple physical functions (PFs). SR-IOV (Single Root I/O Virtualization) [51] is a technology that enables a PF to be virtualized into multiple virtual functions (VFs). Thus, each virtual NIC (vNIC) has a copy of dataplane and a portion of the configuration space (IO space), *i.e.*, Tx/Rx queue heads and VLAN QoS settings for a vNIC. This allows different hosts to use the NIC via a vNIC. By accessing the vNIC's IO space, we can finely control the traffic to each vNIC, *e.g.*, setting QoS to support priority scheduling. As shown in CXL specification [25, 52], CXL.io, one of CXL protocols, maintains backward compatibility with PCIe standard. This ensures connectivity with conventional PCIe devices including IO devices such as NICs, thereby inherently supporting SR-IOV. DRack uses CXL.io for its NICs to DMA read/write the memory pool, as well as other functions such as device discovery, configuration, initialization, *etc.*.

Memory Interleaving. Memory interleaving distributes

memory requests by partitioning the physical address space among multiple memory devices at uniform intervals, forming an interleave set (IS). A host can possess multiple ISs. For example, the Intel Skylake platform with two CPU sockets, configures a unique IS for each socket by default, containing the local memory devices of the respective socket. CXL defines the smallest continuous address partition (interleave granularity, IG) ranging from 256B to 16 KB.

Challenges and Solutions. Although the above techniques pave a promising substrate for DRack, there are challenges to overcome to ensure DRack's efficiency and practicality.

C1: CXL accesses exhibits a large latency. Hosts access to remote memory devices within the pool (*e.g.*, the local memory of other hosts) with CXL.mem load and store, which exhibit at least 2.7x latency than accessing local memory of the same NUMA node [53]. Second, CXL.mem load and store are synchronous, cacheline-based with limited concurrency (*e.g.*, 64 at most [54]), resulting in bandwidth inefficiency compared to DMA. We introduce a cache device installed at each host's CXL port – *DRAM cache*, so that remote data can be cached and even prefetched to hide the latency effectively by exploiting the data locality during the computing and communication stages. (see §5.2).

C2: Compatibility. DCN applications are built on the socket and RDMA verbs programming models, which rely on the TCP/IP and RDMA stack for communication, respectively. When hosts and devices within a rack are interconnected with CXL, existing applications must use CXL memory semantics for intra-rack communication. To maintain compatibility with existing host stacks and applications, we introduce a kernel module that seamlessly translates socket system calls (`SEND` and `RECV`), into pass-by-reference semantics (CXL.mem-based load and store) (see §5.1).

3 DRack Overview

DRack hosts support CXL, as shown in Figure 5, there is a CXL port connected to the root complex of the CPU, which is used to access the NIC pool's IO space and memory pool via CXL interconnect. The NIC pool comprises conventional PCIe NICs, compatible with CXL. Besides existing NICs the NIC pool can flexibly be added more NICs to enhance capacity. Besides hosts' local memory, the memory pool can also be expanded with additional remote memory devices attached in the CXL interconnects. A segment of every host's local memory and possible remote memory devices constitute an interleave set of the memory pool (IS0), saving user data. The remaining local memory becomes another interleave set, storing the data structures (*e.g.*, reference queues) frequently accessed by the host (§4.2). The memory pool and NIC pool's IO space are mapped into a unified address space so that any rack host can allocate, deallocate, and access them. The CXL port of a host is connected to a cache device, which caches hot remote data in the on-die DRAM components [55–57].

Workflow. In BSP-based job, each host has generated intermediate data with its data buffers spanning all memory in IS0, which is being synchronized with other hosts during the communication stage. For intra-rack communication (§4.3), where both sending and receiving hosts are within the same rack, the sender's kernel runtime (§5.1) translates the original `SEND` into CXL.mem store, writing references (packet pointers) into a shared queue (in IS1) accessible by the receiver. The receiver's runtime translates the original `RECV` into a CXL.mem load, loading the references and validating them through the TCP stack. The TCP stack validation involves sequential loads of the header of the referenced packets, potentially accessing IS0 remotely. To accelerate it, the receiver leverages the spatial locality by reading a large block into the DRAM cache (§5.2), and subsequent access to packets will hit the DRAM cache. Once a packet is validated, its payload is ready for application computation. Note that, DRAM cache also caches hot data to accelerate computation by exploring memory access locality.

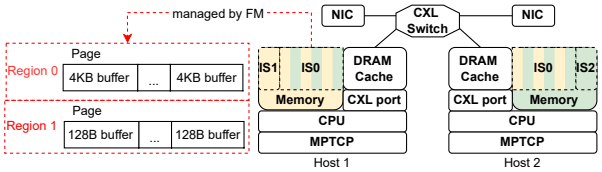


Figure 5: DRack overview and its components

For inter-rack communication, by leveraging SR-IOV, every host in a rack is assigned a virtual NIC (vNIC) for every physical NIC. The sending host splits a flow into multiple subflows with MPTCP. Each subflow is sent by a vNIC. Note that MPTCP is responsible for distributing the data buffers to subflows. The sender notifies every vNIC to trigger DMA by storing the references of the data buffers to the vNIC's descriptor queue via MMIO. Every vNIC DMA reads the data buffer and sends them across racks. At the receiving rack, each vNIC DMA writes the data into its preallocated receive buffers and stores the references of the received packets in the completion queue in IS2. The receive buffers are uniformly distributed across the memory devices of IS0 to utilize the NIC pool's capacity. The host owning the vNIC is interrupted, which triggers its kernel (or CPU) to load those references for TCP validation. Similarly, the DRAM cache prefetches and caches large blocks per remote load issued by the kernel, minimizing remote accesses during both TCP validation and computation.

4 DRack Dataplane

This section presents the architecture of DRack and its integration with the existing DCN, then the communication protocols for intra-rack and inter-rack data, respectively.

4.1 Architecture

DRack changes the traditional multi-tier Clos topology [58] by inserting a CXL interconnect (*e.g.*, CXL fabric) at the edge tier between the hosts and NIC pools, so that every host accesses the NIC pool with its CXL port through the CXL

interconnect. As a result, CXL interconnect becomes ToR tier, and the NIC pool become the uplinks of the ToR tier, while the original ToR switches are repurposed as the aggregation tier. Compared to Clos topology (Figure 1(a)), it enables more paths to transfer inter-rack traffic, and the original aggregation tier can be simply eliminated, and the core of the network remains the same.

Figure 1(b) shows an example of the wiring between 2 racks with each hosting 4 hosts using DRack, and the resultant DCN topology. The wiring between racks also applies to a general case. In a pod comprising m racks and n hosts per rack, Each DRack's NIC pool has n NICs, now there are n uplinks for every pair of racks without uplink oversubscription. Thus, rack 0 has NIC $ID = 0 \sim (n-1)$, rack 1 has NIC $ID = n \sim (2n-1)$, and rack $m-1$ has NIC $ID = (m-1)n \sim (mn-1)$. As explained, the original ToR switches become aggregated switches in DRack, there are m aggregated switches with $ID = 0 \sim (m-1)$. NIC i is linked with the aggregated switch (i mod m), where $0 \leq i < mn$. For example, when $n = 20, m = 10$, NICs 0, 10,..., connect to switch 0, NICs 1, 11,..., connect to switch 1, *etc.*. Similarly, when $n = 20, m = 8$, NICs 0, 8, 16,..., connect to switch 0, NICs 1, 9, 17,..., connect to switch 1, *etc.*. We plot the two examples in Appendix (§A.1).

4.2 Components

CXL interconnect. DRack assumes the existence of the CXL capabilities below based on standards [25] and existing prototypes [59–61]. The CXL Fabric Manager (FM), a software firmware, is responsible for managing the capabilities: 1) setting the mapping between physical addresses and memory devices, 2) configuring the interleave granularity (*e.g.*, 256B to 16KB). These capabilities are the key to efficiently utilizing the NIC pool's capacity by leveraging the total bandwidth of the memory devices. FM can run on a host, a CXL switch, or a device. We run FM on a server in the prototype (§6).

Memory Pool. The memory pool is organized as follows. As shown in Figure 5, the memory pool is mapped to a single Fabric physical Address Space (FAS), which includes multiple ISs. FAS is organized as a series of coarse-grained `Section`s, each with a hugepage size (2 MB). DRack groups a segment of every host's local memory and possible remote memory devices into memory pool IS0, with the smallest IG (256B) to efficiently balance the user data and memory requests across IS0. Each host groups its remaining local memory segment into a separate IS (ISi, where i denotes the host ID). ISi is used to store latency-critical data structures frequently accessed by host i. For example, the descriptor queues of vNICs are accessed by the host that performs multiple load-/store operations to update descriptors, whereas NICs only perform a single DMA read of them in batches. In our prototype, 12GB of local memory is in IS0, while the remaining 4GB is in ISi.

Each IS is organized as a series of 2 MB huge pages. K consecutive `Section`s are grouped into a `region`, K is configurable, and K=512 by default. Note that `region` is used to co-design with DRAM cache (§5.2) to hide the latency of the memory pool. FM is responsible for page allocation/deallocation. The workflow is as follows.

① Every host allocates a `Section` from FM before accessing it to ensure data isolation. A background kernel daemon applies and manages these `Section`s using buddy system: `Section`s from the same `region` are divides into `Buffer`s of same size, and these `Buffer`s are linked as a list.

② Applications at a host apply `Buffer`s from the daemon, which can be used to store application data or as receive buffers for DMA write by NICs. Then, the daemon commits the allocation by removing `Buffer`s from the corresponding list, and creating page table entries (PTE) that map applications' virtual addresses to `Buffer`s' fabric addresses.

③ When an application frees `Buffer`s, it notifies the daemon, which in turn frees the PTEs. To avoid some hosts holding too many free `Section`s, The daemon periodically deallocates excess free `Section`s to FM.

NIC pool. Figure 6 shows the structure and metadata of NIC pool. To share the NIC pool between rack hosts, every SRIOV-capable NIC is virtualized into N virtual NICs (vNIC), with each assigned to a host. For example, Intel 82599 NIC can support up to 64 vNICs [62]. Thus, a host can be assigned M vNICs and interacts with each vNIC using standard PCIe I/O primitives: host processors configure each vNIC using memory-mapped I/O (MMIO), vNICs access the host's data in the memory pool using DMA. However, the vNIC configuration is different by incorporating the memory pool: to interface with a vNIC, host i allocates a dedicated queue pair (`virt_queue`) in its ISi, the local memory segment for storing transmission and reception descriptors. For the receive (RX) path, host i allocates RX buffers uniformly across IS0, minimizing contention at a single memory device and posts RX descriptors to the RX `virt_queue` prior to actual DMA writes by vNIC. Similarly, for the transmit (TX) path, the host allocates TX buffers uniformly across the IS0, populates the TX descriptors with references to consecutive buffers' addresses, and stores them in the TX `virt_queue`. This maximizes the NIC pool throughput when the vNIC performs DMA reads during TX. Each host always uses all NICs in the pool for TX and RX, and balances loading between NICs with a multi-path control (see §4.3).

4.3 Communication

Intra-rack Communication. DRack's intra-rack communication is based on CXL.mem load and store, a pass-by-reference semantics, which reduces the communication time by eliminating data copies in ToR-centric racks. We assume each host has a unique ID (*e.g.*, IP). The communication involves transferring a reference to data in the memory pool from host ID_{src} to host ID_{dst}, so that host ID_{dst} can load/store it. To transfer a reference, ID_{src}'s processor stores a descriptor in ID_{dst}'s `ref_queue`, with each entry containing ID_{dst}, ID_{src},

a reference, and the length it references. A ID_{dst} allocates a separate `ref_queue` for every ID_{src}, denoted by `ref_queue` [ID_{src}], to separate descriptors from different hosts, thus each host needs M-1 `ref_queues` for a rack size of M. Assuming the application has already updated data `Buffers` using load/-store during computation. Figure 6 summarizes the workflow of an intra-rack communication between ID_{src} and ID_{dst}.

① ID_{src} stores the descriptor into the tail entry of ID_{dst}'s `ref_queue` [ID_{src}], where each queue is implemented as a circular buffer. Each queue is associated with context registers mapped to the FAS, such as tail pointer, and ID_{src} stores to these registers will trigger a ID_{dst}'s interrupt.

② After receiving an interrupt, ID_{dst}'s runtime loads the head entry of `ref_queue` [ID_{src}], and invokes TCP stack and application to validate flow reliability and compute with the references sequentially. Note that DRAM cache fetches and cache data from IS0 with a large block size (*i.e.*128B to 4KB) to reduce future remote access (§5.2). The pass-by-reference transfer is realized in Linux and transparent to applications with socket programming model (§5.1).

Inter-rack communication. DRack relies on PCIe I/O primitives (MMIO and DMA) to interact with the NIC pool for inter-rack communication. This design is simple and efficient, as it does not require new hardware support compared to previous works [63–65]. To schedule a data stream between NICs, every host scatters it between all vNICs on a packet basis, so that the NIC pool is utilized fairly for all hosts. However, it may lead to out-of-order packet arrivals, thus underutilizing the NIC pool due to the core network path asymmetry [66–68]. To address it, we exploit MPTCP in existing kernel [69, 70], which can open multiple subflows with each bounding to a vNIC. The receiving host resequences subflows and provides network feedback to the sender, which rebalances the load based on path conditions [69,71]. Figure 6 shows the inter-rack communication workflow.

③ When a ID_{src} has the TX `Buffers` and TX `virt_queues` ready, ID_{src}'s processor rings the doorbells of all vNICs via CXL stores to the MMIO registers. All DMA engines of the vNIC then fetch data from the TX `Buffers` based on descriptors in their corresponding TX `virt_queue`, and perform packetizing. Data `Buffers` are interleaved in the memory pool to use the NIC pool at full capacity, and the descriptors distributed to those TX `virt_queues` are decided by MPTCP.

④ The packet stream intended for ID_{dst} should be received by all vNICs of ID_{dst} uniformly. Each vNIC DMA engine directly writes the payload to the RX `Buffers` specified by the descriptors in the RX `virt_queue`. The ID_{dst} is interrupted by the vNIC via the message signaled interrupts mechanism of PCIe as soon as the DMA engine finishes a batch of the DMA writes. The ID_{dst}'s TCP stack loads the references from all RX `virt_queues` with CXL.mem, and validates the reliability of each subflow by loading the referenced packets' headers. After validation, the application loads and stores `Buffers` during computations. The DRAM cache caches previously accessed blocks and is checked before every load to IS0.

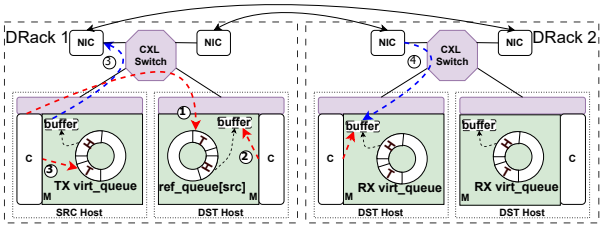

Figure 6: The inter-rack(3,4) and intra-rack(1,2) communication from the SRC host to the DST host. Red and blue lines are memory load/store and DMA read/write, respectively.

Discussion. DRack employs MPTCP to evenly distribute subflows between vNICs. However, this can incur performance overhead when the number of NICs increases. This is because the number of subflows increases with the number of pooled NICs. Each subflow requires separate interrupts, MMIO operations, and kernel processing of subflows merging. However, CPU cores (typically exceeding pooled NIC counts) remain underutilized during bulk data synchronization/shuffling, enabling sufficient cores for NIC pool operations.

5 System Support

5.1 Software Runtime

To enable socket-based applications to use pass-by-reference transparently, a driver below TCP/IP stack acts as an indirection to orchestrate inter-/intra-rack communication with pass-by-reference. The TCP/IP stack operates on the socket buffer object (`sk_buff`), which includes a `data` field that contains the reference to the actual data. The *data* can be headers or payloads of packets, located in the memory pool. For performance consideration, the TCP/IP stack uses the write-around cache policy for `Buffers` so that data is directly written/updated in memory without bringing them to the cache first.

We show a runtime workflow with an example. ① A socket-based application of a host ID_{src} allocates the `Buffers` in memory pool and populates them with application data, before calling the `send` to initiate communication. ② The TCP stack passes a scatter-gather list of `sk_buffs` wrapped with those `Buffers`' references to the driver by calling `ndo_tx`, where `ndo` is the network device operators exposed to the TCP stack by the driver. The first element in the list is a pointer to a kernel `Buffer` storing the packet's header (also in memory pool), and the following elements are pointers to application `Buffers`. ③ The driver stores the references of `sk_buffs` to the intended `virt_queue` of a vNIC (mainstream NICs support scatter-gather I/O) or a `ref_queue` for inter- or intra-rack communication, respectively. For inter-rack communication, the vNIC traverses the list and DMAs data without local-to-pool copies.

ID_{dst} is interrupted to read `virt_queues` or `ref_queue` whenever a batch of new references is available, which is handled by its driver. To enable TCP stack to load the referenced data `Buffers` in the memory pool, ID_{dst} wraps the references

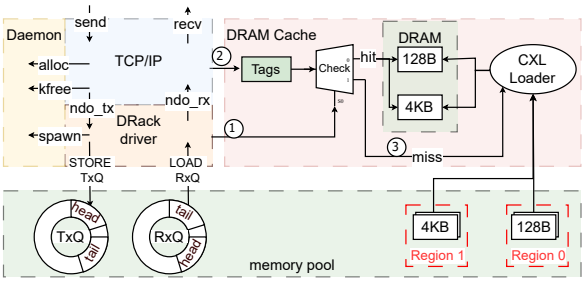

Figure 7: DRAM cache's architecture and working flow.

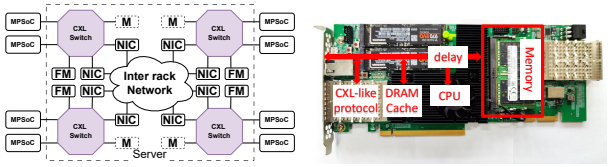
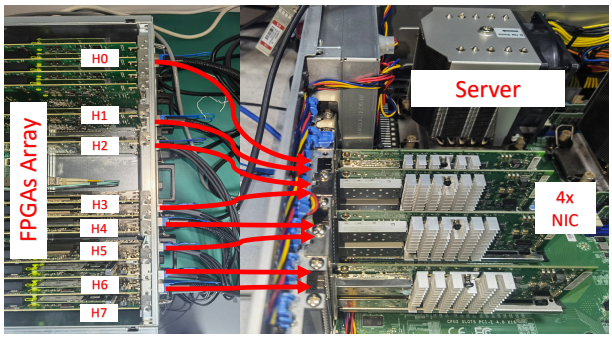


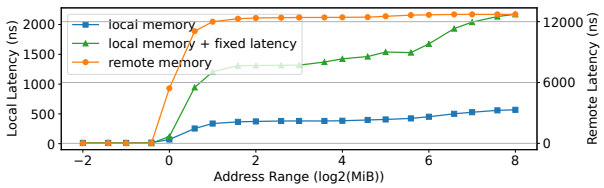
into `sk_buffs` before passing it up to the TCP stack, still no data copy involved. When the TCP stack no longer uses those `Buffers`, it hands the `Buffer` to the daemon for deallocation.

Discussion. Cache coherence is needed if ID_{src} and ID_{dst} use memory sharing for intra-rack communication. However, DRack focuses on the case where applications use message-passing for large data synchronization, simultaneous data accessing between ID_{src} and ID_{dst} is unnecessary, thus no sharing issues. If ID_{src} stores new data to the location of the previously sent `Buffer` after calling the `send` API, ID_{src}'s TCP stack releases ownership of the sending `Buffer`, allocates new `Buffers` from the memory pool, and updates page tables for subsequent stores.



5.2 CXL-attached DRAM Cache.

By analyzing the TCP stack, we summarize the three key points to guide the DRAM cache design. **1) Variable time interval between accessing headers and payloads.** The runtime processes packet headers and data during the bottom half of the interrupt, and the `recv` syscall, respectively. Therefore, there will be a time interval between the two, where the interval length is determined by the utilization rate of the CPU, and the data can be evicted out of the cache. **2) Buffer release function is explicitly called.** the runtime will flush the `Buffer` out of the cache once it calls release function explicitly, **3) Variable packet granularity.** The packet size may be thousands of or dozens of bytes, like TCP SYN and ACK. Caching data with coarse granularity leads to a low cache utilization rate and prolongs the latency, thus different caching granularities should be adopted.



As shown in Figure 7, we add a multi-way DRAM cache to the system. It has a larger capacity compared to CPU caches, which is sufficient to tackle the potential false evictions caused by conflicts during variable intervals. The metadata (`Tags`) is stored separately in the on-chip memory, so that one read can get the whole set's metadata. This cache space can be divided into n parts, each of which uses a different cache granularity (*e.g.*, 128B and 4KB in Figure 7), and the capacity of each part is different, but the total number of lines is the same. The usage of DRAM cache can be summarized as follows. ① The driver configures the FAS of a `region` – a consecutive number of `Sections`, whose `Buffers` will be cached in one part of DRAM cache, and the caching granularity, *i.e.*, `Buffer` size. For the first access to a `Buffer` in the `Region`②, a miss is

triggered and the `Buffer` is fetched from the memory pool via CXL.io ③. Then, the DRAM cache fills valid metadata and evicts the victim `Buffer`. The following accesses to the `Buffer`② will hit the local DRAM cache. When the runtime decides to free `Buffers`, it will explicitly called the release function that flushes the DRAM cache.

6 Implementation

Given the lack of commercial products supporting CXL 3.0, we have developed a proof-of-concept quad-rack system prototype, as shown in Figure 8(c). The prototype is used to simulate both a quad-rack DRack architecture and a quad-rack ToR-centric architecture as the baseline (§7.1). Each rack is equipped with two customized MPSoC FPGAs [72] serving as hosts. Each FPGA has a quad-core CPU, two memory channels, and four optical fiber ports. The MPSoC exports the CPU memory bus to FPGA logic via HP/HPC ports, which can be used to implement a CXL-like load/store. We connect two FPGAs (in a rack) to a dual-port NIC [62] on a server. We emulate the NIC pool, CXL interconnect in DRack, and ToR switches in the baseline using a DPDK-based software network emulator on the server [73].

CXL-like protocol layer. The key to emulating CXL fabric in CXL 3.0 is to externalize loads and stores. This allows applications to access remote memory devices within the

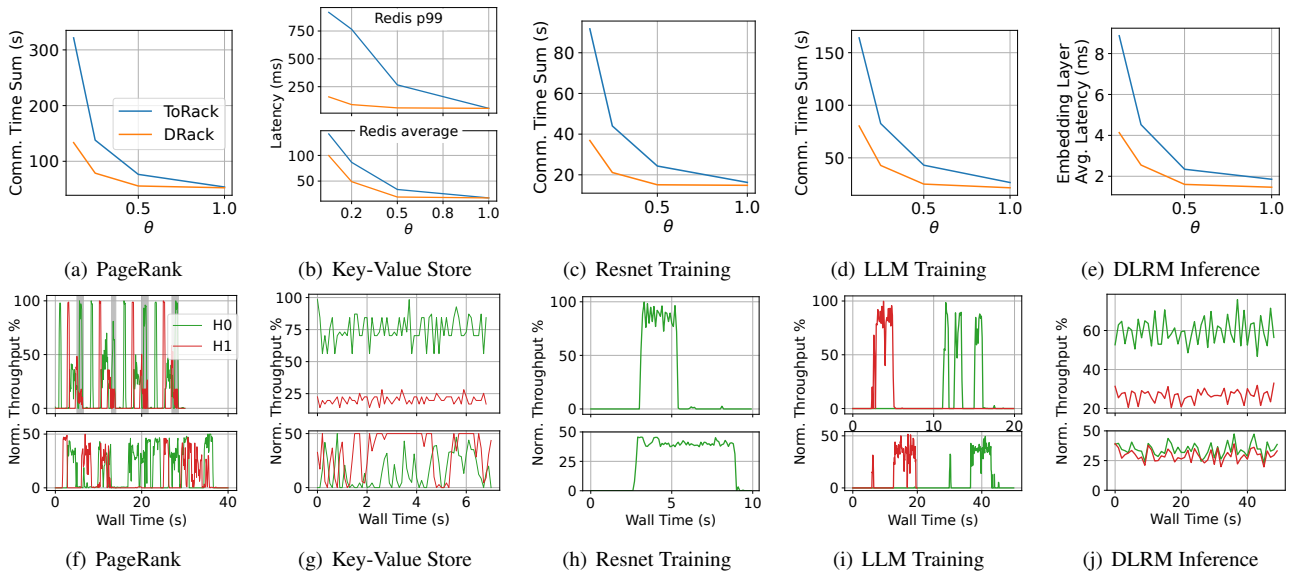
memory pool transparently, enabling the seamless execution of legacy applications. To this end, we leveraged DoCE [32], a hardware protocol stack as the basis of our CXL-like protocol layer. DoCE directly encapsulates all AMBA AXI on-chip interconnect signals within an Ethernet frame which can be delivered via standard Ethernet infrastructure. Instead of packing AXI signals into Ethernet packets with DoCE, we augmented DoCE with a CXL-like protocol layer and implemented them as a hardware module in the MPSoC FPGA (*i.e.*, CXL-DoCE). As shown in Figure 8(b), it transforms AXI signals into relevant CXL transactions, such as MemRd, MemWr, Cmp, and MemData defined in CXL 3.0 specification [25], before encapsulating CXL transactions into Ethernet packets and sending them via an optical fiber port. Similarly, any received Ethernet packet from the port would go through the module, which transforms it into AXI signals to access the local address space if that packet contains CXL-like transactions. Note that an Ethernet packet can encapsulate transactions not limited to CXL-like as long as the module can recognize them, *e.g.*, the module can interrupt the CPU if the Ethernet packet carries an interrupt transaction.

Memory and NIC pool. We use the local memory in all MPSoCs (16 GB) to form a shared memory pool. Any MPSoC can access it with the above CXL-like protocols. Following the design, we divide the local memory of every MPSoC into two parts, 12GB joins an interleave set with 256B granularity, the other 4GB does not interleave with others, so that `virt_queues` and *sk_buf* used can be stored locally. To emulate NIC pool in the server (Figure 8(a)), we use one core to manage a software queue to emulate a vNIC. The server's core can load/store a vNIC's `virt_queue` or DMA read/write data by issuing CXL-DoCE packets via the real NIC. We use inter-processor interrupt (IPI) to forward the packet "across rack" to another CPU core (a vNIC in the other NIC pool).

Example. Here is an example showing the memory pool accessing in the prototype with CXL-like protocol layer. ① In a rack with MPSoC0 and MPSoC1, suppose MPSoC0 HP port exports CPU load/store instructions as AXI signals, an address decoder implemented in the FPGA uses the 8th bit of the physical address (IG=256B) to decide the target memory device. If bit 8 is 0, memory requests target MPSoC0's memory; otherwise, they target MPSoC1's one. ② Recall, to issue requests to the MPSoC1, MPSoC0 leverages CXL-DoCE to transform AXI signals into CXL transactions, *e.g.*, MemRd, and prepend them with an Ethernet header (containing MAC addresses of both endpoints). Then, it sends them via on optical fiber port. ③ As shown in Figure 8(b), the server (network emulator) receives these Ethernet packets via optical fiber links at its physical NICs, and routes them directly to MPSoC1 based on MACs. ④ MPSoC1 receives Ethernet packets from the optical fiber port, and transforms them into AXI signals with CXL-DoCE, to access the local address space. Appendix §A.3 shows an example of NIC pool accesses.

Compared to existing emulation approaches. Due to scarcity of CXL hardware, prior works have employed 3 emulation approaches. ① NUMA nodes. CPUs load/store remote node's memory is emulated as accessing CXL memory [28, 31, 74]. However, this cannot adjust CXL memory latency, and its scalability is limited by the node count. ② Software simulator [75, 76], like Gem5 in full-system mode [77], is thousands of times slower than real prototypes, unable to simulate full application execution. ③ FPGA-based implementation [53, 60, 78], has the flexibility to implement CXL protocols [60, 72], and run real applications transparently. However, FPGA has a lower operating frequency compared to ASICs [53]. ④ Our approach. We utilize the flexibility of MPSoC-FPGAs to realize CXL-like protocols for resource pooling and running real applications. To run distributed applications at scale and test them in various settings, we use software-based emulation for flexible configurations of NIC pool, CXL interconnects, and inter-rack network topology. To rigorously validate DRack performance gain with low frequency in FPGA, we focus on accurately replicating local/remote memory access latency ratios rather than absolute metrics, which aligns with prior FPGA-based emulation [60]. The ratio configurations are explained in §7.1.

Table 1: Key parameters of the two prototypes.



Parameter	Value
`DRack`	
Memory Pool	2×16 GB; remote 13 μs; local 2.2 μs
NIC pool	$2 \times B$ *Gbps* (2 NICs)
Host	1 GB DRAM Cache; 1 CXL port;
`ToRack`	
ToR Switch	2B Gbps Uplink (no oversubscription) 256 KB headroom per port [79–81]
Host	B Gbps NIC; 16GB memory
Common	
Inter-rack Network RTT	60 μs [82]
CPU	4-core ARM A53 CPU; 1.2 GHz
TCP/IP	MTU 4 KB; XPS, RPS enabled

7 Evaluations

We first evaluated DRack's performance gain over the conventional ToR-based rack using the proof-of-concept prototype with both real-world applications (§7.2), and microbenchmarks (see Appendix §A.4). Second, we show DRack can improve existing job schedulers (§7.3). Last, we breakdown the performance contribution of every key components (§7.4).

7.1 Experiments Setup

We evaluate the quad rack DRack proof-of-concept prototype (§6), and use the same implementation to build baseline systems for comparison. By default, each rack has two hosts for both. We use `ToRack` to denote the baseline system—quad ToR-based racks architecture. Table 1 summarizes the parameters and configuration in experiments. The memory pool of DRack is composed of the local memory of MPSoCs. For

ToRack, we ported an example project [93] to our MPSoC FPGA, where the CPU uses one optical fiber port as a NIC. We set Ethernet link latency in network emulator 60μs [82].

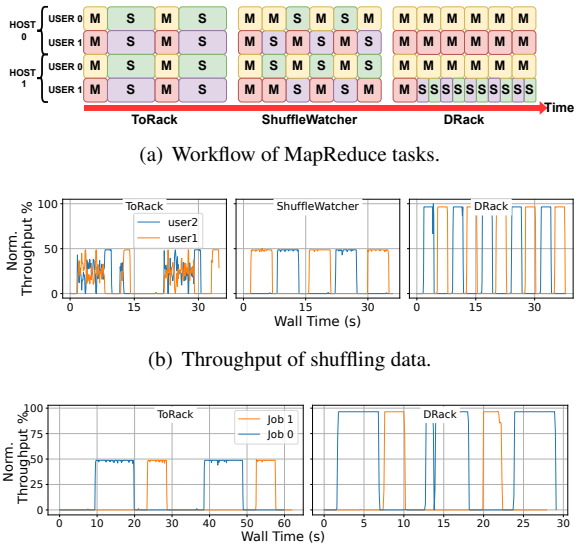
Latency alignments. To align the latency ratio (R) between accessing local (D_{local}) and remote memory (D_{cxl}) with CXL, as shown in Figure 8(b), we add a hardware module on MPSoC FPGAs to add configurable cycles (λ) to local memory accessing from CPUs, such that $R = \frac{D_{cxl}}{D_{local}+\lambda/cpu_freq}$. According to the theoretical latency specified in CXL-related standards [25, 94], accessing the remote memory through a CXL switch is expected to add 170 to 270 ns to the local memory latency. Assuming that the local memory latency is between 50 and 100 ns, the resulting ratio should fall within 2.7 to 6.4. The real measurements of the two latencies align with this range [53]. To illustrate the minimal performance gain achieved by DRack, we configured the latency ratio $R = 6.4$, thus adopting the maximum remote latency. In Figure 8(d), we increase the size of the data array running pointer chasing with Lmbench [95], until accessing it triggers a cache miss, *i.e.*, when the data array size is 256 MB and use the resulted D_{local} and D_{cxl} to compute $\lambda = 460$.

Throughput alignments. The capacity of the emulated NIC pool depends on the maximum achievable throughput of the hosts in the rack, governed by the capabilities of the CPU in the MPSoC. This is because the FPGA NIC (*i.e.*, optical fiber port) is not the bottleneck [93], *i.e.*, the maximum achievable throughput of an MPSoC CPU, denoted by C, cannot saturate the NIC. Thus, the emulated NIC capacity of a host can be set to C at most, as the MPSoC CPU cannot utilize the capacity exceeding C. To emulate the NIC egress/ingress bottleneck in the communication stage, we introduce a reducing factor θ, thus the NIC capacity is adjusted as $\theta \times C$. As the NIC pool is built from existing NICs of the hosts in a rack, to have a fair comparison, the equivalent DRack's NIC capacity is $B = \theta \times 2C$ for 2-host rack. We measure C by sending raw packets to the optical fiber port with DPDK.

7.2 Real-world Applications

We validate the performance gain of DRack compared to ToRack with real applications with various communication properties, as shown in Table 2.

7.2.1 Throughput-sensitive Applications



Graph Processing. We run several graph workloads in a distributed graph engine, Gemini [83], over DRack and ToRack. To execute it, we divided the input datasets among the hosts of 4 racks (8 hosts), each subgraph dataset is incrementally fed to a host's graph engine in batches. For every batch or iteration, hosts run different analytics over the input subgraph and update it iteratively. As the subgraph processed by every host is different, the amount of data for graph synchronization for every host can be very different, thus necessitating different bandwidths. We summarize the communication time of graph synchronization for PageRank, one of the graph workloads, in Figure 9(a). DRack reduces the communication time by an average of 58.5% in the worst case (θ=0.125), and 32.8% in all cases. When the host throughput

is eventually limited by the maximum achievable throughput or MPSoC CPU capability (θ=1), any DRack's host cannot efficiently utilize the NIC pool, thus resulting in a similar performance to ToRack's. To show the root cause of DRack's performance gain, we present network utilization of one rack normalized to the NIC pool, sampled during one run of PageRank in Figure 9(f). Hosts finish iterating and updating their subgraph, *e.g.*, vertices and edges, asynchronously. This is because hosts process subgraphs with varying sizes, leading to different computation times and thus varying amounts of data for communication. Thus, one host may use the NIC pool exclusively during the synchronization stages. Besides, in the time interval with shadowing in Figure 9(f), two hosts can share the NIC pool based on the volume of flows, while the overall utilization is close to 1.

ML Training. We train ResNet18 and TinyStories-33M with all-reduce [96] and parameter server (PS) [97], the two well-known distributed training architectures based on data parallelism. For all-reduce, each host of eight sends its gradient to its right neighbor, while receiving other gradients from its left neighbor during communication stage. For PS, we have 4 hosts as parameter servers, while the others are workers. Every worker sends 1/4 of its gradients to every PS for synchronization and then receives globally-aggregated ones during communication. We summarize the communication time when running ML jobs over DRack and ToRack, respectively, and show the results in Figure 9(c) 9(d). For ResNet training, DRack reduces the communication time by 59.8% and an average of 39.6% in the worst and all cases, respectively. For LLM training, DRack reduces the communication time by an average of 39.9%. This is because 1) for all-reduce, only one host sends/receives data across racks, thus DRack achieves higher inter-rack throughput by allocating the NIC pool capacity to that host, while ToRack's inter-rack throughput is limited by the host's NIC (Figure 9(h)). 2) for PS, Since workers and PSs send and receive data in an interleaved manner – specifically, when workers are sending, PSs are receiving, and vice versa – either can fully utilize the NIC pool over different phases (Figure 9(i)). 3) DRack achieves a high intra-rack throughput with pass-by-reference by removing one data copy compared to ToRack.

7.2.2 Latency-sensitive Applications

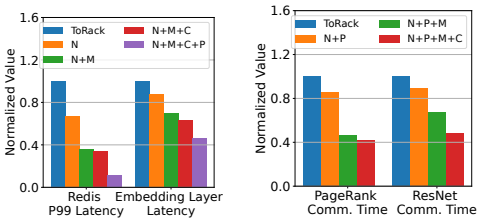
Key-value Store. We organize three racks to form a Redis Cluster and run clients on the remaining hosts to issue Get/Set requests. We set up the experiment as: 1) synthetic workload generated by Memtier_benchmark, 2) a 10:1 Get/Set ratio, and 3) 10 M key-value pairs uniformly distributed across 3 racks, 4) a Gaussian query key distribution. We plot the average and tail latency (*i.e.*, 99th percentile) of the requests in Figure 9(b). Because of the key skewness, the host in ToRack with hot keys can be congested by imbalanced requests, *i.e.*, incast, at its downlink, leading to packet losses and large tail latency. In contrast, DRack reduces p99 and average latency

(a) Workflow of MapReduce tasks.

(b) Throughput of shuffling data.

(c) NIC pool improve comm. throughput.

Figure 10: DRack improves job schedulers' performance.



by 62.2% and 29.2%, respectively. This is because a host with hot keys can utilize the NICs of other hosts within the same rack, which have cold keys. The incast requests are then efficiently absorbed by the memory pool without any loss. Subsequently, the host processes these requests using CXL.mem. Similarly, a hot host can send the corresponding values with the NIC pool. The allocated bandwidth from the NIC pool is proportional to the number of requests/flows that the host is serving, while the hot host in ToRack can only use its limited local NIC (Figure 9(g)).

DLRM Inference. We run a deep learning recommendation model (DLRM [91]) inference task that embedding tables are uniformly distributed across 8 hosts. We plot the average latency of embedding layer processing in Figure 9(e). Because of frequent access to hot vectors, the traffic load at each NIC within the same rack is imbalanced in ToRack that network congestion leads to higher latency and reduced throughput. DRack reduces average latency by an average of 37.4% in all cases, as the NIC pool's bandwidth is proportional to the hot vectors the host stored, as shown in Figure 9(j).

7.3 User Cases

To show the performance gain if existing job schedulers use DRack for the job communication stage, we emulate two user cases (§2.4), ShuffleWatcher [27] and Crux [26].

ShuffleWatcher. Figure 10(a) shows that two users of the same priority issue a series of MapReduce jobs, each comprising 2 map and 2 reduce tasks. The map and reduce tasks are placed in racks 0 and 1, respectively. Assuming there are 2 hosts in rack 0, each with 2 cores, each user rents 1 core per host to run a mapper and shuffler, iteratively. The shuffler begins after the mapper finishes, and then sends the mapper's intermediate output to the reducer in rack 1. All mappers generate intermediate data of equal size. In ToRack without any scheduler, the shuffling tasks of the two users send data to

(a) Perf. breakdown on latency-sensitive APPs.

(b) Perf. breakdown on throughput-sensitive APPs

Figure 11: Key designs' impact on DRack's performance.

the reducers simultaneously, increasing the average shuffling time. With ShuffleWatcher, the two users use the host's NIC to shuffle data alternately (Figure 10(b)). Specifically, user 2 delays its shuffling if user 1 occupies the NIC, while scheduling another map task to reuse the CPU left by shuffling, thus reducing the average shuffling time by half. In DRack, a single CPU of a host can use the NIC pool to send each shuffling task, increasing CPU utilization and reducing the average shuffling time. Although DRack takes the same time as ShuffleWatcher to complete the same number of shuffling tasks (10 in Figure 10(a)), DRack frees up more cores for additional map tasks, improving overall throughput by 20.8%.

Crux. We evaluated Crux on DRack with 3 jobs. Each rack has two hosts. Job 0 (ResNet50 training) spans 4 hosts across 4 racks, while jobs 1 and 2 (ResNet18 training) each span 2 hosts across 2 racks. DRack utilizes the priority flow control function in the optical fiber port IP to throttle the throughput of low-priority hosts (or MPSoC). When high-priority hosts are scheduled by Crux, the network emulator sends a pause packet to the low-priority job's host, causing its hardware IP to cease packet transmission. As shown in Figures 10(c), when running Crux in ToRack, the communication time for job 0 is suboptimal, as it cannot leverage the NICs of jobs 1 and 2's hosts, even if they are deprioritized and halted by Crux. In contrast, DRack enables job 0 to leverage the NICs of hosts assigned to lower-priority jobs, thereby reducing communication time by 47.7%. Once job 0's communication stage is completed and job 1 ascends to the highest priority, its communication can be accelerated by 49.5% with the NIC pool, including NICs from job 0's hosts.

7.4 Performance breakdown

We introduce several key components, including the NIC pool, memory pool, DRAM cache, and MPTCP, to build an efficient DRack. To determine the performance contribution of each component, we incrementally add these components one by one, starting from ToRack. We then evaluate the performance gains of each incremental addition using two latency-sensitive and two throughput-sensitive applications.

As shown in Figure 11(a), for latency-critical Redis, by forming a NIC pool with existing NICs from ToRack, when equipped with only the NIC pool (denoted as DRack-N), reduces tail latency by 32.9%. This reduction is attributed to the fact that hot-key requests are received by the NIC pool, distributively between the NICs. They are first buffered in the NIC pool's headroom before being transferred to the host's local memory with the CXL link. Thus, compared to the case in ToRack, where hot-key requests are received solely by the NIC of the host, DRack has twice the headroom (2 NICs) for buffering those requests, significantly reducing packet loss. By augmenting the memory pool to DRack-N (DRack-N+M), the packet loss is further reduced, resulting in 63.9% P99 latency reduction. The DRAM cache (DRack-N+M+C) fails to reduce the latency further because searching and reading key-value pairs is random memory access that lacks locality (DRAM cache hit rate 59.6%). MPTCP reduces the latency further by 65.9% (DRack-N+M+C+P). This is because a bursty flow is fixed to a single NIC, resulting in imbalanced utilization of NICs. By splitting it into multiple subflows, with each directing to a NIC, MPTCP further reduces the burstiness of the flow and flow collision. The observation is similar for DLRM inference as shown in Figure 11(a).

As shown in Figure 11(b), for data-intensive ResNet training and PageRank, by using the NIC pool and MPTCP (DRack-N+P), the communication time is reduced by an average of 12.7%, as cross-rack traffic can be sent via 2 NICs. However, the throughput is limited by the local memory (or CXL link) bandwidth, thus preventing full utilization of the NIC pool. With an increasing memory bandwidth from the memory pool (DRack-N+P+M), the communication time is reduced by an average of 38.1%. By introducing a DRAM cache (DRack-N+P+M+C), the communication time is reduced by 28.6% for ResNet training. This improvement is due to the DRAM cache that exploits the spatial locality of memory accessing in TCP stack and model computation, achieving hit rates exceeding 86.9%. While DRAM cache only reduces PageRank's communication time by 9.9%, its gain is limited by a cache hit rate of only 56.2%, caused by the irregular memory accessing.

8 Conclusion

We present DRack, a novel rack architecture that provides high inter-rack bandwidth and network utilization with a NIC pool, and optimizes its efficiency with several novel designs such as a shared memory pool, DRAM Cache, and MPTCP. We built a quad-rack prototype and validated its performance with both microbenchmarks and real applications.

Acknowledgments

A Appendix

A.1 Topology Example

(a) 4 racks and 8 hosts per rack. ($m = 4, n = 8$)

(b) 16 racks and 8 hosts per rack. ($m = 16, n = 8$)

Figure 12: Example topology with DRack. Host(H), NIC(N).

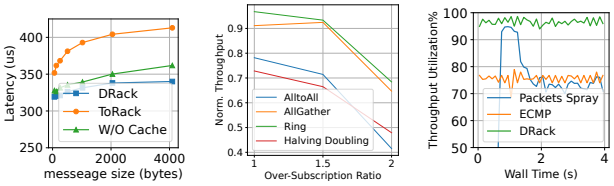
As shown in Figure 12, there exist two system configurations leading to two different topologies.

① DRack topology has more hosts (n) than racks (m), $n > m$. As shown in Figure 12(a), $n = 8$ and $m = 4$, every rack can connect with all aggregated switches (or ToR switches in original ToR-based architecture). Recall, NIC i is linked with the aggregated switch (i mod m), where $0 \leq i < mn$. Thus, NIC 0, 4, 8,.., is linked to switch 0, NIC 1, 5, 9,.., is linked to switch 1, *etc.*.

② DRack has less hosts than racks, $m > n$. As shown in Figure 12(b), $n = 8$ and $m = 16$, a rack can only connect with part switches. In this case, every rack connect with 8 ToR switches, rack 0, 2, 4,..., connects with ToR switch 0 to 7, while rack 1, 3, 5,..., connects with ToR 8 to 15. They both form two pods, respectively. The two pods are interconnected via one or more core switches, with the pod-to-core wiring topology preserving the conventional structure employed in ToR-based architectures. The wiring between NICs of a DRack and ToR switches still follows the principle, *i.e.*, NIC i is linked with the aggregated switch (i mod m), where $0 \leq i < mn$.

A.2 Application semantics

Table 3 provides more application examples that can result in irrgular computation and skewed data accessing.



A.3 An Example of NIC Pool Accessing

When a MPSoC0's application calls *send*, its driver classifies whether it targets MPSoC1 (*i.e.*, intra-rack), or the one across racks (*e.g.*, MPSoC3) based on the IP. For the across-rack case, the server's CPU is notified via a CXL-DoCE transaction carrying an interrupt, sent by the driver. Then, it DMA reads the data to the "vNIC" software queue from the MPSoC0's memory via CXL.io. Packets are then sent to the emulated network queue, delaying for $propagation_delay + queueing_delay + \frac{packet_size}{bandwidth}$ before writing it to the software queue of the other "vNIC", which emulates the network delay. For the intra-rack case, the driver stores data descriptors into the reference queues of MPSoC1 with a CXL-like MemWr. This also embeds interrupt within the CXL transaction to notify MPSoC1's CPU. Upon receiving the interrupt, the CPU initiates a CXL-like memory read (MemRd) to retrieve the data from the memory pool.

Table 3: Application Semantics

Application Category	Example	Causes
Graph Computing	Evolving graphs [98]	Different subgraphs running on each host contribute varying compute time
Database & KV Store	Redis [85]	Imbalanced Hot keys distribution & Varied value size
Model Training	MoE Expert Parallelism	Skewed token load on experts [99]
DLRM Training Inference	Embedding layer [48]	Imbalanced Hot Embedding lookups on Embedding tables

A.4 Communication Efficiency

(a) DRack reduces intra-rack delay via pass-by-reference and DRAM Cache.

(b) Throughput of 4 collective operations across ECMP and packet spray. network settings

(c) MPTCP outperforms

Figure 13: Key designs' impact on DRack's performance.

In this section, we eliminate computations and focus on studying the maximum communication efficiency that DRack can boost, as well as the impact of each individual component.

Intra-rack communication. In the rack, `DRack` eliminates one memory copy by using pass-by-reference, and hides the remote memory latency via DRAM Cache. We evaluate the latency reduction achieved by `DRack` for intra-rack communica-

tion including reliable validation of TCP stack. We conducted the TCP transaction latency test using lmbench [95], which involves repeatedly sending a packet filled with dummy data in a ping-pong fashion. The latency for DRack is measured from the moment the sender stores the packet's reference until the receiver receives the reference, loads its data, and completes its TCP stack processing. As shown in Figure 13(a), DRack achieves an average of 15.9% lower latency than ToRack's pass-by-value. The DRAM cache accounts for 6% of the latency reduction, as the CPU will load a packet's header for multiple times during TCP stack processing that presents high cache locality. Note that the major latency of pass-by-value comes from the TCP protocol stack and controlling DMA for data copy, while DRack eliminates the later one.

Inter-rack Throughput. DRack facilitates a range of collective communications at full capacity, irrespective of the network configuration, *i.e.*, network-oblivious communication. This property frees application designers to tailor communication collectives across network settings (*e.g.*, oversubscription ratio). As shown in Figure 13(b), we run four collective communication operations using Gloo over 8 hosts and increase the rack size, the number of hosts in a rack, from 2 to 4, to have an over-subscription ratio from 1 to 2. As DRack uses the NIC pool as the ToR layer, it provides full-bisectional bandwidth across racks, consistently offering throughput gains for all collectives compared to ToRack. ToRack limits the throughput of collectives with intensive cross-rack traffic due to the ToR's uplinks (*e.g.*, AlltoAll), while it cannot fully utilize the uplink bandwidth for collectives with reduced cross-rack traffic (*e.g.*, ring and halving doubling).

We evaluate the necessity of MPTCP in bandwidth efficiency. DRack leverages MPTCP to balance the inter-rack traffic load between 2 available NICs. We first evaluate the throughput with three popular traffic distribution mechanisms (with the other DRack's component enabled): 1) Packets spray: scattering packets between all NICs [100], 2) ECMP: hashing a flow to a NIC [101], 3) MPTCP. We run Gloo AlltoAll with the above mechanisms, respectively. As shown in Figure 13(c), MPTCP fully utilizes the NIC pool capacity, while ECMP cannot utilize the bandwidth efficiently as a single flow can only use one NIC, even if the other NIC is free, packet spray can result in out-of-order packet arrivals, causing TCP congestion control that actively slows down the throughput.

ShieldReduce: Fine-Grained Shielded Data Reduction

Abstract

Storage savings and data confidentiality are two primary yet conflicting goals in outsourced backup management. While deduplication-aware encryption has been extensively studied to make deduplication viable for encrypted data, it is incompatible with fine-grained delta and local compression for further storage savings. We present ShieldReduce, a secure outsourced storage system that aims for fine-grained shielded data reduction by applying deduplication, delta compression, and local compression to data in a trusted execution environment based on Intel SGX, so as to achieve high storage savings with security guarantees. To mitigate the I/Os of accessing base chunks for delta compression in SGX, ShieldReduce adopts bi-directional delta compression via a novel hybrid inline and offline compression design to maintain the physical locality of base chunks. Evaluation on various backup workloads shows that ShieldReduce achieves significant speedups over a shielded baseline without bi-directional delta compression, while maintaining comparable storage savings to fine-grained data reduction for plain data.

1 Introduction

Outsourced storage in third-party clouds provides a cost-effective solution for organizations to manage backups for multiple clients. Practical outsourced storage systems should be designed with two major goals in mind: (i) *storage savings*, which reduce the storage footprints of outsourced data to save management costs; and (ii) *data confidentiality*, which protects outsourced data against unauthorized access by malicious users and even cloud operators. The goals, however, are inherently conflicting: clients should encrypt their data to ensure confidentiality, but conventional symmetric-key encryption, which uses unique user-specific keys, makes redundant data from different clients incompressible, thereby prohibiting storage savings through compression.

To resolve this conflict, one class of work in the literature focuses on *encrypted deduplication* (e.g., convergent encryption [20] and message-locked encryption [10, 11]), which relaxes conventional symmetric-key encryption by encrypting each data chunk with a deterministic key derived from the chunk content, so as to allow duplicate data chunks from different clients to be mapped into duplicate encrypted chunks that can be removed via cross-client deduplication. However, encrypted data has high entropy, making encrypted deduplication incompatible with delta and local compression for further storage savings (see §2.2 for details).

We explore *fine-grained shielded data reduction*, which performs deduplication, delta compression, and local compression in sequence for high storage savings, and uses shielded execution to realize the whole data reduction workflow with conventional symmetric-key encryption for data confidentiality. We leverage Intel's Software Guard Extensions (SGX) [6] to provide a trusted execution environment called the *enclave* for shielded execution. Client-side organizations can host an enclave-enabled virtual machine in the cloud, ensuring that even cloud operators cannot access any content inside the enclave. The virtual machine can perform fine-grained shielded data reduction for the data chunks originating from multiple clients inside the enclave, encrypt the reduced outputs, and persistently store the encrypted chunks in the cloud. Fine-grained shielded data reduction is compliant with conventional symmetric-key encryption by removing content redundancies *before* encryption inside the enclave [60], so as to maintain the confidentiality guarantees of conventional symmetric-key encryption.

Realizing fine-grained data reduction in an enclave is non-trivial, since the enclave incurs high context-switch overhead to interact with untrusted host applications outside of the enclave [18, 28]. Delta compression, in particular, works by encoding the content difference between a new data chunk and a previously stored *base chunk* identified as similar to the new data chunk [45, 52, 53, 62]. This challenges the management of base chunks for a large number of data chunks: even though the latest SGX generation [9] allows hundreds of gigabytes in enclave memory, the machine hosting the enclave may not have sufficient memory to support a large-size enclave for buffering all base chunks. Storing base chunks in persistent storage and loading them into the enclave on demand incurs significant overhead in both disk I/Os and context switches.

We present ShieldReduce, an outsourced backup storage system based on fine-grained shielded data reduction. Inspired by the locality of backup workloads [38, 66], ShieldReduce operates on data chunks on a per-batch basis and loads the base chunks in batches from persistent storage into the enclave for fine-grained data reduction, as the base chunks are likely to be physically stored together due to locality. This mitigates I/O overhead compared to reading individual base chunks. However, as more versions of backups are stored, the base chunks become more scattered across different versions

*Corresponding author: Jingwei Li (jwli@uestc.edu.cn)

of backups. Thus, ShieldReduce maintains *physical locality* across different versions of backups via *bi-directional delta compression* by examining the physical distribution of base chunks: if the base chunks are stored together (i.e., strong locality), ShieldReduce delta-compresses new data chunks with respect to the corresponding base chunks (i.e., forward); otherwise, if the base chunks are physically scattered (i.e., weak locality), ShieldReduce treats the new data chunks as base chunks and delta-compresses the old base chunks with respect to the new data chunks (i.e., backward). Since the new data chunks are likely to be logically adjacent, making them base chunks can reconstruct physical locality for future backups with low I/O overhead. ShieldReduce adopts a *hybrid* inline and offline compression approach (i.e., on and off the write path, respectively) to limit the I/O interference of bi-directional delta compression with normal backup operations. We emphasize that ShieldReduce differs from a recent work LoopDelta [61], which applies backward delta compression only to mitigate chunk fragmentation. In contrast, ShieldReduce adaptively switches between forward and backward delta compression to balance the trade-off between I/O performance and storage savings based on a single configurable parameter (see §6 for detailed comparisons).

We extend ShieldReduce based on DEBE [60], and compare ShieldReduce in a networked environment with several baselines using various backup workloads (e.g., source code versions, binary snapshots, websites, and operating system images). ShieldReduce achieves an upload throughput gain of up to 3.5× over a baseline without bi-directional delta compression and maintains comparable storage savings as in fine-grained data reduction for plain data (i.e., without data confidentiality). Compared with an existing performance-oriented approach [67] that we adapt to shielded execution, ShieldReduce achieves a comparable upload speed inline, while achieving additional storage savings of up to 3.6× via offline compression. The source code of our ShieldReduce prototype is at: `https://github.com/YangJingyuan99/shieldreduce`.

2 Background and Problem

2.1 Plain Data Reduction

Overview of data reduction. We explore three data reduction approaches for plain data (without encryption): deduplication, delta compression, and local compression. *Deduplication* has been widely adopted in backup systems [12, 37, 38, 55, 57, 66] and achieves storage savings of around 10× in production backup workloads [55]. It partitions file data into *chunks* (e.g., 4 KiB or 8 KiB each [66]), and identifies each chunk by a *fingerprint*, generated by the cryptographic hash of the chunk content. Assuming that fingerprint collisions for non-duplicate chunks are highly unlikely [14], two chunks are said to be *duplicate* if they have the same fingerprint. Only unique copies (called *physical chunks*) are stored, while duplicate chunks refer to the same physical chunk via small-size references. The fingerprint of each physical chunk and its chunk location are kept in a key-value store called the *fingerprint index*.

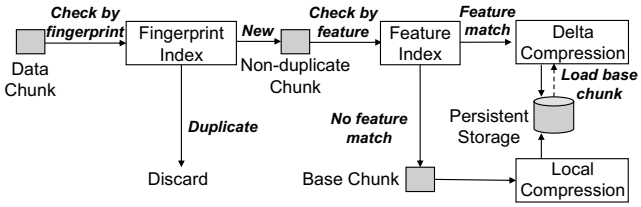

Figure 1: Fine-grained data reduction for plain data.

Delta compression removes duplicate content among non-duplicate but *similar* chunks, which contain large fractions of duplicate content with differences in only a few chunk regions. It can achieve extra storage savings of around 2× on average beyond deduplication and local compression in production backup workloads [53]. One approach of finding similar chunks is to derive *features* from the chunk content [16, 22, 47, 53, 62]; for example, a feature can be the maximum Rabin fingerprint over all sliding windows of the chunk content [22, 40, 47, 53, 62]. Two chunks are considered similar if they share one or more common features. Delta compression stores one of the data chunks (called the *base chunk*) and the content differences from the base chunk to the remaining similar chunks (called *delta chunks*), with each delta chunk typically being smaller than the original chunk. Each feature and its associated base chunk (identified by its fingerprint) are kept in a key-value store called the *feature index*.

Local compression encodes the content of a data chunk into fewer bits in a *lossless* manner for persistent storage, such that the encoded bits can be decoded without information loss. We do not perform local compression on delta chunks, since they are already encoded and local compression only achieves marginal storage savings [53].

Fine-grained data reduction. We apply deduplication, delta compression, and local compression in sequence to achieve fine-grained data reduction for high storage savings [45, 47, 53], as shown in Figure 1. Suppose that a chunk of a file is written to a storage system. The system first queries the fingerprint index to check if the chunk is a duplicate; if so, the chunk is discarded.

If the chunk is new, the system updates the fingerprint index to track the new chunk. It extracts features from the chunk and queries the feature index to check for any similar chunks with common features. If no common feature is found, the chunk is treated as a base chunk. The system locally compresses the base chunk and stores it in persistent storage, as well as adds the feature mappings of the base chunk to the feature index.

If at least one feature of the new chunk is found, the system retrieves the base chunk with the first matching feature from persistent storage and delta-compresses the new chunk with

respect to the base chunk into a delta chunk, which is then stored in persistent storage.

For file reconstruction, the system keeps a *file recipe* in persistent storage to track the fingerprints of delta chunks and corresponding base chunks of each file. All chunks (of several KiB each) in persistent storage are packed and managed in large fixed-size units called *containers* [37] of several MiB each (e.g., 4 MiB). All I/O operations are performed in units of containers. This mitigates the I/O overhead of accessing many small-size chunks.

2.2 Encrypted Deduplication and Its Limitations

Encrypted deduplication. To support data reduction on encrypted data, one extensively studied approach is *encrypted deduplication* [10, 11, 35, 39], in which a client symmetrically encrypts each data chunk to be outsourced to the cloud via a key derived from the chunk content (e.g., via the cryptographic hash of the data chunk [20], or via a server-aided approach where a dedicated key manager returns the same key for the same fingerprint [10]). This ensures that duplicate data chunks, even from different clients, are deterministically mapped to duplicate encrypted chunks that can be removed by deduplication. The client uploads encrypted chunks to the cloud, which cannot access the original data chunks but can still perform cross-client deduplication on the encrypted chunks for storage savings.

Limitations. Encrypted deduplication has two major limitations. First, it must use a deterministic encryption approach [10, 11, 20] to preserve the identical contents even after encryption. This inevitably leaks the number of occurrences of each data chunk in the original plain data, allowing an adversary to launch frequency analysis to infer the plain data chunks based on the frequency distribution of encrypted chunks [33]. From a cryptography perspective, no cryptographic primitive for data reduction can achieve the confidentiality guarantees of conventional symmetric-key encryption [11]. Second, since encryption inherently generates high-entropy encrypted data, it is infeasible to further reduce the sizes of encrypted chunks via delta and local compression for additional storage savings.

One may argue for a simple approach in which clients first perform data reduction on their own data, encrypt the reduced data via conventional symmetric-key encryption, and upload the encrypted reduced data to the cloud. However, this approach prohibits cross-client data reduction for further storage savings in some workloads; for example, multiple clients may perform regular backups on their virtual machine images in cloud environments, while the virtual machine images from different clients commonly share identical content in operating system files [29, 36] that cannot be removed.

2.3 Fine-grained Shielded Data Reduction

Instead of designing new cryptographic solutions, we leverage shielded execution to design *fine-grained shielded data reduction*. We focus on Intel's Software Guard Extensions (SGX) [6] for shielded execution due to its widespread use [19, 30, 42, 46, 49, 50, 60] and long-term support for Intel Xeon platforms [48]. SGX creates a secure running context, called an *enclave*, for code and data processing with confidentiality and integrity guarantees. This contrasts with AMD SEV [2] and Intel TDX [5], which protect the execution of the entire virtual machine (i.e., more coarse-grained) and rely on a sizable trusted computing base [17].

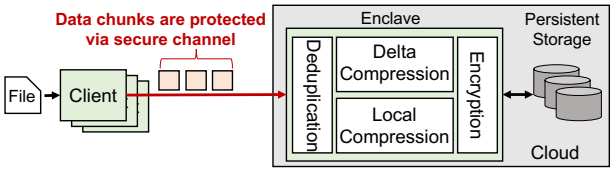

Figure 2: ShieldReduce architecture.

Architecture. We consider an organization that leverages an untrusted cloud to deliver secure backup services to its users. The organization can deploy an enclave-enabled virtual machine instance in the cloud and allow multiple clients to send plain data chunks via secure channels to the enclave [60]. The enclave performs the complete data reduction workflow (i.e., deduplication, delta compression, and local compression) on all received data chunks, encrypts the reduced outputs, and persistently stores the encrypted chunks in the cloud. It eliminates the need for deterministic encryption on data chunks as in encrypted deduplication to mitigate frequency leakage, since fine-grained data reduction is now performed *before* the reduced outputs are encrypted. It further supports delta and local compression, which can now be done before encryption. Note that DEBE [60] also makes a similar observation and supports deduplication-before-encryption, but it does not address delta compression.

We design ShieldReduce to realize fine-grained shielded data reduction for secure and space-efficient backup storage (Figure 2). To upload a backup, a client first sets up a random one-time *session key* with the enclave via the Diffie-Hellman key exchange protocol and establishes a secure session with the enclave, so that any adversary cannot feasibly infer the transferred chunks [60]. The client then partitions the backup file into data chunks, encrypts each data chunk with the random one-time session key, and sends the encrypted chunks to the enclave. Since client-enclave communications are protected by random one-time session keys, they do not leak the frequency information of each data chunk [34]. The enclave decrypts received data chunks with the session key and performs fine-grained shielded data reduction (§2.2). Such *target-based* data reduction [36] prevents a malicious client from inferring the deduplication pattern and launching side-channel attacks [26, 27]. The enclave also maintains a *data key* to encrypt the reduced output data, which is then stored in the cloud for persistence. Note that ShieldReduce does not require a dedicated key manager on the critical I/O path as in

server-aided encrypted deduplication [10] (§2.2).

Threat model. We aim to provide confidentiality guarantees for outsourced backups, which may contain sensitive data. Our threat model considers an adversary that aims to infer the original plain backup data. The adversary can compromise the cloud to access the encrypted contents stored in both untrusted memory and persistent storage, as well as monitor the enclave's interactions with the *untrusted memory* outside the enclave. It can also compromise some clients to access their private information, so as to infer the backup data of other non-compromised clients.

We assume that the adversary and even cloud operators cannot access the contents inside the enclave, even though the enclave is hosted in the cloud. Also, the enclave is securely initialized, and any application code running inside it is authenticated. Enclave authentication is achievable with the aid of a third party (e.g., the organization that provides backup services) [49, 60]. Specifically, the organization compiles the application code into a shared object. It distributes the shared object and its signature to the cloud, which bootstraps the enclave by loading the shared object. The enclave can be publicly verified by remote attestation [6]. Note that the organization *cannot* access any plain data, since the enclave is initialized with the necessary code only without any client data. After attesting the enclave, the organization can go offline, and clients can send backups via secure channels.

The enclave runs the deployed application and verifies the authenticity of the client for each connection via SSL mutual authentication to prevent unauthorized data access. We assume that current countermeasures [15, 24, 44] can be used to protect against attacks for extracting secret information from the enclave [13,43], and we do not further consider such attacks in this work. Finally, the source code of the enclave's binaries can be publicly verified to ensure that it does not include any backdoors. Note that backdoor-free enclaves are commonly assumed in state-of-the-art shielded deduplicated storage [25, 42, 49, 60].

2.4 Challenges

Although previous studies explore SGX-based secure deduplication [25, 42, 49, 60], implementing the complete data reduction process in SGX remains non-trivial.

Resource constraints of SGXv2. In this work, we focus on *SGXv2* [9], the latest SGX generation that supports up to 512 GiB of *enclave page cache (EPC)* (an isolated memory region for an enclave) per CPU socket [23]. SGXv2 significantly mitigates the limited EPC space of its predecessor SGXv1 (which supports up to 128 MiB), yet it still has resource constraints. First, the maximum physical size of an EPC is subject to the available memory size of the hosting machine. In practical cloud environments, an EPC uses only 50% of the overall memory of a virtual machine instance [4]. When an enclave reaches the EPC size limit, it swaps encrypted EPC pages with untrusted memory, leading to expensive paging overhead [18, 23, 28]. Also, SGX provides interfaces for the enclave to securely interact with untrusted memory: *ECalls* for outside applications to securely access in-enclave contents, and *OCalls* for the enclave to access unprotected memory. However, these interfaces incur high overhead, approximately 8,000 CPU cycles per invocation (compared to 150 CPU cycles for a standard system call) [56], due to (i) context switching in the CPU, (ii) operations for preserving the confidentiality of trusted application data, and (iii) flushing of CPU and address translation cache [18, 28].

Expensive base chunk management of delta compression. Fine-grained shielded data reduction should support delta compression (§2.1), yet efficiently managing base chunks is non-trivial, especially when delta compression is applied to numerous data chunks [53, 67]. One option is to keep base chunks inside the enclave. However, the GiB-level memory available in commodity machines for hosting the EPC remains insufficient to buffer all base chunks. Another option is to store base chunks in persistent storage and load them into the enclave on demand. This relieves EPC usage, but incurs significant overhead both in disk I/Os for retrieving the required base chunks from persistent storage and in context switches for loading base chunks from unprotected memory into the enclave.

3 ShieldReduce Design

ShieldReduce is an outsourced backup storage system that aims for the following goals: (i) *storage savings* via deduplication, delta compression, and local compression, (ii) *data confidentiality* via shielded data reduction, and (iii) *high performance* in enclave usage. It builds on DEBE [60] to apply deduplication to data chunks and extend DEBE with delta compression. DEBE mitigates the enclave resource overhead via frequency-based deduplication, which performs first-phase deduplication on the chunks with high duplicate counts using a small fingerprint index inside the enclave, followed by second-phase deduplication on the remaining chunks using a full fingerprint index outside of the enclave. We do not claim novelty in the deduplication design. Instead, our focus is on designing lightweight delta compression and local compression for post-deduplicated chunks (all of which are non-duplicate) inside the enclave and mitigating the base chunk management overhead in delta compression (§2.4).

3.1 Main Idea

To achieve high performance against the challenges in §2.4, ShieldReduce leverages *locality* in backup workloads [32, 41, 53], in which modifications to a backup are often clustered in a few regions. If a data chunk (say M') in the latest backup is modified from a data chunk (say M) in the previous backup, then M is likely to be the base chunk of M', and the neighboring chunks of M are also likely to be the base chunks of the neighboring modified chunks of M'. Our rationale is that small changes are unlikely to alter the features of

data chunks, so the modified data chunks are likely to follow the same sequence as the corresponding base chunks in the previous backup. Specifically, ShieldReduce operates on data chunks on a *per-batch* basis. It loads the base chunks for a batch of data chunks from persistent storage into the enclave and performs delta compression on the data chunks. Due to locality, the base chunks for a batch of data chunks are likely to be stored in only a few containers, thereby mitigating the I/Os of accessing persistent storage.

However, the locality across two backups in persistent storage (i.e., *physical locality*) gradually decreases as they are separated by an increasing number of backups. Existing fine-grained data reduction techniques [53, 62] often choose the *first* data chunk with new features as the base chunk, so earlier backups typically include many base chunks. Thus, a data chunk M' in a recent backup tends to refer to a base chunk M in an older backup. As changes accumulate across backups, the neighboring physical chunks of M may be heavily updated and no longer be the base chunks of neighboring chunks of M'. This causes ShieldReduce to issue more I/Os to load base chunks from persistent storage into the enclave as the number of backups increases.

To preserve physical locality, we propose *bi-directional delta compression*. Our insight is that chunk similarity is *symmetric*, meaning that if a new data chunk M' is similar to a base chunk M, then M is also similar to M'. This allows delta compression to be performed in two directions: (i) *forward delta compression*, which delta-compresses M' with respect to M, and (ii) *backward delta compression*, which makes M' a new base chunk and delta-compresses M with respect to M'. For a batch of data chunks, ShieldReduce performs either forward or backward delta compression *based on the physical distribution of the corresponding base chunks*. If the base chunks are stored in a limited number of containers (i.e., physical locality exists), ShieldReduce loads these base chunks from persistent storage to the enclave and performs forward delta compression on the batch of data chunks. Otherwise, if the base chunks are scattered across many containers (i.e., physical locality drops), ShieldReduce performs backward delta compression to delta-compress old base chunks with respect to new data chunks. Since the new data chunks are likely to be logically adjacent prior to data reduction, letting them be base chunks can reconstruct physical locality.

ShieldReduce's bi-directional delta compression differs from LoopDelta's backward delta compression [61], which focuses on mitigating chunk fragmentation and does not consider the storage-performance trade-off and security guarantees (§6). We choose Finesse [62] as the major similarity matching technique for ShieldReduce to pair base chunks with their similar chunks due to its high performance and delta-compression savings, and extend Finesse to preserve physical locality. There are possibly other similarity matching techniques, and we pose the analysis as future work.

Example. Figure 3 motivates via an example the need for bi-directional delta compression. Suppose that we store a sequence of backups denoted by $\mathbf{V_0}$, $\mathbf{V_1}$, $\mathbf{V_2}$, and $\mathbf{V_3}$, each of which has a single batch of data chunks. $\mathbf{V_0}$ is already stored.

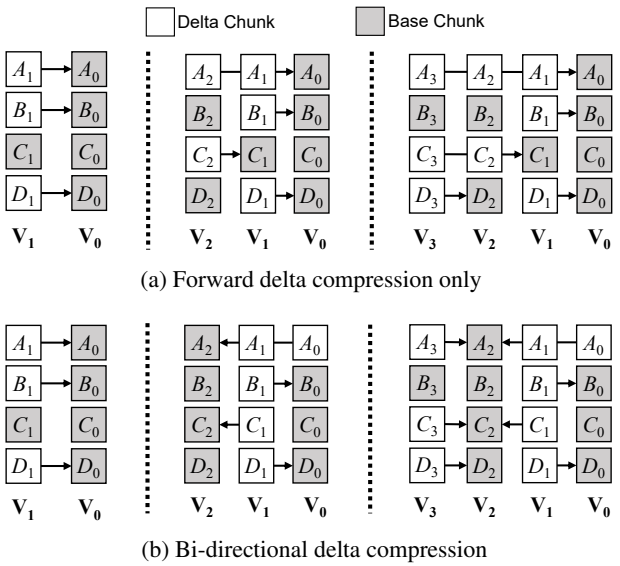

Figure 3: Comparison of forward delta compression only and bi-directional delta compression. The relation $X \rightarrow Y$ for two data chunks X and Y means: (i) both X and Y are similar, (ii) Y is the base chunk of X, and (iii) X is delta-compressed with respect to Y.

Figure 3(a) shows an example of using forward delta compression only. Suppose that $\mathbf{V_1}$ is to be stored, in which A_1, B_1, and D_1 are slightly updated from (and hence are similar to) A_0, B_0, and D_0 in $\mathbf{V_0}$, respectively. Forward delta compression identifies A_0, B_0, and D_0 in $\mathbf{V_0}$ as the base chunks of A_1, B_1, and D_1 in $\mathbf{V_1}$, respectively. Such base chunks are close in persistent storage and are also likely stored in the same container. Suppose that $\mathbf{V_2}$ is to be stored, in which A_2 and C_2 are slightly updated from A_1 and C_1 in $\mathbf{V_1}$. Forward delta compression chooses A_0 in $\mathbf{V_0}$ as the base chunk of A_2, and C_1 as the base chunk of C_2. Now, the base chunks are in both backups $\mathbf{V_0}$ and $\mathbf{V_1}$. When $\mathbf{V_3}$ is stored, we see that the base chunks are scattered in all backups $\mathbf{V_0}$, $\mathbf{V_1}$, and $\mathbf{V_2}$. In other words, physical locality drops.

Figure 3(b) shows an example of bi-directional delta compression. When $\mathbf{V_1}$ is stored, bi-directional delta compression selects the same base chunks in $\mathbf{V_0}$ as in forward delta compression only. When $\mathbf{V_2}$ is stored, it can apply backward delta compression to treat the data chunks A_2 and C_2 in $\mathbf{V_2}$ as the base chunks for A_1 and C_1 in $\mathbf{V_1}$, respectively. Also, it treats A_2 as the new base chunk for the old base chunk A_0, which will be retrieved from persistent storage for delta compression. When $\mathbf{V_3}$ is stored, it can apply forward delta compression again and select A_2, C_2, and D_2 from $\mathbf{V_2}$ as the base chunks for A_3, C_3, and D_3, respectively. The base chunks are still from the same backup and can be readily retrieved.

Design roadmap. Figure 4 presents the design roadmap for ShieldReduce. ShieldReduce adopts a hybrid *inline* (i.e., on

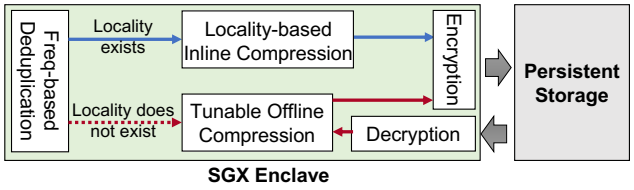

Figure 4: Design roadmap of ShieldReduce. Frequency-based deduplication is proposed by DEBE [60].

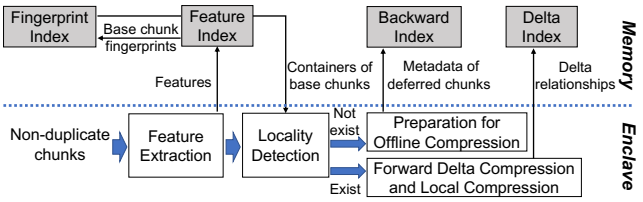

Figure 5: Locality-based inline compression in ShieldReduce.

the write path) and *offline* (i.e., off the write path) approach. After deduplication, if physical locality exists, the enclave performs *locality-based inline compression*, which includes both forward delta compression and local compression, and encrypts and stores the compressed chunks in persistent storage. Locality-based inline compression aims to achieve high performance on the write path.

If physical locality drops, the enclave performs *tunable offline compression*, which reconstructs physical locality via backward delta compression and also provides a tunable mechanism to balance the storage-performance trade-off. As backward delta compression delta-compresses an old base chunk (say M) with respect to a new data chunk (say M'), it should also reapply delta compression on the data chunks that are originally delta-compressed with respect to M; otherwise, any subsequent reconstruction of such data chunks needs to first retrieve and decrypt M' from persistent storage to delta-decompress M, thereby triggering multiple I/Os. ShieldReduce exports a single user-configurable parameter to balance the trade-off between the performance overhead and storage savings from backward delta compression.

ShieldReduce ensures that the enclave always receives data chunks from multiple clients via secure sessions (§2.3) and only stores encrypted data in persistent storage, so as to achieve end-to-end security for the data path.

3.2 Locality-based Inline Compression

Overview. Figure 5 presents the workflow of locality-based inline compression in ShieldReduce. It processes a batch of n data chunks before deduplication ($n = 128$ by default). After deduplication, it extracts three features [62] from each data chunk, queries the feature index for the base chunk (§2.1), and retrieves the container IDs of these base chunks from the fingerprint index. It then detects the physical locality of the base chunks for the batch of data chunks. If physical locality exists, it performs forward delta compression and local compression; otherwise, it prepares for offline compression.

Locality detection. ShieldReduce detects the physical locality of the base chunks of a batch of data chunks based on how they are physically stored in containers. Given n data chunks of a batch, let p be the number of data chunks that have the base chunks and q be the number of containers that contain the base chunks, where $q \leq p \leq n$. ShieldReduce quantifies physical locality as q/n; a small q/n implies strong locality as the base chunks are clustered in a small number of containers. If q/n is no more than some pre-defined *locality threshold* t, we say that physical locality exists. We evaluate the sensitivity of t in §5.3.

Forward delta compression and local compression. If physical locality exists, ShieldReduce performs forward delta compression and local compression in two cases.

- For the p data chunks that have base chunks, it loads the corresponding encrypted base chunks from persistent storage into the enclave. The enclave decrypts the encrypted base chunks, locally decompresses them, and delta-compresses the data chunks with respect to the base chunks into delta chunks. It encrypts and stores the delta chunks in persistent storage. It also updates the file recipe to track the base chunks of such data chunks.
- For the remaining data chunks that do not have base chunks (at most $n-p$ such data chunks due to deduplication), ShieldReduce treats them as new base chunks. The enclave locally compresses, encrypts, and stores the new base chunks in persistent storage. It updates the file recipe and feature index to track the features of the new base chunks.

ShieldReduce maintains a key-value store called the *delta index* in untrusted memory to track the delta relationships, which are later needed by backward delta compression (§3.3) to reapply delta compression on the data chunks originally delta-compressed with respect to old base chunks. Each entry in the delta index maps the encrypted fingerprint of a base chunk to a set of encrypted fingerprints of the corresponding delta chunks. After forward delta compression, ShieldReduce updates the delta index to track the data chunks that have been delta-compressed with respect to the base chunks.

Preparation for offline compression. If physical locality does not exist (i.e., $q/n > t$), ShieldReduce defers the compression for the batch of data chunks offline and performs the following preparation steps. It locally compresses each data chunk and stores the encrypted compressed chunks in persistent storage. It also maintains a key-value store called the *backward index* in untrusted memory to track the chunks for backward delta compression. Each entry in the backward index maps the encrypted fingerprint of a base chunk to a set of encrypted fingerprints of corresponding data chunks that will be delta-compressed offline.

The backward index keeps the mappings until backward delta compression is performed, and the mappings can be cleared afterwards. Thus, ShieldReduce bounds the maxi-

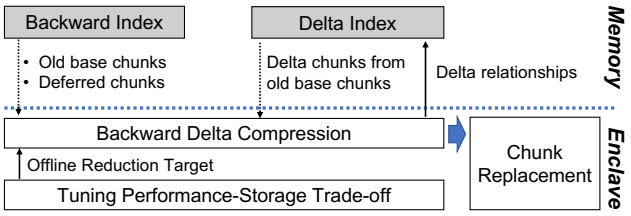

Figure 6: Tunable offline compression in ShieldReduce. The dotted line means that ShieldReduce retrieves chunks from persistent storage based on the backward index and delta index.

mum size of the backward index to limit resource overhead. For example, suppose that each encrypted fingerprint has 32 bytes (from SHA-256) and each data chunk has an average size of 8 KiB. If we configure the backward index with a maximum size of 256 MiB, it can keep the mappings for at least 256 MiB / (32 + 32) bytes $\times$ 8 KiB $\approx$ 32 GiB of data chunks (assuming that each data chunk has a distinct base chunk). If the backward index is full, ShieldReduce performs forward delta compression on the remaining data chunks.

3.3 Tunable Offline Compression

Overview. Figure 6 depicts the workflow of tunable offline compression in ShieldReduce. Based on the mappings in the delta index and backward index, ShieldReduce retrieves from persistent storage the (encrypted) physical copies of (i) the old base chunks, (ii) the data chunks deferred to be delta-compressed, and (iii) the delta chunks already compressed with respect to the old base chunks. It performs backward delta compression based on a user-configurable parameter to balance the storage-performance trade-off. It also replaces the existing physical copies of the above chunks in persistent storage with the new ones that are delta-compressed with respect to new base chunks in offline compression.

Backward delta compression. Recall that each entry of the backward index maps an encrypted fingerprint of a base chunk (say M) to a set of encrypted fingerprints of the data chunks (§3.2). ShieldReduce selects the *most recent* data chunk (say M') in the backward index as the new base chunk. It delta-compresses M, as well as any other data chunk (say $\hat{M}$) that is also mapped by M in the backward index, with respect to M'. Our rationale is that future data chunks are likely to be modified from the most recent data chunks with minimum content differences [61], so choosing the most recent data chunks as new base chunks likely brings more storage savings in delta compression. Note that M' and $\hat{M}$ may not have any common feature, yet we expect that delta-compressing $\hat{M}$ with respect to M' shows storage savings (Exp#1 in §5.2), as they are similar to the same old base chunk M.

We elaborate on the details of backward delta compression. For each old base chunk M, the enclave chooses the most recent data chunk that is mapped by M as the new base chunk M', delta-compresses M with respect to M', and encrypts and stores the delta chunk in persistent storage. It reapplies delta compression on the affected data chunks in two cases. First, for the remaining data chunks that are also mapped by M and deferred to be delta-compressed as tracked by the backward index, the enclave decrypts and recovers such data chunks via local decompression. Second, for the others that are already delta-compressed with respect to M as tracked by the delta index, the enclave recovers them via delta decompression. Then, for both cases, the enclave delta-compresses the data chunks with respect to M', and encrypts and stores the delta chunks in persistent storage. It updates (i) the feature index to track the new base chunk M', (ii) the delta index to track the delta compression relationships, (iii) the fingerprint index to track the new physical copies of the related chunks that are delta-compressed with respect to M', and (iv) the file recipe to change the corresponding base chunks to M'.

Tunable performance-storage trade-off. Since backward delta compression incurs extra I/O and computational overhead (§3.1), ShieldReduce skips the backward delta compression of some old base chunks (i.e., the old base chunks are now directly stored without delta compression). The trade-off is that the physical copies of the skipped base chunks are no longer delta-compressed and the storage size increases. To make the trade-off readily tunable, ShieldReduce introduces a configurable parameter called the *offline reduction target* α (where $0 \leq \alpha \leq 1$) based on the data reduction ratio that is expected to be achieved by offline compression: a smaller (larger) α means that ShieldReduce will remove more (less) data in offline compression.

When processing a backup, ShieldReduce monitors the current storage space occupied by the backup, and tracks the current reduction ratio of offline compression as $\alpha_{current} = S_{current}/S_{inline}$, where S_{inline} is the actual storage space occupied by the backup after inline compression and $S_{current}$ is the currently occupied storage space during offline compression. It collects the old base chunks from the backward index, and sorts them based on the number of data chunks delta-compressed with respect to each old base chunk. It prefers to choose the old base chunk with the least number of data chunks for backward delta compression, and keeps processing the old base chunks until either $\alpha_{current} < \alpha$ or all old base chunks have been processed.

For any remaining old base chunks, ShieldReduce skips their backward delta compression and directly updates the feature index based on the new base chunks. Also, it removes their delta relationships from the delta index to mitigate index overhead. The rationale is that such skipped old base chunks are no longer used for delta compression.

Chunk replacement. After offline compression, ShieldReduce performs the *mark-and-sweep* approach [21] to reclaim the storage space of the old physical copies of the chunks that are delta-compressed by offline compression (e.g., after the old base chunk is delta-compressed with respect to the new data chunk, its physical copy still exists in physical

storage); note that it does not compromise data integrity, as the new delta-compressed copies have been stored in persistent storage. ShieldReduce maintains a temporary *deletion map* in unprotected memory to track the chunks whose old copies need to be deleted. Each entry in the deletion map maps a container ID to a list of deleted chunks, each of which is identified by its offset and length within the container. The deletion map only marks the chunks for logical deletion. Once all chunks have been processed in offline compression, ShieldReduce re-writes the marked containers to reclaim storage space and clears the deletion map.

3.4 Storage Management

Container organization by semantics. ShieldReduce sets each container (§2.1) with a fixed size of 4 MiB, and decouples the management of chunks into two types of containers: (i) the *base chunk container*, which stores encrypted and compressed base chunks, and (ii) the *delta chunk container*, which stores encrypted delta chunks. Our rationale is to improve the I/O efficiency of inline compression (§3.2), since only base chunks are retrieved for delta compression.

Metadata management. ShieldReduce manages the fingerprint index and feature index in unprotected memory, and protects sensitive data fields in both indexes via encryption. In addition to the data key that protects chunk data (§2.3), the enclave persistently manages a *meta key* to encrypt fingerprints. Each entry of the fingerprint index maps an encrypted fingerprint of a data chunk to a container ID where the corresponding chunk data are stored, while that of the feature index maps a feature to the encrypted fingerprint of the corresponding base chunk. Each feature is derived from the original chunk content using a *collision-allowed hash function* [53, 62], so different chunks can have the same features, yet an adversary cannot readily identify the original base chunks based on features only.

ShieldReduce maintains a file recipe (§2.1) for each backup file, so as to track all data chunks of the file. Each entry in the file recipe stores the fingerprint of an encrypted chunk. If the chunk is delta-compressed, the entry also stores the fingerprint of the corresponding base chunk. ShieldReduce encrypts and stores the file recipe in persistent storage.

Download. To restore a backup, a client submits a download request to the cloud. The enclave verifies the client's authenticity (§4). It decrypts the file recipe and restores each data chunk. If the data chunk is a base chunk (i.e., not delta-compressed), the enclave reads the encrypted data chunk, decrypts it, and performs local decompression to recover the original data chunk; otherwise, if the data chunk is delta-compressed, the enclave restores the corresponding base chunk and decompresses the data chunk based on the base chunk. Finally, the enclave sends all data chunks back to the client via a secure channel.

3.5 Security Discussion

We discuss the security guarantees of ShieldReduce against the threat model in §2.3.

Eavesdropping on untrusted memory and cloud storage. An adversary can access the fingerprint index, feature index, delta index, and backward index in untrusted memory of the cloud. Nevertheless, ShieldReduce encrypts fingerprints and generates features via collision-allowed hash functions, so it prevents the adversary from identifying the data chunks from the indexes (§3.4). Note that the adversary may learn from both the delta index and backward index which data chunks are similar to a base chunk, yet it still cannot identify original data chunks, so the practical damage remains an open question. We can still fully encrypt the delta index and backward index to prevent such leakage, yet this adds the overhead of decrypting the indexes inside the enclave for updates and queries. The adversary can access the chunks and file recipes in persistent storage of the cloud, yet ShieldReduce ensures that they are fully encrypted to prevent unauthorized access.

Monitoring interface calls. An adversary can monitor the enclave's boundary on three types of cross-boundary function calls: (i) *index queries*, which query the fingerprint index and feature index based on the encrypted fingerprints and features of data chunks, respectively; (ii) *index updates*, which update the backward index and delta index based on encrypted fingerprints; and (iii) *data transfers*, which move encrypted data via the enclave. The adversary can learn (i) from index queries which encrypted fingerprints and features correspond to a batch of data chunks, (ii) from index updates which chunks will be offloaded to offline compression, and (iii) from data transfers how much data is reduced for each batch of data chunks. Such learned knowledge, however, cannot help the adversary infer original data. For (i), the underlying frequency-based deduplication mitigates the leakage of querying the fingerprint index [60] and ShieldReduce maps distinct chunks to the same feature (§3.4). For (ii), the chunks and fingerprints are encrypted. For (iii), while such leakage is inevitable to support data reduction, an adversary only sees encrypted data without useful information.

Collusion between the cloud and clients. An adversary can compromise both the cloud and a client to additionally access the compromised client's session key and its data chunks. Nevertheless, since the session key is random and used only once, it does not leak other clients' uploaded data that are protected by different session keys.

However, a powerful adversary may now exploit the leakage of how much data is reduced (see above). It can proactively upload artificial chunks via the compromised client and monitor the cloud to see how much data is actually stored. It can learn whether the artificial chunks have been stored by other clients (due to deduplication) and how similar they are to the chunks of other clients (due to delta compression). To defend, we can use selective deduplication [27] to obfus-

cate deduplication patterns and pad delta chunks with random dummy bytes to mitigate compression leakage, at the expense of increasing storage overhead. Alternatively, we can also rate-limit clients' queries to slow down the attack [10].

4 Implementation

We prototyped ShieldReduce based on Intel SGX SDK Linux 2.15. It implements in-memory index structures with `std::unordered_map` and encrypts fingerprints (computed via SHA-256) in each index structure via AES-256 in CBC mode with a fixed zero initialization vector [60], so that identical plain fingerprints are mapped to identical encrypted fingerprints for duplicate detection. It uses multi-threading to parallelize internal operations, and the cloud maintains an in-memory 256-MiB cache to hold recently accessed containers. Our prototype includes 10.5 K lines of C++ code.

Chunking and deduplication. Each client uses FastCDC [59] for content-defined chunking with minimum, average, and maximum chunk sizes of 4 KiB, 8 KiB, and 16 KiB, respectively. It uses the Diffie-Hellman key exchange (§2.3) based on the NIST P-256 elliptic curve. Each client is associated with a per-client master key, which is sent to the enclave during uploads through a secure channel. The enclave encrypts file recipes with the master key to ensure backup integrity. The enclave implements frequency-based deduplication as in DEBE [60] by keeping a small fingerprint index of the 256 K most frequent chunks inside the enclave and a full fingerprint index in untrusted memory.

Compression and storage. The enclave processes batches of 128 data chunks and uses Finesse [62] to extract three features (32 bytes each) from each non-duplicate chunk after deduplication. It uses Edelta [58] for delta compression and LZ4 [8] for local compression. It encrypts each compressed chunk via AES-256 in GCM mode with a random 16-byte initialization vector. It batches the encrypted fingerprints from each batch of chunks to update the delta index, and from all chunks in the entire backup to update the backward index. It stores the encrypted compressed chunks and corresponding initialization vectors in 4 MiB containers.

5 Evaluation

5.1 Methodology

Testbed. We deploy ShieldReduce on Alibaba Cloud [1], using *ecs.r7t.xlarge* virtual machine instances to host cloud storage and multiple clients. Each instance has 32 GiB RAM and a 4-core 2.7 GHz Intel Xeon CPU to support SGXv2, and is installed with Ubuntu 20.04. All instances are connected with a 3 GbE network. The cloud storage instance is attached with a 1 TiB Aliyun SSD (PL0) offering up to 10 K IOPS for persistent storage, except for Exp#4, where we use the Aliyun SSD (PL3) with a maximum of 1 M IOPS to boost aggregate download performance.

Datasets. Our evaluation needs access to data contents, yet no public backup datasets with sensitive contents are available. Thus, we consider three public real-world datasets to mimic sensitive backup workloads: (i) *Linux* [7], which includes 209 versions (from v2.6.11 to v6.4-rc7) of Linux source code with a total of 185.7 GiB of logical data; (ii) *Web* [61, 62, 68], which includes 78 versions (from June 13 to September 1 in 2016) of website backups of `news.sina.com` with a total of 210.8 GiB of logical data; and (iii) *Docker* [3], which includes 95 versions (from v2.1.14 to v4.1) of Docker image snapshots of Cassandra from Docker Hub with a total of 32.2 GiB of logical data. These datasets simulate the development of copyrighted software (Linux) and the maintenance of sensitive services (Web) and environments (Docker). We also consider a synthetic dataset, *SimOS*, where we apply controlled modifications [38] to an operating system image to simulate a user's private activities. We create an initial snapshot from the CentOS 7 virtual disk image (containing 1.25 GiB of data) with a total of 8 GiB of space. We generate a sequence of 30 SimOS snapshots, with a total of 240 GiB of logical data, from the initial image, such that each snapshot is created from the previous one by randomly picking 30% of files, modifying 30% of their contents, and adding 10 MiB of new data.

Baselines. We compare ShieldReduce with three baselines: *DEBE* [60], *ForwardDelta*, and *SecureMeGA*. DEBE performs frequency-based deduplication and local compression in an enclave, but without delta compression (§3). Both ForwardDelta and SecureMeGA extend DEBE with delta compression on a per-batch basis. ForwardDelta loads the base chunks (in containers) from persistent storage into the enclave for forward delta compression (§3.1), but does not perform backward delta compression. SecureMeGA implements MeGA [67] for delta compression in the enclave. It loads the containers with at least three base chunks [67] into the enclave for delta compression and skips the delta compression of data chunks whose base chunks are not in such containers. We use the open-sourced DEBE prototype [60] to implement ForwardDelta and SecureMeGA in C++.

Default configurations. We configure ShieldReduce and all baselines to track the fingerprints of up to 256 K chunks in the enclave for frequency-based deduplication. For ForwardDelta, SecureMeGA, and ShieldReduce, we fix the batch size as 128 data chunks and use three threads to extract features in parallel (except Exp#2, which runs in a single thread to study performance breakdown). We set the locality threshold $t = 0.03$ and the offline reduction target $\alpha = 0$; we study the sensitivity of the parameters in Exp#5.

5.2 Storage Efficiency

Exp#1 (Analysis of data reduction). We compare the data reduction ratios of different approaches. We do not consider metadata overhead, but will study the index overhead of ShieldReduce in Exp#6. Note that ForwardDelta implements

Datasets	DEBE	ShieldReduce				Secure MeGA	Forward Delta
		α=0	α=0.5	α=0.7	α=1		
Linux	5.8	25.8	12.2	8.9	6.3	12.1	25.1
Web	13.1	58.6	27.9	19.9	14.0	16.1	60.6
Docker	8.6	14.9	14.4	12.9	10.3	14.0	15.0
SimOS	59.3	63.6	63.6	63.6	61.0	60.2	63.3

Table 1: (Exp#1) Analysis of data reduction ratio. For $\alpha = 0$, ShieldReduce aims for the highest possible storage savings via backward delta compression, while for $\alpha = 1$, ShieldReduce only updates indexes and skips backward delta compression (§3.3).

fine-grained data reduction (Figure 1) in the enclave and achieves the same data reduction ratio as fine-grained data reduction for plain data.

Table 1 shows the results. ShieldReduce, ForwardDelta, and SecureMeGA achieve higher storage savings than DEBE due to delta compression. When $\alpha = 0$, ShieldReduce has a data reduction ratio comparable to ForwardDelta, with a minor difference attributed to the variation in base chunks used in backward delta compression. ShieldReduce achieves up to a 3.6× data reduction ratio in Web compared with SecureMeGA, since Web includes a large fraction of similar chunks, yet SecureMeGA skips the delta compression of most similar chunks for high performance. Also, the data reduction ratio of ShieldReduce generally decreases with α, since a larger α implies that fewer chunks are compressed offline (§3.3). ShieldReduce keeps almost the same data reduction ratio (63.6×) in SimOS for $0 \leq \alpha \leq 0.7$, as SimOS has very few similar chunks and ShieldReduce's offline compression has limited extra storage savings. In Exp#5 (§5.3), we study the inline and offline time durations to achieve the presented data reduction ratios for different t and α.

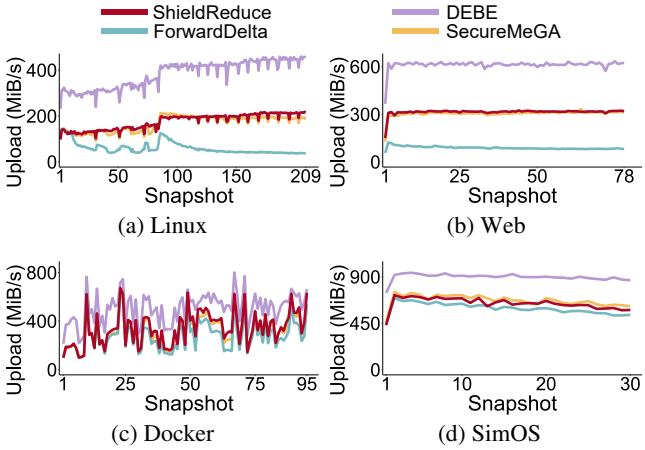
5.3 Performance

Exp#2 (Microbenchmarks). We study the performance breakdown of ShieldReduce in uploading backups. We configure ShieldReduce to run with a single thread. We let a client upload the first 20 backups of each dataset and measure the average computational time of different steps on the write path. Table 2 presents a breakdown of the computational time per 1 MiB of logical data processed. ShieldReduce's bi-directional delta compression, including locality detection and delta compression, takes only 2.8-8.8% of the overall computational time. Notably, feature generation takes 55.9% and 52.6% of the overall computational time in Linux and Docker, respectively, and throttles the performance of ShieldReduce, while it only takes 41.3% in Web and 15.2% in SimOS. The discrepancy is due to the relatively small data reduction ratios from deduplication in Linux and Docker (see the data reduction ratio of DEBE in Table 1), so ShieldReduce needs feature generation from more non-duplicate chunks.

Exp#3 (Inline performance). We compare the inline performance of different approaches. We consider a single client that loads a backup into its memory (to remove client-side disk I/Os) and uploads each backup one by one. We measure the *upload speed* by dividing the logical backup size by the total time of writing backup data into persistent storage.

Steps	Linux	Web	Docker	SimOS
Chunking	0.930	0.756	0.841	0.877
Secure session setup	0.208	0.205	0.202	0.190
Deduplication	1.647	1.186	1.499	0.898
Feature generation	6.541	1.978	4.705	0.375
Locality detection	0.138	0.061	0.094	0.011
Delta compression	0.749	0.168	0.688	0.059
Local compression	1.282	0.364	0.750	0.043
Encryption	0.201	0.067	0.168	0.012

Table 2: (Exp#2) The computational time (unit: ms) per processing 1 MiB of logical data in each step on the write path. The results are averaged from the uploads of 20 backups, and the variances are less than 10.5% of the corresponding average values.



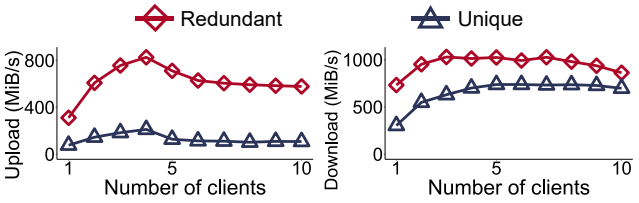


Figure 7: (Exp#3) Upload speed in long-term backups.

Figure 7 shows the upload speeds. DEBE achieves a 1.5-2.2× speedup over ShieldReduce since it does not perform delta compression. Compared with ForwardDelta, ShieldReduce achieves an upload throughput gain of 1.1-3.5× since it preserves physical locality to limit the I/Os of loading base chunks from persistent storage, and further moves delta compression offline if physical locality drops. Notably, SecureMeGA trades storage savings for performance (Exp#1), yet ShieldReduce still accelerates SecureMeGA by up to 7.3%.

We also measure the *CPU utilization* of the cloud machine as the ratio of the actual CPU time to the total processing time on the write path (not shown in figures). ShieldReduce has the highest CPU utilization (50.4%) in Linux among all datasets, since Linux has the most non-duplicate chunks that need encryption. Compared with DEBE, ShieldReduce adds an absolute CPU utilization of 1.1-11.6% for feature extraction and delta compression.

Exp#4 (Multi-client performance). We evaluate ShieldReduce when multiple clients concurrently upload and download backups. We configure ten virtual machines to simultaneously upload (download) data files to (from) the cloud for

(a) Multi-client uploads (b) Multi-client downloads

Figure 8: (Exp#4) Multi-client uploads and downloads.

stress testing. We consider two cases: (i) *Unique*, where each client has a 2-GiB data file with globally unique content (i.e., no redundancies) and (ii) *Redundant*, where each client's data is generated based on controlled modifications like SimOS from the same CentOS 7 virtual disk image.

We measure the *aggregate upload speed* as the ratio of the uploaded data size to the total time taken for the cloud to write all clients' data into persistent storage (in the inline stage). Figure 8(a) shows that the aggregate upload speed of Redundant first increases with the number of clients and achieves 826.7 MiB/s for four clients, and then drops to 578.1 MiB/s for ten clients due to resource contention in the cloud-side enclave. Enhancing the parallelization of SGX is beyond the scope of this paper. However, ShieldReduce can be extended using frameworks like Occulum [51], which supports multi-process execution within a single enclave. Similarly, the aggregate upload speed of Unique gradually increases from 76.3 MiB/s to 211.2 MiB/s for four clients, and is then bounded by disk I/Os in persistent storage.

We also measure the *aggregate download speed* as the ratio of the downloaded data size to the total time taken for all clients to reconstruct files (client-side disk I/Os are not considered). Figure 8(b) shows that the aggregate download speed of Redundant (Unique) first increases to 1024.6 MiB/s (738.1 MiB/s), and then decreases to 862.7 MiB/s (698.0 MiB/s) due to read contention among multiple clients. ShieldReduce in Redundant has a 1.2-1.4× speedup compared with that in Unique, since the container cache (§4) mitigates the disk I/Os of retrieving duplicate data from persistent storage.

Exp#5 (Sensitivity of configurable parameters). We study the impact of the locality threshold t (§3.2) and offline reduction target α (§3.3) on ShieldReduce's performance. We upload each backup by a client, followed by offline compression. We measure the time durations of the data reduction process on and off the write path.

Figure 9 shows the results averaged across all backups when we fix $\alpha = 0$ and vary t. Note that $t = 0$ implies that ShieldReduce locally compresses all data chunks on the write path and defers delta compression off the write path. As t increases, ShieldReduce needs more time to process uploads on the write path, since it loads many containers from persistent storage into the enclave for delta compression. The increase of t only slightly increases inline duration (i.e., the

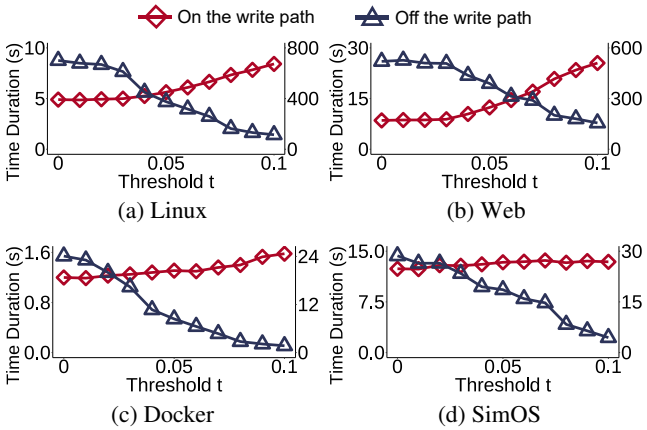

Figure 9: (Exp#5) Impact of t on inline (referred to the left Y-axis) and offline (referred to the right Y-axis) durations.

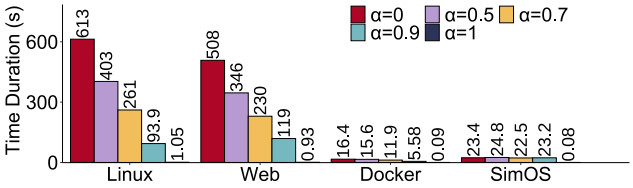

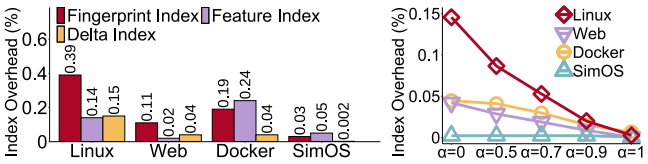

Figure 10: (Exp#5) Impact of α on offline duration.

left Y-axis), but dramatically reduces offline duration (i.e., the right Y-axis), as it avoids reapplying delta compression to many chunks that are already compressed with respect to old base chunks. For example, when t increases from 0.05 to 0.1, the inline (offline) time duration increases (decreases) from 12.4s (389.3s) to 25.5s (155.7s) in Web. Compared to Linux, the write path performance in Docker and SimOS is less affected by t, as they contain fewer similar chunks (Exp#1 in §5.2) and increasing t adds only a small number of chunks for inline delta compression. As future work, we plan to adaptively configure t based on workload characteristics.

Figure 10 shows the average time duration (across all backups) off the write path when we fix $t = 0.03$ and vary α. When $\alpha = 1$, ShieldReduce updates metadata without performing backward delta compression on old base chunks. Clearly, with the increase of α, we can effectively reduce the time duration of offline compression, with the cost of additional storage overhead (Exp#1). Due to the limited number of similar chunks in Docker and SimOS, varying α only slightly affects the number of delta compression operations, leading to a modest impact on the time duration.

5.4 Resource Overhead

Exp#6 (Index overhead). We evaluate the size overhead of index structures in ShieldReduce, including the full fingerprint index outside the enclave, feature index, and delta index. We do not consider the small fingerprint index (based on DEBE) inside the enclave, as it only stores up to 256 K fingerprints (§4) and has a limited size of 8 MiB (assuming

(a) Fraction of index size over logical size

(b) Delta index overhead versus α

Figure 11: (Exp#6) Analysis of index overhead.

32-byte fingerprints). We also do not consider the backward index and deletion map, as both of them will be cleared after offline compression (§3.3). We report the index overhead as the fraction of the size of each index after the last backup over the total amount of logical data.

Figure 11(a) shows that the major index overhead generally comes from the fingerprint index and feature index, which reach up to 0.39% in Linux and 0.24% in Docker. We can mitigate the memory overhead of the fingerprint index and feature index via locality-preserved caching [66] and the stream-informed approach [52], respectively, without introducing extra storage overhead. The delta index incurs 0.14% overhead in Linux. We can increase α to skip the backward delta compression of some old base chunks being used to delta-compress many data chunks (§3.3) to reduce the size of the delta index, at the expense of extra storage overhead (Exp#1 in §5.2). For example, increasing α to 0.5 reduces the overhead of the delta index to 0.09% in Linux (Figure 11(b)).

Exp#7 (Enclave overhead). We evaluate the enclave overhead of ShieldReduce in interface calls. We follow Exp#3 to upload each backup and count ECalls and OCalls on and off (for ShieldReduce only) the write path. We focus on three types of OCalls (§3.5) on the write path: index queries, index updates (for ShieldReduce only), and data transfers.

Table 3 shows the numbers of ECalls and OCalls. On the write path, all approaches issue the same number of ECalls to batch data chunks into the enclave. Compared with DEBE (which issues OCalls to query the full fingerprint index outside the enclave for deduplication), ShieldReduce adds up to 2.4× OCalls (Docker) for two reasons: (i) querying the feature index and loading base chunks into the enclave for delta compression, and (ii) updating the backward index and delta index to offload delta compression off the write path. ShieldReduce reduces the total number of OCalls for ForwardDelta by up to 83.3% (Linux) by preserving physical locality and offloading delta compression from the write path.

To justify the significance of preserving physical locality in ShieldReduce, we disable the offloading of delta compression to offline compression by manually clearing the backward index (i.e., no reconstruction of physical locality). We measure the average amount of data reduced by delta compression per OCall for data transfers and index updates with and without offloading (we exclude index queries as the same number of OCalls are issued in both cases). Table 4 shows that ShieldReduce (with offloading) has up to 4.6× data reduction per

Datasets			DEBE	ForwardDelta	ShieldReduce	
					Inline	Offline
Linux		#ECall	0.2 M			209
	#OCall	Index queries	0.2 M	0.4 M		963.6 M
		Index updates	-	-	0.04 M	
		Data transfers	0.03 M	2.6 M	0.06 M	
		Total	0.23 M	3.0 M	0.5 M	
Web		#ECall	0.2 M			78
	#OCall	Index queries	0.2 M	0.4 M		250.4 M
		Index updates	-	-	0.02 M	
		Data transfers	0.03 M	1.4 M	0.05 M	
		Total	0.23 M	1.8 M	0.47 M	
Docker		#ECall	0.03 M			95
	#OCall	Index queries	0.02 M	0.04 M		19.5 M
		Index updates	-	-	0.01 M	
		Data transfers	0.005 M	0.03 M	0.01 M	
		Total	0.025 M	0.07 M	0.06 M

	#OCall	Index queries	0.03 M	0.05 M		8.8 M
		Index updates	-	-	0.01 M	
		Data transfers	0.02 M	0.05 M	0.03 M	
		Total	0.05 M	0.10 M	0.09 M	

Table 3: (Exp#7) Enclave overhead. We measure the overhead by the number of interface function calls.

Approaches	Linux	Web	Docker	SimOS
Without offloading	14.3	16.8	42.4	8.1
With offloading	65.9	29.9	47.5	10.9

Table 4: (Exp#7) Average amount of data reduced by delta compression per OCall for data transfers and index updates (KiB) with and without offloading (i.e., performing delta compression offline on similar chunks whose base chunks exhibit weak physical locality).

OCall (Linux) compared to without offloading. The reason is that preserving physical locality allows ShieldReduce to keep more base chunks in the same containers and issues fewer OCalls to load containers in data reduction.

Off the write path, ShieldReduce issues ECalls to start offline compression after each backup upload, and many OCalls to load chunks into the enclave and update the delta index after backward delta compression. We argue that the latter only incurs up to a few hundred seconds for the offline compression of each backup (Figure 9 in Exp#5). We can tune α to reduce the duration of offline compression (Figure 10 in Exp#5) by trading storage savings (Table 1 in Exp#1).

6 Related Work

Performance improvements for delta compression. Earlier studies [22,40,47,53] generate features based on Rabin fingerprints. Finesse [62] mitigates the computational overhead of calculating Rabin fingerprints via fine-grained locality within similar chunks. DeepSketch [45] improves the accuracy of base chunk search based on deep learning with specialized hardware. ShieldReduce builds on Finesse [62] to search for base chunks without specialized hardware.

Recent studies explore fast delta compression that trades storage savings for performance. MeGA [67] uses selective delta compression to avoid loading containers with only a

few base chunks, but it significantly degrades storage savings (Exp#1 in §5.2). LoopDelta [61] proposes inverse delta compression similar to ShieldReduce by treating new data chunks as base chunks and delta-compressing old base chunks with respect to the new data chunks, so as to be compatible with rewriting techniques for the mitigation of chunk fragmentation [37, 61]. However, LoopDelta does not address the I/O overhead especially when reconstructing the data chunks that are originally delta-compressed with respect to old base chunks. ShieldReduce maintains I/O efficiency by performing forward or backward delta compression based on physical locality and proposing tunable offline compression to balance the storage-performance trade-off when applying backward delta compression. Also, LoopDelta only considers plain data reduction, while ShieldReduce realizes shielded data reduction and addresses the enclave resource overhead.

Confidentiality for data reduction. Several studies propose encryption mechanisms to allow the reduction of encrypted data via deduplication [10, 11, 20, 35, 54], local compression [31, 65], or a combination of both along with delta compression [64]. However, they necessitate weaker encryption to preserve content redundancies after encryption, and incur information leakage [33]. Shielded execution has been used for secure data reduction. SeGShare [25] and S2Dedup [42] use an enclave to mitigate the key management overhead of deduplication on encrypted data. SGXDedup [49] leverages SGX to speed up secure deduplication. DEBE [60] mitigates the key management overhead by performing deduplication and local compression before encryption inside an enclave. SeedSync [63] builds on SGX to securely reduce transferred data during cross-cloud synchronization. All the above studies do not consider delta compression.

7 Conclusion

We present ShieldReduce, which leverages SGX to realize fine-grained shielded data reduction for outsourced storage. The main novelty of ShieldReduce is bi-directional delta compression, which performs either forward or backward delta compression based on the physical distribution of base chunks, so as to preserve physical locality and mitigate I/O overhead. Experiments show that ShieldReduce achieves high performance and high storage savings.

A Artifact Appendix

Abstract

Our artifact includes the ShieldReduce prototype, which simultaneously supports all baseline approaches, along with scripts for downloading the datasets used in our evaluation and scripts for running all our experiments in §5. The ShieldReduce prototype is a secure outsourced storage system designed to enhance storage efficiency via fine-grained data reduction, while ensuring data confidentiality via shielded execution. It supports upload and download operations and allows multiple clients to securely outsource their backup storage to the cloud. It implements bi-directional delta compression to improve performance and incorporates the hybrid inline and offline designs described in §3. It builds on DEBE [60] to support frequency-based deduplication.

Scope

The artifact can be used to validate all results shown in the figures and tables in §5, especially for our main claims.

- ShieldReduce achieves a similar data reduction ratio to ForwardDelta and higher data reduction ratios than SecureMeGA and DEBE (Exp#1).
- ShieldReduce achieves a similar upload throughput to SecureMeGA and higher upload throughputs than ForwardDelta and DEBE (Exp#3).
- ShieldReduce with offloading reduces more data per OCall compared to without offloading (Exp#7).

Contents

The artifact comprises the following sub-directories:

- `/Prototype` includes the implementation of the ShieldReduce prototype.
- `/MultiClient` includes the implementation of parallel processing of the ShieldReduce prototype (dedicated to Exp#4).
- `/Result` stores evaluation results and scripts for generating plots based on the results.
- `/Dataset` includes scripts for downloading datasets used in our paper. Note that the Web dataset is private and not included in the artifact.
- `/ClientScript` includes scripts for uploading backups from a client.
- `/ServerScript` includes scripts for reproducing all experimental results in §5.

Hosting

The artifact is available on GitHub. Users can obtain the artifact from the repository `https://github.com/YangJingyuan99/shieldreduce`. The version we provided for the artifact evaluation is marked with the `atc25ae` tag. We encourage users to use the latest version of the repository since it may include bug fixes. We also release scripts for downloading (for Linux and Docker) and generating (for SimOS) datasets used in §5. The README file (`https://github.com/YangJingyuan99/shieldreduce/blob/master/README.md`) describes the detailed instructions to produce these datasets.

Requirements

We implement ShieldReduce based on Intel SGX SDK Linux 2.15, Intel SGX SSL 1.1.1l, and OpenSSL 1.1.1l in Ubuntu 20.04 LTS. See our README file for detailed dependencies. We evaluate ShieldReduce on Alibaba Cloud using `ecs.r7t.xlarge` virtual machine instances to host cloud storage and multiple clients. Each instance has 32 GiB RAM and a 4-core 2.7 GHz Intel Xeon CPU to support SGXv2, and is installed with Ubuntu 20.04. All instances are connected with a 3 GbE network. See §5.1 for the detailed evaluation setup.

Workflow

To reproduce the experiments in §5, users can refer to `./AEInstructions.md` for detailed instructions.

MemoryTrap: Booby Trapping Memory to Counter Memory Disclosure Attacks with Hardware Support

Abstract

Code-reuse attacks harvest reusable code gadgets from the vulnerable program's executable memory, posing a severe threat to the widely deployed executable-space protection. With the advent of address space layout randomization, a more complicated tactic of code-reuse attacks, known as just-in-time return-oriented programming (JIT-ROP), has emerged. JIT-ROP relies on repeated memory disclosure to search for available code gadgets in real-time. In response, a series of techniques have surfaced to impede memory disclosure or to prevent disclosed code from subsequently being executed. The most representative countermeasures involve enforcing a stricter memory permission policy, such as execute-only memory or destructive code reads. However, existing methods are either vulnerable to emerging code inference attacks or disallow a mixture of code and data, which is a fundamental property of the von Neumann architecture.

In this paper, we present *MemoryTrap*, a hardware-assisted technique to counter direct memory disclosure attacks while simultaneously allowing the mixture of code and data. MemoryTrap sprinkles unreadable "booby traps" in the program at compile time. Once JIT-ROP attackers land in a booby trap area during memory disclosure at runtime, MemoryTrap can immediately detect and stop the ongoing attack. We take advantage of a hardware feature from Intel, Memory Protection Keys, to offer an efficient memory permission control mechanism for booby traps. MemoryTrap supports the security hardening of applications, shared libraries, and dynamically generated JIT code. Our security evaluation demonstrates that MemoryTrap can reliably thwart the threat of disclosing executable memory in real JIT-ROP attacks and synthetic code inference attacks. Performance experiments with both microbenchmarks and macrobenchmarks show that MemoryTrap only introduces negligible runtime overhead.

1 Introduction

System programs are often developed using memory-unsafe languages (e.g., C/C++), making them prone to memory corruption vulnerabilities. The cyber arms race on this topic has transformed into an intensive tug-of-war [1–4]. The widely deployed Data Execution Prevention in modern OSs has pushed cybercriminals to reuse the existing code snippets from the vulnerable program to craft attacks. Adversaries gather the code snippets, called "gadgets," by searching through the disassembled binary code [5]. With these gadgets, attackers carefully chain them together to construct malicious payloads, subsequently hijacking the normal control flow to these gadgets to complete the attack.

A precise implementation of Control-Flow Integrity (CFI) [6–17] offers significant potential for protecting applications against ROP attacks by effectively preventing control-flow hijacking. However, prior research has demonstrated that CFI implementations can still be bypassed under certain conditions [18–27], and may introduce performance overhead [28]. Therefore, from a defense-in-depth perspective [29], it is imperative for critical systems to incorporate a combination of security measures to effectively mitigate potential threats. Address space layout randomization (ASLR) [30–42] is one of the typical representatives of defense-in-depth. ASLR frustrates the construction of gadgets by shuffling the code layout in memory. However, code randomization has suffered from memory disclosure, which makes the randomized code layout visible to attackers [43]. JIT-ROP (just-in-time return-oriented programming) [44] attackers repeatedly abuse memory disclosure to harvest code gadgets on the fly, based on the leakage of code pointers residing on code pages. Recent ASLR measurement [45] demonstrates that even the expensive re-randomization still leaves a time window for JIT-ROP attackers. The premise of JIT-ROP is memory disclosure—attackers have to first traverse sufficient executable memory pages to collect necessary gadgets. Therefore, the key to JIT-ROP defense is to impede disclosing memory pages or to prevent disclosed code from subsequently being executed. To achieve this goal, many security solutions enforce a stricter memory permission policy.

Execute-only memory (XoM) [46–49] emerges as a representative defense against memory disclosure. XoM disallows

the reading of executable memory, and thus attackers lose the ability to disclose the code layout after randomization. XoM methods typically require the strict separation of code and data, so that the unreadable permission can be safely enforced only on code areas. Unfortunately, the mixture of code and data is not rare in practice. For example, libraries frequently contain hand-written assembly routines that incorporate data within their executable code segments [50–52], and JavaScript JIT engines can generate native code containing both code and data in the same memory pages. Later on, a new class of memory permission enforcement policies, called *destructive code reads* [53–56], are proposed to prevent the execution of disclosed code. They allow memory pages to be disclosed but forbid the disclosed code to be executed subsequently. In particular, as soon as the code read occurs, the disclosed code is garbled to avoid being executed. At the same time, legitimate read operations for data embedded in the code still operate correctly. However, the emerging code inference attacks [57] can penetrate the defense of destructive code reads. They enable the reuse of gadgets that have not been previously read, highlighting the need for further research in restricting adversaries' ability to leverage memory disclosure.

In this paper, we continue the line of research on enforcing memory permission from the perspective of cyber deception [58–60]. The building blocks of our new defense are *booby traps*, which are variable-size code snippets but do not have the read permission. They stand aside from the program's normal execution paths and can only be triggered by JIT-ROP attackers. Our research has led us to the critical observation that, with the deployment of code randomization, JIT-ROP attackers only have a small time window (e.g., a few seconds [45]) to complete the search of the whole gadget chain. By inserting booby traps where these attackers anticipate a gadget, we can effectively detect a JIT-ROP attack when it traverses the code page. In addition to stopping the ongoing attack, we also save the context information for further forensic investigation. Unlike previous XoM methods, we do not revoke the readable permission on code pages except for booby traps, and thus legitimate read operations to code pages are completely unaffected. Compared with destructive code reads, our approach is naturally resistant to various code inference attacks caused by code cloning or implicit reads.

One of our design goals is to efficiently manage the unreadable permission at a fine-grained control of booby traps rather than memory pages. To this end, we capitalize on a hardware feature provided by Intel, Memory Protection Keys (MPK) [61, 62], to manage read requests to different areas (i.e., the original code vs. booby traps) at the kernel level. Our solution is more efficient than using the hardware virtualization support (e.g., via Intel Extended Page Tables). In addition, our study also answers another important question: how to insert booby traps cost-effectively so that attackers can trigger them with a high likelihood? We offer a practical insertion strategy at compile time to strike a delicate balance between security and performance penalty.

We develop our proposed solution, called *MemoryTrap*, to offer a comprehensive security hardening for applications, shared libraries, and JIT compiled code. With MemoryTrap, we aim to address the limitations of existing methods and keep our systems safe from JIT-ROP attacks. We first perform an empirical study to measure the effectiveness of MemoryTrap using the real-world exploits that leverage memory disclosure vulnerabilities. We count the distribution of booby traps between gadget intervals to show that attackers are bound to trigger booby traps under different code page traversal strategies. Then, we use code cloning via JIT compilation as an example to present MemoryTrap's defensive ability against the more sophisticated code inference attacks. At last, we conduct a set of performance experiments with both microbenchmarks and macrobenchmarks, including SPEC CPU 2017 [63], three web servers, four database software, and a custom Chromium browser running Kraken JavaScript Benchmark [64]. In contrast to prevailing XoM methods, MemoryTrap only incurs a marginal runtime overhead, averaging from 0.74% to 1.85%.

In a nutshell, we make the following key contributions:

- We present a new cyber deception idea, MemoryTrap, to detect memory disclosure attempts and eventually prevent JIT-ROP attacks. MemoryTrap tolerates legitimate data reads in executable memory while seamlessly defending against powerful code inference attacks.
- We take advantage of Intel's MPK feature to develop an efficient, fine-grained memory permission control mechanism. Our work advances the proper use of hardware features in systems security.
- We offer a versatile implementation of MemoryTrap to secure regular ELF programs, shared libraries, and JIT-compiled code. Our extensive evaluation shows that MemoryTrap has the potential to tip the balance of the memory war toward the side of defenders.

Open Source We have released MemoryTrap's source code and evaluation data sets to facilitate reproduction, replication, and reuse, as all found at Zenodo.

2 Background, Related Work, and Motivation

We first provide the background about JIT-ROP attacks. Then, we summarize the existing countermeasures against memory disclosure. Their limitations motivate our research. At last, we introduce the underlying hardware feature we leveraged.

2.1 Just-In-Time ROP

With the development of fine-grained randomization [30, 31, 36, 39, 42], traditional code-reuse attacks [65] have upgraded to JIT-ROP to generate the ROP payload at runtime. As shown in Figure 1, a typical JIT-ROP attack involves two stages: 1) adversaries first leverage a memory disclosure vulnerability to

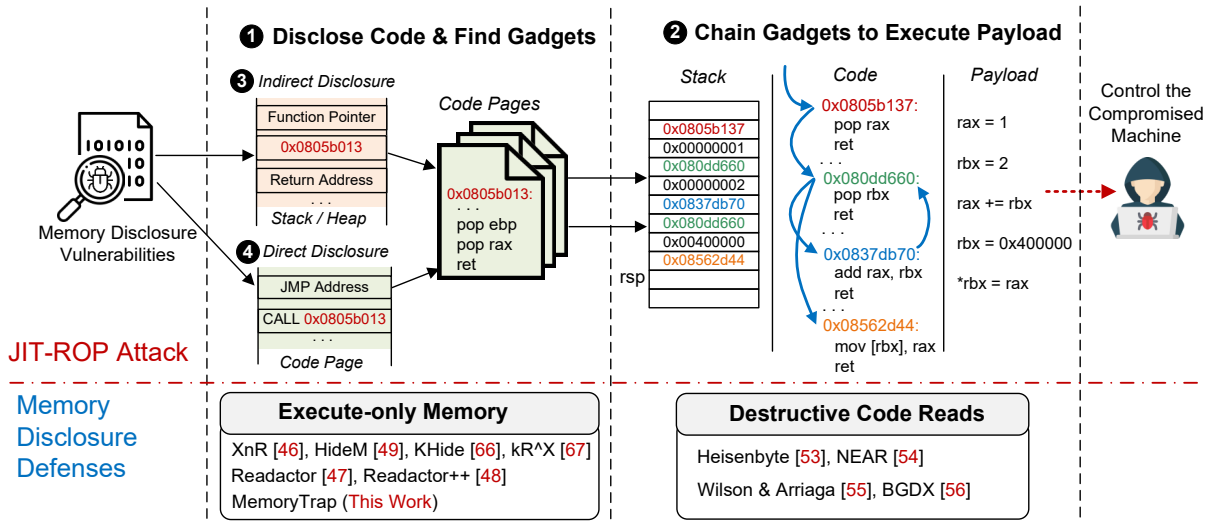

Figure 1: Two stages of a typical JIT-ROP attack workflow and countermeasures on enforcing memory permission.

recursively scan code pages for usable gadgets collection (❶ in Figure 1); 2) after that, they chain the collected gadgets to build the payload and then trigger a memory corruption error (e.g., buffer overflow, use after free, or double free) to hijack the control flow (❷ in Figure 1). In the first stage, attackers can harvest code pointers in a direct way or an indirect way to find executable memory pages. In a direct disclosure, attackers are able to directly read code pointers from code pages. These pointers are typically embedded in instructions such as direct jumps/calls. In an indirect way, code pointers are read from data pages such as stack and heap. This type of pointer is usually the function pointer passed as a parameter of another function or the return address in the stack. The key to the success of a JIT-ROP attack is disclosing enough code pages to find usable gadgets. Programs vulnerable to JIT-ROP attacks primarily fall into two categories. The first category includes server-side applications, which allow multiple user interactions(e.g., web servers and database systems). The second category encompasses client-side applications, which execute user-provided scripts (e.g., Matlab and JavaScript engines).

2.2 Stricter Memory Permission Policies

A set of memory disclosure defense methods have surfaced to combat JIT-ROP attacks. Next, we focus on two types of papers that enforce stricter memory permission policies, because they are the works most germane to our research.

Execute-only Memory The first type of preventative measures focuses on hindering the first stage of a JIT-ROP attack (❶ in Figure 1). They try to disable the read permission of code pages to enforce execute-only memory (XoM). XnR [46] is the first one to achieve the XoM idea via software emulation, without leveraging hardware features. XnR configures the PTE_PRESENT bit in PTE (Page Table Entry) of code pages as the "not_present" state, and thus all read operations will be caught by XnR's page fault handler. Then, XnR detects memory disclosure attempts by checking whether a read request is pointing to a code page. However, due to the large overhead caused by XnR's design, it makes a trade-off to tolerate the co-existence of several code pages with the state of present. As a result, XnR will miss read operations to these co-existence code pages, leaving memory disclosure opportunities for attackers. Readactor [47] and its follow-up work [48] address the security and performance issues of XnR by utilizing the hardware-assisted virtualization via Intel Extended Page Tables [61]. They remove the read permission of all code pages when mapping the virtual machine physical address to the host physical address. HideM [49] implements the XoM idea by desynchronizing ITLB (Instruction Translation Lookaside Table) and DTLB (Data Translation Lookaside Table), so that the same virtual address of code and data is mapped to different physical addresses. In this way, HideM separates data from code pages by redirecting the read operations targeting code pages to the separated data page. KHide [66] uses Hardware Assisted Paging to enforce XoM on kernel, and kR^X [67] implements kernel level XoM by using the Intel Memory Protection Extensions.

Mixture of Code and Data A common assumption of the aforementioned XoM methods is the strict separation of code and data. Such a prerequisite leads to false alarms in practice—XoM will treat legal data-in-code reads as memory disclosure attacks. Although modern GCC and LLVM favor separating code and data, non-code bytes, such as jump table data and static read-only data, often appear in code sections [50]. Pang et al.'s recent study on mainstream binary disassembly tools [52] also confirms that the mixture of code and data is not rare in programs. For example, the authors find 295 hard-coded bytes from the code pages of three test cases and 21,586 jump tables embedded in the code pages of 57 programs. Another example is that handwritten assembly code

in libraries often embeds data in code sections [51]. For example, OpenSSL, BoringSSL, and FFmpeg use handwritten assembly to accelerate their calculation, and VirtualBox uses handwritten assembly for dynamic function loading and its virtual extensible firmware interface. In addition, if a binary dynamically links a library that mixes code and data, the code section of this binary will also contain embedded data. At the same time, XoM conflicts with some security mechanisms. For example, KCFI [8] embedded some function signatures in the code section, and requires read access to the code pages to verify indirect function calls. As acknowledge by the author, KCFI cannot work with execute-only memory.

Destructive Code Reads The second type of memory permission policy, called *destructive code reads* (DCR) [53–56], reacts against the second stage of a JIT-ROP attack (❷ in Figure 1). They allow memory disclosure but prevent executing the previously disclosed code by destroying the disclosed code right after it is read. Heisenbyte [53] is the first approach implementing the idea of DCR. It marks each executable memory page as execute-only and maintains a duplicate copy for each execute-only page. When a read operation occurs in the execute-only page, Heisenbyte overwrites the read data with random bytes and returns the corresponding data values from the duplicate page. In this way, legitimate read operations for data-in-code work properly, but attackers cannot run the disclosed executable memory. NEAR [54] and Wilson & Arriaga's work [55] share a similar idea with Heisenbyte. However, the illusion of protection provided by DCR was soon shattered by the emergence of code inference attacks (a.k.a. ZombieGadgets) [57], in which attackers manage to reuse code gadgets that have not been previously read, rendering DCR's protection ineffective. We provide more details about code inference attacks in Appendix F. BGDX [56] applies a hybrid approach combining DCR and XoM at the byte-granular level and claims to effectively prevent code inference attacks. However, BGDX requires a strict distinction between code and data, and incorrect classification can lead to program crashes. Consequently, BGDX compromises a key advantage of DCR, which is the elimination of the need to differentiate code from data, resulting in reduced compatibility.

CHERI [68] also implements a byte-granularity memory permission control mechanism. However, CHERI requires hardware redesign, including a redesign of the instruction set architecture (ISA), the introduction of multiple new instructions, and the addition of several new registers. CHERI increases the pointer size to 128 bits, resulting in greater cache pressure. Moreover, it demands the integration of a new coprocessor into the Memory Management Unit (MMU) to support its newly introduced fine-grained memory permissions. Additionally, to support the redesigned hardware, CHERI necessitates a CHERI-aware build toolchain and operating system. In contrast, MemoryTrap leverages the existing hardware mechanism, MPK, to achieve fine-grained memory permission control, requiring only minimal modifications to the OS kernel and compiler, thus providing effective security protection with much lower deployment complexity.

Indirect Memory Disclosure Readactor [47] indicates that in some scenarios, attackers can harvest functions pointers stored in data pages (e.g., the stack and heap) and use the whole functions as gadgets to achieve JIT-ROP attacks. This type of attack is called the indirect disclosure attack (❸ in Figure 1). Readactor and Readactor++ [48] have provided a viable countermeasure against indirect JIT-ROP by redirecting code pointers to an XoM area to prevent function pointer disclosure. However, Readactor and Readactor++, together with other XoM methods, have common limitations to prevent direct JIT-ROP (❹ in Figure 1). Therefore, our work is dedicated to direct JIT-ROP defense by offering a new fine-grained memory permission policy.

2.3 Memory Protection Keys

To enforce non-readable permission for our inserted booby traps, we take advantage of Memory Protection Keys (MPK), a hardware feature to support stricter permission control on code pages, without requiring modification of page tables [61, 62]. MPK utilizes a protection key rights register (PKRU) to maintain the access rights of individual keys associated with specific pages, and it supports three different page permissions: read & write, read-only, and no access. Note that the execution permission is still controlled by the traditional permission management mechanism. We can leverage the MPK mechanism to configure a memory page's permission as execute-only by disabling the page's read and write permissions. MPK achieves superior performance because processes only need to execute a non-privileged instruction (*WRPKRU*) to update PKRU, which takes less than 20 cycles and requires no TLB flush and context switching [69]. MPK keys are thread-localized, which means each thread has its own 16 MPK keys. This could lead to inconsistency of MPK keys between different threads within the same process. We use the inter-thread key synchronization primitive provided by libmpk [62] to keep the execute-only MPK key synchronized between different threads in the same process.

MPK Applications in Security Most of the current security approaches rely on MPK for sensitive data isolation [70–74]. For example, ERIM [70] and Hodor [71], take advantage of MPK for efficient intra-process isolation, allowing only trusted code to access sensitive data areas. Jin et al. [73] applies MPK to cryptographic functions to protect sensitive key-related data. IskiOS [74] also uses MPK to revoke the read permission of kernel's code pages. Instead of using MPK as isolation mechanism or simply revoking read permission, we offer efficient fine-grained memory permission policy controlling memory blocks within page.

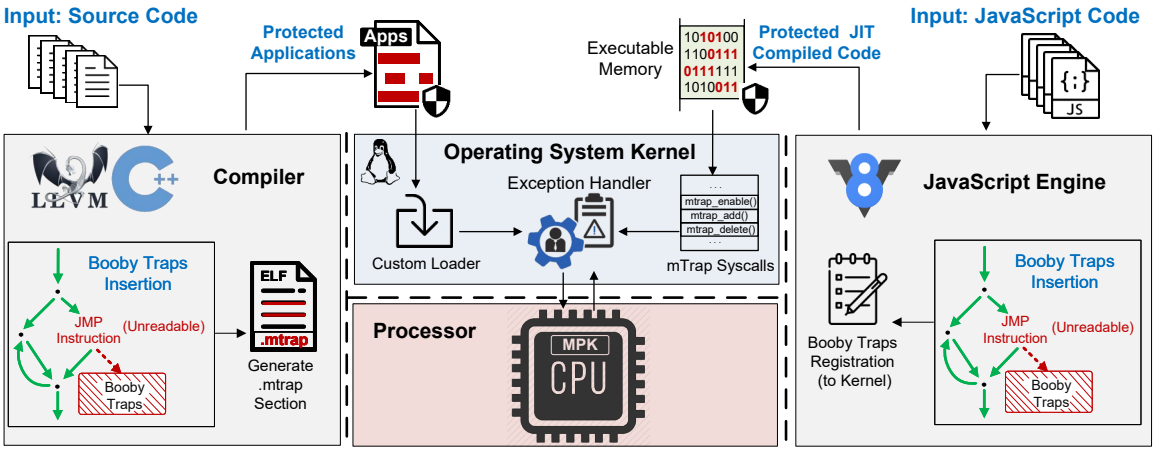

Figure 2: Overview of MemoryTrap.

3 Overview of MemoryTrap

Threat Model Throughout this paper, we assume the attackers possess powerful arbitrary read and write capabilities to the vulnerable program's memory. We do not impose any restrictions on embedding data in code areas. All the aforementioned methods, except for DCR, require that there is no embedded data within the code areas. We assume the target system is equipped with the following protections:

- W⊕X: Memory pages cannot be both executable and writable at the same time. This is the basic assumption of ROP defenses. Otherwise, attackers can directly execute the injected shellcode without performing ROP.
- Randomization: all static code from programs and libraries are randomized via load time fine-grained randomization.

These two protections are also held by related works on memory permission enforcement, such as Heisenbyte [53], Readactor [47], NEAR [54], and HideM [49].

Memory View of Booby Traps MemoryTrap aims to impede the first stage of a JIT-ROP attack (❶ in Figure 1). Different from the existing XoM and DCR, our memory permission policy only works on *booby traps*, which are unreadable, variable-size code snippets that we inserted into the protected program. Figure 3 shows the memory view before/after MemoryTrap's protection. Our insertion strategy ensures that JIT-ROP attackers will inevitably land in a booby trap area when searching for gadgets, while the program's normal execution will never reach any single booby trap. When a read operation to a booby trap happens, MemoryTrap's protection will be triggered instantly to respond to the attack: it terminates the compromised process to prevent further memory disclosure and saves the context information for the future investigation.

Architecture The target programs of memory disclosure attacks cover applications (e.g., web servers and databases), shared libraries (e.g., C standard library) [5], and dynamically

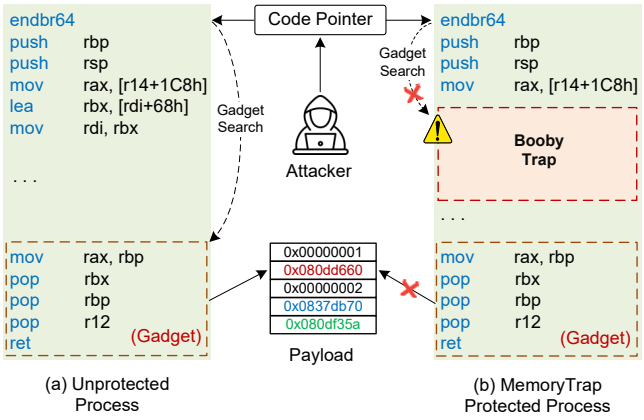

Figure 3: Memory view before/after booby trap insertion.

generated code by a JIT engine like V8 [75, 76]. Therefore, we develop MemoryTrap to support the security hardening of all three types of programs. Figure 2 shows MemoryTrap's architecture that bridges all layers of the software stack. At the user lever, we modify LLVM and TurboFan (V8's JIT compiler) to place booby traps at strategic trigger points. After that, we pass booby traps information (e.g., their numbers and the scope of each booby trap) to kernel components, either via a dedicated ELF section (".mtrap") for applications or via our customized "mTrap" syscalls for shared libraries and JIT compiled code. At the kernel level, MemoryTrap's custom loader loads the hardened applications into memory. With booby traps information, MemoryTrap's exception handler interacts with the low-level MPK mechanism to manage the unreadable permission at the level of booby traps, and it is also responsible for the memory disclosure attack response.

The primary characteristic of JIT-ROP attacks is that the attacker must search through a large amount of program code within a limited timeframe to gather sufficient gadgets. The key insight behind MemoryTrap is to strategically place booby traps along the path attackers follow when attempting to disclose code. To achieve optimal protection, these booby traps

must be distributed throughout memory at an appropriate density. A density that is too high would negatively impact performance, whereas a density that is too low would compromise security guarantees. In the following sections, we describe our approach for establishing insertion strategies that ensure booby traps are effectively distributed across memory at a suitable density.

MemoryTrap's Advantages As a new technique to achieve fine-grained memory permission management, MemoryTrap avoids the limitations of existing XoM and DCR methodologies and amplifies their benefits. Unlike the previous XoM methods [46–49], MemoryTrap allows the mixed use of code and data, and thus legitimate read to code pages works as expected. Compared to DCR [53–56], MemoryTrap can naturally withstand code inference attacks. As booby traps are weaved into the program, a code inference attempt via either code cloning or implicit reads cannot get rid of booby traps in any way. MemoryTrap leverages the new hardware feature MPK, which offers an efficient option to enforce fine-grained memory permission policies. The previous works either use software emulation that reveals high runtime overhead [46, 49], or they rely on the hardware virtualization support via Intel Extended Page Tables (EPT) [47, 48, 53], which is still more costly than MPK [69].

4 Application Protection

In this section, we follow the workflow of hardening an application to present MemoryTrap's details.

4.1 Insert Booby Traps into Execution Paths

We insert booby traps in the protected program at compile-time via a LLVM pass. We randomly generate a variable-size code snippet as a booby trap, which consists of 5 to 30 `NOP` instructions. We adopt variable sizes to further disrupt the code layout, making it more difficult to detect the positions of booby traps. We hide the booby traps from the protected program's normal execution paths by inserting a `JMP` instruction in front of inserted code snippets. When the execution encounters a booby trap, it will skip the inserted code snippets and follow the normal execution path. Please note that we set the whole booby trap, including the prefixed `JMP` instruction, as unreadable. This design enables booby traps to be seamlessly integrated into legitimate code execution paths, making them difficult to detect or circumvent. Because these traps are inherently embedded within valid execution flows, attackers cannot easily bypass them by simply tracking the program's control flow. Moreover, the opacity of inserted `JMP` instructions prevents attackers from identifying trap locations through pattern recognition or signature-based detection methods.

Table 1: The distance distribution of every two adjacent booby traps in the hardened applications' binary code.

	0∼100B	100B∼1KB	1∼2KB	2∼4KB	>4KB
Nginx	0%	73.2%	16.5%	10.3%	0%
Apache	27.5%	65.3%	3.6%	3.6%	0%
Lighttpd	16.0%	73.7%	4.7%	5.6%	0%
MySQL	30.6%	57.2%	6.5%	5.7%	0%
MongoDB	25.5%	62.3%	6.4%	5.8%	0%
Redis	26.1%	65.9%	4.1%	3.9%	0%
SQLite	20.9%	55.2%	7.1%	16.8%	0%
SPEC 2017	47.4%	44.6%	3.9%	4.1%	0%
Average	24.3%	62.2%	6.6%	6.9%	0%

4.2 Insertion Strategy of Booby Traps

We aim to sprinkle booby traps cost-effectively in execution paths to capture memory disclosure attempts.

JIT-ROP's Gadget Search Unlike offline ROP gadget search [77, 78], JIT-ROP requires "*unfettered access to a large number of the code pages*" [44]. JIT-ROP attacks [44, 45] first identify code pointers from data pages (e.g., the stack) and then use these pointers as starting points to locate code gadgets. To avoid disruptions caused by linear searches potentially accessing unmapped memory regions, JIT-ROP incrementally discloses and disassembles code to track control flow. When cross-page code pointers (e.g., long jumps and long calls) are encountered, JIT-ROP employs breadth-first or depth-first traversal strategies to explore memory pages, as shwon in Figure 4. According to the gadget search strategies of JIT-ROP, attackers use 4KB (one memory page's size) as the search granularity to avoid accessing unmapped pages. As a result, if we ensure that the distance between *every* two adjacent booby traps is small enough (e.g., less than 4KB), JIT-ROP attackers will trigger them with a high probability before they complete the search of all required gadgets. At the same time, attackers often use a combination of `pop` and `ret` instructions as gadgets to pass values from the stack into general-purpose registers [65], and such combinations tend to appear at the end of a function.

Insertion Strategy Therefore, our booby trap insertion strategy contains two rules:

1. we insert at least one booby trap in each function.
2. for the function whose size is larger than 4KB, we insert an additional booby trap for every 4KB code.

When adhering to these two rules, the insertion positions of booby traps are randomized. This approach prevents attackers from predicting the locations of booby traps based on fixed positions. Considering the aforementioned factors, our insertion strategy is effective in preventing disclosing sufficient code. We count the distances between every two adjacent booby traps after we apply MemoryTrap to real-world applications and SPEC CPU 2017. As shown in Table 1, the distances between every two adjacent booby traps are all within 4KB. Additionally, the percentage of distances within 1KB is 86.5% on average, representing a high distribution

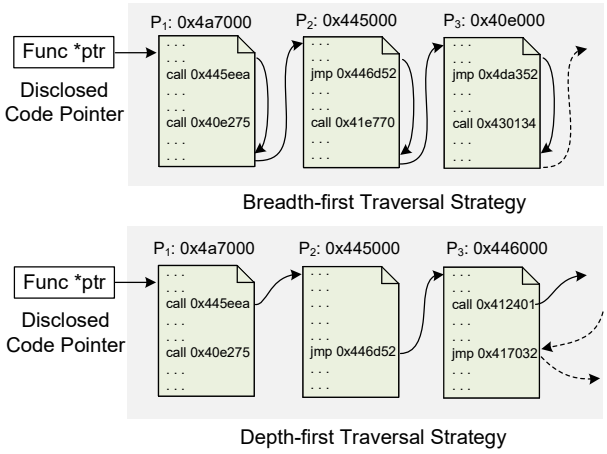

Figure 4: Code page traversal strategies.

density. We conducted an additional experiment to explore the impact of booby traps distribution on security and overhead. It was found that if a booby trap is inserted every 2KB, the average overhead increases by 1.3% for SPEC CPU 2017 benchmarks. On the other hand, if a booby trap is inserted every 8KB, the average overhead decreases by 0.7%, but it leaves a larger memory disclosure window for attackers.

4.3 New ELF File Format

The compiler also needs to pass the number and scope of booby traps to MemoryTrap's kernel components. This requires us to utilize the reserved field and optional section of the ELF file format to embed such metadata in binaries. We illustrate the new ELF file format with a figure provided in Appendix H.

First, we define a reserved byte in the ELF header as the specific flag byte, called **MTRAP_ENABLE**, to indicate whether this program is protected by MemoryTrap. This byte is the first byte in the EI_PAD array, which is a field of e_ident in the ELF header. By reading this byte, our custom loader can decide whether to enable MemoryTrap protection for this process. Then, we embed the number of booby traps and the start and end addresses for each booby trap into an optional section, called ".mtrap. " The beginning of the .mtrap section records the number of booby traps, followed by a booby trap list—each list item stores each booby trap's start and end addresses. We modify LLVM's backend to write booby trap information to the dedicated ".mtrap" section and then set the MTRAP_ENABLE flag to 1.

Please note that the new ELF format is backward compatible with non-customized loaders because they will ignore the MTRAP_ENABLE flag and the .mtrap section. The unmodified kernel can still run the MemoryTrap protected binary files properly as normal programs.

4.4 MemoryTrap's Kernel Components

Our kernel components consist of a custom loader, an exception handler, and mTrap syscalls. We also modify the kernel structures to support MemoryTrap. In this subsection, we introduce the first two components and leave mTrap syscalls in §5, because mTrap syscalls are specifically designed to support shared libraries and JIT compiled code. Our kernel modifications consist of only 312 lines of code, making our approach lightweight and minimally invasive to the kernel.

Custom Loader We customize the binary file loader in the kernel to load the applications protected by MemoryTrap and initialize related structures in the kernel.[1] The custom loader first checks the MTRAP_ENABLE flag in the ELF header to determine whether MemoryTrap's protection is enabled. If so, it will load the booby trap list stored in the .mtrap section. Otherwise, the standard binary file loading process will take over. After loading the booby trap list, the custom loader starts to map the code segment into memory. When mapping the code segment, the custom loader allocates an execute-only PKey, which is a part of the MPK mechanism to set the permission for a group of pages, to enforce the access permission as execute-only. Please note that this PKey is allocated during the loading process, thereby ensuring its availability. Consequently, the way the program utilizes PKeys at runtime does not influence the implementation of MemoryTrap. In this way, our exception handler component can capture every read operation to code pages, and then it further determines whether a memory disclosure attempt or a legitimate code read is occurring.

Exception Handler We implement an exception handler based on the original page fault handler for the MPK mechanism to prevent memory disclosure attacks. Since we have removed the read permission of all code pages via the MPK mechanism, any read request to a code page will trigger a page fault and be caught in our exception handler. Then, the exception handler checks whether the target address is located in the areas of booby traps. If so, we can promptly determine that the running program is under a memory disclosure attack, and thus we terminate the compromised process and save the context information for further forensics investigation. Note that legitimate read operations for data embedded in the code do not trigger MemoryTrap's attack response. Instead, we take the following actions to handle such data-in-code cases: 1) we restore the read privilege of the target page to allow the page to be readable temporarily; 2) we set the single-step trap flag to only execute the read instruction and stop at the next instruction; 3) after the completion of the legal read operation, we revoke the read permission of the code page and subsequently clear the single-step trap flag to enable the program to resume its normal execution. Please note that MemoryTrap only affects the permissions of code pages and primarily in-

[1] Regarding how we organize booby traps information in the kernel structures, please refer to Appendix A.

troduces overhead during code page reads, without impacting data pages. As a result, MemoryTrap does not affect the performance of copy-on-write (CoW) operations because CoW typically occurs on data pages.

4.5 Booby Traps Layout Randomization

MemoryTrap is compatible with load time fine-grained randomization methods to shuffle booby traps' location. We have adapted MemoryTrap to a representative tool, CCR [79]. CCR randomizes the code layout at the granularity of basic blocks by patching the binary code. When CCR randomizes the code layout, the locations of booby traps must be updated synchronously. The randomization process of CCR contains two phases: information collection at compile-time and binary rewriting. In the first phase, we modify CCR to insert booby traps first and then collect pointer and code layout information. In the second phase, we modify CCR's binary rewriter to update the addresses of booby traps when CCR randomizes the code layout. When shuffling a booby trap basic block, CCR will also update the metadata stored in the ".mtrap" section using the new shuffled addresses.

5 Shared Library & JIT Compiled Code

In this section, we discuss the security hardening of shared libraries and JIT compiled code. They exhibit some different challenges from the above application protection.

mTrap Syscalls The first challenge is that both the loader of shared libraries and the JIT engines are user-level programs, but the operations of booby traps, such as enabling MemoryTrap's protection and adding new booby traps, all happen in the kernel only. Therefore, they have to rely on specialized system calls to interact with the kernel and perform the booby trap operations. To this end, we have implemented three new system calls: `mtrap_enable`, `mtrap_add`, and `mtrap_delete`. The `mtrap_enable` enables MemoryTrap's protection explicitly, and the `mtrap_add` and `mtrap_delete` are used to add and delete booby traps, respectively.

Shared Library Protection For shared libraries, their booby trap insertion strategy and the new ELF file format are the same as our application protection. The major difference is that applications are loaded by the custom loader in the kernel, while shared libraries are loaded by the GNU C Library loader, a user-level program. We modify the GNU C Library in several ways to achieve our goal. 1) When loading a hardened shared library, the loader enables MemoryTrap's protection by invoking the syscall `mtrap_enable`. 2) Next, the loader maps the code segments as execute-only memory and fixes the addresses of booby traps due to the relocation of shared libraries. 3) At last, it loads the booby trap list from the ".mtrap" section and registers the booby trap list to kernel by invoking `mtrap_add`. After these steps, MemoryTrap's exception handler will promptly start to monitor memory disclosure attacks.

JIT Compiled Code Protection MemoryTrap's JIT version is built on top of V8's JIT compiler, TurboFan. As shown in Figure 2, we modify the JIT engine to compile JavaScript into the executable code with booby traps inserted. In particular, TurboFan first runs the graph creation and optimization passes to generate IR from source code, and then it compiles IR to the platform-specific machine code. We insert booby traps at the IR level using the same insertion strategy discussed at §4.2. After compilation, the modified TurboFan enforces the execute-only permission on the generated JIT code via MPK. Then, it registers embedded booby traps to the kernel by invoking mTrap syscalls so that the exception handler can start to monitor memory disclosure.

Furthermore, we also adjust our memory permission management accordingly to support some aggressive optimizations of JIT compilers. For example, to save memory, JIT compilers may write the new JIT code to the existing JIT code pages, while the read and write permissions on these pages have been removed to facilitate the booby trap checking. In this case, the modified TurboFan will temporarily recover read and write permissions on these code pages to allow the JIT code update. After that, it will disable read and write permissions for the updated JIT code pages again and invoke the `mtrap_add` syscall to register new booby traps. If TurboFan plans to abandon a generated JIT code snippet, it will also invoke the `mtrap_delete` syscall to unregister all of the booby traps in the abandoned JIT code.

6 Security Evaluation

We implement MemoryTrap on Linux kernel 5.10.11, LLVM 13.0.1, V8 9.7, and GNU C Library 2.31. The testbed is a server machine with Intel i9-13900KF 24 cores CPU and 64GB RAM. We evaluate how well MemoryTrap can defend against memory disclosure attacks under three different scenarios: 1) JIT-ROP attacks on applications; 2) JIT-ROP attacks on JIT compiled code; 3) code inference attacks [57].

6.1 Detect Memory Disclosure on Applications

We use a Nginx arbitrary memory disclosure vulnerability (CVE-2013-2028) [80] to demonstrate MemoryTrap's effectiveness. This is a fairly powerful stack overflow vulnerability that allows an adversary to perform arbitrary memory read. We compile the vulnerable version of Nginx with MemoryTrap protection enabled and run it as a web server. Then, we leverage the JIT-ROP attack framework, jitrop-native [81], to trigger the vulnerability and dynamically search for gadgets.

We collect all gadgets in the exploit of CVE-2013-2028 and measure how gadgets and booby traps distribute in memory. The gadget chain of this exploit consists of seven gadgets to implement two functions: storing a value in memory and

```
1. 0x0804b884: pop esi; pop ebp; ret;
... 192 Booby Traps ...
2. 0x0805ddbb: push ecx; ret;
... 162 Booby Traps ...
3. 0x0806e948: add ecx, [esi]; ret;
... 103 Booby Traps ...
4. 0x0807b586: mov [ecx], eax; mov [ecx+4], edx; mov eax, 0; ret;
... 47 Booby Traps ...
5. 0x08080a57: pop ecx; add al, 0x89; ret;
... 279 Booby Traps ...
6. 0x0809a65b: pop eax; add al, 0x89; ret;
... 50 Booby Traps ...
7. 0x0809ef79: push eax; add al, 0x83; ret;
```

Figure 5: Gadgets and booby traps distribution for the CVE-2013-2028 exploit. Each line of assembly code is a gadget, stating with its address. We show the number of booby traps distributed between two adjacent gadgets.

dereferencing a pointer. As shown in Figure 5, our insertion strategy ensures that booby traps spread over the interval of every two adjacent gadgets. The number of booby traps between two adjacent gadgets ranges from 47 to 279.

Next, we exhibit the attackers' ability to find potential gadgets under MemoryTrap's protection. We are interested in measuring under different code page traversal strategies, how much code can be disclosed, and how many usable gadgets can be found before triggering the first booby trap.

Starting Point & Traversal Strategy The recent work [45] demonstrates that the starting point of code traversal in a page does not affect the disclosure result, because the authors experimentally confirm that choosing any single random code pointer allows attackers to identify all instructions and code pointers in that code page. Besides, selecting which page to start gadget search is not important as well, because code pages are all very well connected [45]. Therefore, we start code disclosure from 100 random positions in every code page. Another factor we must consider is code page traversal strategy, which can affect the disclosure result [44]. We utilize Ahmed et al.'s traversal strategies [45], including depth-first and breadth-first traversal, to find all required gadgets.

The code segment size of compiled Nginx is 815.8KB, which equals 203.9 memory pages. Thus we start code page traversal using two different strategies from a total of 20,390 different positions; once any booby trap is triggered, we record how much code and how many usable gadgets are disclosed. Table 2 shows the results of our code page traversal attempts. When using the breadth-first policy, an average of 657 bytes of code can be disclosed before triggering booby traps, and an average of 299 bytes of code when using the depth-first search. Among all of our code page traversal attempts (40,780 in total), only 25 attempts using the breadth-first strategy and 14 attempts using the depth-first strategy can find **at most one gadget**. The rest of code page traversals are all trapped in booby traps before finding any usable gadget.

More Exploits We conduct a gadget distance statistical analysis on a set of real-world JIT-ROP exploits, which we collect from Metasploit [82] and Exploit-DB [83]. We use the same code traversal strategies to measure how many bytes can be disclosed under the protection of MemoryTrap, and the results are consistent with the previous findings. The disclosed code size ranges from 499∼687 bytes with breadth-first strategy, and 273∼340 bytes with depth-first strategy. As a contrast, the minimum distance from the first gadget to the last gadget is 94.0KB, indicating that the disclosed code is far from enough to find all gadgets. Similarly, only a few code traversal attempts get a chance to find **at most one gadget**. We provide the detailed results in Appendix E.

Table 2: Attackers' ability to find potential gadgets when MemoryTrap is enabled. The vulnerable program is Nginx.

Code Page Traversal Strategy	Average Bytes Disclosed	# of Attempts to Find One Gadget
Breadth-first	657	25
Depth-first	299	14

6.2 MemoryTrap-Aware Disclosure Strategies

If attackers become aware that MemoryTrap has been deployed, they may adopt more sophisticated code disclosure strategies to bypass the inserted booby traps. For instance, attackers might abandon continuous code disclosure and instead attempt to read M bytes of code at intervals of N bytes, or initiate disclosure from leaked code pointers located in the stack or heap. Therefore, we conducted additional MemoryTrap-aware experiments using the same binary described in §6.1 to evaluate attackers' capability to disclose code using these advanced strategies. Specifically, we attempted to read 50-byte code at intervals of 200 bytes, 300 bytes, and 500 bytes. Under the breadth-first search approach, the average amounts of disclosed code were 636 bytes, 649 bytes, and 678 bytes, respectively. Under the depth-first search approach, the corresponding averages were 319 bytes, 290 bytes, and 300 bytes. We also collected code pointers and initiated code disclosure directly from these pointers. Using this approach, breadth-first and depth-first searches triggered booby traps after disclosing an average of 672 bytes and 451 bytes, respectively. All the results presented above are consistent with those shown in Table 2, indicating that under the protection of MemoryTrap, the choice of code disclosure strategy does not significantly affect the probability of triggering a booby trap. In fact, because booby traps are opaque to attackers, the probability that any given disclosure strategy triggers a booby trap follows a hypergeometric distribution.

6.3 Retrofitting XoM for JIT Compiled Code

In this experiment, we evaluate MemoryTrap's protection on JIT compiled code by exploiting a recent vulnerability in V8 JIT engine, CVE-2020-16040 [84]. We modify the vulnerable version of V8 and compile it with the latest version of

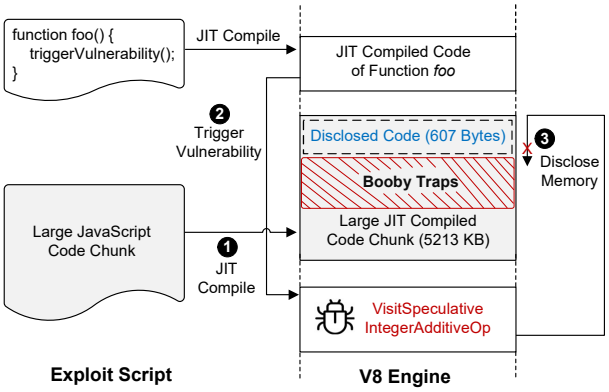

Figure 6: Using exploit of CVE-2020-16040 to disclose memory of JIT compiled code protected by MemoryTrap.

Chromium browser [85] to get a custom Chromium browser. This custom browser can trigger CVE-2020-16040 and generate MemoryTrap-protected JIT code. After that, we use the exploit of CVE-2020-16040 to trigger this vulnerability and start to disclose the generated JIT code.

CVE-2020-16040 is an integer overflow vulnerability caused by missing parameter type checking during the JIT optimization phase, resulting in arbitrary memory read and write. Figure 6 shows how we use the exploit to disclose the code of JIT compiled JavaScript functions. We first write a JavaScript function and a large JavaScript code chunk and trigger the JIT compile mechanism of V8 (❶ in Figure 6) to get a JIT compiled code chunk with the size of 5,213 KB. The modified JIT engine inserted a total of 7,025 booby traps into this large JIT compiled code chunk. When compiling the `foo` function, the `foo` function can trigger the vulnerability in "VisitSpeculativeIntegerAdditiveOp" function (❷ in Figure 6), which is a function of V8 engine used to optimize JIT compiled code. This vulnerability gives us the arbitrary read capability, so we try to disclose the code in the large JIT compiled code chunk. We use the breadth-first strategy to disclose code pages of JIT compiled code, because in Table 2 we found that the breadth-first strategy can disclose more code. When disclosing the JIT compiled code, the exploit triggers booby traps in a very short time. The exploit script only discloses 607 bytes of code before falling into booby traps. Such 607 bytes is the distance from the beginning of the large JIT compiled code chunk to the beginning of the first booby trap, as shown in ❸ of Figure 6.

To determine the amount of JIT compiled code that must be disclosed to find the whole gadget chain, we search for the necessary gadgets in the absence of MemoryTrap's protection. The findings indicate that a staggering 2,739 KB of code must be disclosed to successfully identify the entire chain of gadgets, rendering the previously estimated 607 bytes woefully insufficient for this task.

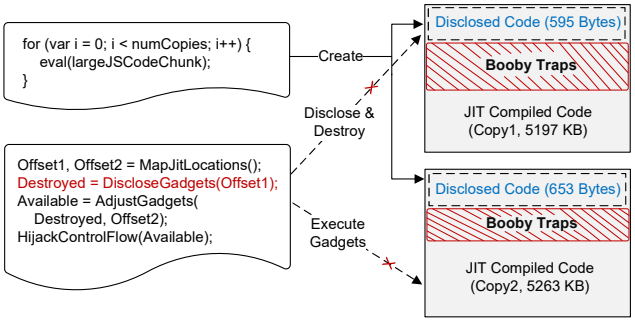

Figure 7: JavaScript JIT cloning attack maintains two copies, but our booby traps spread over in each copy.

6.4 Countering Code Inference Attacks

The first three types of code inference attacks described in [57] operate by maintaining multiple copies of code and inferring the contents of one copy through the disclosure of another. To evaluate the effectiveness of MemoryTrap against these three types of code inference attacks, we use the JIT-compiled code cloning attack as a representative example. We follow the detailed description in Snow et al.'s paper [57] to reproduce the JavaScript JIT compiled code cloning attack. We maintain two copies of a large JIT-compiled code chunk, each over 5MB in size, using the same JavaScript source code as in §6.3. The JIT engine compiles the first copy of code in 5,197KB, and it compiles the second copy of code in 5,263KB, with 7,025 booby traps inserted in each of them. Each copy has a different size due to the variable-size booby traps inserted. We also use the breadth-first code page traversal strategy to disclose these code chunks. Figure 7 illustrates how MemoryTrap stops this type of attack. No matter how many code copies the adversary maintains, our booby traps spread over each code copy. Similar to the evaluation result shown in Figure 6, our code page traversal attempt can only disclose a very small piece of code: 595 bytes in the first copy and 653 bytes in the second copy, before the code read operations were caught in a booby trap. Such little disclosed code is not enough to construct a malicious payload.

The last type of code inference attacks reveals certain portions of code in order to infer the content of related code and thereby evade detection or destruction. MemoryTrap inherently defends against this type of attack by distributing a large number of traps throughout the code, which significantly alters the original code layout. This approach invalidates the attacker's prior knowledge about the code structure, making it difficult to infer the actual content of the code.

7 Performance Evaluation

We tested standard benchmarks and a set of real-world applications to measure the slowdowns caused by MemoryTrap. We run microbenchmarks on the modified kernel to evaluate the overhead caused by kernel modification. We use

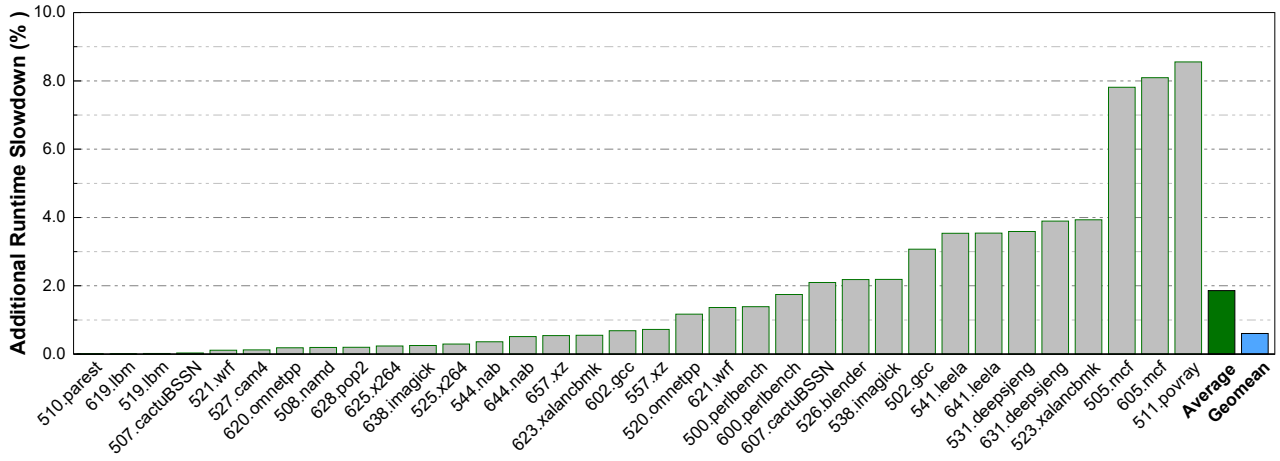

Figure 8: Additional runtime slowdown (%) of MemoryTrap on SPEC CPU 2017 (*ref* workload).

macrobenchmarks to evaluate the overhead of MemoryTrap on CPU-intensive programs. For real-world applications, we use mainstream web servers (Nginx-1.20.1, Apache-2.4.49, and Lighttpd-1.4.59), four popular databases (MySQL-8.0.26, MongoDB-4.2.17, Redis-6.2.5, and SQLite-3.36.0), and a custom V8 engine. Please note that in subsequent experiments, we run the standard version of benchmark or application on the standard kernel and the MemoryTrap protected version on the custom kernel. For the shared libraries that the real-world applications depend on (e.g., PCRE and zlib for Nginx and APR for Apache), we use their MemoryTrap protected version for the performance evaluation.

7.1 Microbenchmarks

MemoryTrap modifies the Linux kernel's binary loader, page fault handler, and process context structure. To evaluate the impact of these modifications on kernel operations, we run lmbench [86] on both the standard Linux kernel and our modified version, and compare the operation latencies of the standard kernel and the modified kernel.

Table 3 displays the running time of kernel operations related to process creation and page fault handling. The *Fork Proc* and *Exec Proc* are process creation operations that use *fork* and *exec*. These operations resulted in an overhead of 0.88% and 0.58%, respectively, due to the additional steps required for loading XoM metadata. Page Fault shows the overhead related to page fault handling, with a 0.52% overhead. Prot Fault denotes the overhead related to protection fault handling. MemoryTrap needs to scrutinize whether the protection fault is enabled, causing a 0.83% overhead.

In order to store MemoryTrap's metadata, such as MPK's PKey and executable data list, we included additional data members in the process context structure. However, this modification may result in overhead during context switches in the kernel. To evaluate the impact of our modification, we conducted experiments measuring the context switching time for two kernel versions, and results are presented in Table 4. The upper half of the first row displays the number of processes involved in the context switches, while the lower half shows the memory usage of each process. For instance, "2p/16k" represents a context switch between two processes, each utilizing 16 KB of memory. All entries exhibit overhead values distributed around zero, suggesting that MemoryTrap exerts an insignificant impact on the performance of kernel context switches. For additional lmbench results with limited correlation to MemoryTrap, please refer to Appendix C.

Table 3: Time for kernel operations related to process creation and page fault handling (in μs). Smaller is better. In the first row are the names of benchmarks in lmbench.

Kernel	Fork Proc	Exec Proc	Page Fault	Prot Fault
Standard	113	347	0.776	0.481
MemoryTrap	114	349	0.780	0.485
Overhead	0.88%	0.58%	0.52%	0.83%

7.2 Macrobenchmarks

SPEC CPU2017 is the latest generation of SPEC CPU benchmark with larger and more complex workloads than SPEC 2006. In the performance evaluation of macrobenchmarks, we compile the standard version of SPEC 2017 and the MemoryTrap protected version of SPEC 2017, and run them with the *ref* workload on our test machine. We take the running time of standard versions as the baseline to measure the overhead incurred by MemoryTrap's protection. We removed the pure Fortran benchmarks from our experiment, because LLVM's Fortran frontend is still under testing and not ready for developers to use [87].

Figure 8 shows the overhead of MemoryTrap protection for each benchmark in SPEC CPU 2017. The green and blue bars on the rightmost side show the average and the geometric mean value of overhead, respectively. From Figure 8, we can see that seven overhead values are very close to zero, and the peak value (8.5%) happens in `povray`. Upon further

Table 4: Context switch time (in μs). Smaller is better.

Kernel	2p	2p	2p	8p	8p	16p	16P
	0K	16K	64K	16K	64K	16K	64K
Standard	2.09	2.10	2.61	2.43	2.59	2.64	2.83
MemoryTrap	2.13	2.15	2.48	2.49	2.62	2.66	2.79
Overhead	1.91%	2.38%	-4.24%	2.47%	1.16%	0.76%	-1.43%

investigation, `povray` has a lot of dispatch loop structures that call numerous small handler functions. According to our booby trap insertion strategy, all of these handler functions are inserted with one booby trap. `Povray` spends most of its running time on executing handler functions, so the accumulated overhead is relatively high. `505.mcf` and `605.mcf` are both derived from `MCF`, a program used for single-depot vehicle scheduling in public mass transportation. Similar to `povray`, `MCF` spends most of its running time on iteratively executing three utility functions (getArcPosition, arc_compare, and spec_qsort), causing a relatively high overhead. Nonetheless, the average overhead of tested SPEC benchmarks is 1.85%, and the geometric mean is 0.60%, indicating a limited performance impact on CPU-intensive programs.

Real-World Applications In addition to SPEC CPU 2017, we also evaluated the performance of MemoryTrap using web servers, databases, and a JIT engine. For web servers, we tested Nginx, Apache, and Lighttpd. The maximum overhead observed for web servers is only 2.11%, with an average overhead of 0.74%; most overhead values are very close to zero. Regarding databases, we evaluated MySQL, MongoDB, Redis, and SQLite, and the average overhead incurred by these databases is merely 1.30%. Then we use Kraken Benchmark [64] to measure the overhead incurred by MemoryTrap, and the average overhead is only 1.54%. Due to the page limit, we put detailed performance results in Appendix B. We have also conducted experiments to evaluate MemoryTrap's disk and memory overhead. Please refer to Appendix G for details.

Worst-Case Benchmark We employ a worst-case benchmark that cyclically reads the code area for 10,000,000 times to trigger extensive embedded data accesses, causing the program to spend most of its execution time performing embedded data reads. This benchmark allows us to evaluate the performance of MemoryTrap under worst-case conditions. We compare the time required to complete this benchmark with and without the deployment of MemoryTrap. With MemoryTrap, the benchmark takes 3.23X longer to complete than without it, which means that MemoryTrap incurs a **3.23** times slowdown in this worst-case benchmark. However, the overall system performance is not significantly impacted by this seemingly unacceptable overhead. This is attributed to the fact that legitimate data-in-code reads are interspersed with numerous other instructions. A more in-depth analysis of this performance impact will be presented in §7.3.

7.3 Overhead Cause Analysis

There are two sources of performance overhead for MemoryTrap: the data-in-code read legitimacy check and the jump instructions introduced by booby traps. Next, we break down each component of MemoryTrap to provide insights into the causes of MemoryTrap's overhead.

As discussed in §7.1, the data-in-code read legitimacy check incurs a 3.23 times performance overhead. However, MemoryTrap causes only a 1.85% overhead on SPEC CPU 2017 and a 0.74% overhead on web servers, which is negligible compared to the read legitimacy check. Our further investigation reveals that this is because legitimate data-in-code reads are interspersed among numerous other instructions. We introduce the term "Read Intensity" here, defined by Equation 1, to assess the density of data-in-code read operations among all instructions.

$$Read\ Intensity = \frac{\#\ of\ Legitimate\ Reads}{\#\ of\ Executed\ Instructions} \quad (1)$$

We have gathered data on legitimate data reads and the total number of executed instructions for SPEC CPU 2017, web servers, and databases used in our evaluation. Additionally, we gathered the same information for OpenSSL, which contains significantly more data-in-code reads than other programs due to the handwritten implementation of cryptographic algorithms. The results show that the Read Intensities are 7.0E^{-11} for SPEC CPU 2017, 1.64E^{-10} for web servers, and 4.80E^{-12} for databases. Even for OpenSSL, it only has a Read Intensity of 1.40E^{-7}, which implies that one data-in-code read is performed for every million instructions executed. The average Read Intensity across all programs is 3.51E^{-8}, signifying that, on average, one data-in-code read is performed after executing ten million instructions. This illustrates that while data-in-code reads are not rare in practice, their frequency is extremely low, which significantly mitigates the impact of the legitimacy check overhead. We conducted another experiment to evaluate the overhead caused by the read legitimacy check. We ran each benchmark without booby trap insertion and found that the read legitimacy check only causes a 0.45% runtime slowdown on average. This indicates that most of MemoryTrap's overhead is caused by the jump instructions introduced by booby trap insertion.

7.4 Performance Comparison

We compare the performance of MemoryTrap with representative approaches shown in Figure 1, including XnR [46], Readactor [47], HideM [49], and Heisenbyte [53]. However, we encountered a major challenge that none of the papers listed in Figure 1 have made their tools publicly available, with the exception of MemoryTrap. In light of this, we compared their SPEC CPU 2006 performance data reported in their papers with ours. Figure 9 shows the performance comparison result. XnR is the first XoM approach; it implements

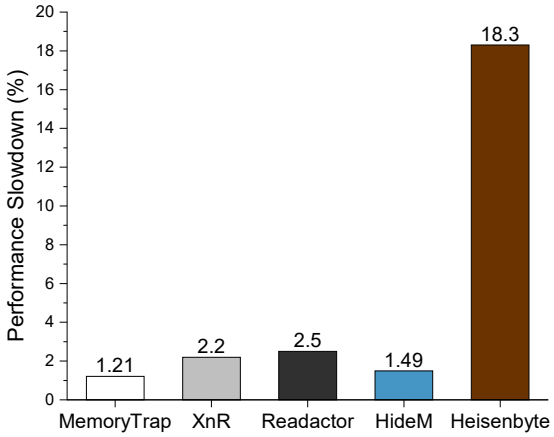

Figure 9: Performance comparison with XnR [46], Readactor [47], HideM [49], and Heisenbyte [53].

XoM through software emulation, incurring 2.2% performance overhead. Readactor uses Intel's virtualization technique to enforce the execute-only permission, exhibiting 2.2% overhead. HideM utilities the split-TLB to achieve XoM protection, which causes 1.4% overhead. Heisenbyte tries to tolerate legitimate data-in-code reads, but it reveals significantly higher overhead (18.3%) than other approaches due to its code destruction and read request redirection operations. In contrast, MemoryTrap exhibits the lowest overhead (1.21%) among all prototypes in Figure 9.

7.5 Compatibility with Embedded Data Reads

Among real-world programs we tested, OpenSSL exhibited the highest frequency of embedded data reads. Therefore, we use OpenSSL to demonstrate the compatibility of MemoryTrapwith embedded data reads. We compiled a MemoryTrap-protected version of OpenSSL and executed it using the `openssl speed` command [88], which is the official benchmarking tool used to measure the performance of cryptographic algorithms in OpenSSL. The compiled OpenSSL binary contains a total of 827,604 bytes of embedded data, distributed across 1,063 embedded data blocks. During the execution of the `openssl speed` command, a total of 656,509,327 embedded data read operations occurred, and the read intensity is $1.40E^{-7}$. All embedded data read operations were executed successfully, and all benchmark tests completed normally. This result demonstrates that MemoryTrap has excellent compatibility with embedded data reads. Notably, although OpenSSL contains a considerable amount of embedded data, the average size of each embedded data block is only 779 bytes. This implies that even if an attacker successfully locates an embedded data block, they can only access, on average, 779 bytes of embedded data. Such a limited amount of embedded data is insufficient to be successfully leveraged by a JIT-ROP attacker.

8 Discussion and Conclusion

Potential Security Problem of WRPKRU In the MPK mechanism, the WRPKRU instruction can write the value in EAX to PKRU to change the permission of page groups. Skilled attackers may try to bypass MemoryTrap's protection by granting read permissions to all page groups using the WRPKRU instruction. However, when executing the WRPKRU instruction, the value of ECX and EDX must be 0. Otherwise, a general-protection exception (#GP) will occur. If attackers change the page permission via WRPKRU, at least four gadgets are needed: 1) write EAX, 2) write ECX, 3) write EDX, and 4) execute WRPKRU. Fortunately, as we demonstrated in §6, with MemoryTrap deployed, at most one gadget can be disclosed before triggering MemoryTrap's protection.
DoS Risk In our current response to a detected memory disclosure attempt, MemoryTrap will terminate the vulnerable process immediately. While this measure can thwart attackers from gaining control of the system, it also poses a potential risk of Denial of Service (DoS). An alternative strategy is to combine MemoryTrap with re-randomization. Instead of terminating the compromised process, we activate a new randomization process to the code layout. This method can prevent the use of collected gadgets and simultaneously avoid the risk of DoS. However, the cost of doing so is the large overhead that comes with the re-randomization process itself.
Multi-Platform Support Currently, MemoryTrap is implemented based on Intel's MPK mechanism. MPK is supported on mainstream Intel and AMD desktop and server CPUs but is unavailable on other platforms. Nevertheless, other platforms provide similar mechanisms that can be used to implement MemoryTrap. For instance, ARM provides AP/XN [89], RISC-V offers PMP [90], and PowerPC includes Protection Keys [91]. These mechanisms can serve as alternatives to implement MemoryTrap. We discuss details in Appendix D.
Conclusion This paper introduces MemoryTrap, a hardware-assisted technique to counter memory disclosure attacks. MemoryTrap inserts unreadable, variable-size code snippets (booby traps) at strategic points to block unauthorized code page reads, utilizing Intel's MPK for efficient, fine-grained memory permission control. Our experiments demonstrate that MemoryTrap reveals a strong resistance to various memory disclosure attempts and negligible runtime overhead.

Appendix

A Kernel Structure Modifications to Support MemoryTrap

Figure A1 is the structures we defined in Linux kernel used to store the basic information about MemoryTrap. Some fields in kernel correspond to the fields in the newly defined ELF format, and some fields are used to store the run-time information for MemoryTrap protection. The *mtrap* structure stores the start and end virtual address of a booby trap in memory. The *mtrap_info_t* structure stores the basic information of a process protected by MemoryTrap: the enable flag, the trap flag, the PKey assigned to enforce execute-only memory, the number of booby traps, and the booby trap list. The mtrap_info_t structure is stored in the *task_struct* structure to save the MemoryTrap information in current process context. Figure A2 is the task_struct structure. We add a mtrap_info_t member at the end of the randomized struct fields, so the mtrap_info_t is compatible with the randomization protection.

```
typedef struct mtrap{
  uint64_t Start; //Start address of booby trap
  uint64_t End; //End address of booby trap
} MTrap;

struct mtrap_info_t{
  int enabled; //MemoryTrap enable flag
  int trap_allowed; //Read operation legality flag
  int pkey; //PKey (in MPK mechanism) of code pages

  size_t mtrap_num; //Number of booby traps
  struct mtrap *mtrap_list; //Booby trap list
};
```

Figure A1: The MemoryTrap structures in Linux Kernel.

```
struct task_struct {
  volatile long          state
  void                   *stack;
  refcount_t             usage;
  unsigned int           flags;
  unsigned int           ptrace;
  ...
  struct mtrap_info_t    mtrap_info ;
  ...
};
```

Figure A2: The task_struct structure in Linux Kernel.

B Performance on Real-World Applications

B.1 Web Servers

We compile and run the standard and protected web server versions, respectively. We use the ApacheBench [92] to simulate 500 clients to send HTTP requests 100,000 times asynchronously, and we record their running time to complete these 100,000 requests. To demonstrate the performance impact of MemoryTrap when requesting different page sizes, we tested five different page sizes: 50KB, 100KB, 200KB, 500KB, and 1MB. Table A1 shows the overhead of MemoryTrap protection on each web server.

Table A1: Overhead of MemoryTrap protected web servers using ApacheBench. The first row presents the request page size, and the data show the overhead for each size.

Web Server	50KB	100KB	200KB	500KB	1024KB	Avg.
Nginx	0.13%	0.54%	0.16%	1.01%	1.71%	0.71%
Apache	1.80%	0.05%	0.72%	0.23%	0.09%	0.58%
Lighttpd	2.11%	0.06%	1.14%	1.21%	0.16%	0.94%
Average	1.35%	0.22%	0.67%	0.82%	0.65%	0.74%

As shown in Table A1, the maximum overhead value is only 2.11%, and the average overhead is 0.74%, and most overhead values are very close to zero. This indicates that the performance impact of MemoryTrap protection on I/O bound web servers is negligible.

Table A2: Performance evaluation result for databases. For each database, the first row is the insertion performance, and the second row is the selection performance. The second column shows the results of the original (unprotected) versions, and the third column shows the results of MemoryTrap-protected version. The unit for the result of MongoDB is second, while the unit of other results is request times per second.

Database	Original	MemoryTrap	Overhead
MySQL	2008.13/s	1969.70/s	1.95%
	20053.05/s	19412.63/s	3.30%
MongoDB	11913.92/s	11905.58/s	0.07%
	14379.11/s	14370.48/s	0.06%
Redis	136138.42/s	134777.04/s	1.01%
	137691.20/s	137484.66/s	0.15%
SQLite	655.14/s	650.75/s	0.67%
	85971.78/s	83298.06/s	3.21%

B.2 Databases & JIT Engine

Databases Performance Results Unlike ApacheBench, there is no such unified performance benchmark for databases. We have to run each database with a customized testing suite.

1. MySQL: We use MySQL's official benchmark *sysbench* [93] to evaluate the insertion and query overhead. We configure sysbench with the *complex* workload to perform insertion and selection for 100,000 rows.

2. MongoDB: We use the official performance benchmark of MongoDB, *mongo-perf* [94], to evaluate the impact

Table A3: Result of Kraken benchmark. "SJCL" is short for Stanford Javascript Crypto Library.

	A*	Audio	Imaging	JSON	SJCL
Original	149.7ms	285.0ms	360.3ms	145.0ms	508.9ms
MemoryTrap	151.6ms	290.7ms	365.1ms	146.1ms	520.8ms
Overhead	1.27%	2.00%	1.33%	0.76%	2.34%

of MemoryTrap on MongoDB. We execute the *simple insert* and *simple query* workload and record how long the workloads can be completed to evaluate the insertion and selection overhead.

3. Redis: For Redis, we also use the official benchmark, *redis-benchmark* [95], to measure the overhead. We execute the *SET* and *GET* operation 100,000 times and record how many requests can be processed per second.

4. SQLite: Since there is no official benchmark for SQLite, we design a custom benchmark for SQLite to simulate other database benchmarks' workloads. We insert 100,000 rows of random data and select the inserted data by their primary key. We record the execution time and calculate how many requests that SQLite can process per second.

Table A2 shows the results of database evaluation. For each database, the first row shows the insertion performance, and the second row shows the selection performance. The last column shows the overhead incurred by MemoryTrap. As shown in Table A2, most of the databases have a very low overhead when enabling MemoryTrap's protection, and the average overhead is only 1.30%. This shows that MemoryTrap has a negligible overhead on protecting databases.

JIT Engine Performance Result We compile the custom V8 engine together with the latest Chromium to get a browser that can generate MemoryTrap protected JIT compiled code and run Kraken Benchmark. The benchmarks in the first row of Table A3 are: 1) A* search algorithm [96]; 2) audio processing using Corban Brook's DSP.js library [97]; 3) image filtering routines [98]; 4) JSON parsing [99]; 5) Stanford Javascript Crypto Library (SJCL) [100]. Table A3 shows the overhead of JIT engine protection using Kraken Benchmark. In all cases, the small overhead caused by MemoryTrap ranges from 0.76% to 2.34%, and the average overhead is only 1.54%.

Table A4: Time for process-related kernel operations in μs. Smaller is better.

Kernel	Null Call	Null I/O	Stat	Open Close	Select TCP	Signal Install	Signal Handle	sh Proc
Standard	0.09	0.14	0.46	1.11	1.60	0.14	1.03	760
MemoryTrap	0.09	0.14	0.47	1.13	1.60	0.14	1.02	764
Overhead	0.00%	0.00%	2.17%	1.80%	0.00%	0.00%	-0.98%	0.53%

C Other Microbenchmark Results

Table A4, Table A5, and Table A6 show the lmbench results for MemoryTrap low-correlation kernel operations.

Table A5: Local communication latencies in μs. Smaller is better.

Kernel	Pipe	AF UNIX	UDP	TCP	TCP Conn

Overhead	0.42%	1.30%	-3.20%	0.66%	0.77%	0.00%

D Applicability to Other Platforms

Windows Platform Support The user-space components of MemoryTrap are OS-independent. However, the Windows kernel currently does not yet provide APIs to support the MPK mechanism. To transplant MemoryTrap to Windows platforms, we can resort to the mature Intel hardware virtualization mechanism EPT instead of MPK to remove the read permission of code pages. Then, we reimplement the exception handler in hypervisor to react to memory disclosure attempts.

Transplant MemoryTrap to ARM A series of papers have transplanted the idea of execute-only memory to various ARM platforms using different hardware features [101–103]. The diversity of ARM specifications offers multiple alternatives to implement MemoryTrap on ARM. All we need to do is to reimplement the fine-grained memory permission control with different hardware features. For example, we can use the unprivileged memory instructions and Memory Protection Unit hardware feature to implement MemoryTrap on Cortex-M [101]. On ARMv7-M and ARMv8-M, we can leverage the hardware-supported debugging facilities [102] to implement MemoryTrap. On AArch64, we can combine the Unprivileged Execute Never bit, Privileged Execute-Never bit, and two Access Permission bits [103], to implement MemoryTrap. Even without any hardware support, we can still implement the software-emulation version of MemoryTrap. For example, we can use the most significant bit to mark booby traps as non-readable memory. Then, we check if the targets of read instructions land in booby trap areas via instrumentation [35].

Table A7: The gadget distance distribution of real-world exploits. The data from Column 2 ∼ Column 6 indicate the count of two adjacent gadgets' distances within that range. "Avg." and "Max." represent "Average Distance" and "Max Distance " of two adjacent gadgets. "Fir.-Las." represents the distance between the First gadget and the Last gadget.

	<1KB	1∼2KB	2∼4KB	4∼8KB	>8KB	Avg. (KB)	Max. (KB)	Fir.-Las. (KB)
CVE-2013-2028	0	0	0	1	3	123.7	193.8	494.7

Average	579	307	23	12

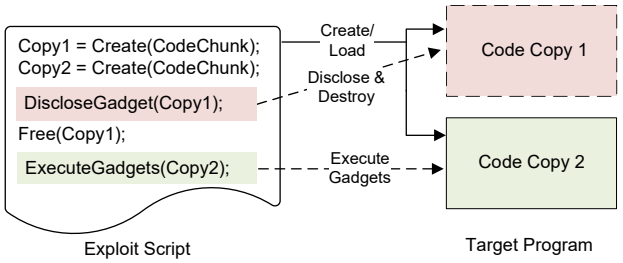

Figure A3: An example of code inference attacks. Code copy 1 is only used for code disclosure, while code copy 2 is only used for gadgets execution.

E Statistical Analysis of Real-world Exploits

We collect publicly available real-world exploits that can reproduce JIT-ROP attacks from Metasploit [82] and Exploit-DB [83]. For every two adjacent gadgets, we count the number of distances within different ranges, from less than 1KB, 1KB∼2KB, 2KB∼4KB, 4KB∼8KB, and greater than 8KB. Table A7 shows the gadget distance distribution data for these exploits. For the exploits without CVE number, we show their Exploit-DB ID (EDB-ID) instead. In Table A7, there are 131 different distance types between two neighboring gadgets, but only 18 of them are less than one memory page's size (i.e., 4KB), accounting for 13.7% of the total. This means that the probability of having two available gadgets in one memory page is less than 13.7%. In Table A7, the average gadget number for an exploit is 8.2, and thus the probability that all gadgets are located in one memory page is at most $0.137^{8.2} \approx 0.000000083\%$, an almost negligible number. In all gadget chains we collected, the minimum distance from the first gadget to the last gadget is 94.0KB, which means the attackers have to disclose at least 94.0KB of code to build the whole payload.

For the exploits we collected from public databases and the vulnerable programs that can also be protected by MemoryTrap, we use the strategies in §6.1 to measure code page traversal results as well. Table A8 reveals a similar pattern to that of CVE-2013-2028: MemoryTrap leaves adversaries with little wiggle room to harvest all of the required gadgets, and only a few attempts get a chance to find **at most one gadget**. The data in Table 2 and Table A8 demonstrate that our booby trap insertion strategy is effective in preventing JIT-ROP gadget search.

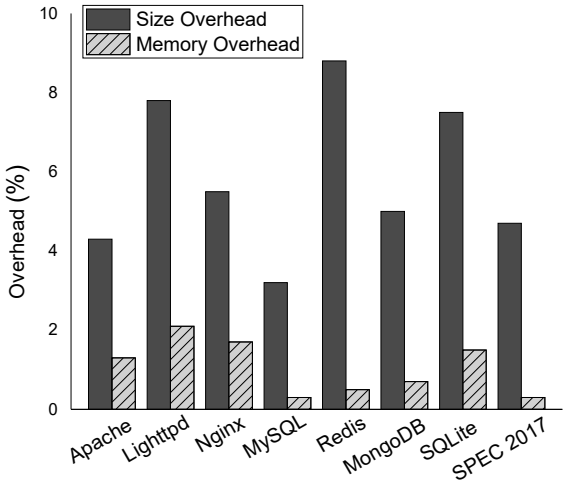

Figure A4: Disk size and memory overhead of MemoryTrap.

F Code Inference Attacks

Snow et al. [57] proposed four types of *code inference attacks*, rendering DCR ineffective. The core principle of code inference attacks is to disclose a segment of code without executing it directly. Instead, another piece of code that is strongly related to the disclosed code will be executed, such as an exact copy of the disclosed code residing in a different memory region, or relevant code that can be inferred based on the disclosed segment. The core idea of code inference attacks is to disclose a piece of code but not to execute it. Instead, another piece of code that is strongly related to it will be executed, such as an exact same copy of the disclosed code in a different memory area, or the relevant code that can be predicted based on the disclosed ones. As shown in Figure A3, adversaries maintain two copies of the same code, and they only disclose one copy to collect gadgets and execute the other copy. The four code inference attacks are as follow:

T1. JavaScript JIT Cloning: Load two copies of the same JIT code to disclose one copy and use the other.

T2. Shared Library Reloading: Disclose a library's code and let it be destructed, and then reload it to use the previously disclosed code.

T3. Process Reloading: Disclose the code of an active process and then reload it to use the refreshed code.

T4. Implicit Reads: Disclose some code to infer the content of another code copy to avoid being destroyed.

G Other Overhead

Since we insert booby traps into the program and attach the ".mtrap" section into the ELF file, the binary size will increase naturally. When executing the protected binary, the size of these contents are fixed after being loaded, and does not change during program execution. We measure the disk size and memory overhead for real-world applications and SPEC CPU 2017 benchmarks that are protected by MemoryTrap. Figure A4 shows the disk size and memory overhead. The disk size overhead rages from 3.2% to 8.8%, and the average disk size overhead is only 5.85%. Memory overhead is smaller than disk size overhead due to the allocation of stack and heap during the program execution. The memory overhead varies between 0.3% and 2.1%, with an average memory overhead that remains negligible at just 1.05%.

When employing MemoryTrap with code randomization, in addition to code pointers, all booby trap pointers also need to be fixed to their shuffled positions, allowing the kernel to recognize the relocated booby trap positions. This introduces overhead during binary loading. To measure this overhead, we collect the booby trap count during compilation with our toolchain and determine the number of pointers requiring fixups using CCR's toolchain [79]. The overhead is calculated by dividing the number of booby traps by the total number of pointers needing fixups. The average overhead for web servers, databases, and SPEC 2017 benchmarks is 5.67%, 2.78%, and 4.01%, respectively, demonstrating a minimal fixup burden. It is noteworthy that this overhead is a one-time cost and does not impact runtime performance.

Abstract

Confidential computing based on Trusted Execution Environments (TEEs) allows software to run on remote servers without trusting the administrator. Remote attestation offers verifiable proof of the software stack and hardware elements comprising the TEE. However, setting up a secure channel to such a TEE requires a security guarantee that the channel actually terminates inside the TEE. TLS is an existing protocol for secure channel establishment, and in its most common use on the Web, it uses a key pair to assert the server identity encoded in a certificate. Various approaches have been proposed to integrate remote attestation into TLS. Unfortunately, they all have shortcomings. In this paper, we present a protocol that combines the existing certificate-based assurances of TLS with remote attestation-based assurances in a way that they can be *deployed independently* and can *fail independently*. We design these two assurances to be additive without relying on each other, a property that has not been considered by existing approaches.

1 Introduction

Remote attestation, originally developed for Trusted Platform Modules (TPMs) [1], recently experiences a revival due to the availability of Trusted Execution Environments (TEEs) [2] in processors and initiatives towards confidential computing [3]. With confidential computing, a cloud server runs client workloads inside a TEE, with the security guarantee that the code being executed and the data being processed is not accessible even to a malicious system administrator with control over the hypervisor. During execution, TEE state is shielded from software outside the TEE and physically never leaves the processor unencrypted. Remote attestation offers a cryptographic proof to a remote party that the TEE is backed by genuine hardware and asserts which software is running inside it.

However, to communicate with a TEE, the remote party also requires a secure channel into the TEE. Establishing such a channel should be compatible with multiple TEE implementations, and the protocol must guarantee channel termination inside the TEE. Transport Layer Security (TLS) [4] is a widely-deployed and well-analyzed protocol providing secure channels, but needs to be extended to support remote attestation. Such extensions to TLS were explored when TPMs were introduced [5, 6] and more recently with Intel SGX [7, 8] and other TEEs [3]. Such a TLS extension is non-trivial as it must take care of relay attacks [9, 10], where the attestation report of a valid TEE is used by a malicious intermediary to terminate the encrypted connection outside the valid TEE. Therefore, TLS and attestation cannot be used side-by-side, but must be cryptographically linked with each other to guarantee that the encrypted channel terminates at the origin of the attestation report [9].

The existing approaches differ in the way both aspects are linked: One option is to establish a regular TLS connection first and then arrange an attestation exchange through the TLS channel to establish a second, attestation-based communication channel inside the outer TLS channel. However, this construction [8] results in additional handshake round trips and an additional layer of encryption for the inner channel. Another option is to include attestation information in the certificate used to establish the TLS connection, thus linking both aspects statically at deployment [9]. Such linking risks losing the attestation-based assurance in case the long-lived TLS private key is ever leaked, for example through a Heartbleed-like side channel [11].

In this paper, we present TLS+RA, an attestation extension to TLS. To maintain best practices and the resulting trust relationships, TLS+RA keeps the deployment of certification authorities (CAs), which issue end-entity certificates to TLS servers, separate from attestation-related information and vice versa. Therefore, we opt for a late linking of TLS and attestation during the connection handshake, rather than modifying certificates. Using short-lived, per-session handshake secrets rather than long-lived TLS keys, the failure behavior remains independent, resulting in truly additive security assertions. We have not seen this property considered in existing approaches. Two key enablers to revisit this problem now are the compulsory use of ephemeral Diffie-Hellman key agreement (when

used with certificate-based authentication) and the extension mechanisms available in TLS protocol version 1.3 [4].

In summary, TLS+RA combines attestation and TLS in a new way, so that channel termination inside the TEE is guaranteed while both connection aspects are kept separate in terms of deployment and failure behavior. Our contributions are:

1. The introduction of *deployment and failure independence* (Section 2) and a survey of related work (Section 3).
2. The TLS+RA protocol (Section 5), a TEE-agnostic attestation extension to TLS offering deployment and failure independence. While server-side TEEs are our main motivation for use in confidential computing, the protocol supports client-side and mutual attestation as well.
3. An implementation based on OpenSSL (Section 6), which we evaluate regarding handshake latency and channel throughput (Section 7). The code is available as open source [12].

2 Background and Properties

After reiterating the fundamental security properties of TLS and attestation, we explain our desired properties of deployment and failure independence for the combination of both.

2.1 Properties of TLS and Remote Attestation

The TLS protocol establishes a confidential and integrity-protected channel between a client and a server. For a typical use of TLS 1.3 [4] on the Web, the channel is based on an ephemeral shared secret established by Diffie-Hellman key agreement. This key agreement ensures that a passive eavesdropper listening to the exchange cannot derive the shared secret. To prevent active attacks, the server uses an X.509 certificate and key confirmation to authenticate to the client (typically a browser). These server certificates associate an endpoint identifier, typically a Fully Qualified Domain Name (FQDN) [13], with a public key. The certificate is signed by a CA in response to a certificate request from the operator of the server, after the requester has demonstrated that it controls the FQDN. Only the valid endpoint can prove possession of the matching private key, unless this private key is leaked or stolen. To authenticate a server, the TLS client compares the expected FQDN (e.g. the URL entered into the browser) with the FQDN found in the subject name of the certificate to decide whether to trust the server or not [14].

Rather than demonstrating control over a domain name, remote attestation offers an assertion of the hardware and software stack running on the remote machine [1]. A pre-requisite for remote attestation is a set of components on the remote machine that are trusted to reliably ascertain the running software stack and sign a cryptographic report of its state. Collectively, this set of components forms the root-of-trust

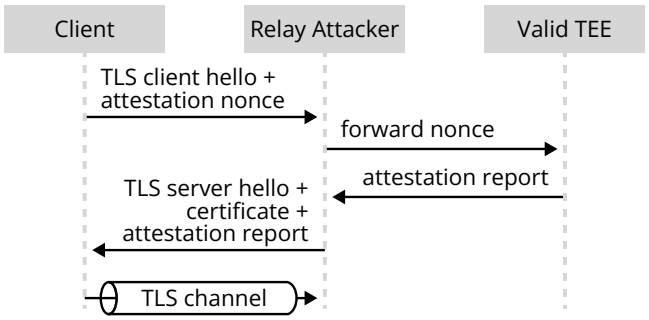

Figure 1: Relay attack when combining TLS and attestation.

(RoT). Each TEE comes with its own RoT implementation, typically involving a secret securely kept inside the device hardware. SGX, for example, implements the RoT as part of the main CPU, including software components performing the report signature. Processor-independent RoTs like TPMs can externally inspect and attest the software being booted on a CPU, effectively treating this boot state as one large execution environment. When connecting to a TEE, the TEE is sent a challenge in the form of a nonce. The TEE asks its RoT to respond with a signed quote, containing the nonce and measurements of the current hardware/software state. The key pair with which this attestation report gets signed is confirmed to be valid by the RoT's manufacturer, usually also in the form of a certificate. As long as the private key pertaining to the RoT is not leaked, only valid hardware with this RoT can create the signature. The connecting party can make a trust decision based on the TEE state encoded in the attestation report.

We believe both trust decisions are useful and orthogonal to each other: While attestation makes an assertion about the internal state of the TEE, the TLS certificate asserts the endpoint identity and administrative control, i.e., factors external to the TEE. As TEEs do not exist in a vacuum, the infrastructure around it may influence the trust decision. Therefore, we intend to combine both assertions into one protocol but keep them independent enough that their properties are additive.

2.2 Combining TLS and Remote Attestation

Past research [9] has shown that combinations of both these protocols can be insecure. Figure 1 illustrates a relay attack. When TLS authentication and attestation are performed next to each other, i.e., without cryptographically interlinking the handshake, the resulting secure channel is not guaranteed to terminate in the TEE issuing the attestation report. In case an attacker obtains the private key of the TLS certificate, a fake endpoint can be set up running an invalid software stack. The attacker forwards the attestation nonce to a correct TEE and thus obtains a valid-looking attestation report, which is forwarded to the client. This attack shows that protocol combinations without adequate cryptographic linking are not independent in their properties: here, the credibility of the

attestation relies on the protection of the TLS private key. If, for example, the TLS private key is handled by cloud provider infrastructure, we suddenly trust the cloud provider as to the validity of attestation reports, undermining the promises of TEEs and confidential computing. Therefore, we postulate five properties a combined TLS+RA protocol should provide:

1. Retain the properties of the secure channel, like confidentiality, integrity, and replay protection, but additionally transmit an attestation report. Currently, there is no Internet protocol standard for establishing a secure channel with remote attestation. Hence, building upon the battle-hardened [15] TLS protocol is natural. The protocol must guarantee that the tunnel terminates in the TEE to prevent relay attacks.

2. Do not add extra network message round trips to the connection handshake. Attestation should not unduly increase the cost of establishing a TLS channel.

3. Once the channel is established, do not add encryption layers. The regular TLS payload encryption should suffice.

4. Independent deployment: To remain compatible with the existing certificate practices (issuance, expiration, revocation, use in transparency logs), the use of certificates and the underlying public-key infrastructure (PKI) should not be changed. Especially, TLS certificates should not contain attestation information, which would complicate load balancing in data centers, where the same domain name may be served by different machines with different attestation technologies. Equally, attestation deployment should only involve the TEE vendor, not a Web PKI CA issuing certificates typical for use on the Web.

5. Independent failure: If either the TLS certificate private key or the attestation RoT are compromised, the assertion of the other should remain intact. The TLS private key can be leaked through side channels like Heartbleed [11]. Then, the connecting party can no longer be sure to connect to the expected machine in the expected administrative environment. But the attestation assertion to the validity of the software stack should remain correct. Vice versa, if the attestation RoT is compromised, the validity of the stack can no longer be assured. However, the TLS certificate should continue to demonstrate that the domain is still under the control of the owner.

With these properties in place, TLS+RA offers additive security properties of TLS and remote attestation.

3 Related Work

While prior work exists that designs such protocols from scratch [10], we focus on combinations of attestation and TLS, because we want to retain and augment the properties of TLS rather than replace it. Points in the solution space differ by the method of combining TLS and attestation, which we cover in the following (Table 1) from coarse-grained linking towards more intricate merging of both. We note that all solutions offer protection against relay attacks if neither the TLS private key nor the attestation RoT private key are leaked. However, only few offer failure independence in case the TLS private key is compromised. The protocol should still ensure that the TLS channel terminates in the TEE that created the attestation report.

Table 1: Related work compared to the TLS+RA properties.

	Prevents Relay Attacks	No added round trips	No added encryption	Independent deployment	Independent failure
HTTPA [8, 16]	✓			✓	✓
Platform Certificate [9]	✓	✓	✓		
RA-TLS [7]	✓	✓	✓		
RA-TLS with CA [7]	✓		✓		
Extending TLS [6]	✓		✓		✓
RATLS [17]	✓	✓	✓	✓	
Trusted Channels [5]	✓	✓	✓	✓	

HTTPA [8, 16] offers such failure independence. It does so by nesting an attestation-based encrypted channel inside the TLS-based encrypted channel, doubling handshake and encryption effort. To avoid this cost, the linking has to happen in the TLS handshake, resulting in a single layer of encryption. Goldman et al. [9] postulate binding the TLS key pair to the attestation RoT key pair by way of a platform certificate, which is signed by a regular CA. If the valid TEE obtains such a certificate and afterwards loses its TLS private key, a relay attack can be launched by presenting this same platform certificate plus the relayed attestation report. Since certificates are connection-independent, they cannot prevent such connection relaying.

Per-connection certificates may offer a way out. RA-TLS [7] creates an ephemeral, self-signed certificate, which contains the attestation report itself. Due to the use of self-signed certificates it does not provide the certificates used in Web PKI environments. The same paper proposes an extension where the ephemeral certificate is signed on-the-fly by a PKI CA. However, this increases connection latency and does not offer failure independence: to automate this per-connection process, a long-lived secret or proof-of-domain-control [13] must be presented to the CA, both of which an attacker could replicate to mount a relay attack without compromising the TEE RoT. Instead of using a TLS certificate as a transport vehicle for the attestation report, Aziz et al. [6] obtain for every connection an ephemeral attestation-key certificate for the RoT and bind this RoT to the TLS handshake nonce. This is enough to prevent

relay attacks even when the TLS key is compromised, but the described approach adds handshake messages and a full round trip for the certificate signing request to the critical path.

Walther et al. [17] and Armknecht et al. [5] describe two protocols very closely integrated with TLS. Both use the existing TLS extension mechanism to add additional data fields to regular TLS handshake messages. TLS certificates remain unmodified. However, both protocols use the TLS private key to link the attestation report to the TLS connection being established. Should the TLS private key be leaked, this linking can be performed outside the TEE on another machine, thus enabling a relay attack.

Finally, co-authors of this paper contribute to an Internet protocol draft [18] that aims to standardize how TLS message extensions carry attestation evidence. The draft seeks interoperability with a related standard proposal [19] and therefore links attestation to the TLS private key. Hence, it offers security guarantees similar to the works of Walther et al. [17] and Armknecht et al. [5] that we already discussed above.

In summary, promising approaches exist, but only designs costly in terms of handshake messages or encryption overhead fulfill our desired property of failure independence.

4 Deployment and Threat Model

We assume that the TLS public-key infrastructure and its CAs are operated independently of the TEE manufacturer and associated remote-attestation infrastructure. However, we do require that the TLS+RA library, the application using it, and any security-critical code they depend on run inside a TEE. This requirement ensures that the code implementing the combined TLS+RA handshake is captured in the attestation report; some TLS+RA state must also be included, as described in the following section. The exact procedure of how to start software in a TEE, what else to include in an attestation report, and how to validate it are orthogonal to the TLS+RA approach. However, we assume that all necessary steps for TEE provisioning have been executed securely.

Under these assumptions, we consider an attacker who can compromise either the TLS private key or the attestation RoT, but not both. A TLS private key or an RoT private key can be leaked (e.g., through a side-channel attack or information-disclosure bug) or a fake key can be certified (in case the responsible CA has been compromised). If an attacker compromises only the RoT key material but *not* the isolation of the associated TEE, then an invalid attestation report can be forged but the TLS private key inside the TEE is not assumed to be compromised.

5 Protocol Design

Although our TLS+RA protocol supports mutual attestation of client and server, let us consider a confidential computing scenario where a client interacts with a workload running inside a TEE hosted by a cloud provider. The client wants to establish a TLS channel with the guarantee that the channel terminates inside the TEE running the expected software. Thus, the server should attest its TEE state to the client. The flow starts with the client checking its attestation verifier for supported attestation evidence formats. This verifier can be a local library or a remote service, but this is orthogonal to the design of TLS+RA. The client then initiates the TLS+RA handshake with the server by sending a client hello message. As part of this message, the client forwards supported attestation evidence formats and an attestation nonce for freshness from the verifier to the server as part of an *attestation request*. If the server supports one of the evidence formats presented to it, it returns a corresponding attestation report as part of its TLS certificate message. If none of the formats match, the handshake terminates.

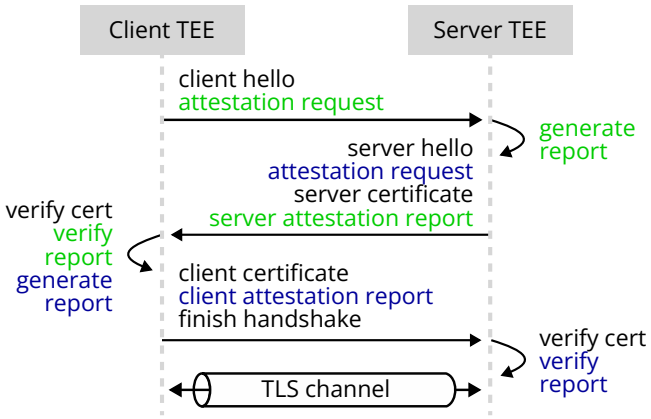

Figure 2: TLS+RA handshake with mutual attestation (server attests to client in light green, client attests to server in dark blue, black is standard TLS).

Building upon TLS In order to ensure deployment independence, we do not want to change how TLS certificates are managed or what information they carry. Thus, attestation data must be added next to the existing TLS data as part of the TLS handshake. As demonstrated by prior work [5,17], it is possible to exchange attestation-related information between the client and the server via *message extensions* available in TLS version 1.3. Figure 2 shows the additional attestation request and report encapsulated in extensions to the hello messages (extended with respective attestation request) and certificate messages (extended with respective attestation report). These extensions are transmitted together with the regular TLS handshake messages and do not incur additional network round trips.

To prevent relay attacks, the TLS+RA session and the attestation report must be cryptographically linked. To construct this link, we exploit another feature of TLS 1.3: the compulsory use (outside of special cases using pre-shared keys-only mode) of Ephemeral Diffie-Hellman (DHE) key agreement. DHE key agreement gives both parties a freshly-generated shared

secret that is unknown to any third party. However, there are no assurances about who the two parties are. Regular TLS solves this problem by linking the shared secret to the TLS certificate. For this, a cryptographic hash called *transcript hash* is computed over a log of the exchanged messages up until this point in the handshake, meaning the client hello message received by the server as well as the server hello response generated by the server. This hash therefore subsumes TLS nonces and the public parts of the DHE key material that each peer must use to compute the shared secret. The transcript hash is then signed using the private key belonging to the TLS certificate. This signature offers cryptographic proof of possession of the TLS private key and thus establishes a link between the TLS session and the endpoint identity (typically the domain name).

Linking TLS and Attestation Handshakes To this existing link in standard TLS, TLS+RA adds a second, independent link: We generate a *linking hash* and forward it as the challenge to the attestation RoT. As the key difference compared to the transcript hash, this linking hash is computed over the same TLS handshake messages, but also includes the DHE-derived shared secret. Without this shared secret, the linking hash would only cover publicly visible information of handshake messages, therefore opening the possibility of a relay attack. Including the shared secret, which is only known to the connecting parties, prevents this attack. The verifying peer can compute the same hash, because it actively participated in the DHE key exchange. Note that the linking hash also ensures freshness by including the attestation nonce, which is part of the attestation request transmitted via a message extension. In summary, this hash links the attestation report to the TLS session in the same way the TLS certificate is linked to it. The secure tunnel is therefore guaranteed to terminate where the TLS private key is kept *and* where the attestation report was generated.

Additive Security in TLS+RA As shown in Figure 3, this *double linking* causes both links to be symmetric (they are derived from the same message log) and independent from each other (they use different signing keys and deployment infrastructure). If the attestation RoT fails, but TEE isolation remains unaffected as described in our threat model (Section 4), the TLS assurances remain intact. If the TLS private key is compromised, the client can still trust and verify the attestation evidence. The attacker can only set up a rogue server with the same TEE hardware and the same software the client expects; otherwise the client will reject the attestation evidence.

Furthermore, double linking prevents relay or other intercept attacks [20]. TLS+RA inherits the property of *forward secrecy* from TLS 1.3: A stolen TLS private key cannot be used to decrypt previously intercepted traffic, because message payloads are instead encrypted using a key derived from the randomly-generated, per-session DHE shared secret. However, unlike the standard protocol, TLS+RA also prevents the attacker from using the TLS private key to mount *future* relay attacks. If the attacker sets up a fake server running malicious software using

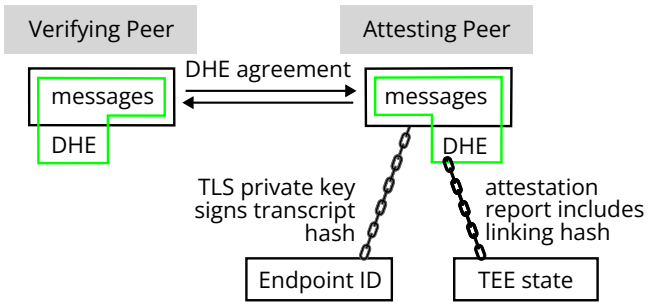

Figure 3: Double linking of TLS+RA handshake. While the TLS private key signs the message transcript, the linking hash in the attestation report also includes the shared DHE secret.

the stolen key, this fake server cannot attest itself and must therefore establish separate channels with the client and the original server. Since the attacker cannot predict the randomness used by the other two machines, both TLS+RA channels will use different DHE secrets resulting in different linking hashes. Hence, the client will detect the mismatch between the linking hash based on its own DHE computation and the one that has been attested by the original server; it will then abort the handshake.

Other protocols lack this property, because they link the attestation with the TLS certificate private key [7, 9], thus not forming two independent links. Or, they link it only with the TLS nonce [5, 17] but not with the DHE key material, which would additionally protect against relay attacks. The attestation linking we propose matches the protocol that Stumpf et al. designed from scratch without TLS integration [10]. TLS+RA thus integrates remote attestation with the state-of-the-art and widely deployed TLS 1.3 protocol, benefitting from its known security properties.

6 Implementation

Similar to the work done by Armknecht et. al. [5] and Walther et. al. [17], we built our TLS+RA prototype on top of OpenSSL. With `SSL_CTX_add_custom_ext`, this TLS library offers a public API for adding callbacks that can create or inspect message extensions during the TLS handshake. Another callback registered with `SSL_CTX_set_verify` is invoked, when the attestation report has been received as an extension to a certificate message. Using `SSL_CTX_set_ex_data`, we embed user-defined data in the TLS session context. Using these APIs, we implement a remote attestation state machine as a set of callback functions that runs in parallel to the TLS handshake.

However, there is one modification we have to make to the OpenSSL codebase: to link the attestation report to the TLS session, we must compute the linking hash over the log of handshake messages and the DHE-derived shared secret. This information is readily available internally in OpenSSL, but not accessible through an API. As part of the TLS specification,

RFC 5705 [21] defines so-called *exporters*, which do give applications access to TLS keying material. However, the corresponding APIs can only be called after the completion of the handshake. This is too late for our approach. We therefore add an additional, non-standard exporter function that generates the linking hash during the handshake, right after OpenSSL has computed the shared secret using DHE key agreement. Note that this extension does not change the TLS wire protocol, but merely derives the linking hash from internal state of the TLS implementation to facilitate the cryptographic link between the TLS session and the attestation report.

The way in which TLS+RA extends standard TLS is agnostic to the TEE in which it is running, the underlying attestation RoT, and the data formats used in attestation reports. TLS+RA treats these reports as opaque data when shipped inside TLS message extensions, so any data format can be carried. To demonstrate the separation between TLS+RA as a protocol and the underlying attestation RoT, we integrate a simple API for platform-specific TLS+RA plugins. At the core, plugins for this API must implement two functions: `remote_attest` and `check_report`, which request and validate attestation reports, respectively. Two of these plugins, one for industry-standard TPMs and one for AMD's Secure Encrypted Virtualization with Secure Nested Paging (SEV-SNP), will be evaluated quantitatively in the next section. Another plugin targeting Arm Confidential Compute Architecture (Arm CCA) has been developed and tested using an emulator. This plugin will not be used in benchmarks, because Arm CCA-enabled hardware is not available to the public yet.

7 Evaluation

With our experiments, we want to demonstrate the following properties of TLS+RA:

1. Qualitatively show interoperability with different TEE implementations.
2. Quantify the overhead of TLS+RA over standard TLS to demonstrate the feasibility of TLS+RA.
3. Compare TLS+RA against approaches that layer attestation on top of TLS to demonstrate the benefit of merging TLS and attestation into a combined protocol.

We evaluate TLS+RA on AMD SEV-SNP (representing a cloud server TEE), firmware TPMs (representing end user devices), and hardware TPMs (representing Internet-of-things devices). For AMD SEV-SNP, we use an Amazon c6a.large instance running Amazon Linux 2023 with Linux kernel 6.1. The firmware TPM (fTPM) implements the TPM 2.0 specification and is provided by a 13th Gen Intel Core i5-13400 desktop machine running Ubuntu Linux kernel 6.5. The discrete hardware TPM (dTPM) is an Infineon Optiga SLB 9670, also implementing TPM 2.0. It is connected to a Raspberry Pi 4 Model B Rev 1.4 with four Cortex-A72 cores and running kernel 5.15. For Arm CCA, we use an emulator by Arm which allows to test functionality, but is not suitable for performance measurements. To qualitatively test the interoperability of TLS+RA, we successfully executed combined TLS and remote attestation flows with these four technologies. TLS+RA supports server-to-client, client-to-server, and mutual attestation.

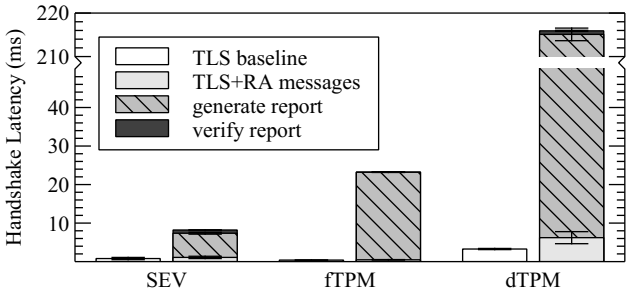

Figure 4: Handshake latency for TLS+RA compared to standard TLS. Note: The y-axis skips the range from 50 to 210 ms.

Attestation Overhead TLS+RA does not add any network round trips compared to standard TLS. Thus, to measure the worst-case processing overhead of the combined protocol, we co-locate both client and server on different cores of the same machine and let them communicate over the loopback interface. We disable idle sleep states on these cores to reduce measurement noise. Figure 4 compares a standard TLS baseline against TLS+RA for each attestation technology. Each measurement is repeated 100 times after two warmup runs; mean and standard deviation (some error bars are too small to be visible) are plotted. The overall handshake duration for TLS+RA is broken down into the time required to generate the attestation report on the server, the time required to verify the report on the client, and the processing and transmission of all messages by the OpenSSL library.

We see that TLS+RA adds overhead over standard TLS, which is dominated by the generation and verification of the attestation report. The remaining gap between TLS+RA message processing and baseline TLS is caused by increased computation and system-call overhead, as TLS+RA handshake messages are larger due to the additional report data. While baseline TLS sends approximately 1.5 KiB of data, TLS+RA for the fTPM technology has to transfer 6.4 KiB. The increase in data volume is dominated by the attestation report (called a *quote*) and the public part of the TPM's *attestation identity key*. The prototype plugin for TPMs serializes this information into JSON format. The SEV plugin forwards the original binary representation of both the roughly 1 KiB attestation report and the key certificate of the host platform. All reports are coarse-grained, describing the software stack as a whole.

Network Latency To quantify the end-to-end overhead of TLS+RA across various network distances, we plot in

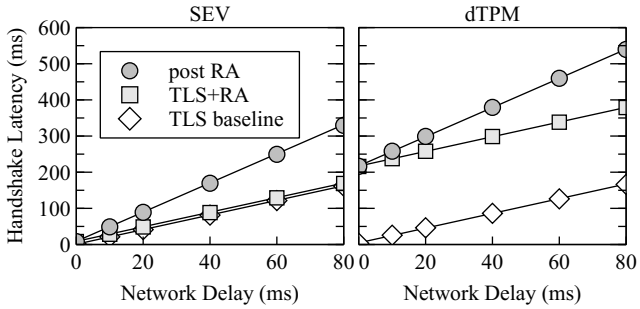

Figure 5: Handshake latency for TLS+RA compared to standard TLS and TLS with post-handshake attestation for various network delays. Lines between measurement points are linear fits to help with readability.

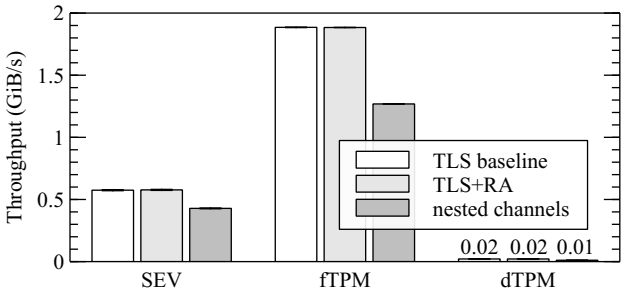

Figure 6: Channel throughput for TLS+RA compared to standard TLS and nested channels.

Figure 5 the handshake duration including network latency. We use Linux' *netem* facility to simulate network delays of up to 80 ms per direction, which is representative of client and server being on different continents. Again, the mean of one hundred runs is presented, after two warmup rounds. For SEV, which takes only 6 ms to generate the report, the relative overhead of TLS+RA shrinks to 5 percent at 80 ms network latency. With dTPM, report generation needs 210 ms, resulting in a 1.3x handshake overhead at 80 ms network distance.

Comparison to Related Work To compare TLS+RA not only against standard TLS as a baseline, we re-implemented the composition approaches of related works, while keeping the TLS protocol version, its implementation, and the hardware the same. The lines labeled "post RA" in Figure 5 show the performance impact of extra network round trips, when attestation is performed *after* the TLS handshake. For this experiment, we re-implemented the approach used by related work solutions such as HTTPA [8] and others, which require twice as many network round trips between client and server. In the case of SEV, for 10 ms network delay and greater, performing the TLS and attestation handshakes sequentially incurs more than 100% overhead compared to baseline TLS.

Solutions like HTTPA also nest two independent channels, requiring redundant encryption and integrity protection of all message payload. To quantify the associated costs, we compare throughput of standard TLS, TLS+RA, and a re-implementation of the nested channel solution. The nested channel is simulated using a second layer of AES-GCM authenticated encryption for sending 1 GiB of payload from server to client. Client and server again run on the same machine, so throughput is limited by cryptographic operations protecting the payload. The mean of 10 runs after two warmup runs is plotted. Figure 6 illustrates that TLS and TLS+RA perform similarly after the initial connection handshake, because they perform exactly the same cryptographic operations. Adding remote attestation introduces no overhead post-handshake. Throughput is therefore not determined by the TEE technology, but by the processor performing cryptographic operations. A nested channel solution achieves a lower overall throughput because of the additional cryptographic overhead.

Similar to TLS+RA, related works such as [5, 7, 17] avoid the cost of additional network round trips and nested channels, too. However, they offer weaker security properties by lacking failure independence (Table 1).

8 Conclusion

We have presented TLS+RA, a network protocol combination of TLS and remote attestation. TLS establishes an encrypted and integrity-protected channel to a specific endpoint, whereas remote attestation cryptographically verifies the hardware and software state of that endpoint. Both protocols are combined at the handshake level using standard TLS message extensions. The novel properties of deployment and failure independence set TLS+RA apart from related work. During the handshake, double linking of both the TLS certificate and the attestation report against the secret established during handshake is performed. Thereby, TLS+RA guarantees that the encrypted channel terminates at the attested machine even if the TLS certificate private key is compromised. By adding this security assertion to standard TLS, we hope to make attestation more accessible and thus more pervasively used in today's connected world.

Abstract

Atomic Data Definition Language (Atomic DDL) is fundamental in DBMSs, ensuring that schema modifications are executed completely or not at all, preserving database integrity. Despite their critical importance, bugs persist in the Atomic DDL, leading to severe consequences such as data corruption and system inconsistencies. However, there is a limited understanding of the characteristics and root causes of these bugs. Furthermore, existing testing methods often fail to effectively identify Atomic DDL bugs, particularly under conditions of high concurrency and unexpected system failures.

This paper presents a comprehensive study of 207 Atomic DDL bugs across three widely used DBMSs. It reveals that Atomic DDL bugs primarily manifest as incorrect results, post-recovery data inconsistency, and system unavailability, which are mainly triggered by metadata conflicts between DDL statements. Based on these findings, we developed DDLUMOS, a testing tool that detects Atomic DDL bugs with metadata conflict-guided DDL synthesis and graph-based consistency analysis. We applied DDLUMOS to six popular DBMSs (e.g., PostgreSQL and MySQL) and found 73 previously unknown Atomic DDL bugs. DBMS vendors responded promptly, fixing 14 issues, highlighting the effectiveness of DDLUMOS in improving the reliability of DBMSs.

1 Introduction

Atomic Data Definition Language (Atomic DDL) is foundational in Database Management Systems (DBMSs), ensuring that schema changes (e.g., creating, altering tables) are executed entirely or not at all, thereby preserving database integrity [22, 23]. Traditional DDLs modify the data structure immediately without rollback mechanisms, so any interruption or failure can leave the DBMS in an inconsistent state.

To address this flaw, modern DBMSs such as MySQL and PostgreSQL introduce Atomic DDL mechanism, ensuring that schema modifications either fully succeed or leave the DBMS in its original state, thus preventing partial updates that could cause inconsistencies or corruption.

```
CREATE TABLE t1 (c1 int,);
CREATE TABLE t2 (c2 int,  FORIGEN KEY(c2) REFERENCE c1);
INSERT INTO t1(···);
INSERT INTO t2(···);
ALTER TABLE t1 DROP COLUMN c2, ADD COLUMN c3 INT;
-- Execute failed with [ERROR 1553 (HY000)]: Cannot drop
column 'c1': needed in a foreign key constraint
-- Check table t1
-- Expected: t1 only have 1 column c1 due to execution failure
-- Actual: t1 has two columns c1 and c3
```

Figure 1: An Atomic DDL bug in MySQL8.0.

The implementation of Atomic DDL is complex due to the involvement of multiple components(e.g., rollback mechanisms, metadata synchronization, and concurrency control), all of which must work together to ensure atomicity and consistency during schema changes. Consequently, implementation errors in the Atomic DDL are difficult to avoid. We define *Atomic DDL bugs* (**ADBs**) as issues that arise during the execution of Atomic DDL operations, which can lead to partial updates, data corruption, or inconsistencies within the DBMSs. For example, Figure 1 illustrates an Atomic DDL bug in MySQL 8.0, which is caused by the implementation errors in rollback mechanisms. The `ALTER TABLE` statement tries to drop column `c1` and add a new column `c3` on table `t1`. However, it fails due to the foreign key constraint. Therefore, table `t1` would still have one column `c1`. However, the `ALTER TABLE` statement is not correctly rolled back, resulting in the `t1` table having two columns (i.e., `c1` and `c3`), which is inconsistent with the expected state. ADBs have distinct characteristics that make them particularly problematic:

(1)*Widespread Impact:* ADBs have a widespread impact due to their role in maintaining the consistency and integrity of the database schema. When these bugs occur, they can propagate inconsistencies across multiple layers of the DBMS. In a typical scenario, a partially executed `CREATE TABLE` operation caused schema discrepancies that disrupted not only the

*Jie Liang and Yu Jiang are the corresponding authors.

current statement but also subsequent DDL or DML operations. For instance, among the recently reported 119 Atomic DDL bugs in MariaDB, 48% of them affected subsequent operations beyond the initial DDL statement, leading to cascading failures in query execution and schema management.

(2)*High Severity:* ADBs pose significant threats to DBMS stability, often leading to severe consequences such as system crashes, data corruption, and even permanent data loss. For example, among the recent 50 CVEs related to Atomic DDLs in MySQL [30], 29 CVEs scored over 7.0. Among them, 28% ADBs caused system crashes, while 33% ADBs resulted in data corruption or data loss. In 15% of cases, the damage was irreversible, causing prolonged downtime and necessitating database restoration from backups.

(3)*Complex and Hard to Detect:* The complexity of ADBs lies in the intricate interactions between different schema elements during DDL operations. Additionally, many ADBs can only be triggered under specific conditions (e.g., specific sequences of DDL operations), which are not easily replicated during standard testing. This complexity makes them particularly challenging to isolate and resolve. Moreover, these bugs are difficult to detect because they might not cause immediate or obvious failures; instead, they may lead to latent inconsistencies that only become apparent under certain query patterns or after further schema modifications.

Despite the substantial damage ADBs can cause, there is a lack of testing methods for ADBs. Current DBMS testing approaches, such as fuzzing and random query generation, primarily target functional correctness [35–37], performance bugs [15], and memory safety [16, 39, 46]. They mainly focus on generating complex SQL syntax structures or sequences of SQL operations to trigger more behaviors in DBMS components. However, due to the limited understanding of the specific manifestations and trigger conditions of ADBs, existing works struggle to identify them.

To understand and detect ADBs, we conducted a comprehensive study of 207 ADBs across three widely used DBMSs, namely PostgreSQL, MySQL, and MariaDB. Our research focused on identifying the manifestations of ADBs, the root causes of the ADBs, and the conditions that trigger these bugs. Our investigation revealed that approximately 44% of ADB lead to incorrect results, 32% cause post-recovery data inconsistency, and 24% result in system unavailability. We found that about 32%, 22%, 18%, and 22% of ADBs are caused by the implementation errors in rollback mechanisms, metadata synchronization, concurrency control subsystem, and error handling mechanisms, respectively. More importantly, we found that 94% of ADBs are triggered by the metadata conflicts between DDL statements.

Building on these findings, we developed DDLUMOS, a testing tool that detects ADBs with metadata conflict-guided DDL synthesis and graph-based consistency analysis. DDLUMOS was applied to six DBMSs, uncovering 73 ADBs. DBMS vendors responded promptly, fixing 14 bugs. Meanwhile, DDLUMOS can rediscover 94.7% studied bugs in one week. Moreover, we compare DDLUMOS with state-of-the-art DBMS testing tools. The 48-hour results show that DDLUMOS detects 27, 31, 32, and 26 more bugs than SQLancer, SQLsmith, SQUIRREL, and TXCHECK, respectively. In summary, this paper makes following contributions:

1. We conduct a comprehensive analysis of 207 ADB across three widely used DBMSs, revealing that ADBs manifest as incorrect results, post-recovery data inconsistency, and system unavailability.

2. We identify the root cause and trigger conditions that lead to ADBs, particularly arising from the metadata conflicts of DDL operations. Based on the findings, we developed DDLUMOS to detect the ADBs.

3. DDLUMOS uncovered 73 previously unknown ADBs in six popular DBMSs. 20 bugs have been fixed, demonstrating the effectiveness of the tool in improving the reliability and consistency of the DBMS.

2 Preliminaries of Atomic DDL

Definitions. Database Management Systems (DBMSs) are software that allows users to define, create, maintain, and control access to databases [1]. *Structured Query Language (SQL)* is a standard language for interacting with DBMS [41], used to create, modify, and query relational databases. *Data Definition Language (DDL)* is a subset of SQL that is used to define and manage the structure of database objects like tables and indexes. It plays a key role in schema design and maintenance. For example, the *CREATE TABLE* statement in DDL is used to define a table and its columns, specifying data types and constraints Atomic DDL arises from the risk of partial updates during schema modifications, which can cause data corruption and system inconsistencies. Traditional DDL operations may fail midway, leaving the database in an inconsistent state. Atomic DDL addresses this by ensuring that schema changes either fully succeed or fail without residual effects, preserving database stability and reliability.

There are two main implementations for Atomic DDL: *Atomic DDL Statement*, where individual DDL statements are treated as atomic transactions by the DBMS, ensuring either full success or full rollback (e.g., MySQL); and *Atomic DDL Transaction*, which allows grouping a series of DDL statements into a single atomic transaction, enabling multiple DDL statements to commit or rollback together (e.g., PostgreSQL).

Key Features. Atomic DDLs are designed to ensure that schema changes are executed in a reliable, consistent, and robust manner. They have the following features:

Comprehensive Rollback Mechanism. Atomic DDL ensures that any changes made during a schema modification are either fully applied or fully rolled back. This all-or-nothing approach prevents partial updates that could otherwise leave

the database in an inconsistent state. For instance, if a table alteration operation fails midway due to a system error, Atomic DDL automatically rolls back the changes, restoring the DBMS to its original state before the operation began. This comprehensive rollback mechanism is crucial for safeguarding data integrity and consistency, especially in complex production environments.

Concurrency Control. In environments where multiple users may attempt to modify the schema simultaneously, Atomic DDL plays a critical role in managing concurrency. It uses locking mechanisms to ensure that only one operation can alter a specific part of the schema at any given time, preventing conflicts and potential corruption. This control is vital for avoiding race conditions and ensuring that all schema changes are applied in a controlled and predictable manner.

Failure Handling and Recovery. One of the key strengths of Atomic DDL is its robust failure handling and recovery mechanism. In case of failure, it ensures no partial changes remain by using detailed logging and transactional controls to track schema modifications. This enables precise rollbacks or retries, protecting the database from corruption while streamlining the recovery process, reducing downtime, and ensuring operational continuity.

3 Methodology

To better understand the characteristics of Atomic DDL Bugs (ADBs), we investigate ADBs across three widely-used DBMSs: PostgreSQL, MySQL, and MariaDB from these DBMSs' issue tracker systems and commit histories [2, 3, 6, 7, 11]. The number of ADB issues we collected is summarized in Table 1.

Table 1: The numbers of collected ADBs in selected DBMSs.

DBMSs	PostgreSQL	MySQL	MariaDB	Total
Studied Issues	351	301	2103	2755
Unique Bugs	38	50	119	207

These DBMSs, developed over long periods (e.g., 27 years for MySQL), often contain a large number of issues (e.g., over 109k issues in MySQL). Manually inspecting all these issues to identify ADBs is time-consuming and challenging. Therefore, we apply filtering rules to identify relevant issues in the recent 10 years. Since DBMS developers typically do not label issues as related to ADBs, we use keywords like "atomic", "DDL", "CREATE", "Atomic DDL", and their variations to retrieve potentially relevant issues. We then manually review the bug descriptions and developer comments, excluding those that do not involve Atomic DDL mechanisms. As a result, we find 2755 related issues. Then, we filter these issues into two steps. First, we exclude bugs labeled as "duplicate" to refine our dataset. Second, we manually reproduce each bug by extracting the provided SQL statements and transaction sequences, ensuring that only distinct issues are included in our study. Through this process, we identified 38, 50, and 119 ADBs in PostgreSQL, MySQL, and MariaDB, respectively.

Threats to Validity. Similar to other studies, our research has several limitations that should be considered.

Invisibility of high-severity vulnerabilities. High-severity vulnerabilities, such as those leading to data breaches or unauthorized access, are often not disclosed publicly by security teams. For example, severe security issues in MySQL and PostgreSQL are typically reported directly to their security teams and are not made available in public bug trackers. Consequently, our study may miss some of the most critical vulnerabilities, potentially limiting the completeness of our findings. However, the focus on transaction-related bugs still provides valuable insights into detecting atomicity issues.

Representativeness of selected DBMSs. Our study focused on three popular relational DBMSs: PostgreSQL, MySQL, and MariaDB. While these systems represent a significant portion of the market, our findings may not fully apply to other databases, such as NoSQL or graph databases, with different transaction models and atomicity guarantees. Nevertheless, the insights gained could still provide useful guidance for understanding atomicity in various DBMS.

4 General Findings of ADBs

In this Section, we analyze 207 collected unique ADBs to identify their common characteristics, focusing on the manifestations, root cause, and trigger conditions of ADBs.

4.1 Manifestations of ADBs

To understand the potential damage of ADBs, we examined the manifestations of the collected bugs by manually reviewing the bug descriptions and reproducing them. Regarding the manifestations of ADBs, we have the following findings:

Finding 1. *Among the studied bugs, about 44% (91/207) of them manifest as incorrect results, about 32% (66/207) of them manifest as post-recovery data inconsistencies, and about 24% (50/207) of them manifest as system unavailability.*

Incorrect Result. Our investigation indicates that approximately 44% of the ADBs result in incorrect outcomes, undermining the accuracy and reliability of data returned to users. These incorrect results contain various forms, such as schema errors, metadata mismatches, trigger errors, function errors, and constraint violations. Such manifestations arise when a DDL operation (e.g., `ALTER TABLE` or `CREATE INDEX`) aborts but fails to roll back all of its catalog mutations, leaving the database in a partially updated state. As a result, query results may be incorrect due to a misalignment between the database schema and the intended structure. For instance, the `ALTER TABLE` statement in Figure 1 fails to execute but still modifies the metadata of table `t1`, resulting in the incorrect result.

Post-Recovery Data Inconsistency. Post-recovery data inconsistency is a prominent issue in ADB, potentially leading to long-term corruption or loss of critical information, occurring in 32% (66/207) studied cases. This problem typically arises during system recovery when a DDL operation is interrupted by a fault (e.g., power outage), and the DBMS attempts to restore the previous state upon restart. If the atomicity of the DDL operation is not properly maintained, the recovery process may fail to fully restore the schema, leading to the loss of recently added or modified schema objects. Figure 2 illustrates an example of post-recovery data inconsistency in MariaDB. In this case, table `t1` is modified through several DDLs, such as adding and dropping columns, when the server process is unexpectedly terminated. Upon restart, MariaDB shows that table `t1` does not exist, indicating data loss.

```
(1) Create initial add and add constraints
CREATE TABLE t1 (col1 INT, col2 INT, col3 INT,
col4 TEXT) ENGINE = InnoDB ;
ALTER TABLE t1 ADD PRIMARY KEY(col4(10),col2);
INSERT INTO t1 (col2,col4) VALUES(2, 'data');
(2) Runs random alter statements in the same session
ALTER TABLE t1 ADD COLUMN extra INT;
ALTER TABLE t1 DROP COLUMN col3 ;
ALTER TABLE t1 CHANGE COLUMN extra col3 INT ;
(3) Kill the server process at some point of time
(4) Restart the server and show tables;
SHOW KEYS FROM `test`.`t1` harvests;
⚠ ERROR[1932]: Table 'test.t1' doesn't exist
```

Figure 2: A post-recovery data inconsistency in MariaDB.

System Unavailability. The complete system unavailability is a severe manifestation of ADBs, causing significant downtime and affecting the accessibility of the DBMS, accounting for 24% (50/207) studied cases. This includes issues such as system crashes, assertion failures, memory errors, and system hangs, where the entire system becomes unresponsive or fails to recover, causing prolonged downtime and potential data loss. This typically occurs when the DBMS engine encounters an unhandled exception or fatal error during the execution of a DDL operation. The instability introduced by these bugs makes them particularly dangerous, as they can compromise the availability and reliability of DBMSs.

4.2 Root Cause of ADBs

We manually checked each bug report and further identified several underlying causes that directly contribute to the manifestations described earlier. We discovered that all the ADBs are caused by the implementation errors of Atomic DDL, which are inherently complex due to the intricacies involved in ensuring atomicity, consistency, and rollback mechanisms during schema modifications. We categorize the root causes into four categories, and we have the following findings:

Finding 2. *Among the studied bugs, four main causes of ADBs were identified, with the following distribution: incomplete rollback mechanisms accounted for 32%, improper synchronization for 22%, inadequately implemented concurrency control for 18%, and incorrect error handling for 22%.*

The four categories collectively account for 94% of the studied ADBs. Figure 3 illustrates how frequently each root cause appears in ADBs manifesting as incorrect results, data loss, or system crashes. Inappropriate metadata synchronization is the most common trigger for incorrect results, while inadequate rollback mechanisms frequently lead to data loss, and faulty error handling is often responsible for system crashes. Besides them, other ADBs (6%) are caused by implementation errors in various auxiliary mechanisms, such as improper handling of system-level configurations, and rare edge cases in DBMS extensions or plugins.

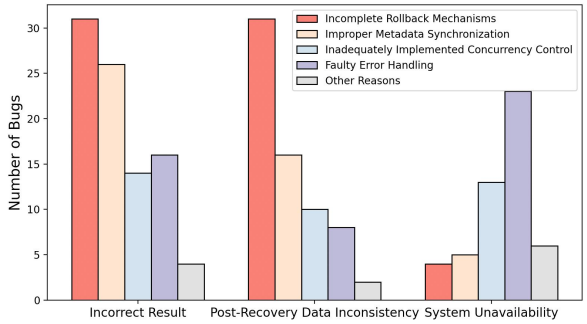

Figure 3: Statistic of bugs and root causes.

Incomplete Rollback Mechanisms. The implementation error in the rollback mechanisms is a prevalent root cause for ADBs, responsible for 65 bugs, including 31 incorrect results and 31 post-recovery data inconsistencies. These bugs arise when a failed Atomic DDL operation leaves the schema in an inconsistent state due to incomplete rollbacks. For example, in MDEV-25506 of MariaDB, the server is forcibly crashed while executing `CREATE TABLE IF NOT EXISTS tt11 AS SELECT...` statement. After crash recovery, both `DROP TABLE tt11` statement and a new `CREATE TABLE tt11` statement fail to execute successfully with error messages. The drop statement returns “Unknown table tt11” while the create statement complains that the "tablespace tt11 already exists". The main reason is that InnoDB discovers both tt11.frm and tt11.ibd on disk, yet the internal data dictionary believes the table is already being dropped and raises an error that test.tt11 does not exist [24]. The root cause of the bug is a flaw in the rollback mechanism of Atomic DDL recovery: the DDL log rolled back the dictionary-level create operation but failed to purge the tablespace, leaving the recovery state inconsistent.

Improper Metadata Synchronization. The implementation errors in synchronization between schema metadata and physical data structures cause 47 ADBs, including 26

incorrect result cases. This issue arises when metadata is updated to reflect a schema change, but the corresponding data structures remain unchanged due to an interruption in Atomic DDL operations. For example, in bug#18570 of PostgreSQL, when an `DROP EVENT TRIGGER` statement appears to succeed in detecting the trigger, while the event trigger remains active in memory. After the command, catalog queries such as `information_schema.triggers` show no trigger remains, yet every subsequent DDL statement still invokes the trigger's function; meanwhile, attempting to drop that function fails because the system claims the (supposedly deleted) trigger depends on it [33]. The mismatch between system catalogs and the in-memory trigger cache creates a "ghost trigger" that blocks normal maintenance until the function is forcibly dropped, breaking Atomic DDL semantics.

Inadequately Implemented Concurrency Control. The implementation errors in the concurrency control subsystem represent another major root cause, accounting for 37 ADBs. These issues typically arise when multiple DDL operations or concurrent transactions contend for the same resources, such as locks on tables or indexes. For example, in BUG#116502 of MySQL, during an online build of a unique index that includes a `NULL-able` column, MySQL 's Atomic DDL mishandles a concurrent sequence of `DELETE → ROLLBACK` combined with an `INSERT`. The engine incorrectly treats rows containing NULL as duplicates, so the rollback cannot re-insert the original row, and the entire DDL aborts—violating its all-or-nothing guarantee [28].

Faulty Error Handling. Faulty error handling during DDL operations is another root cause for ADBs, accounting for 18% of incorrect result cases and 46% of system unavailability. This issue occurs when the DBMS fails to properly handle errors or exceptions that arise during DDL operations. For instance, in MDEV-13205 of MariaDB, an unexpected error happens during the executing the `ALTER TABLE` statements to add unique key and foreign key [25]. The `ALTER TABLE t2 ADD UNIQUE(c)` is aborted due to a duplicate key error, but the DBMS fails to remove the partially created index stub from the data dictionary. Because that orphaned metadata is left intact, executing `ALTER TABLE t3 ADD FOREIGN KEY (c) REFERENCES t2(c)` statement will consult the corrupted data dictionary, trigger the assertion !dict_index_is_online_ddl(index), and finally crash the server.

4.3 Trigger Conditions of ADBs

Following the identification of root causes, we analyze the specific conditions that trigger ADBs.

Finding 3. *Most ADBs (approximately 93%) are triggered in scenarios involving data conflicts between DDL statements, where multiple DDL statements operate or interact with the same metadata elements in the test case.*

We define **metadata conflict points** as the specific locations in test cases where multiple DDL statements operate or interact with the same metadata elements, such as a table, column, index, or constraint. In other words, the conflict points reflect the data dependency between different statements, which can help trigger more code behaviors of Atomic DDL for detecting ADBs. Figure 4 illustrates an example of metadata conflict points. The two `CREATE TABLE` statements establishes two tables(`t1` and `t2`) with three columns and one column, respectively. The subsequent `ALTER TABLE` statement adds two indexes on table `t1`, which will change the three metadata elements `t1`, `t1.c1`, and `t1.c2`. Here, we identify `t1`, `t1.c1`, and `t1.c2` as the 3 metadata conflict points in the test cases. The second `CREATE TABLE` statement does not make any metadata conflict points due to it does not change any existing metadata elements.

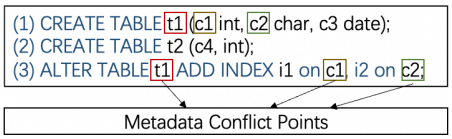

Figure 4: An example of metadata conflict points.

In our study, 193 (93% of 207) studied bugs contain metadata conflict points, and 174 (84% of 207) cases contain over 4 metadata conflict points. Among the 193 studied bugs containing metadata conflict points, 94% (181/193) were directly triggered by metadata conflict points with the corresponding statements. The remaining 6% (12/193) were not directly triggered by conflict points, but the bug-triggering statements have dependency relationships with those conflict points. Our investigation results demonstrate that metadata conflict points are essential to trigger ADBs.

Finding 4. *Incorrect result, post-recovery data inconsistency, and system unavailability have different trigger scenarios and test oracle.*

In our study, incorrect results and system unavailability can occur during DDL execution. Incorrect results are identified by comparing the execution output and metadata. For example, the `ALTER TABLE` statement in Figure 1 should fail without modifying any metadata, which was confirmed by detecting unexpected changes in metadata. System unavailability is detected by checking the server's response after executing the test cases. If the server disconnects or becomes unresponsive, it is confirmed as a bug. In contrast to incorrect results and system unavailability, post-recovery data inconsistency occurs when the server is restarted mid-Atomic DDL execution. If the recovery metadata differs from the expected state after rollback, developers confirm it as a bug.

4.4 Limitations of Existing Methods

According to the conditions outlined in Section 4.3, detecting ADBs requires generating DDL statements that involve more

metadata conflict points. Moreover, these test cases must be examined in various scenarios to detect the three manifestations: incorrect results, system crashes, and post-recovery data inconsistency. However, existing DBMS testing tools are limited in both aspects.

First, most existing tools focus on generating DQL (Data Query Language) statements, with minimal attention paid to DDLs. Even when DDLs are included, they are generated with few metadata conflict points. For example, SQLsmith [39] and EET [14] focus on generating `SELECT` queries, and the DDLs they produce are typically simple, making it difficult to simulate the complex interactions between different DDL operations. Similarly, SQLancer [37] generates equivalent queries to detect logic bugs by transforming SQL expressions, which will overlook potential conflicts between DDLs.

Moreover, existing testing tools struggle to detect ADB manifestations, particularly those resulting in inconsistencies. For instance, when a DDL operation is interrupted mid-execution, the DBMS may enter an inconsistent state with only partial changes applied—a scenario that current tools fail to detect. Furthermore, these tools also struggle to identify data inconsistency after recovery, as this requires precise tracking of Atomic DDL execution and metadata modifications, capabilities that are often lacking in existing approaches.

Following the findings, we design DDLUMOS which targets ADBs with metadata conflict-guided DDL synthesis and graph-based consistency analysis. The main idea is to analyze DDL dependencies to generate more metadata conflict points, while also designing detection methods for three manifestations. Specifically, DDLUMOS generates more metadata conflict points by tracking schema elements and guiding test case generation through a metadata table. On the other hand, it constructs a metadata graph to analyze schema inconsistencies and identify ADBs based on predefined detection scenarios.

5 Design of DDLUMOS

Figure 5 illustrates the workflow of DDLUMOS, which consists of two key modules: an *Test Case Generator* for synthesizing high-quality DDL sequences and a *Metadata Consistency Analyzer* for detecting ADBs. The process follows four main steps: In Step ①, DDLUMOS initializes a metadata table to record schema elements used during test case generation, as well as the metadata conflict points associated with each DDL operation. In Step ②, DDLUMOS alternates between generating DDL statements and other SQL statements. After each DDL operation, DDLUMOS analyzes the resulting metadata conflict points and updates the metadata table accordingly, guiding subsequent DDL generation to maximize conflict scenarios. In Step ③, DDLUMOS constructs a metadata graph for the generated test cases and sends them to the target DBMS. The metadata graph captures the relationships between schema elements before and after DDLs, providing a structural foundation for analyzing schema consistency and correctness. In Step ④, DDLUMOS uses the metadata graph to detect ADBs by comparing the execution results with predefined detection scenarios for three bug manifestations.

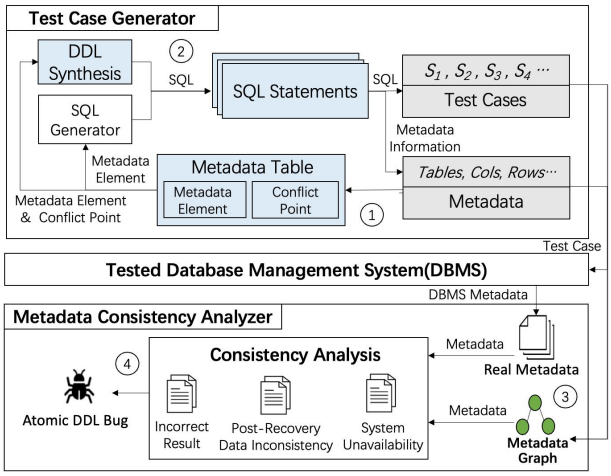

Figure 5: The workflow of DDLUMOS. It includes two main components: (1) Test Case Generator for generating test cases with metadata conflict guided DDL synthesis. (2) Metadata Consistency Analyzer for detecting atomic DDL bugs with graph-based consistency analysis.

5.1 Metadata Conflict-Guided DDL Synthesis

Metadata Conflict-Guided DDL Synthesis generates test cases that maximize metadata conflict points to trigger ADBs effectively. This approach consists of two components: Conflict Point Tracking and Test Case Synthesis, which work together to trigger deep behaviors of Atomic DDL.

Conflict Point Tracking. Based on the findings in Section 4.3, incorporating *metadata conflict points* into DDL test cases significantly increases the likelihood of exposing ADBs. To achieve this, DDLUMOS continuously collects and updates *Metadata Information* during test case generation, using these details to guide the synthesis of subsequent DDL operations. Specifically, DDLUMOS maintains a metadata table that records critical information about schema elements relevant to conflict scenarios, including the DDL identifier (e.g., operation type), table name, column, index, and constraint data. After each DDL statement executes, DDLUMOS updates the corresponding entries in the metadata table based on the statement type (create, alter, or drop) and the targeted objects (tables, columns, indexes, or constraints).

For example, as shown in Figure 6, when processing the 5th `ALTER TABLE` statement, DDLUMOS identifies the affected table (i.e., t2, t1) in the metadata table and increments its "conflict point" field by the value introduced by that operation (e.g., t1(1)). Likewise, if new columns or indexes are added or removed(e.g., 6th statement), DDLUMOS revises the corresponding fields to reflect the latest state and constraints.

Synthesized Test Case

(1). CREATE TABLE t1 (c0 INT, c1 FLOAT);
(2). INSERT INTO t1 () VALUES (1) ,(2);
(3). CREATE TABLE t2 (c3 CHAR, c4 INT);
(4). CREATE INDEX i1 on t1(c0);
(5). ALTER TABLE t2 ADD FOREIGN KEY(c4) REFRENCE t1(c0);
(6). ALTER TABLE t2 ADD COLUMN c5 INT, ADD COLUMN c6 DATE;

⇩ Metadata Information Collection

	Type	Metadata	Conflict Points
(1)	CREATE TABLE	t1 | t1.c0 | t1.c1	NULL
(2)	NOT-DDL	t1.c0 | t1.c1	NULL
(3)	CREATE TABLE	t2 | t2.c3 | t2.c4	NULL
(4)	CREATE INDEX	t1.i1	t1(1), t1.c0(1)
(5)	ALTER TABLE	t2.c4 | t1.c0	t1(1),t2(1),t2.c4(1),t1.c0(1)
(6)	ALTER TABLE	t2.c5 | t2.c6	t2(2)

Figure 6: An example of metadata information collection.

This metadata-driven update process accurately captures how the schema evolves over time and provides precise conflict guidance for generating subsequent test cases.

Test Case Synthesis. By tracking conflict points in the metadata table, DDLUMOS synthesizes test cases that strategically exploit these conflict points to maximize the likelihood of uncovering atomic DDL bugs. During test-case generation, DDLUMOS interweaves DDL statements with DML (e.g., `INSERT`, `UPDATE`) and DQL (e.g., `SELECT`) statements, creating comprehensive and high-coverage input sequences. DDLUMOS generates statements of each test case iteratively: First, it determines the statement type. Second, it builds the skeleton of the statement based on its type and then populates objects into the skeleton with the metadata table.

Algorithm 1: Test Case Synthesis with Metadata Table

Input : L: The length of test cases
MT: The metadata table
Output : T: The test cases

```
1  T = initalTestCase ();
2  while L > 0 do
3      M_e, C_p = getMetadataAndConlictPoint(MT);
4      S_type = pickStatementType(T);
5      if S_type = DDL then
6          M_u = sortMetadataWithConflictPoint(M_e);
7          S = synthesizeDDL(M_u, C_p);
8      end
9      else
10         S = synthesizeDMLorDQL(M_e);
11     end
12     MT = updateMetadataTable(MT, S);
13     T = addToTestCase(T, S);
14     L = L − 1;
15 end
```

Algorithm 1 details the process of test case synthesis with the metadata table. DDLUMOS first initializes an empty test case(T) and then iterates to synthesize the statement until the desired length of the test case (L) is reached (Line 1-2). The length of the test case(L) is critical for the performance of DDLUMOS. We will give the specific length of the test case(L) in Section 6. In each iteration, DDLUMOS first retrieves the current metadata state (M_e) and conflict point information (C_p) from the metadata table (MT) (Line 3). Next, it determines the type of the next SQL statement to be synthesized (S_{type}) (Line 4). Specifically, DDLUMOS uses a predefined ratio (80% for DDL, 20% for other types in our implementation) to determine whether to generate DDL statements. If true, DDLUMOS then randomly selects the least frequently used DDL statement types (e.g., ALTER TABLE, CREATE INDEX) to synthesize, ensuring diversity in the generated statements. Otherwise, DDLUMOS similarly randomly chooses from the available types of non-DDL statements, maintaining variability in the types of statements generated. If the statement type is DDL, DDLUMOS sorts the existing metadata by conflict point frequency and synthesizes the DDL with stored metadata(M_u) and corresponding conflict points(Lines 5-8). Otherwise, if the selected statement type is DML or DQL, DDLUMOS uses the existing metadata(M_e) to synthesize to ensure semantic correctness (Lines 9-11). The implementation details of the DDL synthesis process can be found in Section 6. Once the statement (S) is generated, DDLUMOS updates the metadata table (MT) to reflect changes introduced by the new statement and adds it to the test case (T) (Lines 12-13).

5.2 Graph-Based Consistency Analysis

After generating test cases using Metadata Conflict Guided DDL Synthesis, DDLUMOS distributes the test cases across multiple client threads, while controlling concurrency based on the sequence of these statements (Details can be found in Section 6). Besides, DDLUMOS employs *Graph-Based Consistency Analysis* to verify the correctness of test case execution results. This analysis involves two critical steps. First, for a test case, DDLUMOS constructs a metadata graph that represents the schema elements and their relationships before and after executing each DDL statement. Then, based on the metadata graph and DDL execution scenario, DDLUMOS analyzes the metadata state resulting from the DDL operations. It compares the expected metadata derived from the graph with the actual metadata in the database after execution. Any discrepancies between the expected and actual metadata indicate a potential atomic DDL bug.

Metadata Graph Construction. For each test case, DDLUMOS constructs a metadata graph that represents the metadata state of the DBMS both before and after executing each SQL statement in the test cases. Unlike a full dataset dump, this metadata graph focuses on essential metadata information, which can be influenced by DDL operations, including tables, columns, constraints, triggers, row counts, indexes, views, as well as their relationships. Each element of the metadata information is modeled as a node in the graph, while edges represent dependencies or hierarchical relationships.

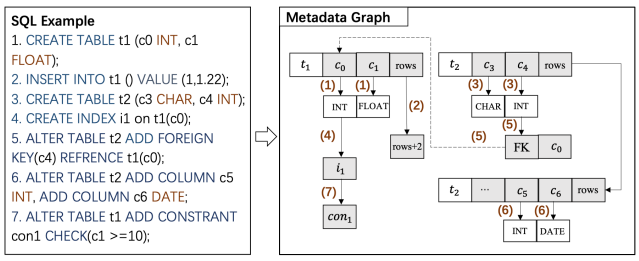

Figure 7: An example of metadata graph construction.

For instance, Figure 7 demonstrates the construction process of the metadata data graph with a test case in MySQL. The left side of the figure shows the SQL statements executed sequentially in the order(e.g., `(1)->(2)->(3)->...`). The right side illustrates the effects of these statements on the graph structure (such as the data structure, dependencies, etc.). The numbers(e.g., (1), (2)) on the arrows indicate which SQL statement generated each corresponding effect.

For statement (1), DDLUMOS first creates a node for table `t1` along with child nodes for each column (`c0` and `c1`), connecting the parent table node to its columns. In addition, DDLUMOS initializes a `rows` node that records the row count of `t1`. When statement (2) inserts records into `t1`, DDLUMOS updates the `rows` node accordingly. Similarly, statement (3) adds another table node (`t2`) and its corresponding column nodes (`c3` and `c4`). Attributes such as data types, constraint types, and dependency properties are also stored within nodes and edges, ensuring comprehensive tracking of schema changes. For example, when statement (4) creates index `i1` on `c0` of `t1`, DDLUMOS adds an `i1` node to the metadata graph and draws a direct edge from the existing `c0` node to this new `i1` node. When statements (4), (5), and (7) further alter the metadata of `t1` and `t2`, DDLUMOS adds or updates the corresponding nodes and edges to capture the new information and relationships and reflect these changes in the metadata graph. Throughout the entire test execution process, the metadata graph is dynamically updated to provide an accurate and consistent representation of the schema's state at each stage.

Metadata Consistency Analysis. After constructing the metadata graph, DDLUMOS evaluates the correctness of DDL operations by comparing it with the actual metadata state after each operation. Specifically, the metadata information(e.g., schema information, tables, columns, row counts, triggers, and indexes) stored in the metadata graph should align precisely with the metadata in the real databases. For each DDL statement, DDLUMOS identifies affected metadata objects and checks for inconsistencies between the metadata graph and their actual counterparts in the DBMS. Discrepancies are flagged as potential bugs.

For example, the sixth `ALTER TABLE` statement in Figure 7,modifies table `t2` along with columns `c5` and `c6`. DDLUMOS first determines that this operation could affect the metadata for `t2, c5`, and `c6`, and updates the metadata graph accordingly. More concretely, upon executing the sixth statement, the metadata graph adds two child nodes `c5` and `c6` under the node `t2`, including their data types. Once the database finishes processing this statement, DDLUMOS retrieves the relevant metadata from the graph (namely the node information for `t2, c5`, and `c6`), and compares it with the actual metadata stored in the DBMS. Any mismatch discovered in this process is reported as a potential bug.

By comparing the metadata graph with the actual metadata stored in the database, DDLUMOS can evaluate the correctness of DDL operations. However, as highlighted in Section 4.1, ADBs manifest in three distinct forms: incorrect results, system unavailability, and post-recovery data inconsistencies, each arising from different triggering scenarios. To comprehensively detect ADBs, DDLUMOS extends its graph-based consistency analysis to incorporate the detection scenarios described in 4.3.

Algorithm 2: Detect ADBs with Consistency Analysis

Input : T: The test case to be executed
K: The kill signal to simulate the crash
G: Initial metadata graph
Output : The ADBs detected by DDLUMOS

```
1  S ← splitToStatements(T)
2  foreach s ∈ S do
3      G ← constructGraph(G, s)
4      M ← executeToGetMetadata(s)
5      if isSimulateCrash(K) = false then
6          if connectionCheck () = false then
7              return System Unavailability
8          end
9          if !ConsistencyAnalysis(M, G) then
10             return Incorrect Result
11         end
12     end
       // asynchronously trigger crash
13     spawn(AsyncCrashRecovery(K, G))
14 end
15 procedure AsyncCrashRecovery(K, G):
16     sendKillSignal(K)
17     M_n ← RebootandGetMetadata()
18     if !ConsistencyAnalysis(M_n, G) then
19         return Post-Recovery Data Inconsistency
20     end
```

Algorithm 2 details the process of identifying ADBs with these three manifestations. Given a test case generated with metadata conflict-guided DDL synthesis, DDLUMOS first splits it into individual SQL statements (Line 1). For every statement, DDLUMOS constructs and updates the metadata graph to represent the expected metadata state after the execution. DDLUMOS will also send the statement for execution and get real metadata information from the DBMS (Lines 3-4). Following the SQL execution, DDLUMOS systematically evaluates the three types of Atomic DDL bugs: system un-

availability, incorrect results, and post-recovery data inconsistencies. To detect system unavailability, DDLUMOS performs a connection check to assess the server's responsiveness. If the system becomes unresponsive during execution, DDLUMOS identifies this as a system unavailability issue (Lines 6-8). For detecting incorrect results, DDLUMOS compares the actual metadata state (M) retrieved from the database with the expected metadata graph (G) following the consistency analysis. Any discrepancies between the actual metadata and the expected graph indicate an incorrect result (Lines 9-11). To identify post-recovery data inconsistencies, DDLUMOS asynchronously simulates a server crash by sending a kill signal to abruptly terminate the database process. After rebooting the server, DDLUMOS retrieves the post-recovery metadata and compares it with the metadata graph. Any mismatches between the recovered metadata and the expected state are flagged as post-recovery data inconsistencies, highlighting failures in the database's recovery mechanism (Lines 13-20). Note that the process of killing the server to simulate the crash is independent and asynchronous from the process of executing the SQL statements and identifying the system unavailability and incorrect results.

6 Implementation

Based on our approach, we realized DDLUMOS. The overall codebase consists of 10k lines of C++ code, 4k lines of Bison and Flex code, and 1k lines of Python code. Then, we explain some other implementation details, which we consider significant for the outcome.

Effort to Adaption. Adapting DDLUMOS to a new DBMS requires minimal effort and involves two primary steps. First, we need to write the metadata information query statements retrieve schema elements such as tables, columns, indexes, and constraints. This step typically requires no more than 10 lines of SQL, tailored to the specific metadata structures of the DBMS under test. Second, we find the SQL grammar file (e.g., Yacc files) of the target DBMS for grammar adaption. DDLUMOS can leverage these grammar files to automatically adapt to the SQL operators of the target DBMS with a grammar adaptor(implemented with python and bison code).

Length of Test Case Setting. The length of test cases generated by DDLUMOS is critical to the testing performance. Overly long test cases will increase the storage and computational burden of maintaining and analyzing the metadata graph, thereby reducing testing efficiency. Conversely, overly short test cases may fail to adequately trigger the deeper logic associated with Atomic DDL operations. We analyze the test cases of 207 studied bugs and we observed that 98% of them contained no more than 15 SQL statements. Consequently, we set the length of test cases to 15 SQL statements in our testing framework to balance efficiency and effectiveness.

Details of DDL Synthesis. Synthesizing DDLs with the picked statement type and metadata table contains two steps. (1)DDLUMOS first constructs a DDL skeleton based on the chosen statement type (e.g., `ALTER TABLE [`*table_name*`] ADD COLUMN [`*column*1 *datatype*`], ADD COLUMN [`*column*2 *datatype*`]...)`. The clause of this skeleton is randomly generated(e.g., `ADD COLUMN [`*column*1 *datatype*`]`. To increase potential conflict points, each skeleton contains at least two objects (named metadata elements such as *table_name*). (2)DDLUMOS populates the skeleton objects (e.g., *table_name*) with entries (e.g., `t1, t1.c1`) from the metadata table, which tracks existing metadata elements along with their corresponding conflict point counts. During the population, entries with fewer conflict points are selected more frequently, and these chosen entries must conform to the relevant data type semantics. If DDLUMOS cannot find suitable entries in the metadata table, it generates new entries to fill the skeleton objects.

Distributing Test Cases with Multiple Clients. As the study shows, about 18% of ADBs arise from those implementation errors, and they still manifest as incorrect results, post-recovery data inconsistency, and system unavailability. To cover the codes of the concurrency control mechanism, DDLUMOS constructs concurrent scenarios by leveraging multiple clients to distribute SQL statements, while controlling concurrency based on the sequencing of these statements. Specifically, DDLUMOS tags every SQL statement with a sequence identifier, then launches N client worker threads (typically 2–5) and assigns the statements to them in that predefined order. Note that each client issues its own statements sequentially so that DDLUMOS can reconstruct an accurate metadata graph of the execution. To trigger more behaviors of DBMS's concurrency control mechanism, DDLUMOS occasionally sends a subsequent statement before the completed execution of the previous one, thereby intentionally triggering concurrency control behaviors to detect ADBs in them.

7 Evaluation

To evaluate the effectiveness of DDLUMOS, we conduct experiments to address the following research questions:

- **RQ1:** Is DDLUMOS effective in finding ADBs in real-world DBMSs?
- **RQ2:** How does DDLUMOS's performance compared with state-of-the-art methods?
- **RQ3:** How many bugs collected in the study can be rediscovered by DDLUMOS?

7.1 Evalution Setup

Tested DBMSs. To evaluate the generality and efficiency of DDLUMOS, we select six popular open-source and well-tested DBMSs, namely MySQL [29,43], MariaDB [4,26], Percona [5], PolarDB [32], GreatSQL [10], and PostgreSQL [27, 34]. These DBMSs are also widely used in industry.

Table 2: DDLUMOS discovered 73 bugs in six DBMSs within two weeks. (MySQL: 14, MariaDB: 15, Percona: 14, PolarDB: 11, GreatSQL: 15, PostgreSQL: 4). [**IRM**: Incomplete Rollback Mechanisms, **IMSYN**: Improper Metadata Synchronization, **IICC**: Inadequately Implemented Concurrency Control, **FEH**: Faulty Error Handling, **Others**: Other Root Causes for Bugs.

DBMS	Bug Type and Number	Bug Status	Root Cause
MySQL	Incorrect Result(7)	Confirmed(7), Fixed (1)	IRM(2), IMSYN(1), IICC(1), FEH(1), Others(2)
MySQL	System Unavailability(4)	Confirmed(4), Fixed(1)	FEH(3), IICC(1)
MySQL	Post-Recovery Data Inconsistency(3)	Confirmed(3)	IRM(1), IMSYN(1), IICC(1)
MariaDB	Incorrect Result(8)	Confirmed(8), Fixed(1)	IRM(3), IMSYN(2), FEH(2), Others(1)
MariaDB	System Unavailability(3)	Confirmed(3), Fixed(1)	FEH(1), IICC(1), IRM(1),
MariaDB	Post-Recovery Data Inconsistency(4)	Confirmed(4)	IMSYN(2), IRM(1), FEH(1)
Percona	Incorrect Result(4)	Confirmed(4), Fixed(1)	IRM(1), IMSYN(2), FTH(1)
Percona	System Unavailability(4)	Confirmed(4)	Others(2), FEH(1), IICC(1)
Percona	Post-Recovery Data Inconsistency(6)	Confirmed(6), Fixed(2)	IMSYN(3), IRM(2), FEH(1)
PolarDB	Incorrect Result(4)	Confirmed(4)	IICC(1), FEH(1), IRM(2),
PolarDB	System Unavailability(4)	Confirmed(4), Fixed(1)	FEH(3), Others(1)
PolarDB	Post-Recovery Data Inconsistency(3)	Confirmed(3), Fixed(1)	IRM(3)
GreatSQL	Incorrect Result(7)	Confirmed(7)	IMSYN(3), IRM(3), IICC(1)
GreatSQL	System Unavailability(3)	Confirmed(3), Fixed(1)	FEH(1), IICC(2)
GreatSQL	Post-Recovery Data Inconsistency(5)	Confirmed(5), Fixed(1)	IRM(1), IICC(2), FEH(1), Others(1)
PostgreSQL	Incorrect Result(1)	Confirmed(1)	IMSYN(1)
PostgreSQL	System Unavailability(2)	Confirmed(2), Fixed(2)	FEH(2)
PostgreSQL	Post-Recovery Data Inconsistency(1)	Confirmed(1), Fixed(1)	IRM(1)
Total	**73 ADBs**	**73 confirmed, 14 fixed**	

Basic Setup. The experiments were conducted on a machine running 64-bit Ubuntu 20.04 with an AMD EPYC 7742 Processor @ 2.25 GHz, 128 cores, and 504 GiB of main memory. All DBMSs were tested using docker containers that were downloaded directly from their websites, each with 5 CPU cores and 50 GiB of RAM.

Compared Techniques. We compare DDLUMOS with four state-of-the-art DBMS testing tools, including SQLancer [37], SQLsmith [39], SQUIRREL [46], and TXCHECK [13], which are widely used in industry and detect amounts of bugs SQLancer and TXCHECK detect the logic and transactional bugs, respectively, while SQLsmith and SQUIRREL focus on detecting crashes in DBMSs.

7.2 ADBs in Real-World DBMS

We apply DDLUMOS to six DBMS under test for atomic DDL bug detection evaluation. DDLUMOS successfully detected 73 ADBs in two weeks. Table 2 shows DDLUMOS discovered 14, 15, 14, 11, 15, and 4 ADBs in MySQL, MariaDB, Percona, PolarDB, GreatSQL, and PostgreSQL, respectively. 14 ADBs of them have been fixed due to the high severity. As described in Section 4.1, the 73 ADBs contain three types, 31, 20, and 22 bugs corresponding to incorrect results, system unavailability, and post-recovery data inconsistency, respectively.

Root Cause and Severity. We analyze the root causes of discovered bugs based on the response of the vendor. The right part of Table 2 shows the statistics of ADBs' root causes in six DBMSs. Specifically, DDLUMOS detected 21, 15, 11, and 19 ADBs caused by incomplete rollback mechanisms, improper metadata synchronization, inadequately implemented concurrency control, and faulty error handling, respectively. Besides, 7 bugs are caused by other root causes (e.g., untracked schema element orphaning, errors in parsing DDLs).

Feedback from DBMS Developers. We have actively reported all 73 bugs to the corresponding DBMS vendors and received their confirmation feedback. At the time of the paper writing, 73 ADBs have already been confirmed, and 14 ADBs have been fixed. Besides, 9 bugs have been assigned with CVE IDs due to their severity. More importantly, the detected bugs have garnered the attention of the DBMS developers. For example, when we were reporting bugs to PolarDB, the developers responded for them immediately.

Case Studies. We give the following case studies to demonstrate the effectiveness of DDLUMOS.

Case Study 1: No trigger exists after CREATE OR REPLACE TRiGGER in MySQL. Figure 8 illustrates a case of incorrect result in MySQL. This bug occurs when attempting to create a trigger on one table (`t1`) and then replace it with another table (`t2`) using the `CREATE OR REPLACE TRIGGER` statement. Instead of successfully replacing the original trigger on `t1` with a new trigger on table `t2`, an error is thrown and both triggers disappear finally in DBMS. The root cause is the implementation errors in metadata synchronization, where the new trigger can not be saved correctly due to the metadata inconsistency and return error messages.

```
CREATE TABLE t1 (c1 int );
CREATE TABLE t2 (c1 int );
CREATE OR RPLACE trigger tr0 AFTER INSERT on t1 for
each row set @X =1;
CREATE OR RPLACE trigger tr0 AFTER INSERT on t2 for
each row set @X =1;
-- ERROR 1360 ( HY000 ): Trigger tr0 does not exist
```

Figure 8: A case of incorrect result in MySQL.

Case Study 2: Tablespace id Confilt and Data Loss upon Crash Recovery. Figure 9 illustrates a case of post-recovery

data inconsistency in GreatSQL. This bug occurs when attempting to execute an `ALTER TABLE` statement to modify a table (`t0`) by changing its storage engine. During the execution of this statement, the server is forcibly killed. Upon restarting the server, an error is thrown, indicating a tablespace mismatch. Additionally, table `t0` is found to be empty after the restart, resulting in data loss. The root cause lies in the implementation errors in rollback mechanisms. The modification to table `t0` affects the underlying tablespace information, which does not properly rollback after the crash. As a result, after the server recovery, the data in table `t0` is lost.

```
CREATE TABLE t0(c1 int, c2 char);
INSERT INTO t0(·····);
-- Kill the server when executing below statement
ALTER TABLE t0 ENGINE = InnoDB , ADD COLUMN IF NOT
EXISTS c2 MEDIUMINT UNSIGNED ZEROFILL DEFAULT 2,
LOCK = SHARED
-- Reboot the server
-- [ ERROR ] InnoDB : Expected tablespace id 43
but found 0 in the file ./db/ t2 . ibd
-- Table t0 is empty
```

Figure 9: A post-recovery inconsistency case in GreatSQL.

7.3 Comparison with State of the Art

To evaluate the effectiveness of our approach, we compared DDLUMOS with four state-of-the-art DBMS testing tools: SQUIRREL, SQLancer, SQLsmith, and TXCHECK, all of which are widely recognized in the industry. The evaluation focused on three key metrics: (i) the number of code branches covered in DDL operation modules, (ii) the average number of metadata conflict points generated per DDL statement within 48 hours, and (iii) the number of unique ADBs identified by each tool during the same 48-hour period. For a fair comparison, after each testing session, we collected all generated queries and reran them to unify branch measurements. Each experiments were run for 5 times.

Table 3: Number of related branches covered by each tool.

DBMS	SQLancer	SQLsmith	SQUIRREL	TXCHECK	DDLUMOS
MySQL	1083	401	954	571	3184
MariaDB	1,206	593	1103	452	2994
Percona	1,120	374	853	501	3201
PolarDB	1075	524	812	532	2814
GreatSQL	938	412	1063	447	2597
PostgreSQL	2041	953	1443	1202	3405
Total	7463	3257	6228	3705	18195
Variance	2304	8049	15293	9984	8852

Related Code Branches. Tables 3 show the average number of covered code branches in DDL operations modules by those DBMS testing tools in 48 hours within 5 runs. The results indicate that DDLUMOS outperformed other DBMS testing tools in triggering DDL behaviors. Specifically, DDLUMOS covered 10732, 14938, 11976, and 14490 more branches in Atomic DDL modules than SQUIRREL, SQLancer, SQLsmith, and, TXCHECK, respectively. The variance shows that different tools exhibit variations during testing.

Average Metadata Conflict Points. Table 4 shows that DDLUMOS generates more metadata conflict points for each DDL statement on average than other tools within 5 runs. Specifically, each DDL statement generated by DDLUMOS contains an average of 1.24 metadata conflict points, which is 0.93, 1.21, 0.17, and 0.76 more than the average metadata conflict points for each DDL statement generated by SQUIRREL, SQLancer, SQLsmith, and TXCHECK, respectively.

The improvement achieved by DDLUMOS is primarily due to its metadata conflict-guided DDL synthesis. This approach enables DDLUMOS to systematically generate test cases that specifically stress the atomicity of DDL operations by creating scenarios that involve metadata conflicts. These targeted test cases not only enhance coverage but also uncover deep logical flaws in the DBMS's handling of concurrent and interrupted DDL operations. In contrast, other tools lack specialized mechanisms for generating Atomic DDL scenarios. For example, SQLancer primarily generates random DDL operations without focusing on metadata conflicts, which limits its effectiveness in testing atomicity. Similarly, SQUIRREL and SQLsmith prioritize syntax correctness over conflict-driven test case design, resulting in lower coverage of Atomic DDL components in DBMSs.

Table 4: Number of average metadata conflict points per DDL.

DBMS	SQLancer	SQLsmith	SQUIRREL	TXCHECK	DDLUMOS
MySQL	0.33	0.03	0.15	0.43	1.28
MariaDB	0.27	0.03	0.17	0.46	1.31
Percona	0.29	0.02	0.16	0.44	1.26
PolarDB	0.29	0.04	0.17	0.5	1.25
GreatSQL	0.34	0.04	0.22	0.48	1.18
PostgreSQL	0.28	0.03	0.23	0.39	1.16
Average	0.3	0.03	0.18	0.45	1.24
Variances	0.00067	0.00047	0.0092	0.00127	0.00283

Triggered ADBs. Table 5 displays the average number of bugs detected by each tool in 48 hours within 5 runs. It shows that DDLUMOS outperformed the other tools, uncovering 27, 31, 32, and 26 more bugs compared to SQLancer, SQLsmith, SQUIRREL, and TXCHECK, respectively.

Table 5: Number of bugs detected by each tool in 48 hours.

DBMS	SQLancer	SQLsmith	SQUIRREL	TXCHECK	DDLUMOS
MySQL	2	1	2	3	8
MariaDB	1	0	0	1	9
Percona	2	1	1	2	5
PolarDB	2	2	0	1	4
GreatSQL	1	1	1	2	8
PostgreSQL	1	0	0	1	2
Total	9	5	4	10	36
Variances	2	0.8	0.4	2	6

To better understand the relationships between the bugs detected by the different tools, we analyzed their bug reports. Figure 10 illustrates the overlap between bugs detected by DDLUMOS and the other tools. DDLUMOS uniquely identified 36 bugs, demonstrating its ability to uncover a broad range of ADBs. Among these, 2 bugs and 3 bugs are overlapped with SQLancer and TXCHECK, respectively, while no overlap was observed with SQLsmith or SQUIRREL. The overlapping bugs detected by DDLUMOS, SQLancer, and TXCHECK were primarily related to simple schema modifications involving basic DDL operations, which both tools focus on. However, DDLUMOS significantly outperformed SQLancer in detecting bugs involving concurrent schema modifications and recovery scenarios, as SQLancer does not target these conditions.

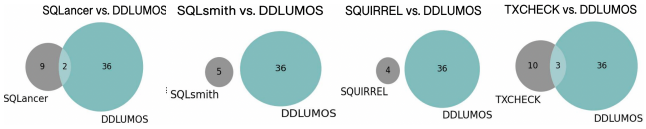

Figure 10: Venn diagram for bugs found by different tools.

The bugs detected by DDLUMOS and SQLsmith were entirely orthogonal. SQLsmith primarily focuses on generating complex `SELECT` statements to detect crash bugs, producing limited DDL statements that do not involve metadata modifications. In contrast, DDLUMOS targets metadata conflicts, incomplete rollbacks, and concurrency issues during DDL operations, making it uniquely suited for detecting ADBs. Similarly, the bugs detected by DDLUMOS and SQUIRREL were also orthogonal. SQUIRREL explores a broader range of DBMS behaviors with coverage guidance to detect memory safety bugs and crashes. The four bugs detected by SQUIRREL are unrelated to DDL statements.

7.4 Rediscovery of Surveyed ADBs

To further evaluate the effectiveness of DDLUMOS, we examined whether DDLUMOS could rediscover 207 known Atomic DDL bugs previously collected in our research. Our goal was to evaluate whether DDLUMOS could systematically rediscover these ADBs in realistic settings. Specifically, we applied DDLUMOS to the versions of PostgreSQL, MySQL, and MariaDB corresponding to each bug report in the dataset. For each DBMS version, DDLUMOS ran for one week to detect ADBs. Whenever a bug was detected, we compared its triggers and observed symptoms with those in the surveyed dataset. A bug was considered rediscovered if it manifested in the same way as originally reported, such as incorrect results, system crashes, or data loss.

Figure 11 presents the cumulative number of Atomic DDL bugs rediscovered by DDLUMOS in PostgreSQL, MySQL, and MariaDB in one week. Within the first two days of testing, DDLUMOS successfully rediscovered 86.5% of the bugs (179/207), demonstrating its efficiency in quickly exposing a significant portion of critical DDL-related issues. By extending the test period to one week, DDLUMOS increased the total number of rediscovered bugs to 196, representing approximately 94.7% of the 207 reported Atomic DDL bugs. This includes 34 out of 38 bugs in PostgreSQL, 48 out of 50 bugs in MySQL, and 114 out of 119 bugs in MariaDB.

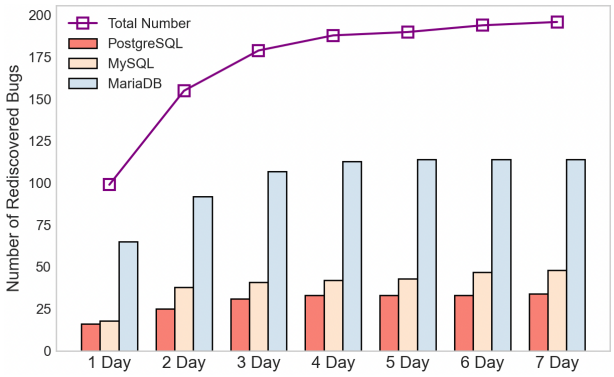

Figure 11: Number of rediscovered bugs in one week.

The high rediscovery rate primarily stems from two key design features in DDLUMOS. First, its *Metadata Conflict Guided DDL Synthesis* systematically constructs test scenarios that faithfully reflect real-world DBMS usage, such as concurrent schema modifications and transaction rollbacks. As a result, DDLUMOS rapidly surfaces problems that can lead to data corruption, server crashes, or anomalies during recovery. Second, the *Graph-Based Metadata Consistency Analysis* enhances DDLUMOS's effectiveness by identifying subtle inconsistencies in the database schema and system that may not be immediately obvious. Through a graph-based representation of schema states, DDLUMOS can efficiently explore diverse execution paths and detect bugs that would remain hidden under conventional testing.

8 Discussion

Missed Rediscoveries. Despite the bugs being rediscovered, there are still 11 bugs that did not resurface in the one-week experiments. A closer inspection revealed two main reasons for these missed rediscovered. First, 8 out of the 11 unrediscovered bugs relied on specialized plugins or configuration features. Since DDLUMOS does not modify system environments during testing (e.g., it does not install plugins or enable specific configurations), the required conditions for these bugs to occur were not present. These environment-dependent issues represent a small fraction (8 out of 207) of the total. Second, 3 bugs required specific execution paths that DDLUMOS's current generation strategy did not systematically explore within one week. When the testing period was extended to two weeks, DDLUMOS was able to rediscover

these three bugs, demonstrating its ability to detect rare or timing-sensitive defects when given sufficient time.

Extend Existing DBMS Testing Tools with DDLUMOS. While DDLUMOS primarily focuses on detecting atomic DDL bugs, its metadata conflict tracking and DDL synthesis patterns can also aid in discovering other types of DBMS bugs. First, DDLUMOS can be integrated into existing grammar-based DBMS testing frameworks to enhance their bug detection capabilities. For example, grammar-based tools typically focus on generating syntactically correct SQL queries, but they may not always consider how DDL operations interact with schema elements. By incorporating DDLUMOS, these existing frameworks can trigger scenarios that may expose rare or hard-to-find bugs in DBMS schema handling. Furthermore, DDLUMOS can be used in conjunction with other DBMS testing tools, such as those focused on transaction-level bugs or logical errors, to cover a broader range of potential issues.

9 Related Work

DBMS Testing. DBMS testing has evolved significantly over the years, with efforts primarily focusing on crash bug detection [12, 16, 39, 46], correctness verification [14, 17, 35, 37, 40, 45], and performance evaluation [15, 18].

Crash bug testing aims to identify scenarios where the DBMS may fail or crash under specific conditions. Tools like SQLsmith [39] generate a variety of SQL queries to stress test the DBMS, revealing potential crash points. SQUIRREL [46] and RATEL [42] introduce coverage-feedback into the query mutation to cover more branches. LEGO [16] enhances code coverage with sequence-oriented SQL mutation. LEGO [16] proposes sequence-oriented mutation to improve the code coverage by combining different SQL Type Sequences of the statements. Griffin [9] designs grammar-free mutation methods to detecting crash bugs in DBMS. Correctness verification is another crucial aspect of DBMS testing, focused on ensuring the accuracy of query execution. Techniques such as metamorphic testing [14, 17, 35–37] and differential testing [40, 45] have gained widespread adoption. For example, SQLancer uses oracles [35, 37, 37] to detect logic bugs by comparing the outcomes of different queries that should theoretically yield the same result. Additionally, RAGS [40] and Grand [45] utilize differential testing to uncover logic discrepancies by comparing the results of similar queries across different execution paths. Performance evaluation tests how efficiently a DBMS handles diverse workloads. Tools like APOLLO [15] conduct performance regression testing to identify degradation over time. Meanwhile, AMOEBA [18] assesses the performance consistency of semantically equivalent queries to uncover unexpected performance bottlenecks. Puppy [44] detects performance degradation bugs with limited-optimization plan construction.

While these approaches have significantly advanced DBMS testing, they primarily focus on query execution and general DBMS stability, often overlooking the specific challenges associated with Data Definition Language (DDL) operations. With the growing complexity of DDL operations, particularly in high-concurrency environments, there is an urgent need for testing frameworks that focus specifically on ensuring atomicity and consistency in these operations.

Atomicity Bug Detection. Atomicity bugs pose significant challenges to DBMS reliability. These bugs occur when a sequence of SQL operations, expected to be atomic, fails to execute completely, leaving the DBMS in an inconsistent state. Existing work related to atomicity has largely focused on transaction management [8, 13, 19–21, 31, 38]. For example, techniques like transactional memory testing [19, 21] and atomicity violation detection in multithreaded programs [20, 31, 38] can also be applied to detect atomicity issues. In the context of DDL operations, Atomic DDL bugs are often triggered by metadata conflicts, insufficient rollback mechanisms, and concurrency issues. Tools specifically designed to detect such Atomic DDL bugs are still scarce. While some research has explored the use of fuzzing techniques to generate DDL operations for testing purposes [8, 13], these efforts are still in their infancy and lack the sophistication needed to fully capture the complex interactions that can lead to atomicity violations in real-world DBMSs.

DDLUMOS addresses this gap by focusing specifically on detecting atomicity bugs in DDL operations. By generating DDL sequences that intentionally create metadata conflicts and simulating high-concurrency environments, DDLUMOS is able to uncover vulnerabilities that are typically missed by conventional testing approaches. This focus on DDL atomicity represents a significant advancement in DBMS testing, providing a new avenue to improve the reliability of schema modifications in modern databases.

10 Conclusion

In this paper, we have presented an in-depth analysis of 207 ADBs across three widely used industry DBMSs. Our investigation reveals that ADBs primarily manifest as incorrect results, data loss during recovery, and system crashes, which are mainly triggered by the metadata conflicts between DDL statements. To address these issues, we developed DDLUMOS, a testing tool that detects ADBs with metadata conflict-based DDL generation. By employing DDLUMOS across widely used DBMSs (e.g., MySQL and MariaDB), we discovered 73 previously unknown bugs, all of which have been confirmed.

SpaceExit: Enabling Efficient Adaptive Computing in Space with Early Exits

Abstract

Advances in satellite technology and reduced launch costs have led to a proliferation of Earth observation (EO) satellites in low-Earth orbit (LEO). These satellites generate massive high-resolution imagery, creating a significant downlink bottleneck due to limited satellite-to-ground communication bandwidth. While orbit edge computing (OEC) can reduce data volume, existing static approaches fail to adapt to the varying complexity of satellite imagery, resulting in limited system performance and inefficient resource utilization.

We therefore propose *SpaceExit*, an integrated system for efficient adaptive computing on satellites. *SpaceExit* introduces three key components: (1) a geospatial-contextual adaptive detector that leverages both visual semantics and geospatial context to adjust processing complexity for each image, (2) a complexity-driven adaptive task scheduler that partitions images into tiles and allocates inference tasks across onboard devices based on content complexity and device capabilities, and (3) a satellite resource adaptive controller that ensures safe and efficient execution under changing conditions. Evaluations of diverse satellite settings and hardware platforms demonstrate that *SpaceExit* increases the performance by 5.2%-37.6% compared with the SoTA design.

1 Introduction

Recent advances in satellite technology and reduced launch costs have led to a significant increase in Earth observation (EO) satellites in low-Earth orbit (LEO) [37]. These advanced satellites, equipped with high-resolution cameras, can generate terabytes of imagery data per day, providing valuable insights for applications such as precision agriculture [4, 29], disaster response [33, 35], and environmental monitoring [28]. However, this massive data generation creates unprecedented challenges for satellite-based computing systems that differ fundamentally from terrestrial computing environments in three critical aspects.

First, *satellite computing occurs in an extremely constrained and hostile environment*. Satellites face severe thermal variations (e.g., -22°C to +77°C [34]) as they move between sunlight and Earth's shadow during their orbital periods. Such extreme conditions can significantly impact onboard chips and other equipment. As a result, effective satellite computing requires careful thermal management strategies that extend beyond conventional resource optimization. For instance, existing analysis of operational LEO satellites shows that thermal constraints alone can reduce computation performance by up to 10% [39].

Second, *satellite resources exhibit unique dynamic characteristics tied to orbital mechanics*. As micro-datacenters in space, satellites face network and power constraints that differ fundamentally from terrestrial systems. Satellite-to-ground communication bandwidth varies dramatically (e.g., from 0 to 220 Mbps) based on orbital position and ground station visibility [1]. Similarly, available power fluctuates with solar panel orientation and eclipse periods. Traditional "bent pipe" approaches that simply downlink raw imagery become impractical under these constraints [10].

Third, *satellite observation tasks present distinct workload patterns that challenge conventional computing paradigms*. Continuous Earth monitoring generates spatially and temporally correlated image sequences with varying complexity from simple ocean scenes to intricate urban landscapes [37]. These images often contain redundant information across overlapping observation swaths, yet may also capture rapidly evolving phenomena requiring immediate analysis.

While recent orbital edge computing (OEC) approaches [37] attempt to address these by performing onboard analysis, existing solutions rely largely on static processing pipelines that fail to adapt to the dynamic nature of both satellite operations and EO data [9–11]. They typically attempt to reduce computational overhead by selectively discarding imagery or employing varying models for different scenes [9, 10]. Despite these methods leveraging

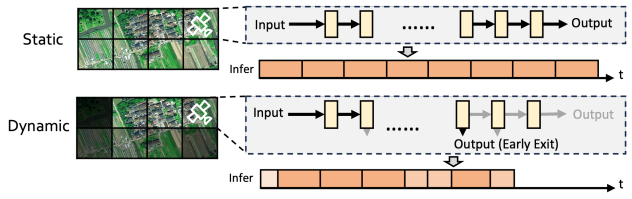

Figure 1: Comparison between the existing static OEC method and the proposed adaptive OEC method (*SpaceExit*). Unlike static approaches that process all imagery indiscriminately, *SpaceExit* adapts its processing to image complexity, performing early exiting for simple images and full processing for complex ones.

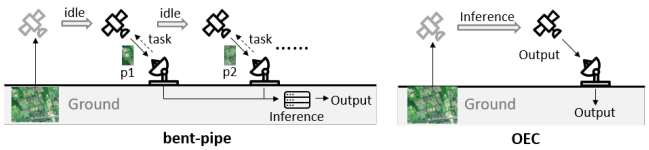

Figure 2: Comparison of classic bent-pipe with OEC.

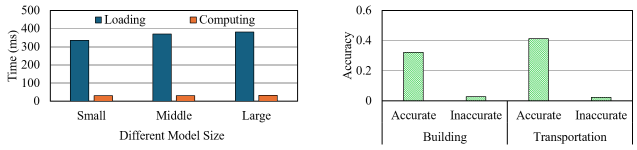
prior knowledge about images to implement differentiated processing, they ultimately rely on static models. This inherent rigidity presents significant limitations in EO contexts, where scene complexity, illumination conditions, and orbital parameters undergo constant flux. Moreover, these systems cannot adaptively respond to runtime variations in both computational resources (like chips) and environmental factors which is a critical requirement for resource-constrained satellite platforms. As illustrated in Figure 1, an adaptive processing pipeline that *adaptively modulates computational intensity based on real-time scene complexity and resource* can achieve superior efficiency by enabling early termination for simpler inputs while maintaining high-fidelity processing for challenging scenarios.

We therefore propose *SpaceExit*, an integrated system that addresses all three satellite-specific characteristics through algorithm-system co-design. Unlike previous methods that merely simulate adaptive behavior through predefined rules, *SpaceExit* continuously adjusts its processing based on current input and system conditions, offering a truly flexible and efficient solution to the growing demands of EO missions.

At its core, *SpaceExit* features a geospatial-contextual adaptive detector that serves as the foundation for adaptive computation. This module incorporates a multi-scale feature extraction pipeline with an innovative exiting mechanism, adaptively adjusting processing complexity for each image region based on visual semantics and geospatial context. The system's architecture enables efficient handling of both fine-grained details and large-scale patterns while allowing early termination for easily recognizable images. To enhance adaptability, a geospatial context component integrates auxiliary information such as geographical location, time of day, and historical data to guide exit decisions and optimize resource allocation. For example, it can prioritize more complex processing in urban areas while enabling quicker exits in open-water regions, thus optimizing resource allocation based on contextual information.

Complementing this adaptive processing capability, *SpaceExit* features a complexity-driven adaptive task scheduler designed to optimize onboard computing resource utilization, which is crucial for long-term stable execution of in-orbit computing tasks [39]. It employs an adaptive tiling strategy, partitioning input images into regions of varying sizes based on their estimated complexity. Then it implements an adaptive allocation scheme that distributes these tiles across available onboard devices, considering factors such as tile complexity, device capabilities, and current workload. Additionally, to ensure robust operation in the challenging space environment, *SpaceExit* incorporates a satellite resource adaptive controller. This component continuously monitors system parameters including computing load, bandwidth utilization, temperature, and energy consumption. It adaptively adjusts scheduling and exiting strategies to maintain safe operating conditions while maximizing processing throughput.



Our comprehensive experiments simulate various scenarios and hardware configurations with real-world datasets. The results demonstrate that *SpaceExit* consistently outperforms existing static detection pipelines, increasing the performance by 24.3% on average compared with the SoTA design.

The contributions of this work are multifaceted. To the best of our knowledge, *SpaceExit* represents the first integrated system for adaptive onboard earth observation that is optimized across both algorithm and system levels for satellite deployment. The novel geospatial-contextual adaptive detector pushes the boundaries of efficient inference in resource-constrained environments. The complexity-driven adaptive task scheduler offers a new paradigm for managing heterogeneous computing resources in space, while the satellite resource adaptive controller ensures reliable operation under the unique constraints of orbital platforms.

2 Background and Challenges

2.1 Static OEC Systems

To address the limitations of classic "bent-pipe" approaches, OEC is proposed to process data onboard satellites before transmission (Figure 2). Existing OEC systems mainly rely on static methods for data processing. TargetFuse [40] deploys a DNN model serving as a counter, while Kodan [9] provides several context-based models to yield higher accuracy in different scenes. These static approaches also adopt selective discarding techniques or data deduplication, achieving significant data reduction. However, these methods struggle to

(a) Model loading overhead of different models.

(b) Inaccurate priors significantly impact performance.

Figure 3: Limitation of static methods.

adapt to the diverse and dynamic nature of Earth observation data, often leading to suboptimal results when confronted with unexpected or complex scenes.

A major limitation of multi-model systems for satellite-based image processing is the substantial overhead associated with model loading and storage. Satellites have limited onboard storage capacity, constraining the number and complexity of models that can be deployed [3]. Our analysis, as shown in Figure 3a, reveals that the time spent loading different object detection models is often much longer than their computation time. This overhead significantly impacts system efficiency and responsiveness. Furthermore, the typical approach of applying simple models first and escalating to more complex ones if necessary can result in significant delays and computational waste. If a simple model proves inadequate for a given scene, the resources expended on its application and the time spent loading subsequent models are essentially lost. These limitations force a trade-off between model diversity and processing capability, highlighting the need for a more efficient and adaptive onboard processing approach.

Another critical drawback of static methods is their reliance on prior knowledge, which may be inaccurate or unavailable in the dynamic domain of Earth observation [7]. Pre-defined rules for scene classification or object detection may fail when confronted with unexpected phenomena or rapidly changing environments. Our analysis, illustrated in Figure 3b, demonstrates this vulnerability. We trained two models specifically designed for Building and Transportation detection. When the prior knowledge aligns with the input data, these models achieve high performance. However, when confronted with unexpected scenes or objects, their performance drops significantly. This inflexibility leads to suboptimal resource utilization across heterogeneous scenes, as the system cannot adaptively adjust its processing strategy based on the current input and operational context.

2.2 Challenges of Adaptive OEC

While implementing a truly adaptive method for Earth observation processing holds great potential, implementing such a system presents several significant challenges:

Challenge-1: Adapting multi-scale information and geospatial context for object detection in OEC. Dynamic object detectors have shown great promise in non-satellite scenarios, where they can adjust computation based on the complexity of the input data. However, applying these methods to satellite imagery introduces additional challenges. Satellite imagery requires the processing of multi-scale image information and incorporation of geospatial context, which is not typically considered in traditional methods. Furthermore, the constraints of the satellite environment, such as limited computational resources and the need for real-time processing, make dynamic methods in satellites more energy-sensitive compared to ground-based systems. Developing an adaptive approach that can adjust computation cost without sacrificing accuracy while leveraging both visual and geospatial information is a complex task requiring careful algorithm design.

Challenge-2: Scheduling dynamic task across heterogeneous onboard devices. Unlike static methods where processing requirements can be predicted in advance, adaptive approaches must continuously adjust resource allocation based on current input and system state. This is particularly challenging in the satellite environment where multiple heterogeneous computing devices with varying capabilities are often deployed. Designing a scheduling algorithm that can efficiently distribute workload across these devices while adapting to dynamic processing requirements is non-trivial.

Challenge-3: Runtime resource management under varying onboard constraints. The ever-changing space environment and varying mission requirements pose unique difficulties in runtime management. Satellites face severe constraints such as bandwidth, power, and thermal budget, which fluctuate based on orbital position and mission phase. Additionally, onboard resources like power and memory are limited and must be carefully managed. Prior work [39] has shown that these constraints can significantly impact the stablitity and performance of onboard processing systems. Ensuring safe and efficient execution under these dynamic conditions requires careful design of the resource management system.

3 *SpaceExit* System Design

The *SpaceExit* system architecture is designed to address the key challenges of onboard object detection on satellites holistically. As shown in Figure 4, *SpaceExit* takes the high-resolution satellite images as input and processes them with an efficient adaptive object detector on heterogeneous onboard computing devices.

Specifically, *SpaceExit* contains three main modules that synergistically optimize the detection pipeline across various dimensions of algorithm-system co-design:

- **Geospatial-Contextual Adaptive Detector (GCAD, Section 3.1)**: This module forms the core of *SpaceExit*'s adaptive processing capability to address *Challenge-1*. It employs a multi-scale feature backbone with a novel exiting mechanism that leverages both visual semantics and geospatial context. The GCAD can adaptively adjust

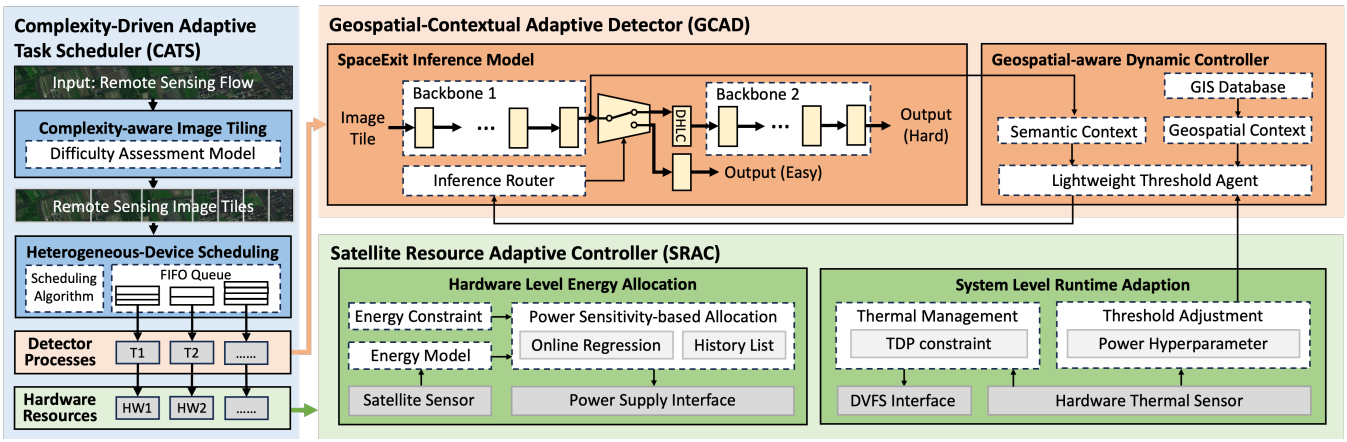


Figure 4: Overview of the *SpaceExit*.

the processing complexity for each tile, allowing for efficient early exits on simpler areas while dedicating more resources to complex regions. This approach enables *SpaceExit* to balance detection accuracy and computational efficiency across diverse satellite imagery.

- **Complexity-Driven Adaptive Task Scheduler (CATS, Section 3.2)**: The CATS optimizes the utilization of onboard computing resources across multiple devices to address *Challenge-2*. It implements a complexity-aware scheduling algorithm that partitions input images into tiles based on their estimated complexity. These tiles are then allocated across available onboard devices, considering factors such as tile complexity, device capabilities, and current workload. This adaptive approach ensures efficient load balancing and maximizes overall system throughput.

- **Satellite Resource Adaptive Controller (SRAC, Section 3.3)**: The SRAC is responsible for maintaining safe and efficient system operation under the dynamic constraints of the space environment to address *Challenge-3*. It continuously monitors system parameters including computing load, temperature, and energy consumption. Based on these inputs, the SRAC adaptively adjusts system configurations and exiting strategies to optimize resource utilization while ensuring the system operates within safe limits.

These three modules work together to enable *SpaceExit*'s efficient and adaptive approach to onboard object detection. The GCAD provides content-aware processing, the CATS ensures optimal resource utilization across devices, and the SRAC maintains system stability and efficiency in changing environmental conditions.

3.1 Geospatial-Contextual Adaptive Detector

The GCAD forms the core of *SpaceExit*'s adaptive processing capability, addressing the challenge of efficiently processing satellite imagery with varying complexity. It consists of two key components: a multi-exit network architecture and a geospatial-aware threshold adjustment mechanism.

3.1.1 Multi-exit network architecture

GCAD employs a multi-scale feature backbone with multiple exit points, allowing for adaptive adjustment of processing complexity based on image content. This backbone is designed to capture features at various scales, which is essential for detecting both large-scale structures and small details in satellite images. Specifically, a L layer feature extraction process can be defined as,

$$f_{\mathbf{x}}^{L} = \mathcal{F}_L(\cdots \mathcal{F}_2(\mathcal{F}_1(\mathbf{x}))), \tag{1}$$

where $\mathbf{x}$ is the input image and $\mathcal{F}_i$ represents the feature extractor at the i-th scale. Each $\mathcal{F}_i$ is designed to extract features at a scale lower than $\mathcal{F}_{i+1}$ and higher than $\mathcal{F}_{i-1}$, allowing for a comprehensive multi-scale representation of the image. The overall detector design builds upon the concept of progressive feature refinement [23], it consists of multiple connected networks: a primary feature extractor and multiple enhancement networks. The primary extractor processes the input image to generate an initial set of multi-scale features, while the enhancement network further refines these features to capture more complex patterns and relationships.

To implement adaptive computing for different images, the central question is how to estimate the uncertainty score of the model's prediction on different images. Existing methods may use confidence-based estimation to measure uncertainty. However, the neural network is known to be over-confident [2]. Thus, we introduce an additional router that takes multiple features as input and outputs the estimated uncertainty of

the model's prediction on this image. Simialr to the squeeze-and-excitation (SE) module [20], we first pool the multi-scale features F independently and concatenate them all as,

$$\widetilde{F} = \|_{i=1}^{L} \mathcal{P}(f^i), \tag{2}$$

where $\mathcal{P}$ denotes global average pooling, $\|$ denotes channel-wise concatenation, and f^i represents the features from the i-th scale of the feature. This operation compresses the multi-scale features into a compact representation $\widetilde{F}$, which is then used by the router to make its decision. Specifically, the uncertainty score can be calculated as,

$$u = \sigma(W_2(\delta(W_1\widetilde{F} + b_1)) + b_2), \tag{3}$$

where δ, σ denote the ReLU and Sigmoid activation functions respectively, and W_1, W_2, b_1, b_2 are learnable parameters.

After each processing stage, the router will be activated to judge whether the model should processed to the next block or go to the head to get the prediction and exit. Specifically, for images deemed "easy" (i.e., those with an uncertainty score below a certain threshold), the system proceeds directly to the detection head. Conversely, for "hard" images, the system activates the enhancement networks for more sophisticated processing until it gets enough certainty score or reaches the end of the detector.

This adaptive routing allows GCAD to allocate computational resources efficiently, dedicating more processing power to complex images while quickly handling simpler ones. Such an approach is particularly valuable in satellite imaging applications, where images can vary greatly in complexity and where processing resources may be limited.

Training a adaptive detector like GCAD presents unique challenges. We employ an adaptive offset-based training method [25] to balance the performance of the different processing paths. This method introduces adaptive offsets to the loss function, encouraging the network to utilize both the simple and complex processing paths effectively.

3.1.2 Geospatial-aware adaptive inference

With the multi-scale features and early exit branches, the next question is how to adaptively decide which scale to extract and use for each image tile. Considering both the semantic and geospatial context in satellite computing is essential. However, interweaving complex multi-exit network training with geographic information and resource margin will greatly increase the difficulty and cost of model training. To this end, we propose a two-stage approach, which introduces a lightweight auxiliary model based on the adaptive model to fuse geospatial information.

Firstly, we adjust the trained adaptive neural network based on the difficulty score which is irrelevant to the geospatial information. This ensures that we can use vast amounts of satellite images without geospatial information to train our model. Specifically, consider a validation set $\mathcal{S}_{val}$, the threshold can be estimated as,

$$\tau_{val} = \mathcal{P}(\mathcal{S}_{val}, k), \tag{4}$$

where $\mathcal{P}(\cdot, k)$ means the k-th quantile of $\mathcal{S}_{val}$.

Then, we utilize a small dataset with geospatial information to train a lightweight agent to adaptively adjust the threshold. Specifically, the agent takes two inputs: (1) The semantic features r from each exit scale, which encodes the semantic information. (2) The geospatial embedding g, which encodes the geographic context like terrain type, land cover, POI density, etc. The geospatial priors are pre-computed offline and stored in a GIS database. At runtime, they are efficiently queried based on the region coordinates and resolutions. The priors are used as soft guidance and can be overridden by the visual patterns if there is a discrepancy. This adaptive fusion of visual and geospatial information improves the detection accuracy and efficiency.

Based on the above strategy, *SpaceExit* can adaptively select the most appropriate scale and exit point for each image tile, optimizing both accuracy and computational efficiency. By integrating geospatial information and image features, *SpaceExit* ensures that the inference process is not only context-aware but also adaptive to varying operational conditions. This results in improved performance in terms of both speed and accuracy, making *SpaceExit* highly suitable for real-time on-board satellite image analysis.

3.2 Complexity-Driven Adaptive Scheduler

CATS optimizes the utilization of onboard computing resources across multiple devices. It implements a complexity-aware scheduling algorithm that partitions input images into tiles based on their estimated complexity and allocates them across available onboard devices.

3.2.1 Complexity-aware image titling

CATS first uses a difficulty assessment model that estimates the processing complexity d_t of each image. This model can leverage simple heuristics (e.g., color variation) or train a simple low-complexity model.

Based on the difficulty assessment, CATS employs an adaptive tiling strategy to partition input images. This approach is motivated by the observation that satellite images often contain regions of varying complexity, and uniform tiling can lead to inefficient resource utilization.

Assume there are N onboard devices, where each device i has a processing rate v_i (in pixels/s) and memory capacity m_i. Given a raw input image I with dimensions $W \times H$, CATS partitions it into a grid of N_r tiles $\{r_1, \ldots, r_{N_r}\}$, where each tile has dimensions $w_i \times h_i$.

The tile size is chosen to satisfy two key constraints:

1. Memory constraint: $wh < \min_i m_i$, ensuring that a tile can fully fit into any device's memory.

2. Accuracy-complexity balance: The tile size should be large enough to guarantee fast processing, but small enough to capture meaningful context for object detection [40].

The actual tiling process is adaptive, with tile sizes varying based on the difficulty scores. More complex regions (higher d_t) are divided into smaller tiles for more focused processing, while simpler regions use larger tiles to reduce overhead:

$$w_t = h_t = \frac{w_{base}}{\sqrt{d_t}}, \tag{5}$$

where w_{base} is a base tile width chosen to satisfy the above constraints.

3.2.2 Heterogeneous-Device Scheduling

The core of CATS is its multi-device scheduling algorithm, which allocates tiles to available onboard devices. This allocation considers three primary factors as: tile complexity (from the difficulty assessment), device capabilities (processing rate, memory capacity) and Current device workload.

CATS maintains a FIFO queue Q_i for each device i to manage pending image tiles. The scheduling process for each tile r involves assigning it to a device queue:

$$Q_{\sigma(i)} = Q_{\sigma(i)} \cup \{r\}, \tag{6}$$

where the device selection function $\sigma(i)$ is defined as:

$$\sigma(i) = \arg\min_j \left\{ \frac{n_j}{v_j} \middle| j \in [1,N], |Q_j| < K_j \right\}. \tag{7}$$

Here, n_j is the current unprocessed workload on device j, v_j is its processing rate, and K_j is the maximum queue size for device j. This policy aims to equalize processing time across devices while avoiding queue overflow.

Unlike static task where workload depends solely on the number of tasks, our system must account for both quantity and complexity. Thus, we modify the workload measure n_j to incorporate the difficulty scores:

$$n_j = \sum_{r \in Q_j} d_r \cdot |r|, \tag{8}$$

where $|r|$ is the size of tile r in pixels.

CATS updates these workload counters n_j adaptively as new tiles are enqueued or processed tiles are dequeued. This process repeats for each raw image until all tiles are distributed, providing global load balancing across the heterogeneous onboard devices.

Furthermore, CATS implements a priority system within each device queue. Each tile r is assigned a priority score based on its deadline urgency and complexity:

$$s(r) = \eta \cdot \frac{1}{d(r) - t} + \lambda \cdot d_r, \tag{9}$$

where $d(r)$ is the tile's deadline, t is the current time, d_r is the tile's difficulty score, and η, λ are weighting factors that can be tuned based on mission requirements. This dual consideration of deadline urgency and processing complexity addresses the unique requirements of OEC tasks. The urgency factor ensures time-critical observations aren't missed, which is essential for applications like disaster monitoring. The complexity factor ensures that challenging tasks start processing earlier, reducing the risk of missing deadlines.

Tiles are processed in descending order of these scores: $r^* = \arg\max_r s(r)$. After each tile is processed, CATS updates the resource usage and checks if it exceeds the current budget allocated by the SRAC module. If so, it pauses scheduling until more resources become available in the next cycle.

This sophisticated, multi-factor scheduling approach ensures efficient utilization of limited onboard resources, adapting to both the varying complexity of input data and the heterogeneous capabilities of onboard devices.

3.3 Satellite Resource Adaptive Controller

The SRAC module is responsible for maintaining safe and efficient system operation under the dynamic constraints of the space environment. It continuously monitors system parameters including computing load, temperature, and energy consumption, and adaptively adjusts system configurations to optimize resource utilization while ensuring the system operates within safe limits.

3.3.1 Energy Allocation

A primary function of SRAC is the adaptive allocation of energy resources among onboard computing devices. This is particularly challenging in the satellite environment due to the highly variable nature of solar power availability and the critical importance of maintaining overall system stability.

Let $I(t)$ denote the total available power at time t, which varies based on factors such as solar panel orientation, eclipse periods, and battery state of charge. SRAC must allocate this power among N heterogeneous computing devices. Let $P_i(t)$ denote the power budget for device i at time t. The allocation must satisfy:

$$\sum_{i=1}^{N} P_i(t) \leq I(t). \tag{10}$$

SRAC employs an adaptive allocation policy $\pi : I(t) \to \{P_i(t)\}_{i=1}^N$ designed to maximize overall system throughput. This policy operates in two stages:

1. Reserve a base power P_{base} for critical satellite systems (e.g., attitude control, communication).

2. Allocate remaining power $I(t) - P_{base}$ among computing devices based on their performance sensitivity to power.

Formally, the allocation for each device is computed as:

$$P_i(t) = P_{base,i} + (I(t) - P_{base}) \cdot \frac{\partial X_i / \partial P_i}{\sum_{j=1}^{N} \partial X_j / \partial P_j}, \tag{11}$$

where X_i is the measured throughput of device i, and $\partial X_i / \partial P_i$ represents its performance sensitivity to power. This approach allocates more power to devices that can translate it into higher throughput gains.

The performance-power relationship $\partial X_i / \partial P_i$ is learned and continuously updated during system operation using online regression techniques. This allows the system to adapt to changes in device characteristics over time, which is crucial for long-duration space missions.

SRAC updates this allocation whenever there is a significant change in available power ($\Delta I > I_{th}$) or periodically (e.g., every T_{update} seconds) to account for gradual changes in system state.

3.3.2 DVFS and Threshold Adjustment

Given the power budget $P_i(t)$ for each device, SRAC employs fine-grained control to optimize performance within these constraints. This is achieved through a combination of Dynamic Voltage and Frequency Scaling (DVFS) and adaptive adjustment of processing thresholds.

Specifically, SRAC adjusts frequencies f_j based on measured utilization u_j:

$$f_j = f_{min} + (f_{max} - f_{min}) \cdot \frac{u_j - u_{min}}{u_{max} - u_{min}}, \tag{12}$$

subject to the Thermal Design Power (TDP) constraint [13]:

$$\sum_j A_j C_j V_j^2 f_j \leq P_i, \tag{13}$$

where A_j is the switching activity level, C_j is the capacitance of the circuit, and V_j is the voltage of core j. This approach allows higher frequencies (and thus higher performance) when utilization is high, while saving power during periods of low utilization.

Thermal management is a critical aspect of SRAC. It continuously monitors chip temperatures T_i and proactively adjusts power states when temperatures approach the limit T_{max}. SRAC employs a learned thermal-power model:

$$T_i(t+1) - T_i(t) = \alpha[P_i(t) - \beta(T_i(t)^4 - T_{amb}^4)], \tag{14}$$

where α and β are thermal parameters and T_{amb} is the ambient temperature. Using this model, SRAC estimates the power adjustment ΔP needed to maintain safe temperatures:

$$\Delta P = \frac{1}{\alpha}[T_{max} - T_i(t)] - [P_i(t) - \beta(T_i^4(t) - T_{amb}^4)]. \tag{15}$$

This allows for smooth throttling of DVFS settings to maintain safe operation without abrupt shutdowns.

Finally, SRAC adaptively adjusts the processing thresholds used in the GCAD module based on current resource availability. The exit threshold τ in GCAD is modulated as:

$$\tau = \tau_{base} \cdot \frac{\gamma P_{current}}{P_{nominal}}, \tag{16}$$

where $P_{current}$ is the current power availability, $P_{nominal}$ is the nominal power level and γ is the hyperparameter modeling the influence of threshold in power usage. This allows the system to become more conservative (exiting earlier) when resources are constrained, and more thorough when resources are plentiful.

3.3.3 Bandwidth Allocation

SRAC implements a priority-based bandwidth allocation strategy to maximize the value of limited satellite-to-ground communication opportunities. The allocation strategy operates on two timescales: inter-pass accumulation and intra-pass transmission. During inter-pass accumulation, SRAC accumulates data between ground station passes into priority queues. The intra-pass transmission phase occurs during a ground station pass, where SRAC allocates bandwidth based on the priority.

SRAC maintains three priority queues: Q_1 for onboard calculation results (highest priority), Q_2 for routine telemetry and housekeeping data (second highest priority), and Q_3 for uncertainty-scored image data. This ordering ensures that critical operational data and high-value scientific results are always transmitted before any additional image data.

During a ground station pass, SRAC follows a strict priority-based transmission protocol. The system first transmits all data from Q_1, ensuring that all onboard calculation results are downlinked. Once Q_1 is empty, it moves on to Q_2, transmitting all routine telemetry and housekeeping data. Only after both Q_1 and Q_2 are fully transmitted does the system begin to downlink data from Q_3, which contains the uncertainty-scored image data.

This priority-based allocation strategy ensures that SpaceExit always transmits critical operational data and high-value scientific results first. By using a simple, deterministic protocol for the highest-priority queues and a lightweight heuristic for managing lower-priority data, SRAC achieves robust and efficient bandwidth utilization while keeping computational overhead low.

4 Experimental Setup

4.1 Computational Hardware

We design and implement a heterogeneous computing testbed that faithfully emulates the resource-constrained environment of 3U CubeSat onboard computers. Our experimental platform incorporates two primary computing units that represent typical space-grade hardware configurations, carefully selected to balance performance and power constraints.

Firstly, we employ the NVIDIA Jetson Nano, which is equipped with a Quad-core ARM Cortex-A57 MPCore processor clocked at 1.43 GHz, paired with a 128-core Maxwell GPU that delivers 472 GFLOPS of compute performance. The system is supported by 4 GB of LPDDR4x memory, offering 25.6 GB/s bandwidth. Operating in a 10W TDP configuration, the Jetson Nano supports both FP16 and FP32 precision computations, making it suitable for efficient neural network inference within a compact 70 mm × 45 mm form factor [27]. Additionally, we utilize the NVIDIA Jetson Xavier NX, which offers higher performance in a similar size to the Jetson Nano. It features a 6-core NVIDIA Carmel ARMv8.2 64-bit CPU, a 384-core Volta GPU with 48 Tensor Cores, and 8 GB of LPDDR4x memory with 59.7 GB/s bandwidth. It delivers up to 21 TOPS of AI performance and supports TDP configurations of 10W, 15W and 20W, making it ideal for demanding AI applications in space-constrained environments.

To emulate a 3U CubeSat onboard computer with heterogeneous payloads, we setup an NVIDIA Jetson Nano with a 10W power mode connected to NVIDIA Jetson Xavier NX with 20W power mode. This configuration provides substantial AI computing power within the 4kg mass and 30W power budgets of a typical 3U bus [11], making it faithfully model the real onboard setup.

4.2 Satellite dataset

Following previous research [40], we evaluate *SpaceExit* using the DOTA (Dataset of Object deTection in Aerial images) dataset [38], a comprehensive satellite imagery dataset designed specifically for object detection tasks. The dataset contains 403k annotated instances across 15 object categories, including various vehicles, ships and infrastructures, with objects captured at arbitrary orientations to reflect real-world conditions. We preprocess to resemble the conditions encountered in EO applications closely.

4.3 *SpaceExit* Implementation

In *SpaceExit*, the adaptive router takes the terrain-type embedding (one-hot vector) and four visual embeddings as input. The selected scale then passes through a feature fusion module to combine the coarse semantics and fine details. The terrain type is predicted by a pre-trained MobileNet classifier fine-tuned on the DOTA images with ground-truth land cover labels. We use 2 categories: land and ocean, which are visually distinctive. This router requires only about 130KB of memory (approximately 2.4% of the full model's memory footprint), which is negligible.

We construct our geospatial embeddings by concatenating terrain type, land cover, and pre-processed POI data. Each geospatial embedding requires at most 32B of storage, resulting in a total database size under 100MB to cover the entire Earth. For single-orbit operations, this requirement decreases significantly to less than 100 KB. Given the inherent spatial locality of satellite imagery, our system retrieves 50 geospatial embeddings simultaneously. This efficient batching strategy means database access is required only once per minute, rendering the access time negligible in our overall processing pipeline. As for the complexity estimation model, we experimented with both a simple two-layer CNN and a color variation-based method. While both performed well, the latter proved significantly more efficient, leading us to adopt it as our default model.

The model is trained end-to-end with Adam optimizer at 1e-4 learning rate for 100 epochs. We use 0.1 weight decay and a cosine learning rate schedule with 5 epochs of warmup. The input size is 2048×2048 pixels, randomly cropped from the full images. The batch size is 8 per GPU (32 total) with synchronized BN. For augmentation, we apply HSV jittering, flipping, translation, and multi-scale training.

4.4 Baselines

We evaluate *SpaceExit* against four satellite image processing systems that represent the state-of-the-art system in OEC:

- BentPipe [11] implements the traditional ground-centric approach, where satellites downlink raw imagery to ground stations for processing. This system maximizes processing capability but is severely limited by communication bandwidth constraints.
- SpaceOnly [11] performs all object detection computations onboard using deployed neural networks, transmitting only the detection results to ground stations. While this minimizes bandwidth usage, it faces significant onboard computational resource constraints.
- Kodan [9] leverages specialized machine learning models selected based on prior knowledge about observation targets. This approach improves efficiency through targeted processing but is heavily dependent on the accuracy of prior information.
- TargetFuse [40] employs a combination of adaptive tiling, object clustering, and bandwidth-aware transmission scheduling to minimize detection errors under resource constraints. This hybrid approach balances onboard processing with efficient data transmission.

These baselines, ranging from fully ground-based to completely onboard processing, provide comprehensive reference points for evaluating *SpaceExit* 's performance.

4.5 Metrics

For detection performance, we adopt the standard MS COCO evaluation protocol, reporting mean Average Precision (mAP) at different Intersections over Union (IoU) thresholds. Specifically, we report the standard MS COCO metrics [24], including AP@IoU=0.5 and AP@IoU=0.5:0.95 for each category.

For efficiency, we measure the end-to-end processing time and total charge on the satellite system. This includes the time taken for taking photos, inference, and the communication of information from the satellite to the ground station. We use the total amount of information transmitted from the satellite to the ground station as the benchmark for evaluating the system's processing speed.

To evaluate the overall performance of our system, we use goodput which combines both accuracy and throughput. The goodput of a system is defined as the correct information produced per unit time. Goodput takes into account not only the amount of data processed but also the quality and relevance of the processed data, ensuring that our system meets the stringent requirements of satellite-based Earth observation.

5 Results Analysis

5.1 *SpaceExit* Consistently Outperforms SoTA OEC Systems

To compare the overall performance of *SpaceExit* with the existing systems, we systematically evaluated the system using three distinct hardware configurations: HW Set-1 (heterogeneous deployment with Jetson Xavier NX and Jetson Nano), HW Set-2 (homogeneous deployment with two Jetson Nanos), and HW Set-3 (high-performance setup with two Xavier NXs). Each configuration was tested under three network bandwidth conditions: 100Mbps, 50Mbps, and 10Mbps, providing insights into system behavior under varying resource constraints.

The results in Figure 5 reveal that *SpaceExit* consistently outperforms baseline approaches across all scenarios, with performance improvements varying based on hardware capabilities and network conditions. In the heterogeneous setup (HW Set-1), *SpaceExit* achieves remarkable improvements of 27.1%, 29.5%, and 29.4% for 100Mbps, 50Mbps, and 10Mbps bandwidths respectively. This demonstrates the system's ability to effectively leverage diverse computational resources. The performance gains are more modest in HW Set-2, ranging from 5.2% to 8.4%, indicating that computational constraints become a limiting factor when using lower-powered devices. However, HW Set-3 showcases *SpaceExit*'s full potential, with substantial improvements of 36.9-37.6%, highlighting the system's capability to efficiently utilize powerful computation resources.

The impact of network bandwidth on system performance presents interesting insights, particularly when examining BentPipe's behavior. Under high bandwidth conditions (100Mbps), BentPipe maintains competitive performance relative to other baselines, though still significantly below *SpaceExit*. However, its performance deteriorates dramatically under constrained bandwidth (10Mbps), achieving only approximately 5% normalized goodput. This stark contrast underscores the importance of bandwidth-aware design in distributed inference systems. *SpaceExit*, in contrast, maintains robust performance across all bandwidth conditions, demonstrating its resilience to network constraints.

Among the baseline approaches, Kodan emerges as the strongest competitor, particularly in computationally constrained scenarios like HW Set-2, where its lightweight detectors provide a strategic advantage. TargetFuse and SpaceOnly exhibit similar performance trajectories but consistently underperform compared to *SpaceExit*. The performance gap between *SpaceExit* and these baselines becomes particularly pronounced in scenarios with powerful hardware and adequate bandwidth, suggesting effective resource utilization by our proposed system.

To further analyze these methods, we measure the throughput as shown in Figure 6. Here, the Kodan outperforms other systems in most cases with the help of specialized light detectors. However, this may result in a significant performance drop when the prior knowledge is not accurate (the goodput of Kodan is lower as shown in Figure 5). What's more, as the computational capabilities of the devices increase, Kodan's advantage in throughput gradually diminishes. When using higher-performance hardware, specifically in the most powerful HW Set-3, Kodan is eventually surpassed by *SpaceExit*.

These results collectively demonstrate *SpaceExit*'s superior performance across diverse deployment scenarios. The system's ability to maintain significant improvements under various hardware configurations and network conditions validates its design principles and resource management strategies.

5.2 GCAD Enables Adaptive Computing

We evaluate the effectiveness of GCAD's adaptive processing capability by comparing its performance to that of static detectors on the DOTA test set. Our implementation is based on the YOLOv7 framework, where the static detector is configured with a fixed computational load of 3.4 GFLOPS, while GCAD adapts its computational load between 2.0 and 3.5 GFLOPS, depending on the complexity of the input image.

Figure 7 illustrates an example of how GCAD adapts its processing strategy based on image complexity. In Figure 7(a), we show a relatively simple scene containing well-separated ships on a uniform water background. For such images, GCAD successfully achieves early exit after the first

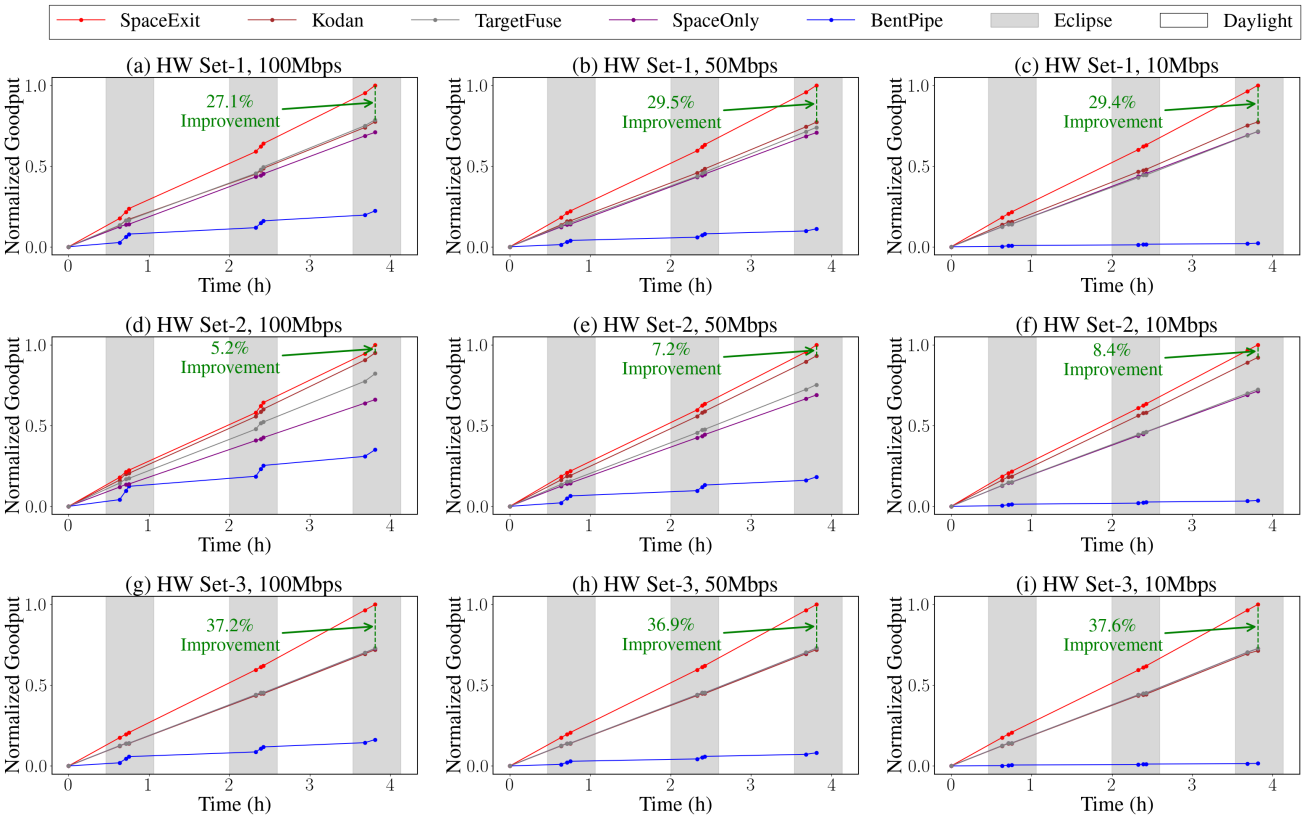

Figure 5: Performance comparison of *SpaceExit* against baselines across varied hardware configurations and network bandwidths.

backbone, maintaining detection accuracy while reducing computational cost by approximately 40%. In contrast, Figure 7(b) presents a complex urban scene with densely packed buildings and various objects at multiple scales. Here, GCAD correctly identifies the need for full processing through both backbones to maintain detection accuracy. This adaptive behavior demonstrates GCAD's ability to intelligently allocate computational resources based on scene complexity.

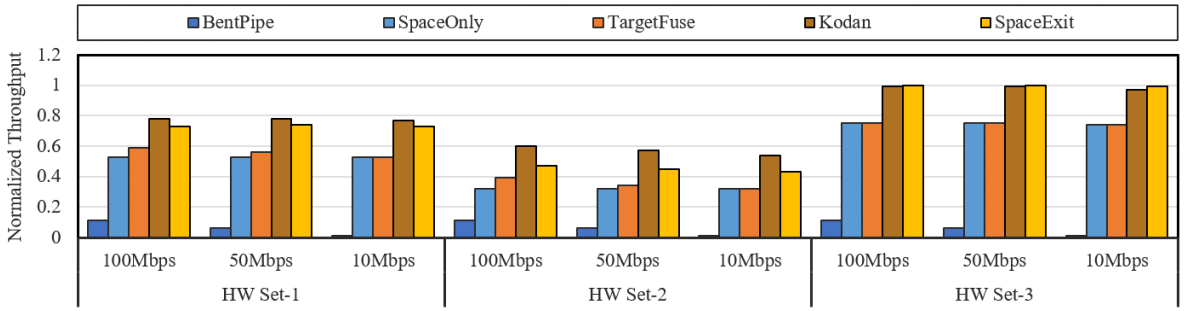
The quantitative results in Table 1 validate that our adaptive approach maintains or improves detection accuracy while reducing the average computational cost. The adaptive detector achieves an overall mAP@0.5 of 0.64 and mAP@0.5:0.95 of 0.404, outperforming the static detector's scores of 0.635 and 0.394, respectively. Performance improvements are particularly notable for challenging object categories - for instance, Bridge detection improves from 0.159 to 0.192 AP@0.5:0.95, and Road Aircraft (RA) detection shows a significant gain from 0.595 to 0.607 AP@0.5.

The class-wise analysis reveals that GCAD maintains robust performance across object categories with varying complexity. For simpler objects like planes and ships, which often appear against uniform backgrounds, the adaptive detector achieves comparable accuracy to the static detector while frequently enabling early exits. For complex categories like small vehicles (SV) and Harbor, where more detailed analysis is often necessary, GCAD appropriately opts for full processing to maintain accuracy. This balanced approach demonstrates that our adaptive detection strategy successfully adapts to both image-level and category-level complexity variations.

To further illustrate the performance of our adaptive model, we present a comparison between the static and adaptive models in terms of mean mAP across all categories, as well as mAP for selected object categories. Additionally, we show how the mAP of the adaptive model varies with computational load (measured in GFLOPS). Figure 8 illustrates the comparative performance of adaptive and static models. The plot depicts the mean mAP for adaptive models across all categories, as well as the mAP for specific categories such as Harbor, Large Vehicle (LV), and Roundabout (RA). The static models' mAP values are indicated by the triangular markers. This visualization underscores the adaptive model's ability to maintain high accuracy while adapting computational load based on image complexity.

5.3 CATS Improves Detection Throughput

To evaluate the effectiveness of CATS in improving system throughput, we conduct experiments comparing system per-



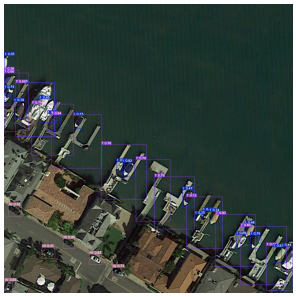


Figure 6: Normalized transmitted tile numbers of existing systems.

(b) Complex image that requires full execution.

Figure 7: Examples of images used to illustrate the effectiveness of the GCAD's early exit decision.

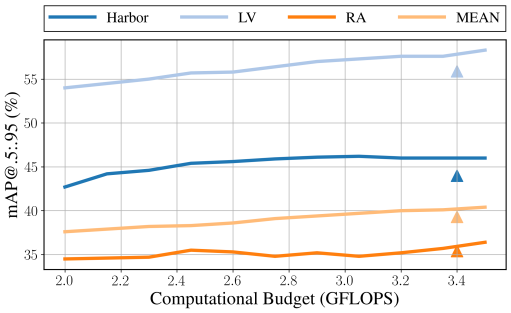

Figure 8: Comparison between GCAD (lines) and static detectors (triangles) on the DOTA test set across different computational budgets.

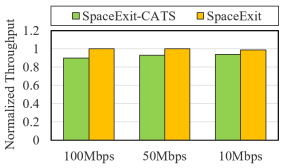

Figure 9: CATS improves the processing throughput.

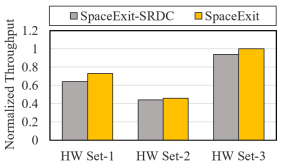

Figure 10: SRAC improves the processing throughput.

formance with and without our adaptive task scheduler. We test it with HW Set-1 under varying communication bandwidths to assess scheduler performance across diverse operational scenarios.

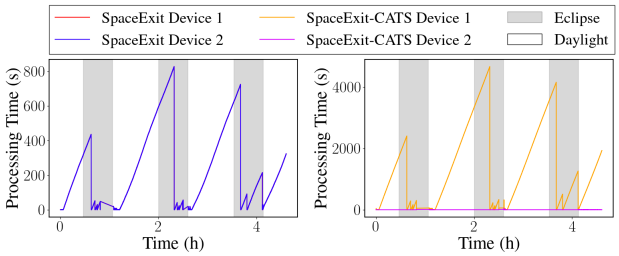

Figure 9 demonstrates that CATS significantly improves system throughput across all configurations. At 100 Mbps bandwidth, CATS achieves 11% improvement in throughput compared to the baseline without scheduling. This improvement is attributed to CATS's ability to effectively distribute workloads based on device capabilities and current utilization levels. The performance gain is particularly pronounced in the heterogeneous configuration, where intelligent task allocation can better leverage the complementary capabilities of different devices.

Figure 11 shows the estimated processing time for each device to complete all queued tasks at 100 Mbps bandwidth. With CATS, the processing time is balanced across devices, whereas without scheduling, the more powerful device finishes quickly, leaving the less powerful device with a backlog. From the data in the figure, the estimated processing time without scheduling is approximately five times higher than with scheduling. This imbalance highlights the inefficiency of not using CATS, as it leads to underutilization of the more capable device and overloading of the less capable one. Additionally, the figure shows a sharp decline in processing time at certain points, which corresponds to the moments when the satellite begins communication with the ground station. These moments act as deadlines for task processing, preventing storage from being overwhelmed by pending tasks.

These results demonstrate that CATS successfully addresses the challenge of efficient resource utilization in heterogeneous satellite computing environments. The scheduler's ability to maintain high throughput while reducing waiting times is particularly valuable for time-sensitive Earth observation applications, where processing delays can significantly impact the utility of collected data. The consistent performance improvements across different hardware configurations and bandwidth conditions underscore the robustness of our scheduling approach.

Table 1: Comparison of static method and GCAD.

Class	Static		GCAD	
	mAP@.5	mAP@.5:.95	mAP@.5	mAP@.5:.95
Plane	0.911	0.643	0.918	0.666
Ship	0.866	0.577	0.872	0.598
ST	0.732	0.427	0.764	0.464
BD	0.721	0.395	0.723	0.405
TC	0.937	0.831	0.932	0.833

5.4 SRAC Guarantees Safe Execution In Space

We evaluate SRAC's effectiveness in maintaining safe and efficient system operation across different hardware configurations under realistic space constraints. Using a bandwidth of 100 Mbps, we tested HW Set-1, HW Set-2 and HW Set-3. Our experiments demonstrate SRAC's ability to balance processing throughput with thermal and power constraints.

Figure 10 illustrates the normalized throughput across different hardware configurations, comparing performance with and without SRAC. With SRAC enabled, the system achieves consistently higher throughput while operating within safe thermal limits. This improvement stems from SRAC's ability to adaptively adjust workload distribution based on real-time temperature and power measurements.

The thermal management capabilities of SRAC are clearly demonstrated in Figure 12. With SRAC enabled (Figure 12 (a)), device temperatures are maintained below the critical threshold of 80°C through proactive DVFS adjustments. The temperature profile shows stable thermal management with minimal fluctuations, maintaining a consistent range within

(a) Temperature of computing devices with SRAC.
(b) Temperature of computing devices without SRAC.

Figure 12: Temperature profiles of computing devices with and without SRAC.

70-80°C during normal operation. In contrast, systems without SRAC (Figure 12 (b)) frequently experience temperature spikes above 80°C, triggering emergency thermal throttling that significantly impacts performance.

These results highlight the crucial role of SRAC in satellite operations, where thermal management directly impacts system reliability and longevity. The system's ability to proactively adjust processing loads and power states ensures consistent performance without compromising hardware safety, making it well-suited for the challenging thermal environment of space operations.

6 Related Work

6.1 Orbitital Edge Computing

Orbital Edge Computing (OEC) has emerged as a promising approach to address the growing challenges of Earth observation data processing and transmission [9, 11, 37, 39]. The foundational concept and architecture of OEC were introduced by Denby and Lucia, who demonstrated that processing remote sensing images onboard satellites can significantly alleviate the communication bottleneck between space and ground segments [11]. Subsequent research has expanded the scope of OEC, with numerous systems built to process Earth observation tasks [8, 9, 40]. For instance, Kodan maximizes the utility of saturated satellite downlinks while mitigating the computational bottleneck [9], while EagleEye proposes a mixed-resolution, leader-follower constellation design [8]. Recent proposals have even discussed the possibility of building microdatacenters with 4KW power in space [5], further expanding the potential capabilities of OEC.

While these OEC approaches have made significant progress in enabling onboard data processing and reducing transmission volumes, they generally rely on fixed processing pipelines or pre-defined decision criteria. This limits their adaptability to the diverse and dynamic EO tasks.

6.2 Resource Management in Satellite Systems

Resource management in satellite systems, particularly in OEC contexts, faces fundamental challenges in balancing limited bandwidth, computation, and energy resources [7, 12]. Research has explored various approaches to optimize computation offloading and resource allocation, including deep reinforcement learning and game theory [14,41]. Energy management remains critical for solar-powered satellite operations [42], with optimization frameworks employing techniques like mixed-integer programming to balance latency, energy consumption, and computational throughput [6].

Despite these advancements, current resource management strategies for satellite systems often lack close integration with the specific requirements of dynamic onboard image processing and object detection tasks.

6.3 Dynamic Neural Network Inference

Dynamic neural network inference has emerged as a promising approach to balance accuracy and efficiency in various applications [15, 18, 30, 31]. Early exit networks, which dynamically terminate inference at earlier layers, represent a significant advancement in this field [22]. Several methods have been proposed in this direction, including BranchyNet [32], SkipNet [36], MSDNet [21], LoRAExit [26] and MMexit [17]. These approaches typically add early exit points to neural networks, enabling dynamic inference times for classification tasks and reducing average computation time for easily classifiable inputs. Few works have extended dynamic inference to object detection. For instance, DynamicDet employs an adaptive router to analyze multi-scale information and automatically determine the inference route [25]. The computational efficiency of these methods has led to their adoption in resource-constrained environments [16, 19].

Despite these advancements, current dynamic inference methods primarily target classification tasks and general-purpose computing environments. They have yet to fully address the unique challenges posed by object detection in satellite imagery or the specific constraints of orbital edge computing systems.

7 Conclusion

In this paper, we presented *SpaceExit*, an integrated system that enables efficient adaptive Earth observation on satellites. By leveraging a novel multi-scale feature backbone with adaptive exiting, a unified adaptive scheduling framework, and a runtime resource management module, SpaceExit addresses the unique challenges of orbital edge computing. Our comprehensive evaluations across diverse satellite settings and hardware platforms demonstrate that SpaceExit significantly outperforms existing methods. By enabling adaptive, efficient onboard processing, SpaceExit paves the way for a new generation of autonomous and capable Earth observation satellites. It demonstrates the potential to maximize the value of limited downlink bandwidth, opening new possibilities for space-based data analytics and real-time global monitoring.

A Artifact Appendix

Abstract

This artifact provides the computational environment, codebase, datasets, and detailed instructions necessary to reproduce the key experimental results presented in the paper.

Scope

This artifact allows readers to validate the following core claims and results from the paper:

- **Simulation Results**: The performance metrics (goodput, processing time, temperature impact) of CATS and SRAC schedulers are presented in Figures 5, 11, 12. The data underlying the scheduler behavior visualizations in Figures 6, 9, 10.
- **Static and Dynamic Object Detection Accuracy**: The static and dynamic object detection accuracy results (mAP) are reported in Table 1 using YOLO and multi-exit detector implementations.
- **Accuracy-Computation Trade-off Analysis**: The accuracy-computation trade-off curve for the dynamic detector presented in Figure 8.

Contents

This artifact contains the following elements:

- **Environment Configuration:**
  - The `env.yml` file provides Conda environment specifications for dependency management.
  - Docker setup instructions are included for GPU-accelerated experiments.
- **Code & Scripts:**
  - Simulation Framework: The `simulator/` directory contains the complete implementation of CATS and SRAC scheduling algorithms, execution scripts, and Python visualization scripts for generating experimental figures.
  - Image Complexity Analysis: The `image_tiling/` directory provides the computational framework for calculating the image complexity metric.
  - Geospatial-Contextual Adaptive Detector: The `gcad/` directory implements the GCAD with subfolders for YOLO static experiments, multi-exit dynamic detector, and geospatial threshold tuning.
- **Dataset & Resources:**
  - Links to download required external datasets (DOTA, pre-generated simulator data).
  - Pre-trained model weights for YOLO and multi-exit detectors.
  - Pre-aggregated results file for Figure 8.

Hosting

The artifact is hosted on GitHub: https://github.com/zhuxz0299/ATC-artifact-submission. Datasets are available via Google Drive links in the README.

Requirements

We developed and tested the artifact with the following specifications:

- **Software Dependencies**: Docker, Python 3.8+, CUDA-capable GPU drivers
- **Hardware Requirements**: NVIDIA GPU with CUDA support (tested on RTX 4090), Multi-core CPU (tested on Intel Xeon Platinum 8336C @ 2.30GHz)
- **Operating System**: Linux distribution (tested on Ubuntu 20.04)

A.1 Installation

Python Environment (Conda)

1. Create Conda environment: `conda env create -f env.yml`
2. Activate environment: `conda activate <env_name>`

Docker Environment (GPU required)

1. Pull base image:

```
docker pull nvcr.io/nvidia/pytorch:21.08-py3
```

2. Create and run container:

```
docker run --gpus all -it -v ./gcad:/GCAD \
--shm-size=64g --name atc_artifact \
nvcr.io/nvidia/pytorch:21.08-py3
```

3. Install dependencies inside container:

```
apt update && apt install -y zip libgl1-mesa-glx
pip install seaborn thop
```

XRT: An Accelerator-Aware Runtime for Accelerated Chip Multiprocessors

Neel Patel
Cornell University
Ithaca, NY, USA

Mohammad Alian
Cornell University
Ithaca, NY, USA

Abstract

Datacenter applications spend a considerable portion of compute resources executing common functions. This has led to the deployment of accelerators capable of executing these functions with higher performance and energy efficiency. At the same time, datacenter applications require microsecond-scale response times and low tail latency. To meet these strict requirements, recent Chip Multi-Processors (CMPs) incorporate several on-chip accelerators. This enables fast communication between the general-purpose cores, direct accelerator access to the on-chip memory subsystem, and scalable sharing of accelerator resources across applications running on many general-purpose cores. Despite hardware support for on-chip accelerators, a lack of support at the runtime level prevents their efficient use at scale.

Our key insight in this work is that current runtimes are unsuitable for applications that make heavy use of on-chip accelerators, yielding suboptimal throughput–sometimes even worse than a system without accelerators. To address this problem, we develop XRT, a runtime for accelerated CMPs designed to scale to many-core, many-accelerator CPUs. Across a set of representative services, XRT achieves up to 3.2× higher throughput-under-SLO compared to an unoptimized runtime and never experiences slowdowns compared to a system that executes all request processing on general-purpose cores.

1 Introduction

The integration of accelerators onto server processors, positioned near general-purpose cores, represents a significant advancement in datacenter computing [20, 34, 39, 40, 48]. We refer to these server processors as Accelerated Chip Multi-Processors (XMPs). The accelerators on XMPs are designed to efficiently execute fixed-function kernels, offering the potential for substantial performance improvements and energy savings. As XMPs enter the datacenter [6, 8], it becomes increasingly important to increase accelerator utilization so their performance efficiency and application-level throughput benefits can be realized at scale.

State-of-the-art runtimes can meet the strict tail-latency Service-Level Objectives (SLOs) expected of datacenter applications [25, 29, 30, 36, 41], but they do not consider accelerators. These runtimes instead assume the entire end-to-end execution of a request takes place on a general-purpose core. With the current runtimes, there is no guarantee that application throughput increases when requests offload to accelerators. Our results show that, without a specialized runtime for XMPs, offloading to an accelerator can result in worse performance than performing all processing on the cores.

To enumerate the challenges with adapting existing CMP runtimes for XMPs, we perform a design space exploration of prevailing CMP runtime architectures which yields three insights. First, we find that a centralized scheduler–similar to the one used in state-of-the-art runtimes like Concord [29]–quickly becomes the bottleneck on an XMP–as it is tasked with both managing accelerator notifications and load balancing requests to the worker cores. Second, we observe that even a runtime like Tiny Quanta [36]–which implements a scalable two-level scheduling policy–incurs unnecessary context switches as the scheduler resumes threads that are still waiting on an offload to complete. Last, we find that, on an XMP, both cores and accelerators can become the system bottleneck. Since an accelerator must be invoked by a core, a contended accelerator can stall a core when offloading a function, reducing system throughput.

To address these challenges, we develop a scalable system architecture that divides the work of managing accelerator notifications across the many cores in the system. XRT mitigates stalls in request processing when accelerators are contended through the use of an efficient software fallback mechanism. XRT also implements an accelerator-aware request scheduler, which eliminates unnecessary context switches by only resuming threads whose offloads are guaranteed to be complete. Across a set of representative services, our design achieves up to 3.2× higher throughput under SLO than state-of-the-art CMP runtimes, up to 32× higher throughput than an unaccelerated system, and never experiences slowdowns compared

to a system without accelerators.

2 Background

The State of On-Chip Acceleration on Server CMPs. Today's commodity server processors integrate a multitude of accelerators for datacenter taxes and key functions like (de)compression, de/encryption, database queries, data movement, and AI workloads [20, 22, 23, 39, 40]. Large-scale fleet studies show these taxes consume a measurable share of CPU cycles, energy, and infrastructure spending, making it lucrative to move them from the cores to the more efficient accelerators [31, 32, 49]. Software support for accelerators comes in the form of vendor-provided libraries that expose APIs for programmers to invoke an accelerator's functionality. In many cases, these libraries implement the same APIs as the functions that run on the general-purpose core, enabling applications to integrate accelerators without any changes to the source code [5, 16, 44, 53]. Intel Xeon 4th and 5th generation XMPs offer SKUs with four different accelerators–the Data Streaming Accelerator (DSA), the In-Memory Analytics Accelerator (IAA), QuickAssist Technology (QAT), and the Dynamic Load Balancer (DLB) [54]. IAA targets analytics primitives, compression, and checksum operations, while DSA targets data movement and transformation. QAT also provides compression support as well as cryptography capabilities. DLB accelerates communication between cores using hardware-managed queues.

Hardware support has been introduced into Intel XMPs to reduce communication and data movement overheads between the cores and accelerators. To reduce memory access overheads, XMPs implement shared virtual memory (SVM) and device-side translation lookaside buffers, enabling accelerators to efficiently access a process's address space using the same virtual addresses as the core. To enable efficient sharing of accelerators between multiple cores, accelerators implement shared work queues, which are device-side hardware queues that contain in-flight offloads submitted from multiple processes. Shared work queues are useful in multi-tenant settings since they enable cores to enqueue offload descriptors (that include operations such as memcpy, decompress, etc.) to an accelerator using specialized instructions that return a "success" or "retry" status. A "retry" lets the core know that its submission failed due to insufficient work queue capacity or other errors [7].

A low overhead interface minimizes the *offload tax*, which is an overhead paid by the core when it submits an offload to an accelerator and when it checks for a notification that the offload has been completed. This enables even microsecond-scale requests to benefit from the increased performance efficiency provided by accelerators [54]. On an XMP, the end-to-end execution of a request can look like any of the three modes of execution shown in Figure 1: NoAcceleration, Block&Wait, and Yield. NoAcceleration does not utilize the available accelerators on the XMP, executing all functions on the core. As explained previously, on state-of-the-art XMPs, it is possible to run some functions on one of the available accelerators. We use the term Accelerable function to refer to any function which can be run on either an accelerator or a core. Block&Wait seeks to improve on the NoAcceleration mode by offloading an Accelerable Function to a specialized accelerator, however it leaves the core underutilized. Yield makes use of the wasted core cycles left behind by Block&Wait, using them to execute a Filler function, which can be a function from another request (Pre- or Post-Processing Function in Figure 1) or an entirely different application.

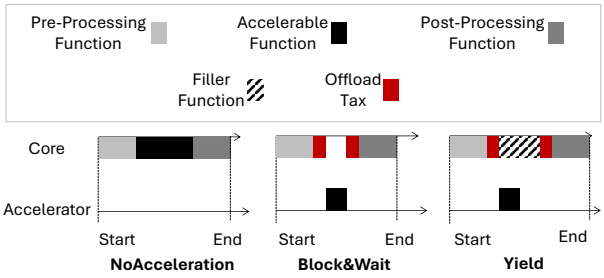

Figure 1: XMPs enable offloading Accelerable Functions to specialized accelerators. A Yielding mode of execution can make use of Blocking stalls when the core would otherwise be waiting for offload completion.

Current CMP Runtimes. State-of-the-art runtimes consider homogeneous CMPs, composed entirely of cores, and develop load balancing and scheduling policies to meet the SLOs of production workloads [25, 29, 30, 36]. These runtime systems use a dedicated thread, called the *dispatcher*, that runs on a single core and polls the NIC for incoming requests and enqueues them to a set of *worker* threads running on other cores. The workers are responsible for executing the requests [29, 30, 36].

A runtime system has two roles: (1) load balancing requests across the processing elements in the system and (2) scheduling the requests–choosing the request that executes next. State-of-the-art CMP runtimes fall into two categories: (1) *Dispatcher-Centric* where the dispatcher performs both load-balancing and request scheduling [29] and (2) *Worker-Centric*, which uses a two-level scheduling policy in which the dispatcher only distributes requests while each worker's local scheduler determines the execution order of its own requests [36]. Recent work has identified that more complex scheduling policies, like processor sharing [33], require a worker-centric, two-level scheduling policy–where the tasks of load-balancing and scheduling requests are divided between the dispatcher and workers–if they are to remain scalable to many-core systems [36]. In the era of XMPs, where even more intricate scheduling policies are needed to schedule functions on both cores and accelerators, this division of responsibilities becomes critical. A required feature of two-

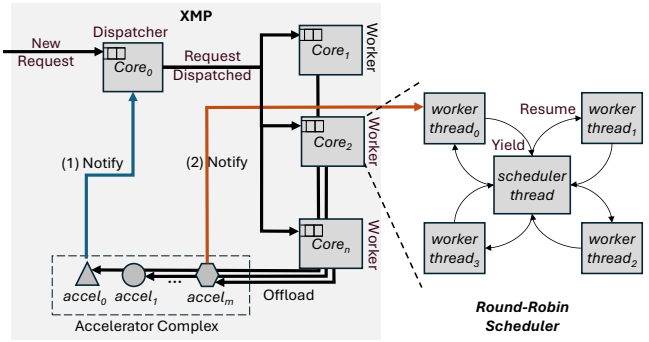

Figure 2: Integration of accelerators into existing CMP runtimes. In a Dispatcher-Centric system (Path 1), accelerator notifications are handled by the centralized dispatcher thread. In a Worker-Centric system (Path 2), notifications are handled by the core's local worker threads.

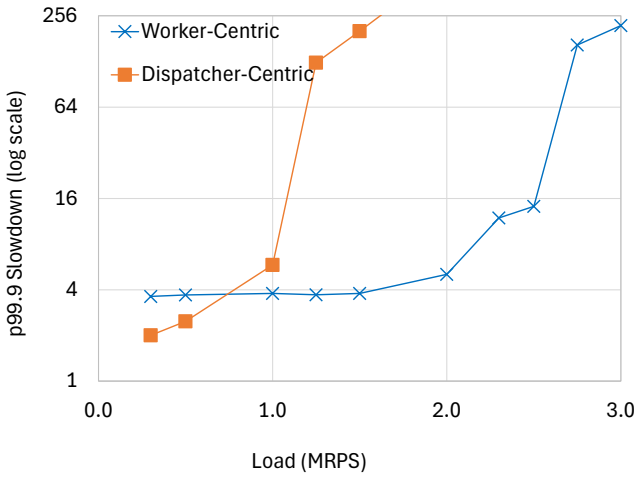

Figure 3: Comparison between Worker-Centric and Dispatcher-Centric runtime executing DDH workload on an XMP.

level scheduling policies is a userspace thread abstraction to enable worker cores to quickly context switch between different requests.

TinyQuanta [36]–which is the state-of-the-art Worker-Centric runtime–implements a shallow local queue per worker core that contains four outstanding requests, each represented by a userspace thread implemented using Boost coroutines [4]. TinyQuanta also maintains a fifth userspace thread context per worker core that implements the scheduling functionality of the runtime. The per-worker-core *scheduler thread* approximates processor sharing by cycling through its local queue in round-robin order, scheduling a thread that has either cooperatively yielded or is waiting to be scheduled for the first time.

3 A Runtime for XMPs

In this section, we search the space of CMP runtimes for a scalable system architecture suitable for XMPs. We start by integrating accelerator support into the two prevailing system architectures explained in Section 2, Worker-Centric and Dispatcher-Centric. Dispatcher-Centric can be advantageous since it has global visibility when making scheduling decisions, but complex scheduling algorithms, such as processor sharing, and notification signals from many accelerators can make the dispatcher a bottleneck. Worker-Centric removes the burden of scheduling from the dispatcher, but can only schedule a subset of the requests–those it has been given by the dispatcher. It is not abundantly clear which design better fits XMPs. To evaluate the tradeoffs of both designs, we develop runtimes that follow both approaches, adding support to enable applications to offload Accelerable Functions to accelerators.

We extend the centralized dispatcher in the baseline Dispatcher-Centric runtime to collect accelerator notifications (Path 1 in Figure 2). To enable a Worker-Centric runtime with accelerator support (Path 2 in Figure 2), we extend TinyQuanta [36]. This baseline Worker-Centric XMP runtime implements the Yield mode of execution by switching the worker core's context to the scheduler thread every time a thread yields. A thread yields after an offload, request completion, or failed polling of the accelerator. In this implementation, the thread context that performs an offload is responsible for polling the accelerator for completion. The polling is transparent to the scheduler thread, and the scheduler thread does not know whether a worker thread is going to begin executing a Pre-Processing or Post-Processing Function, or is polling for the completion of an Accelerable Function.

We compare the performance of the two runtime systems processing requests for an in-memory data stream processing workload (DDH in Table 1). Specifically, we evaluate the 99.9th percentile *slowdown* in request processing at different load levels. *Slowdown* at a given load is defined as the request processing latency normalized to the execution time in the Block&Wait mode. See Section 6 for more details on our methodology. Figure 3 shows that a Worker-Centric system avoids violating a 50× 99.9th percentile request slowdown SLO for this service up to approximately 2.5 MRPS, whereas the Dispatcher-Centric system only reaches around 1.0 MRPS. Our results indicate that the added burden of handling accelerator notifications at the dispatcher imposes a significant system throughput overhead. This highlights a fundamental limitation of Dispatcher-Centric in supporting XMPs, and thus we implement XRT as a Worker-Centric runtime.

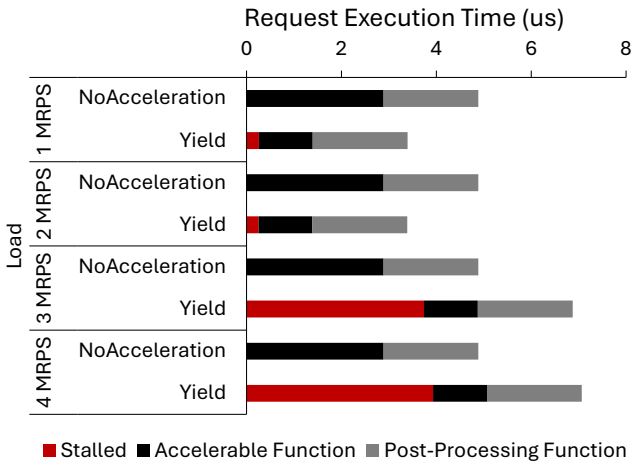

Figure 4: End-to-end breakdown of request execution time for a workload executing a memcpy Accelerable Function followed by a Post-Processing Function using the NoAcceleration and Yield modes of execution. "Stalled" is the time that a core waits for a full accelerator to become available.

4 Motivation

Despite demonstrating the potential of using Worker-Centric principles to develop a scalable runtime for XMPs, we identify two limitations in this baseline Worker-Centric runtimes:

Unnecessary Resumption Overhead. We find that a naive scheduler–unaware of requests' in-flight offloads–is unable to efficiently resume requests once their respective offloads are complete. Under the Yield mode of execution, worker threads relinquish the core to the scheduler after offloading. To complete request processing, the scheduler must later resume the offloading thread. The Worker-Centric runtime handles this by iterating through each busy worker thread in a round-robin manner, giving each thread a chance to complete any remaining Post-Processing Function after its offload has finished on an accelerator. However, this approach provides no guarantee that a worker thread's offload is complete when the scheduler resumes it. This leads to unnecessary resumptions, where the thread is woken up only to find that the offload is still in progress, causing it to yield the core back to the scheduler. In the experiment presented in Figure 3, each request experiences, on average, 21 unnecessary resumptions–indicating a substantial context-switching overhead. While the overhead of a single context switch is only ∼30 cycles, these wasted cycles accumulate. For the `DDH` workload, which has an unloaded per request latency of approximately 4μs with the Block&Wait mode of execution, unnecessary resumptions account for 13% of each request's end-to-end execution time.

Stalls on Contended Accelerators. Under the Yield mode of execution, an accelerator can become highly utilized as worker threads submit offloads and yield the core. This allows a single worker core to maintain multiple offloads in flight simultaneously. In contrast, under the Block&Wait mode of execution–where control is not yielded to the scheduler after offloading–the number of concurrent offloads is limited by the number of cores in the system (26 on our testbed system; see Section 6). Depending on the workload and request arrival rate, the accelerator's queue can become full as hundreds of worker threads issue concurrent offload requests. This results in threads stalling at offload time, as the accelerator is unable to accept additional requests.

To quantify the execution time spent stalling during an offload to a saturated accelerator, we run a synthetic workload that executes a memcpy function (i.e., Accelerable Function) followed by a Post-Processing Function that spins for 2μs. Figure 4 shows the breakdown of end-to-end request execution time as the server load increases under both Yield and NoAcceleration modes. As load increases toward the system's maximum sustainable throughput, request execution time in the Yield mode grows, eventually surpassing that of the NoAcceleration mode after reaching 3 MRPS. At high loads–where accelerator contention causes cores to spend a majority of their time stalled on a full accelerator–it becomes preferable to execute the Accelerable Function directly on the core rather than offloading it to the accelerator.

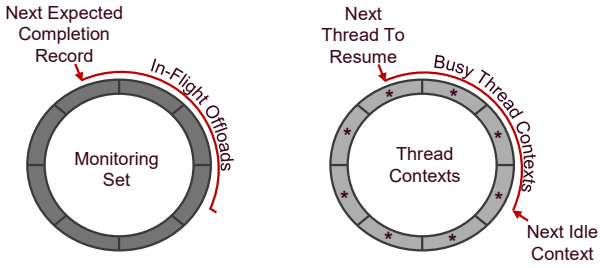

Figure 5: Ring buffers maintained by a worker core's scheduler thread. The scheduler periodically polls the `Next Expected Completion Record` to check for completion of an accelerator-offloaded function. If the *completion record* is set by the accelerator, the `Next Thread To Resume` is ready to run on the core.

5 XRT: An Optimized Runtime for XMPs

We develop **X**MP **R**un**T**ime (XRT) to address the limitations of the naive Worker-Centric runtime discussed in Section 3. Similar to TinyQuanta [36], XRT's two-level scheduling policy designates a single dispatcher core as the request load balancer and delegates request scheduling to the worker cores. At the dispatcher, XRT employs Join-the-Shortest-Queue (JSQ) load balancing, which has been shown to achieve near-optimal load distribution [45]. XRT maintains a shallow queue at each worker, eliminating the overhead incurred when worker cores poll an empty queue [29].

XRT mitigates unnecessary resumption overhead and reduces stalled core cycles on contended accelerators through a notification-aware scheduler and a software fallback mechanism.

5.1 Notification-Aware Scheduler

To avoid unnecessary request resumptions and the associated context-switching overhead, we design the worker's scheduler around the accelerator notification mechanism. The scheduler thread uses two ring buffers, shown in Figure 5, to track the state of pending offloads and manage the contexts of busy and idle userspace work threads.

The *Monitoring Set* ring buffer is an array of cacheline-sized *completion records*–simple data structures used by accelerators to notify the worker core when an offload is complete. Intel's accelerator interface implementation [52] includes a field in the offload descriptor specifying the address where the completion record should be written by the accelerator upon offload completion. XRT leverages this capability to populate the *Monitoring Set* ring buffer.

The *Thread Contexts* ring buffer is an array of pointers to worker thread contexts. The scheduler maintains a logical mapping between completion records and thread contexts, allowing it to promptly wake the correct idle thread once its offload completes.

By exploiting the fact that accelerators process offloads in a first-come, first-served order, the scheduler only needs to poll the completion record corresponding to the next expected offload completion.

XRT's notification-aware scheduler addresses unnecessary resumption overhead by allowing the scheduler to directly check the status of the next expected completion record in the L1 cache–within 2–3 cycles–compared to the baseline, where the scheduler context-switches to the worker thread and incurs approximately 30 cycles before determining that the offload has not yet completed.

5.2 Software Fallback

We leverage instruction set extensions on Intel XMPs [28] to implement a simple offload decision-making procedure. When attempting to offload an Accelerable Function, the worker core uses the ENQCMD instruction [7] to write an offload request descriptor to a memory-mapped register on the accelerator. In addition to performing a write-combined, uncacheable store operation, ENQCMD also returns a status indicating whether the offload was accepted by the accelerator. Rather than stalling on a full accelerator, XRT falls back to a core-executed software implementation of the Accelerable Function. This avoids wasting core cycles on repeated offload attempts.

5.3 Putting It All Together

Figure 6 shows the design of XRT. To illustrate its operation, we walk through the lifetime of a single request executed using XRT. For simplicity, we consider a three-phase application with a single Accelerable Function, similar to those shown in Figure 1.

A request is first received and parsed by the Dispatcher. The Dispatcher identifies the worker with the shortest queue of pending requests using a priority-queue-based implementation of the JSQ algorithm, which uses counters to track the number of enqueued requests at each worker. The request is then enqueued to the core of the worker with the fewest pending requests.

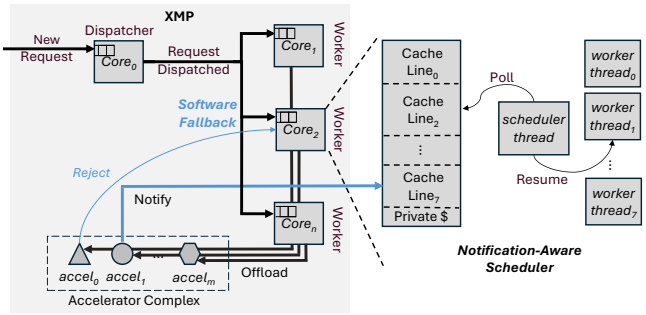

Figure 6: XRT uses a scalable two-level scheduling policy that features a notification-aware scheduler and a software fallback mechanism.

When the request reaches the head of the worker's queue, the scheduler thread assigns it to an idle thread and performs a context switch into that thread. The Pre-Processing Function then begins execution on the worker core. After the Pre-Processing Function completes, the worker attempts to offload the Accelerable Function to an accelerator. As described in Section 5.2, the worker makes a single offload attempt and falls back to a software implementation if the offload is unsuccessful.

If the offload is successful, the thread yields the core, allowing the worker to process other requests. Between request executions, the worker periodically polls the monitoring set for notifications from the accelerator. Upon receiving a notification, the worker resumes the corresponding ready-to-run thread, which is now guaranteed to have completed its offload. The thread then executes its Post-Processing Function, completing the request.

6 Methodology

Runtime Configurations. We compare the following runtime configurations: one that makes no use of accelerators (NoAcceleration); traditional block and wait runtime (Block&Wait); the naive XMP runtime presented in Section 3, which employs a round-robin scheduling policy to cyclically context-switch between threads that have yielded the core after offloading (RR-Worker); and XRT, which incorporates the optimizations described in Section 5.

Workloads. We develop the five representative workloads presented in Table 1. We select the combination of workloads to capture different computational intensities, access patterns, and use cases for the DSA and IAA accelerators on 4th and 5th generation Intel Xeon CPUs. Except for `DC` and `MC`, each workload follows the three-phase execution model illustrated in Figure 1. A request executes three functions: a Pre-Processing Function, an Accelerable Function, and a Post-Processing Function. The Pre-Processing Function and

Post-Processing Function always execute on a core, while the Accelerable Function can either run on a core or be offloaded to an accelerator. DC and MC do not have a Pre-Processing Function, modeling workloads where the request performs no core preprocessing and executes the Accelerable Function immediately. A request's response time is dependent on the input data size. Similar to prior work, we use an exponential service time distribution to represent μs-scale workloads with a light tail [29, 30, 36, 43] and choose the average input data size to match the respective workload [15, 27, 49–51].

Testbed. We run experiments on a 5th generation Intel Xeon 8571N CPU with four IAA and four DSA accelerators. We enable process address space identifiers (PASID), SVM, and configure accelerators with shared work queues using the accel-config library [17]. By configuring the accelerators with shared work queues, multiple cores can simultaneously submit offloads to the same accelerator, and receive notification of a failed offload attempt using the ENQCMD instruction [52], as explained in Section 5.2. Our testbed's CPU has two NUMA nodes. One NUMA node is configured to be the load generator, and the other is the server node. We have the load generator send requests according to a Poisson process to emulate bursty production traffic [29, 43].

In all experiments, all 26 cores are utilized–one for the dispatcher and the remaining as workers. Depending on the workload, worker threads offload to the two DSA or two IAA accelerators on the server node. Each accelerator is configured with a single shared work queue.

Metrics. The workloads under evaluation have very different latencies, so we report a single metric: 99.9th percentile slowdown, similar to prior work [29]. To calculate the slowdown of a request, the end-to-end request latency, including system overheads such as request dequeue and enqueue operations, is divided by the execution time of an uninterrupted, accelerated request running using the Block&Wait mode of execution.

7 Evaluation

In this section, we seek to evaluate XRT's performance on the workloads presented in Table 1. We compare against runtimes that have not been specialized for on-chip accelerators to show how XRT's optimizations improve performance.

For both workloads that use decompression (DDH and DC), NoAcceleration is outperformed by all other systems. The compute-intensive decompression function running on a core causes slowdowns even at low load levels. Despite most of the performance improvement coming from offloading decompression to the accelerator, XRT still outperforms RR-Worker on DDH and DC. Both XRT and RR-Worker outperform Block&Wait since they yield the core after submitting an offload to an accelerator, enabling higher core utilization.

Both workloads that perform memory copies only benefit from offloading when executing under the XRT runtime. Block&Wait cannot outperform NoAcceleration on DMD or MC because using an accelerator to perform memcpy of data held in a worker core's private caches actually takes longer than executing the memcpy on the core. RR-Worker succumbs to the throughput overheads that come with blocking on an accelerator, mentioned in Section 4. Since DMD and MC are accelerator-bound workloads, the accelerator becomes the bottleneck. We observe that, at high load, requests executing under the RR-Worker scheduler are slowed by 14% on MC and 188% on DMD, due to blocking on a full accelerator. Without a software-fallback mechanism, like the one implemented by XRT, both Block&Wait and RR-Worker suffer from the throughput overheads associated with blocking on an accelerator. RR-Worker outperforms Block&Wait due to the higher core utilization enabled by the Yield mode of execution, but it still suffers from overheads from unnecessary resumptions.

The only workloads in which XRT's tail latency improvements are negligible are MMP and UFH. This is because MMP is dominated by a lengthy Pre-Processing Function, which consumes 99.6% of the end-to-end execution time. Any overheads in the scheduler and offload mechanism are dwarfed by the long-running matrix-multiply which executes on the core, causing all systems to get similar performance. UFH also shows the same performance across the board since its Pre-Processing Function and Post-Processing Function make up the bulk of the execution time.

Workload				Description
ID	Pre-Processing	Accelerable	Post-Processing	
DDH	**D**eserialize	**D**ecompress	**H**ash	Representative of message processing in distributed streaming platforms [1, 2]. (De)serializes data structures [10], (de)compresses [42] to save network bandwidth, and applies a hashing algorithm [19, 37] to route between servers.
DC	—	**D**ecompress	**C**hase	Representative of data-intensive workloads like databases [26], key-value stores [27], and graph processing applications [47] which perform pointer chasing.
MC	—	**M**emcpy	**C**hase	Similar to DC but operates on uncompressed data.
MMP	**M**atMul	**M**emfill	**P**CA	Performs Principal Component Analysis (PCA) [51] after matrix multiplication and zeroing out half of the matrix. Representative of data analysis and preprocessing applications [46].
UFH	**U**pdate	**F**ilter	**H**istogram	Updates a table, extracts a subset of its entries, and constructs a histogram. Representative of data analytics workloads.
DMD	**D**ecrypt	**M**emcpy	**D**otProduct	Representative of similarity scoring services used for content recommendation [49, 50].

Table 1: List of workloads.

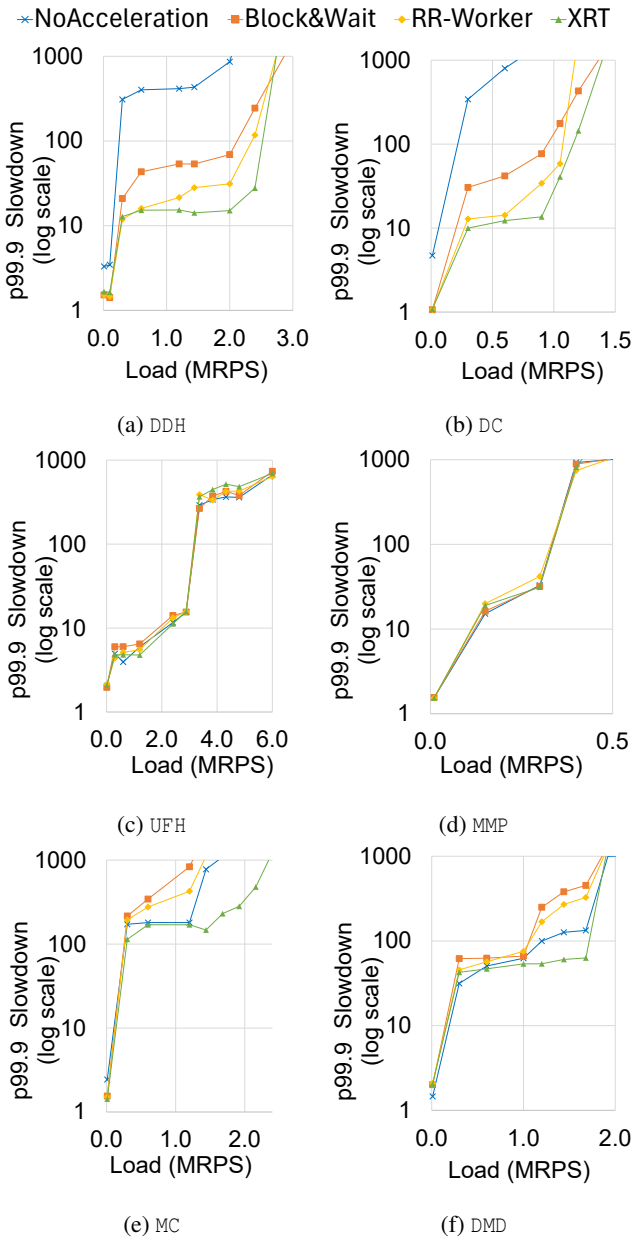

Figure 7: Performance comparison of workloads executing with different runtime configurations.

8 Discussion

Hardware Support for XRT. XRT relies on SVM to implement its notification-aware scheduler. Intel, AMD, and ARM already support SVM [12, 14, 52] and, given the support from vendors and industry standards [9, 13, 24, 38], future XMPs will likely support SVM. XRT also relies on instruction set extensions to implement software fallback. In our implementation, the ENQCMD [7] instruction from Intel's accelerator interface implementation [52] is used, but similar primitives, like RISC-V's Atomic IO Enqueue [11] and ARM's ST64BV [3], have been integrated on other architectures. These instructions would serve as drop-in replacements for ENQCMD when deploying XRT on other architectures.

Programming and Deployment XRT improves programmer productivity by enabling programmers to focus on application development rather than accelerator management and scheduling. Programmers write sequential programs using synchronous APIs [21], while XRT transparently handles scheduling decisions and accelerator management. XRT can be readily implemented in private clouds where the service provider has control over the entire hardware and software stack. Public cloud deployment is challenged by the fact that XRT is a single address space, userspace runtime, making it unsuitable to run mutually untrusted applications from multiple tenants. This could be addressed using userspace process abstractions which enforce isolation [35].

9 Conclusion

In this work, we demonstrated that existing runtime systems–originally designed for CMPs–are suboptimal for XMPs. We introduced XRT, a runtime system that efficiently integrates on-chip accelerators to support accelerable datacenter applications. XRT employs a scalable two-level scheduling policy to prevent the dispatcher thread from becoming a bottleneck. Additionally, it incorporates two key mechanisms–a notification-aware scheduler and a software fallback mechanism–to mitigate unnecessary resumption overhead and stalls on contended accelerators when worker threads offload parts of request processing to on-chip accelerators. We evaluated XRT using six representative accelerable workloads that utilize four distinct functions offered by accelerators on an Intel 5th Generation Xeon CPU. Across all workloads, XRT matches or outperforms an unaccelerated system and achieves up to 3.2× higher throughput compared to a runtime system without accelerator-specific optimizations. XRT represents an early but significant step toward enabling microsecond-scale accelerator offloads in future highly heterogeneous systems at scale.

Acknowledgments

This work was supported in part by NSF award 2239020 and by ACE one of the seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program sponsored by DARPA. A Artifact Appendix

Abstract

This appendix describes the hardware and software needed to build and run XRT.

Hosting

XRT is hosted on GitHub.

Requirements

Tested on Intel Xeon 8571N CPU with two IAA and two DSA accelerators on Ubuntu 24.04. Our implementation of XRT uses the idxd-config [17] library version 4.1.6 to map IAA/DSA work queues into userspace. For enc/decryption, we use the ipp-crypto library version 2021.6 [18] for enc/decryption. For (de)serialization, we use protobuf version 28 [10]. The Principal Component Analysis, Matrix Multiply, and histogram kernels were taken from the pheonix benchmark suite [51]. All of these dependencies are built automatically using the convenience build script in the repository.

Abstract

Shuffle is a crucial operation in distributed data processing, responsible for transferring intermediate data between nodes. However, it is highly resource-intensive, consuming significant CPU power and often becoming a major performance bottleneck, particularly in data analysis tasks involving large datasets.

In this paper, we introduce DShuffle, an efficient framework that leverages DPUs to offload and accelerate shuffle operations. The DPU, with its specialized compute and I/O hardware, is ideally suited for offloading on-path shuffle tasks. However, its complex architecture requires careful design for effective offloading. To fully harness the DPU's capabilities, DShuffle divides the shuffle process into three stages: serialization, preprocessing, and I/O, and organizes them in a pipelined manner for efficient execution on the DPU. By leveraging high-concurrency memory access units to accelerate the serialization phase and using the DPU to directly write intermediate data to disk, DShuffle effectively accelerates the shuffle process and eliminates unnecessary data copies. Our experiments on a real DPU platform with industrial-grade Spark demonstrate that DShuffle enhances both host CPU and I/O efficiency and effectively reduce Spark task completion times.

1 Introduction

Distributed data processing frameworks, such as Hadoop [11] and Spark [47], have been widely used in large-scale data analytics over the past decade, including real-time analysis [3], machine learning [33], and data mining [4]. These frameworks enable parallel computation by distributing data across multiple nodes, effectively addressing the challenge of processing massive datasets that cannot be handled by single-node systems. At the same time, distributed data processing frameworks offer high scalability, allowing for the flexible addition of computational resources to accommodate the growing volume of data and increasing computational complexity.

Data shuffling is a fundamental component of these distributed data processing frameworks, responsible for exchanging intermediate data between nodes. Shuffling is a data-intensive operation involving complex preprocessing, serialization, network, and storage I/O operations. These operations consume significant CPU and memory resources on the host and can interfere with foreground computations, often becoming a performance bottleneck for the entire data analysis task. For example, in the commonly used sort workload, shuffle operations can account for up to 70% of the total execution time, with most of that time spent on serialization and memory garbage collection. As a result, many efforts have been made to optimize the shuffle process, from both software [9, 25, 30, 39, 41] and hardware [22, 28] perspectives.

DPU [2, 5, 7, 21, 31] is a new type of infrastructure widely deployed in cloud data centers [10, 15, 27]. Built on traditional NIC, DPUs are equipped with additional computing and memory units, which can be used to offload and accelerate host workloads, thereby providing opportunities to reduce shuffle overhead. In fact, the shuffle operation aligns well with the hardware features of the DPU. First, DPUs are accelerators situated in the data path, making them a natural fit for handling I/O-intensive data exchange operations. Second, DPUs include general-purpose computational cores that can be used to offload operations such as partitioning, aggregation, and sorting in the shuffle process. Finally, DPUs are equipped with highly concurrent memory access units (e.g., DPA) that can efficiently access host memory via load/store instructions, which offers an opportunity to significantly accelerate the serialization computation. By offloading the shuffle operation to the DPU, we can reduce the consumption of CPU and memory resources on the host, allowing the CPU to focus on higher-level application logic, thereby improving the overall efficiency of the cluster.

However, offloading shuffle to the DPU poses challenges. First, the number of general-purpose computational cores on

*Equal Contribution
†Corresponding Author

the DPU is limited, and their frequency is lower than that of host cores. As a result, simply offloading the entire shuffle operation to the DPU may not yield performance benefits and could even slow down the overall task execution. Second, the DPU's onboard memory capacity is limited, and when the intermediate data generated by host computation exceeds the DPU's memory capacity, the system must wait for the DPU to free up memory before continuing, which can lead to computation stalls.

To address these challenges, we propose DShuffle, a DPU-optimized shuffle framework. DShuffle decomposes the shuffle operation into three steps—serialization, computation, and I/O, and introduces three novel techniques to enhance the efficiency of shuffle operations on the DPU. (1) A DPA-accelerated serializer, which uses the multiple hardware threads to concurrently perform the serialization process, reducing CPU consumption and memory interference on the host. (2) A fine-grained pipeline shuffle strategy, which organizes different shuffle steps in a pipelined fashion, improving the overall execution efficiency and DPU usage. (3) A DPU-direct data spilling mechanism, which uses the DPU instead of the CPU to manage the spilling of intermediate data, eliminating redundant data copies and further reduces the CPU overhead.

We implemented a DShuffle prototype based on Spark [47] and NVIDIA's BlueField-3 DPU [36] and conducted detailed tests using the HiBench [20] benchmark suite. The test results show that DShuffle completely eliminates the CPU and memory overhead associated with shuffle operations, effectively reducing the execution time of Spark jobs and improving the overall resource efficiency of the cluster.

In summary, our contributions include:

- A comprehensive quantitative analysis of shuffle overhead from the perspectives of CPU, network, and I/O (§2).
- An exploration of the opportunities and challenges of offloading shuffle operations to DPUs (§3).
- A DPU-optimized shuffle framework (§4), incorporating three novel techniques: DPA-offloaded serialization (§5), fine-grained pipeline shuffle (§6), and DPU-direct data spilling (§7).
- A prototype system implemented on a real platform (§8), with an evaluation of its effectiveness (§9).

2 Shuffle Overhead

2.1 Spark Shuffle

Data shuffle is a fundamental operation in big data analysis and processing systems, such as Spark [47] and Hadoop [11]. It occurs when data needs to be redistributed across partitions to facilitate specific operations, such as groupByKey, sortByKey, or reduceByKey. The shuffling process ensures that related data elements are colocated within the same partition, enabling subsequent computations to run efficiently.

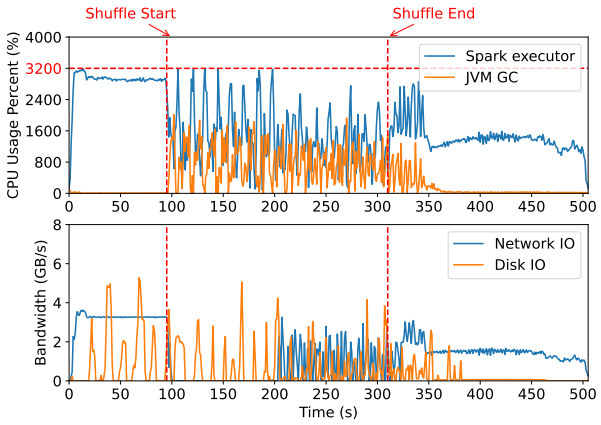

Figure 1: CPU Utilization, Disk and Network Bandwidth of a Two-node Spark Cluster under Sort Application.

Here, we use the popular Spark as an example to explain the shuffle process. In Spark's shuffle process, (1) mappers first partition the data and reorganize tuples within each partition using operations like aggregation and sorting to prepare for parallel processing in the reduce stage. (2) They then serialize and compress the data into byte streams, store the intermediate results on disk, and notify the Spark driver of the data's location. (3) Reducers subsequently retrieve the data over the network, deserialize it, and apply user-defined reduce functions to complete the computation.

2.2 CPU Overhead of Shuffle

Shuffle supports efficient and scalable distributed computing by redistributing data across nodes. However, it is a CPU- and IO-intensive operation and is often the bottleneck of the entire task. To quantify the overhead of shuffle operations, we ran a 285GB HiBench sort workload on a 2-node Spark cluster.

Figure 1 illustrates the CPU, network, and IO consumption of the cluster during the task execution. It can be observed that the shuffle phase takes the longest time in the entire task execution, consuming approximately 226 seconds, while the rest map and reduce phases each take around 100 seconds. Additionally, we observed a significant amount of network and disk IO during the shuffle phase. Traditionally, shuffle operations have been limited primarily by these slow IOs. However, with the improvement in IO device performance, the CPU overhead of the shuffle has become increasingly noticeable. In our tests, shuffle consumed approximately 30 CPU cores, while the utilization of network and storage bandwidth was only 25% and 51%.

To further demonstrate the CPU overhead of the shuffle,

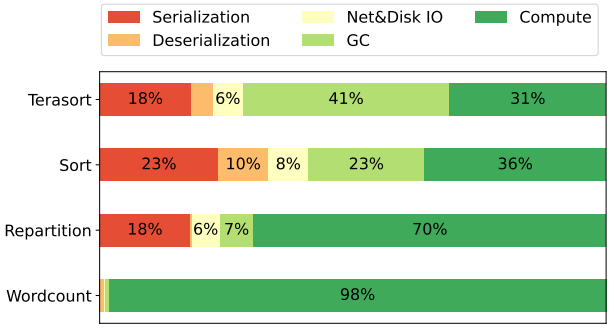

Figure 2: Time Breakdown of Different HiBench Workloads.

we conducted a fine-grained breakdown of the execution time for different types of workloads using HiBench [20]. As shown in Figure 2, network and disk I/O accounts for only about 1% to 8% of the total execution time, with most of the time spent on computational tasks such as (de)serialization, garbage collection, and map/reduce functions. For shuffle-intensive workloads, such as sort and terasort, (de)serialization and garbage collection account for approximately 64% to 69% of the total execution time. This indicates that these two steps are the primary factors that affect shuffle performance. We will now analyze these two operations in more detail.

Frequent (De)Serialization. During the shuffle process, a large amount of intermediate results are generated. These data are either persisted to disk or transmitted over the network. Each I/O operation requires data (de)serialization, which involves traversing, encoding, and converting Java object trees into byte streams. This process incurs significant CPU overhead. Although various optimization techniques (e.g., Kryo [14], Skyway [35]) have been proposed to reduce the computational overhead of serialization, they cannot entirely eliminate serialization costs since they still rely on host CPU cores for serialization. ZCOT [45] introduces a global metadata server to share JVM memory metadata across different nodes, allowing objects to be directly copied to the target node's memory via RDMA, thereby eliminating serialization overhead. However, it relies on additional CPU servers and results in a large number of small network I/O operations.

Expensive Garbage Collection. Shuffle serialization and I/O processes involve the allocation and release of a large number of temporary objects (e.g., byte streams, memory buffers, file handles). This is particularly true for large-scale datasets, which significantly increase the garbage collection (GC) pressure on the JVM [6, 24]. The test results in Figure 1 also support this point, showing that once the shuffle phase begins, CPU overhead caused by GC increases significantly. When the JVM performs garbage collection (GC), shuffle serialization and I/O processes must wait for it to complete, which can significantly impact the overall performance of the shuffle operation.

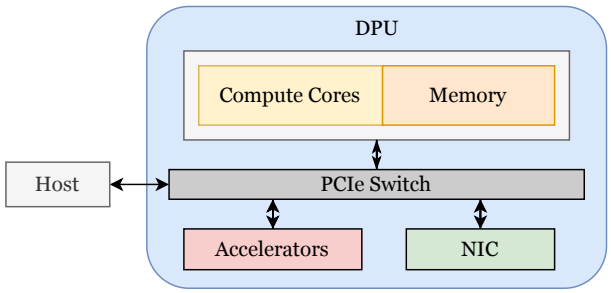

Figure 3: The DPU Architecture.

3 DPU as An Opportunity

3.1 Data Processing Units

The DPU (Data Processing Unit) is a programmable network card based on SoC, which adds additional compute, storage, and interconnect units compared to traditional network cards. These units can offload storage and networking functions from the host, reducing the CPU load. Nowadays, major chip manufacturers have released their own DPU products [2, 5, 7, 21, 31], and leading cloud service providers have widely deployed DPU chips in their infrastructure [10, 15, 27]. Figure 3 shows a typical DPU architecture which consists of five components:

- **High-performance network card** capable of providing hundreds of Gbps of network bandwidth. For example, the BlueField-3 is equipped with a ConnectX-7 network interface card, which includes one or two ports, each supporting up to 200 Gbps.
- **General-purpose compute cores**, often energy-efficient ones like ARM or RISC-V cores, offer high programmability that can be used to offload and execute arbitrary host logic.
- **Onboard memory**, typically with a certain amount of DDR memory and onboard flash storage for the operating system. For example, the BlueField-3 features 32 GB of onboard DDR5 memory.
- **Accelerators**, including those for data-intensive tasks (e.g., compression, encryption) and those for accelerating memory access operations (e.g., DMA, DPA).
- **PCIe switch** for interconnecting with the host and other PCIe devices.

3.2 Offload Opportunities and Challenges

The DPU offers an opportunity to reduce the CPU overhead of data shuffling. As an accelerator in the data path, offloading the shuffling operations of data flow across multiple devices

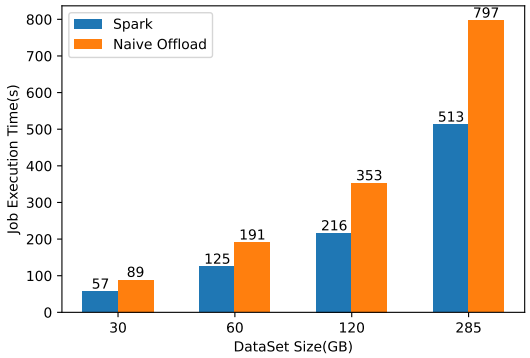

Figure 4: Task Completion Time for Spark and Naive Offload with Different Dataset Sizes under Sort Application.

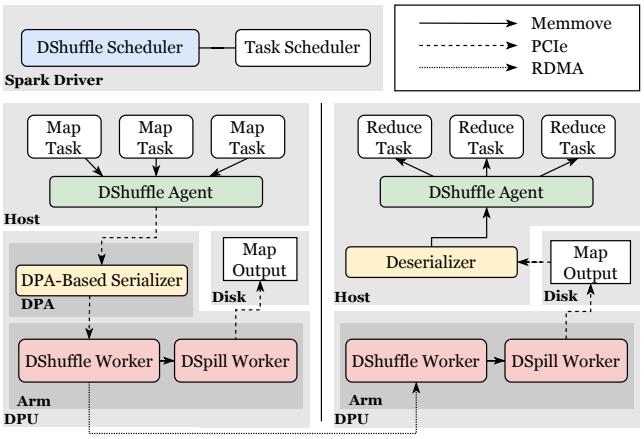

Figure 5: The DShuffle Architecture.

and nodes to the DPU is a natural idea. Additionally, we found that the hardware characteristics of the DPU align well with the shuffle process. In this section, we provide a detailed analysis of the opportunities and challenges of offloading data shuffling operations to the DPU.

Opportunities. Firstly, the DPU has efficient memory access units that can be used to accelerate the serialization process. Serialization operations primarily involve traversing the Java memory object tree, which is mostly a series of memory-intensive operations. The DPU offers high memory access efficiency, especially with its DPA (Data Path Accelerator), which has numerous memory access units (e.g. 256 hardware threads in BlueField-3) that can execute concurrently, allowing for efficient access to host memory through load/store instructions. By leveraging these concurrent memory access units for parallel serialization, serialization speed can be significantly improved, and the CPU overhead on the host can be reduced.

Secondly, the DPU is capable of coordinating data flow between nodes. It can communicate with storage devices on the host through PCIe P2P, and with remote nodes via network interfaces. Therefore, data transfer across devices and nodes can be managed by the DPU without involving the host CPU. This not only reduces the CPU overhead on the host but also effectively mitigates the impact of the large number of temporary objects generated during serialization and I/O on the host JVM, thus reducing GC overhead.

Furthermore, the DPU features general-purpose computation cores that can be used to perform preprocessing computations during the shuffle process, further reducing the CPU overhead on the host.

Challenges. However, there are several challenges associated with offloading shuffle operations to the DPU. Firstly, the general-purpose computation cores on the DPU are slower compared to x86 cores on the host. This can slow down the execution of certain data-intensive tasks, such as partitioning and sorting. Secondly, the DPU has limited onboard memory resources, which cannot accommodate large volumes of intermediate results generated by the shuffle. When the volume of intermediate results exceeds the DPU's memory threshold, the data produced by the map tasks on the host must wait until the DPU completes its processing before it can be sent back to the DPU, thereby affecting the overall execution efficiency of the task. Figure 4 illustrates the overall execution time of the task after decoupling and naive offloading the shuffle operation to the DPU. It can be observed that after offloading, the task completion time increased by a factor of 1.52 to 1.68, and as the dataset size increases, the performance degradation becomes more pronounced.

4 DShuffle Overview

Design goals. DShuffle aims to bridge the gap between the resource demands of data-intensive shuffle operations and the characteristics of DPU hardware. Its specific design goals are as follows:

- **Minimize shuffle overhead.** Shuffle operations consume significant host CPU and memory resources. DShuffle aims to reduce the consumption of host resources by offloading the shuffle task to the DPU, thereby freeing up more host computational resources for actual tasks like map and reduce.
- **Ensure shuffle performance.** The limited computational power and memory resources of the DPU may affect the execution efficiency of shuffle operations. DShuffle aims to accelerate the shuffle process through pipelining parallelism and hardware acceleration.
- **Ease of deployment.** Data systems often require major changes to adopt new technologies. DShuffle seeks to enable data systems to leverage its benefits with minimal modification.

Architecture. Figure 5 illustrates an architecture designed to achieve the aforementioned goals, which comprises a set

of components for collaboratively optimizing the shuffle process. Specifically, DShuffle offloads the shuffle execution to the DPU, leaving only a lightweight *DShuffle Agent* on the host. This agent receives shuffle requests initiated by the host, forwards them to the DPU for processing, and polls to retrieve the results. As previously mentioned, traditional shuffle processes are CPU-intensive and impose significant pressure on garbage collection (GC) in host memory. Executing the shuffle on the DPU effectively saves host CPU resources, allowing more computational power to be allocated to complex tasks such as map and reduce operations.

On the DPU, there are three components responsible for executing the shuffle operation:

- *DPA-Based Serializer.* It runs on DPA hardware threads and is primarily responsible for serializing Java objects in host memory and copying them into DPU memory.
- *DShuffle Worker.* It operates on the general-purpose compute cores of the DPU. For the map side, it handles data partitioning and aggregation, while on the reduce side, it focuses on merging and sorting the data.
- *DSpill Worker.* It manages the process of writing intermediate preprocessing results to local disks or transmitting them to remote nodes over the network. Leveraging the DPU's PCIe peer-to-peer (P2P) and networking capabilities, the DSpill worker can directly read/write local disks and send data to remote nodes without CPU intervention, thereby significantly reducing the host CPU load and memory pressure.

In addition to the above components, there is a *DShuffle Scheduler* running on the Spark driver node. This scheduler coordinates and manages host task execution based on the runtime states of the *DShuffle Worker* and *DSpill Worker* on the DPU. We next present a workflow to better illustrate how these components collaborate and work together.

Workflow. (1) When the intermediate results of a map task exceed the predefined threshold (e.g., 32MB), the Spark executor sends a signal to the DPA. The DPA then launches multiple hardware threads to perform serialization and transfers the results to the DPU memory via DMA, notifying the DShuffle Worker that a request has arrived. (2) The DShuffle Worker on the map side performs aggregation, partitioning, sorting, and other operations on the serialized data, and caches the intermediate results in DPU memory. When the amount of intermediate data exceeds the predefined memory threshold, the Map side triggers a DSpill Worker, which either spills the data to local disk or communicates with the DShuffle Scheduler to notify it to schedule a reduce target node. (3) If the target node is successfully acquired, the DSpill Worker on the map side sends the data to the reduce node via RDMA. (4) Upon receiving the data, the DSpill Worker on the reduce node notifies the DShuffle Worker on the reduce side to execute data merging. (5) The merged results are written to disk by the DSpill Worker on the reduce side, awaiting subsequent computational tasks to read directly from the disk.

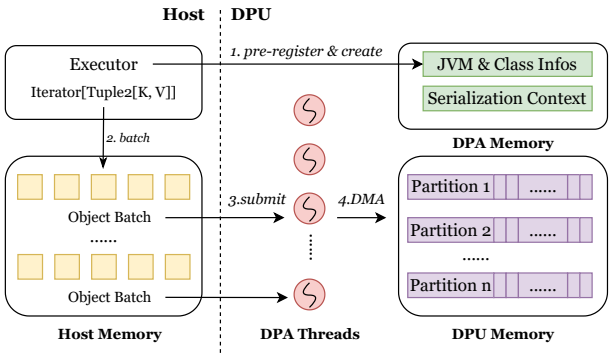

Figure 6: The DPA-based Serializer.

5 DPA-Offloaded Serialization

The state-of-the-art SmartShuffle offloads only the shuffle computation and network data transmission, leaving the serialization operations to be handled by an agent on the host. As demonstrated in Chapter 2, frequent serialization during the shuffle process incurs significant CPU overhead. Serialization involves intensive memory access and encoding operations, which consume substantial CPU cycles on the host. Additionally, the creation of numerous temporary objects during serialization imposes a heavy burden on the JVM's garbage collection (GC). Consequently, reducing serialization overhead on the host is also a must.

Offloading serialization to the DPU is a feasible solution as it reduces the strain on the host CPU and isolates its impact on JVM memory. However, utilizing the DPU for serialization is non-trival and comes with several challenges: (1) The input for serialization consists of discrete memory objects linked by pointers, which the DPU cannot inherently interpret; (2) The latency for DPUs to access host memory is higher than that of CPUs, and the clock speed of individual DPU cores is lower, potentially affecting serialization performance. To address these challenges, DShuffle introduces a DPA-based serializer. This serializer takes advantage of the DPA's hardware capabilities for byte-addressable and highly concurrent access to host memory, accelerating the serialization process.

DPA-based Serializer. Figure 6 shows the architecture of DPA-based serializer. It provides the same interface as other Java serializers, including initialization, type registration, serialization, deserialization, and destruction. As a result, the upper-layer application remains unaware of the specific serializer being used. Unlike CPU-based serializers, the DPA-based serializer retrieves the current JVM runtime parameters during initialization and passes them to the DPA. These parameters include the base address and size of the JVM heap memory, as well as JVM's compressed object pointer optimization settings.

Given that the DPA can access host memory using load/store instructions, it can use these parameters to access objects at any address within the JVM heap memory. When the serialization interface is invoked, the user only needs to provide the root object's address. The DPA hardware threads can then traverse the Java object tree from that address, copying scattered memory object fields into contiguous hardware memory to complete the serialization process. This approach effectively resolves the first challenge.

For the second challenge, the DPA-based serializer overcomes the long latency of single-threaded serialization by parallelizing the process using multiple DPA hardware threads. Specifically, the DPA serializer batches the objects to be serialized and, once a certain threshold is reached, activates multiple DPA hardware threads to serialize these objects in parallel, thereby improving serialization efficiency. As mentioned earlier, DPA has more than 190 hardware threads. By combining batching with multi-threading, the DPA serializer can achieve serialization speeds comparable to or even faster than those of the host machine.

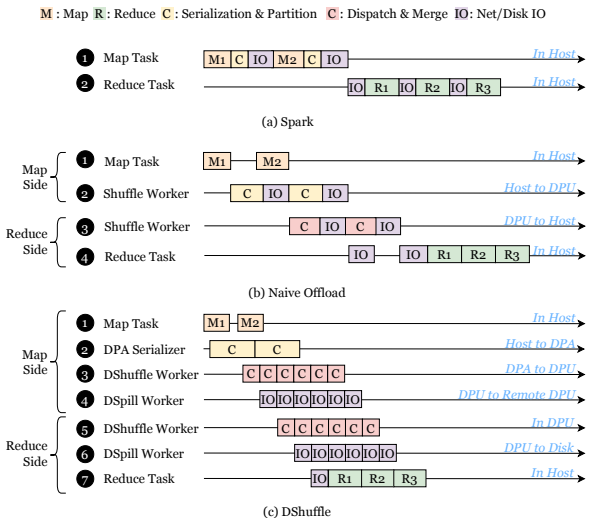

Figure 7: Execution Pipeline of Native Spark, Naive Offload Scheme and DShuffle.

6 Fine-Grained Pipeline Shuffle

The DPA-based serializer ensures fast serialization, but the shuffle process still involves additional steps such as preprocessing and I/O operations. Since the DPU has a limited number of general-purpose compute cores and is slower than the host CPU, the execution speed of these steps may be constrained, potentially impacting the overall shuffle performance. To address this challenge, existing approaches dynamically allocate tasks between the host and DPU based on the DPU's load. Although this prevents performance degradation, it introduces additional overhead on the host CPU.

In this paper, we propose a fine-grained pipelined shuffle technique that guarantees shuffle efficiency on the DPU, without consuming any host CPU resources. This is achieved by exploiting parallelism both across different shuffle workers and within individual shuffle workers. We will explain this approach in detail in this section.

Inter-Worker Parallelism. Figure 7 illustrates the differences between DShuffle, native Spark, and naive offload. In native Spark, map computations and shuffle operations are interleaved within the same thread, causing these two operations to block each other. The same applies to the reduce side, where the reduce task must wait for the shuffle to complete before it can start. Naive offload decouples the shuffle operation and offloads it to the DPU, enabling some overlap between map and serialization computations. However, due to the slower processing speed and limited memory capacity of the DPU, having it execute all preprocessing and I/O tasks in a single thread can negatively impact shuffle efficiency, thus blocking subsequent map computations. DShuffle improves the shuffle operation's execution efficiency on the DPU by splitting the data into fine-grained blocks and assigning them to preprocessing threads and I/O threads for pipelined execution. The specific process is described as follows.

On the map side, once the DPA Serializer completes serializing the intermediate results of the map computation, the corresponding DPA hardware thread is freed to serialize the next batch of intermediate results. Simultaneously, the DShuffle worker can start preprocessing the serialized results from the previous batch. After the DShuffle worker finishes its task, the results are passed to the DSpill worker for I/O, allowing the DShuffle worker to immediately begin preprocessing the next batch of serialized results. Through pipeline parallelism among workers, the shuffle operation's execution efficiency on the DPU is significantly enhanced.

On the reduce side, the pipeline process is essentially the reverse of the map side, with the distinction that the deserialization operation is handled by the DShuffle agent on the host. DShuffle assigns deserialization to the host CPU primarily because it involves creating a large number of Java objects. If the DPA were to handle this task, it would need to communicate with the JVM on the host, resulting in numerous small cross-PCIe requests, which would introduce significant access latency. By having the host agent handle this process, it can read a batch of data from the local disk at once for processing, ensuring the efficiency of deserialization.

Intra-Worker Parallelism. In the pipeline described above, if a worker in a specific stage processes data at a slower speed, it will impact the overall efficiency of the pipeline. To address this issue, DShuffle segments the data being processed by slower workers based on keys and then initiates multiple threads to process different segments in parallel. This approach enhances the execution speed of slower workers, ensuring that the throughput of different stages is balanced.

In addition to thread-level parallelism, DShuffle employs coroutines to enhance the resource utilization of DPU proces-

sors. Specifically, DShuffle breaks down each worker's execution process into finer-grained tasks, allowing these tasks to overlap on DPU computational cores. For example, a DShuffle worker's process is divided into three tasks: polling requests from the DPA Serializer result queue, performing preprocessing computations, and submitting I/O requests to the DSpill worker's request queue. These tasks are scheduled on demand to the DPU's general-purpose computational cores, avoiding the continuous occupation of CPU resources. For DPUs with a limited number of cores, this approach effectively prevents resource waste.

7 DPU-Direct Spilling

Beyond the computational overhead of serialization and preprocessing, the shuffle process can lead to significant data spill costs. When the intermediate result data generated by serialization and preprocessing exceeds the host memory threshold, spill operations are triggered to free up memory. This process not only blocks foreground computation but also consumes a considerable amount of host CPU resources to perform I/O operations. DShuffle mitigates these issues by leveraging high-speed DPA serialization to rapidly transfer intermediate results to DPU memory, thereby reducing foreground computation blocking and host memory usage. However, since DPU memory has limited capacity, spill operations remain unavoidable when its memory is insufficient.

To address this challenge, SmartShuffle spills unprocessed intermediate results to remote DPUs or the local host when the DPU memory reaches a certain threshold. While this approach alleviates the memory pressure on the DPU, it introduces redundant data movement and additional host CPU overhead. This is because data spilled to the local host or remote DPU is eventually handed over to the host CPU after preprocessing, which then writes the data to disk. These I/O operations not only consume host CPU resources but also create temporary objects during the process, increasing JVM garbage collection (GC) overhead.

In this paper, we propose a **DPU-Direct Spilling** scheme to further eliminate I/O overhead during the spill process. Figure 8 shows the key idea. Compared with native Spark, DShuffle leverages the DPU to manage data flow across devices and nodes. When shuffle intermediate results need to overflow or be written to disk, DShuffle enables the DPU to directly write intermediate results to the local disk via PCIe P2P or transmit them to remote DPUs via RDMA for direct disk writes. This approach completely eliminates CPU consumption and memory interference caused by I/O operations during the shuffle process.

The key to implementing DPU-Direct Spilling lies in enabling the host CPU to be aware of the data written to disk by the DPU. To achieve this, DShuffle employs a file preallocation strategy. Specifically, during node initialization, a disk partition is created, and several fixed-size files are allocated within this partition to accommodate spilled data. Once created, the metadata of these files remains unaltered. The partition is mounted as read-only on the host and as read-write on the DPU.

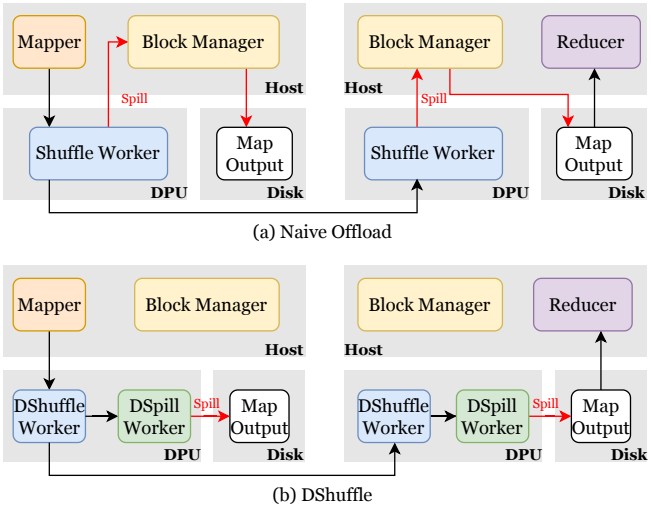

Figure 8: The Data Spilling Workflow of Naive Offload Scheme and DShuffle.

At runtime, when the shuffle scheduler dispatches shuffle requests to a node, the DPU on that node directly writes data to the partition through the local file system. After writing a fixed-sized block (e.g., 32MB), the DPU notifies the reducer on the host via DMA that new data is available. The reducer reads the file blocks based on metadata provided by the DPU and performs the necessary computations. Both the DPU's data writes and the reducer's reads utilize direct I/O to bypass the local file system cache, ensuring data consistency.

To effectively utilize the spill partition's space, the DPU also tracks the metadata of free file blocks. Once a file block is consumed by the reducer, the corresponding space is released and made available for subsequent spilled data writes.

8 Implementation

We use NVIDIA's BlueField-3 (BF-3) DPU as the platform for development and deployment. The BF-3 connects to the host system via a PCIe Gen 4.0 interface and runs Ubuntu 20.04 along with the DOCA 2.9 programming suite. The codebase for all DShuffle modules consists of approximately 6,700 lines and will be open-source.

Host. The DShuffle agent is divided into two parts. The first part is an interface integrated with Spark, comprising approximately 500 lines of Java code. The interface includes methods such as *Initialize*, *TriggerSpillStart*, *BatchAppendKV*, *WaitForSpillDone*, and *RegisterClassInfo*. Among these, *Initialize* and *RegisterClassInfo* handle preprocessing of Java type information or retrieve and register JVM startup parameters.

BatchAppendKV collects batched key-value objects into the serializer queue and then partitions them into the DMA buffer. Based on these interfaces, we developed a *DShuffleWriter* compatible with the native Spark shuffle writer, allowing seamless replacement and deployment. The second part is the native interface implemented via JNI, with approximately 1,000 lines of C++ code. This primarily handles interactions with the DPU, such as notifying the DPU to pull intermediate result buffers via DMA.

DPU. The DPU worker component consists of approximately 4,000 lines of C++ code. We implemented a unified data transmission layer that supports DMA, RDMA, and TCP communication protocols. On top of this layer, we developed two types of workers using the Boost.Fibers coroutine runtime: SpillWorker and ShuffleWorker. Tasks are passed between workers on the same DPU via single-producer single-consumer (SPSC) lock-free queues. The DPA Serializer, developed using the DOCA DPA module, is split into two parts. The first part, about 1,000 lines of code, is implemented using the JNI framework. It processes type metadata information in the JVM and handles interactions with the DPA hardware. The second part, approximately 1,200 lines, is the hardware code for the DPA, which implements serialization logic for Java object trees on DPA threads.

9 Evaluation

9.1 Goals

We evaluate DShuffle to answer the following questions:

- How much does DShuffle reduce the host CPU usage and improve the IO efficiency? (§9.3)
- How much can DShuffle reduce the completion time of spark jobs? (§9.4) How DShuffle performs under different workloads? (§9.5)
- How effective are the optimizations in each component at improving the efficiency of DShuffle? (§9.6)

These questions correspond to the first two design goals of DShuffle, while the third design goal has already been analyzed in 8.

9.2 Testbed and Methodology

System Setup. We evaluated DShuffle on a 2-node testbed, where each node is equipped with an Intel Xeon Gold CPU and an NVIDIA BlueField-3 DPU [36]. The detailed hardware and software configurations are shown in table 1. Note that we locked the CPU frequency at 4.0 GHz and disabled hyper-threading to ensure consistent performance across multiple runs. On each node, we deployed a 16-core, 32 GB Spark Executor, forming a two-node Spark cluster.

Intel Xeon 6418H Server
CPU: 24 Xeon cores @ 4.0GHz w/HT disabled **Memory:** 64GB DDR4 DRAM **SSD:** Samsung 980 pro 2TB **OS:** Ubuntu 22.04 LTS, Linux Kernel 6.8
NVIDIA BlueField-3 DPU
Network: ConnectX-7 two 100Gbps Ethernet ports **CPU:** 16 ARMv8.2 A78 cores **Memory:** 32GB DDR5 DRAM **DPA:** 16 RISC-V cores with 256 hardware threads **OS:** Ubuntu 20.04 LTS, Linux Kernel 5.15

Table 1: The Node Configuration of the Testbed

Workloads. We use HiBench [20] as our primary benchmarking tool. HiBench provides various types of workloads, including Sort, TeraSort, WordCount, and Repartition. Most of our tests are conducted using the Sort workload because it contains only a single Shuffle phase, making it ideal for demonstrating the optimization effects on the shuffle process. Nevertheless, we also evaluated other types of workloads. Unless otherwise specified, the dataset size used for evaluation is 285 GB with 32 partitions. Additionally, data compression in the Shuffle process was disabled during all tests to avoid additional CPU overhead on the host, which could reduce overall performance.

Baselines. Since the most relevant SmartShuffle [28] is not open-sourced, we use the following baselines to evaluate DShuffle:

- **Native Spark:** Using Spark 2.4.3 [17] as the baseline implementation without any offloading.
- **Naive Offloading:** Similar to the existing SmartShuffle, it offloads tasks such as partitioning, sorting, and network I/O of shuffle operations to the DPU, while serialization computation and intermediate data spilling are still handled by the host. The only difference from SmartShuffle is that Naive Offloading does not implement dynamic offloading logic. Since the goal of DShuffle is to fully offload the shuffle operation without sacrificing performance, using Naive Offloading as a baseline allows for a clearer demonstration of DShuffle's optimization benefits. Nevertheless, we provide a theoretical comparison between DShuffle and SmartShuffle in Section 10.
- **DShuffle:** The shuffle process offloads serialization, preprocessing, network I/O, and intermediate result spilling entirely to the DPU. These steps are organized in a pipeline manner, leveraging DPA for offloading and accelerating serialization. The DPU directly writes intermediate data to disk, ensuring efficient data handling throughout the process.

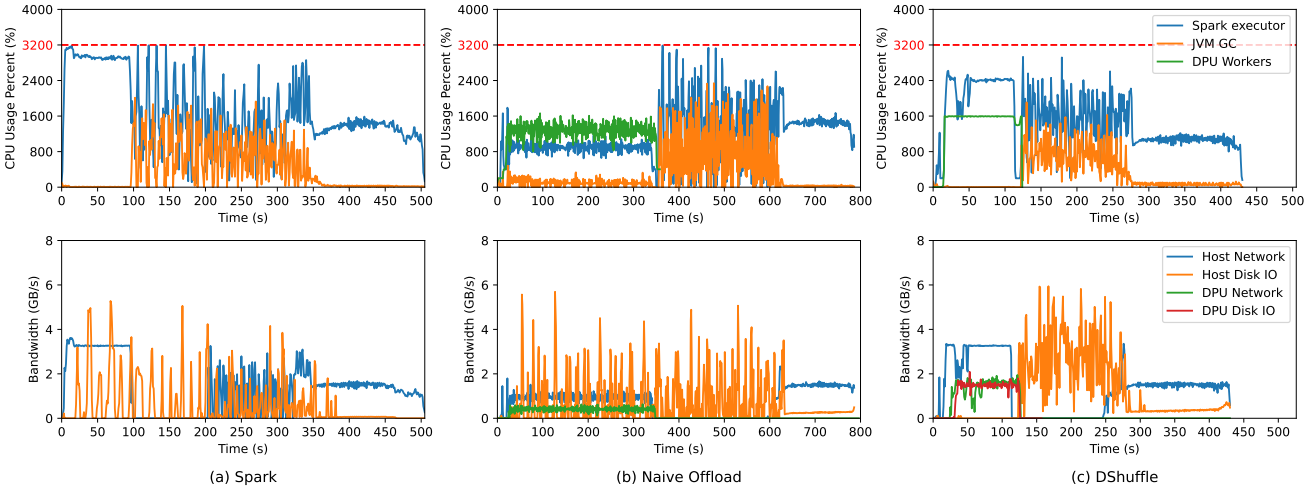

Figure 9: The CPU Utilization, Disk and Network Bandwidth of the Spark Cluster During the Execution of the Sort Application.

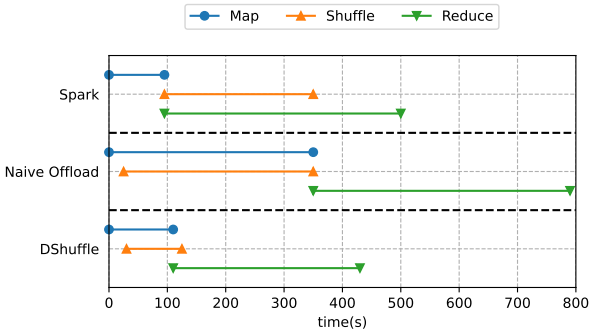

Figure 10: Execution Timeline for Native Spark, Naive Offload Scheme and DShuffle under Sort Application.

9.3 Resource Efficiency

Figure 9 illustrates the CPU utilization, disk, and network IO bandwidth of the Spark cluster during the execution of the sort application. It is worth noting that simple offloading increased the overall execution time of the task by 57%, while optimization through DShuffle reduced the overall execution time by approximately 16%. Below, we analyze the execution performance during the map and reduce phases for different comparison objects.

Map phase. Compared to native Spark, the naive offloading method decouples the shuffle from the host and offloads it to the DPU, overlapping it with the host's map computation. As a result, during the map phase, we observe the consumption of DPU compute cores and network IO. However, the naive offloading method does not reduce the overall execution time of the task. This is because the DPU cores are slower than the host cores, and naive offloading leads to a decrease in shuffle speed. When the DPU's memory capacity reaches its threshold, the map computation on the host needs to wait for the shuffle to complete, thereby affecting the overall task execution efficiency.

In contrast, DShuffle improves the execution speed of shuffle operations on the DPU through optimization techniques such as serialization acceleration, pipeline parallelism, and direct spilling, effectively eliminating the stall of map computations. This is also confirmed in Figure 10, which illustrates the execution timelines for each phase of different comparison groups. Compared to native Spark and naive offloading, DShuffle reduces the shuffle execution time by 62.7% and 70.7%, respectively. Additionally, since DShuffle offloads serialization to the DPA, the CPU resources consumed by the host during the map phase (24 cores) are lower than those in native Spark (30 cores).

Reduce phase. In native Spark, the reduce nodes pull data from the map nodes to the local machine for computation, which results in a significant amount of small network and disk I/O. Naive offloading improves network I/O efficiency by aggregating data and sending it to the reduce nodes in advance. However, during the reduce execution phase, naive offloading still relies on the host to perform serialization and file I/O, which introduces additional data copies and significant garbage collection (GC) overhead. Additionally, serialization can block the reduce computation, negatively impacting task execution efficiency.

In contrast, DShuffle leverages the DPU to directly write intermediate data to disk, eliminating redundant data transfer and improving I/O efficiency. As shown in Figure 1, DShuffle's I/O bandwidth is significantly higher than that of native Spark and naive offloading. Additionally, DShuffle uses DPA to offload and accelerate serialization, which reduces both the blocking effect on reduce tasks and the garbage collection (GC) overhead. This is also evident in Figure 1, where DShuffle exhibits lower CPU overhead due to GC and a more stable CPU utilization for reduce tasks. Overall, by implementing these optimization techniques, DShuffle reduces the execution time of reduce phase by approximately 45.6% and 50.2%, respectively, compared to native Spark and naive offloading.

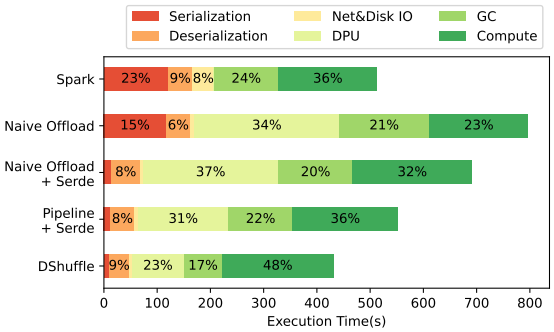

Figure 11: Time Breakdown of Spark Tasks with Different Optimization Techniques Turned on.

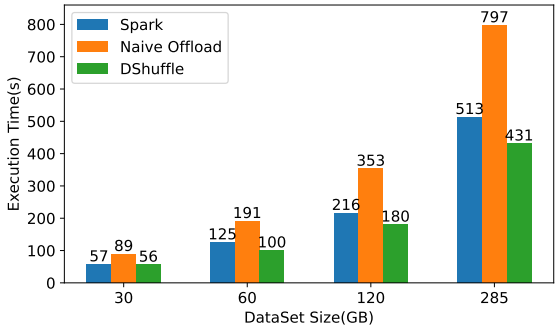

Figure 12: Execution Time of Different Comparison Groups under Different Dataset Size.

9.4 Performance Analysis

In this section, we will provide a detailed analysis of the performance advantages of DShuffle. First, we evaluate the performance gains brought about by different optimization techniques. Then, we examine the scalability of DShuffle's performance with respect to dataset size and the number of partitions.

Performance Breakdown. To demonstrate the performance gains from different optimization techniques, we progressively enabled various optimizations based on naive offloading: DPA-accelerated serialization, pipelined parallelism, and direct spilling via DPU. We then measured the overall execution time and performed a fine-grained time breakdown under different configurations. The test results are shown in Figure 11. Here, "Naive Offload + Serde" refers to enabling DPA serialization on top of the Naive Offload approach, while "Pipeline + Serde" further accelerates the shuffle steps on the DPU through pipelined parallelism.

It can be observed that DPA-accelerated serialization reduced the overall execution time of naive offloading by 13.2%, with serialization time decreasing from 15% to 3%. Additionally, offloading serialization reduced the GC pressure on the host, leading to a lower overall GC time. After enabling pipelined parallelism, the overall execution time was further reduced by 17.4% due to more efficient shuffle computation on the DPU. Finally, enabling direct spilling via DPU reduced the overall execution time by another 15.1%. This optimization eliminated redundant data copying, significantly reducing data transmission time on the DPU. Furthermore, offloading the I/O process to the DPU further alleviated GC pressure on the host, leading to a further reduction in GC time.

Performance with dataset size. To demonstrate the scalability of DShuffle with respect to dataset size. We generated sort datasets of 30GB, 60GB, 120GB, and 285GB to evaluate the task execution time of native Spark, naive offloading, and DShuffle. As shown in Figure 12, with the dataset size increases, the performance improvement of DShuffle becomes more pronounced. This is primarily because, with larger datasets, the IO overhead during the shuffle process becomes more significant, and the proportion of serialization and GC overhead is higher. DShuffle's optimizations effectively reduce these two types of overhead, resulting in greater performance gains.

Performance with partition number. We also tested the scalability of DShuffle in terms of partition number. We measured the task execution times of native Spark, naive offloading, and DShuffle under different partition numbers. As shown in Figure 13, with the number of partitions increases, the total task execution time for all comparison groups decreases, as the reduce tasks are more finely divided, which increases parallelism. The execution time for reduce tasks decreases because the amount of data being processed is smaller. However, for Map tasks, naive offloading becomes slower as the number of partitions increases. This is due to a higher number of network requests for data forwarding, which increases network overhead. In contrast, DShuffle, with its fixed pipeline granularity, ensures stable Map task execution times, thereby maintaining the same partition scalability as native Spark.

9.5 HiBench

In this section, we evaluate the benefits of DShuffle using different types of workloads from HiBench. The test workloads include Sort, TeraSort, Repartition, and Wordcount. The Sort workload involves sorting a 285GB dataset containing random-length random strings. TeraSort is similar to the Sort workload but mainly consists of smaller random strings, which results in greater GC pressure. The Repartition workload focuses on re-partitioning 300GB of random strings. Wordcount is primarily concerned with counting word frequencies in a 150GB dataset of random strings which is computationally heavy but has low shuffle overhead.

Figure 14 shows the test results. It can be observed that for workloads with high shuffle pressure, DShuffle exhibits a significant performance gain, as it significantly reduces serialization and GC overhead. However, for workloads with high computational pressure, DShuffle's performance is similar to native Spark, as most of the overhead occurs in the map computation, with a small proportion spent on shuffle. Overall,

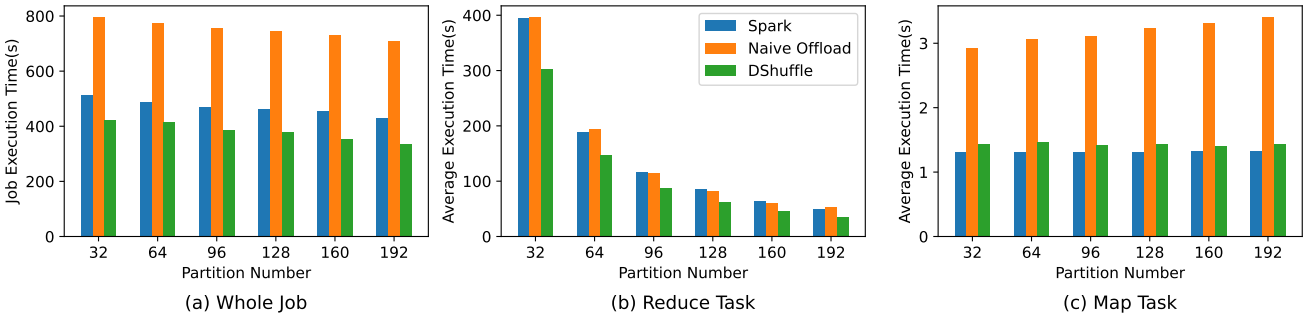

Figure 13: Execution Time of Different Comparison Groups under Different Partition Numbers.

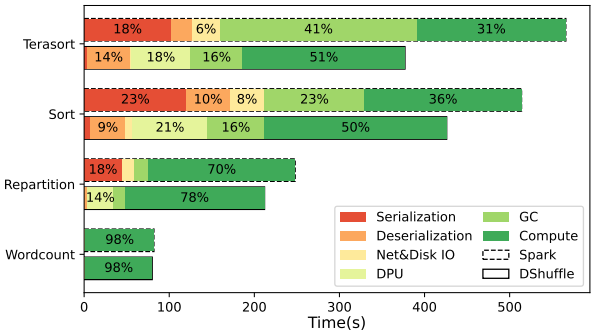

Figure 14: The Time Breakdown of Different HiBench Workloads.

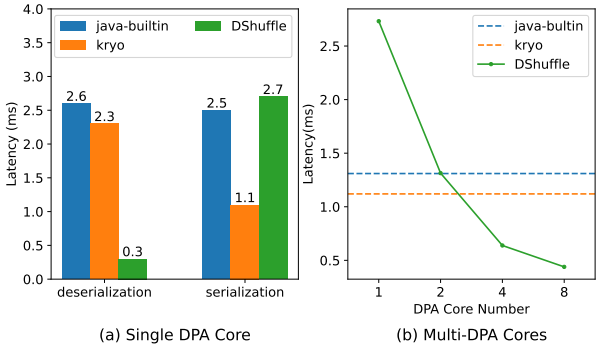

Figure 15: Serialization Latency of Different Serialization Libraries.

DShuffle can effectively accelerate the execution speed of tasks with high shuffle overhead, without affecting the execution efficiency of tasks with high computational overhead.

9.6 Component Efficiency

In this section, we test the efficiency of the key components of the DShuffle, including the DPA-based serializer and the pipeline workers in the DPU.

DPA-based Serializer. To evaluate the DPA-based serializer, we use HiBench to generate a dataset and extract the strings to be serialized from the dataset, forming key-value data with a length of 128, where both the key and value are 4KB each. We used the native Java serialization library, Kryo serialization library, and DShuffle serialization library to process the dataset, recording the execution times for each comparison group. For all tests, we first performed a 5-second warm-up, followed by a 5-second testing period.

Figure 15(a) shows the serialization and deserialization latency for different comparison groups in a single-core scenario. For DShuffle, deserialization runs on the CPU, while serialization runs on the DPA (as explained in §5). It can be observed that the deserialization speed of the DShuffle library is significantly faster than that of the native Java and Kryo libraries. This is primarily because DShuffle's serialization library directly copies the object content to the target buffer address rather than invoking the Java constructor to create the object, thereby reducing the number of interactions with the JVM. For serialization, however, the processing delay is higher than Java native and Kryo due to the lower clock speed of a single DPA core (16 hardware threads) compared to the host CPU.

Nevertheless, the DPU has a large number of DPA cores that can execute concurrently. By leveraging multiple hardware threads for parallel serialization, the DPA serializer can achieve throughput higher than Java native and Kryo. Figure 15(b) illustrates the throughput of the DPA serializer with different numbers of DPA cores, showing that when more than 2 cores (32 hardware threads) are used, the DPA serializer's latency becomes lower than that of Java native and Kryo. While multi-threading on the host can also be used for parallel serialization, it consumes significant CPU resources. DShuffle avoids this issue by offloading the serialization process to the DPA.

Pipeline Workers. To test the maximum throughput of the workers on the DPU, we generated 640GB of key-value data using the HiBench tool, with both keys and values being random strings. We used this key-value data to stress the DPU, evaluating the maximum throughput that DShuffle can achieve and the resource consumption on the DPU with different numbers of workers. The results are shown in Figure 16. It can be observed that as the number of workers increases, the processing bandwidth of DShuffle gradually increases. With 15 workers, the bandwidth reaches approximately 10.53GB/s,

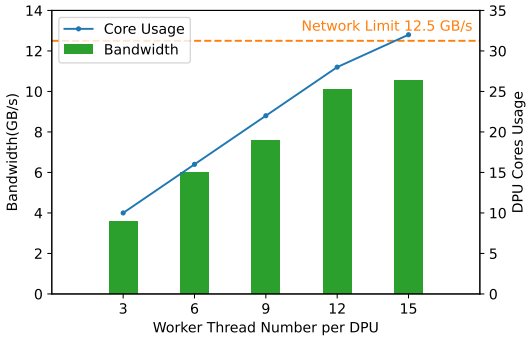

Figure 16: The bandwidth of DShuffle workers with different thread numbers.

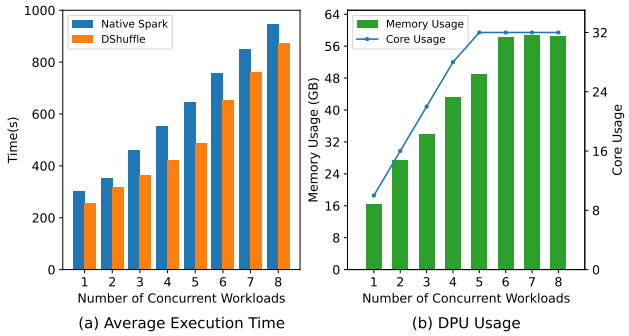

Figure 17: The scalability of DShuffle with different numbers of workloads.

which is close to the limit of a 100Gbps network. At this point, the number of DPU cores consumed by the map and reduce nodes is around 32, which also reaches the maximum number of DPU cores.

9.7 Scalability

In this section, we evaluate the scalability of DShuffle. Specifically, we gradually increase the number of concurrently running Sort workloads. Each 100GB Sort workload is executed by two executors distributed across two physical machines, with each executor provisioned with 6 CPU cores and 12GB of memory.

Figure 17 presents the evaluation results. As shown in Figure 17(a), the average execution time of native Spark increases steadily with the number of concurrent workloads. This trend is primarily attributed to two factors: (1) resource contention among concurrently running Spark executors, particularly during the reduce phase where intensive garbage collection significantly consumes CPU resources and impairs computation efficiency; and (2) network bandwidth contention across executors, which slows down data fetching in the map phase and data exchange during the shuffle phase.

DShuffle mitigates these bottlenecks by offloading shuffle operations, thereby reducing CPU contention and minimizing garbage collection overhead during I/O. As a result, it delivers superior performance under increasing load. The scalability of DShuffle is mainly bounded by the hardware capacity of the DPU. As depicted in Figure 17(b), when the number of concurrent workloads approaches 6, the compute and memory resources of the DPU become saturated. Beyond this point, additional workloads exacerbate resource contention on the DPU, diminishing incremental performance benefits.

Despite this limitation, DShuffle consistently outperforms native Spark and can efficiently support workloads equivalent to a host server with up to 48 CPU cores and 128GB of memory, which is sufficient for the majority of practical applications.

10 Discussion

Comparison with non-DPU solutions. Software-based shuffle optimizations [9, 16, 25, 29, 39, 41, 45] focus primarily on improving I/O process, such as using dedicated shuffle service clusters to schedule subsequent tasks. However, these approaches do not eliminate CPU and memory consumption on the host and may even introduce additional overhead from intermediate servers. Hardware-based shuffle optimizations typically target specific stages of the shuffle pipeline, but lack a comprehensive end-to-end solution. For instance, Spark RDMA [32] leverages high-bandwidth RDMA NICs to accelerate intermediate data transfers but ignores the computational overhead of shuffle. Cereal [22] uses custom hardware to speed up Spark's serialization, while other approaches [8, 37] offload compute-intensive operations—such as joins and merges—to GPUs or FPGAs. However, these solutions often fail to mitigate the I/O overhead associated with intermediate results. By contrast, DShuffle leverages the hardware capabilities of DPUs to provide a holistic optimization of the shuffle process, effectively addressing both computational and I/O bottlenecks.

Difference between DShuffle and SmartShuffle. There are two main differences between DShuffle and SmartShuffle [28]: (1) First, DShuffle is designed to fully offload shuffle operations to DPUs without sacrificing performance. It achieves this through fine-grained pipelined acceleration, which allows for efficient execution of shuffle steps. As a result, DShuffle frees up more host resources for map and reduce computations. In contrast, SmartShuffle, tailored for older-generation DPUs, adopts a dynamic offloading strategy that still relies on CPU and host memory resources. (2) Second, SmartShuffle's evaluation primarily focuses on small datasets (20–50GB) that fit entirely within host memory (64GB), thereby avoiding disk I/O as well as the associated serialization and garbage collection overheads. However, our experiments reveal that these overheads become significant when processing large datasets (several hundred GB) that exceed host memory capacity. DShuffle mitigates these overheads by leveraging DPA-accelerated serialization and DPU-direct spilling, demonstrating strong effectiveness in large-scale data processing.

Portability of DShuffle for other DPU architectures. For SoC-based DPUs (e.g., AMD Pensando [2], Stingray PS1100R [5], Intel IPU E2100 [21], Marvell OCTEON [31]), DShuffle can be easily ported since most of its logic is implemented on general-purpose Arm cores. The hardware serialization logic implemented on the DPA can also be replicated on the host CPU, albeit with some resource consumption, but it remains faster than Java's native serialization library. For FPGA-based DPUs (e.g., AMD Alveo U200 [1]), DShuffle's logic can also be migrated, but fully hardening the implementation presents significant development challenges and longer development cycles. Additionally, FPGAs are costly and better suited for parallel computing tasks. Therefore, we believe SoC-based DPUs are more suitable for shuffle tasks.

11 Related Work

Improving Shuffle I/O Efficiency. For large-scale data analytics workloads, I/O speed is a critical factor affecting shuffle performance [46]. A lot of work has been done to optimize network and disk I/O in the shuffle process. Sailfish [39], AggShuffle [29], and Riffle [25] propose aggregating fragmented intermediate shuffle results into large files to convert random small I/O requests into large sequential I/O, effectively improving the utilization of network and disk bandwidth. Magnet [41], Celeborn [16] and OPS [9] propose directly pushing intermediate results from the map side to the reduce side, allowing network and disk I/O to overlap with the map computation process, thus effectively improving task execution speed. Exoshuffle [30] introduces a shuffle framework that integrates various optimization techniques such as pre-aggregation and push-based shuffle. However, all of these works require reserving host resources or using additional servers to implement aggregation operations. In contrast, DShuffle offloads these processes to the DPU, completely eliminating the dependency on extra hardware resources.

Accelerating Shuffle Serialization. Serialization occupies a significant portion of CPU time during the shuffle process. Many works have focused on accelerating Spark's serialization operations from both software and hardware perspectives. Kryo [14] is a widely used and mature Java serialization library that avoids the extensive string comparison operations in the native Java serialization type reflection mechanism through unique type encoding, effectively improving serialization speed. Skyway [35] extends JVM heap space based on type encoding to achieve lightweight object direct transfer, reducing serialization overhead. ZCOT [45] avoids serialization during the object transfer process through distributed shared memory, but it relies on an additional central metadata server and increases the number of network I/O operations during object transfer. Cereal [22], Zerializer [44], and Cerebros [38] use customized hardware to accelerate serialization operations. In contrast to these approaches, DShuffle uses widely deployed DPUs to offload and accelerate serialization operations without the need for additional hardware modifications, effectively reducing serialization CPU overhead.

Using DPUs to offload and accelerate distributed applications. With the widespread deployment of DPUs in data centers, numerous tasks are leveraging DPUs to offload and accelerate distributed applications, such as distributed file systems [18, 23, 26, 50], distributed key-value stores [13, 19, 40, 43], and disaggregated storage servers [12, 34, 42, 48, 49]. Among these, SmartShuffle [28] is the most relevant to our work. It uses the Stingray DPU to offload shuffle operations. Since its code is not open source, we provide a qualitative analysis here. The goal of SmartShuffle is to offload the shuffle computation to the DPU to reduce the host CPU overhead. However, it focuses only on offloading preprocessing computations and network I/O. For large-scale datasets, serialization and disk I/O also have a significant impact on shuffle performance. DShuffle addresses these two issues by accelerating serialization via DPA and using DPU direct spilling. In addition, SmartShuffle adopts a partial offloading policy, which still requires substantial host resource consumption. In contrast, DShuffle accelerates the shuffle process on the DPU through fine-grained pipeline parallelism, effectively eliminating the consumption of host resources during shuffle operations.

12 Conclusion

In this paper, we demonstrate that shuffle operations introduce significant CPU and IO overhead, often becoming a key performance bottleneck in data-intensive applications. We propose a novel architecture, DShuffle, which leverages DPUs to offload and accelerate shuffle operations. DShuffle introduces three key techniques to enhance the execution efficiency of shuffle operations on DPUs: DPA-accelerated serialization, fine-grained pipelined parallelism, and DPU-direct spilling. We have implemented DShuffle based on Spark and a real DPU hardware platform. The experimental results show that DShuffle effectively reduces CPU consumption, improves IO efficiency, and decreases the completion time of Spark jobs.

Abstract

Training large-scale deep learning (DL) models is a resource-intensive and time-consuming endeavor, yet optimizing training efficiency poses significant challenges. The sporadic performance fluctuations during long training require advanced profiling capabilities. It is not easy to perform comprehensive and accurate bottleneck analysis amidst numerous influencing factors. Selecting effective optimization strategies without proper guidance further complicates the process. This paper shares our practical insights on optimizing training on Huawei Ascend chips based on three years of experience with 135 typical cases. We propose a systematic optimization system, *Hermes*, including a lightweight profiling approach, a hierarchical bottleneck analysis framework, and an optimization advisor. Our real-world experiments demonstrate significant acceleration in training for models like PanGu-α, MobileNetV1, and MoE (Mixture of Experts), with respective speedups of 3.05×, 1.91×, and 1.19×.

1 Introduction

Large-scale deep learning model training is notoriously costly and time-consuming. For example, training a GPT-3 model with 100.8 billion parameters using 3,072 NVIDIA A100 GPUs took 84 days [41]. Similarly, training the BLOOM-176B model with 384 A100 GPUs required approximately 3.5 months [60]. Even the optimized M6 model with 10 trillion parameters took 10 days on 512 V100 GPUs [32].

In optimizing large-scale training, various roles are involved, including developers, deployers, and maintainers. Developers must precisely identify bottlenecks hindering training efficiency to develop targeted optimization strategies. Deployers, on the other hand, are responsible for efficiently deploying models on hardware. However, as models and hardware evolve, bottlenecks also shift, requiring precise identification and appropriate optimization choices. Meanwhile, maintainers confront random performance fluctuations [27] during long training and require the ability to accurately capture the underlying causes to maintain stable training. Overall, there is an urgent need for a comprehensive and systematic approach to profile, analyze, and optimize training.

However, existing solutions for profiling, analysis, and optimization face significant limitations. First, capturing transient performance fluctuations requires continuous monitoring. However, mainstream profiling tools like Pytorch Profiler [50] not only incur substantial overhead but also frequently interrupt training because users must manually adjust the profiling granularity. Second, existing bottleneck analysis relies largely on manual effort, with available tools focusing solely on specific bottlenecks (PRESTO [24] for I/O, R-Pingmesh [34] and Meta's work [19] for RDMA), leaving out a comprehensive analysis. Last, current optimization heavily depends on the expertise of users, and the few available optimization tools are limited to particular scenarios, such as DayDream [70] and dPRO [22] designed for data parallelism. The lack of guidance makes selecting the appropriate optimizations challenging.

In this paper, we share our 3 years of experience in bottleneck optimization of deep learning model training on Ascend chips (NPUs) [31]. From January 2022 to December 2024, we resolved 223 performance anomalies for over 40 clients and summarized 135 key cases. Our practice reveals several critical lessons that have guided our optimization efforts (§3.1). CPU bottlenecks are prevalent but often overlooked. Computation bottlenecks are mainly due to underutilization, which requires joint software and hardware optimization. We also found that overlapping computation and communication may degrade performance due to resource contention. I/O bottlenecks primarily result from CPU-side data reading overhead, and minimizing remote access is crucial. Hardware faults like port flapping and link failures usually cause network issues.

To address the complex and diverse bottlenecks in production, we introduce *Hermes*, a system based on these lessons to guide the optimization of DL model training on Ascend NPUs. *Hermes* supports the common DL frameworks PyTorch [2] and MindSpore [39] and tackles the following problems. (i)

*Corresponding author: wzbwangzhibin@nju.edu.cn

Besides profiling common performance anomalies, how can we effectively detect performance fluctuations in large-scale training, a newly emerging issue? (ii) For the vast and complex bottleneck space in training, how do we achieve systematic and accurate bottleneck analysis? (iii) Finally, how do we select effective optimizations for identified bottlenecks or potential new arising bottlenecks?

Our contributions can be summarized as follows.

Coarse-to-fine profiling (§4.1): We propose a lightweight monitor to collect critical metrics and identify problematic steps and devices, as well as a detailed profiler to further capture the performance of each operator[1] for bottleneck analysis in problematic steps and devices. These two tools work together to provide a complete view of the training process with minimal overhead. Combined with our dynamic profiling mechanism, they enable efficient profiling of performance fluctuations without interrupting the training.

Hierarchical bottleneck analysis framework (§4.2): We observe that the training pipeline operates hierarchically, with different types of bottlenecks occurring in the corresponding components (host, device, and network). Thus, we propose a hierarchical analysis that first considers the inter-operator parallelism and then delves into the intra-operator implementation. The inter-operator analysis verifies the existence of a poor overlap between components and further identifies the bottleneck operators with the critical path when the overlap is sufficient. In the intra-operator analysis, we delve into the execution process of each component (e.g., data processing, dispatch of operators, memory and compute competition, network communication) to identify the root cause.

Bottleneck cause-optimization match (§4.3): Based on 3 years of training optimization experience and 135 typical bottleneck cases, we have matched different bottleneck causes with possible optimization strategies (Table 4). We also developed an automatic optimization tool, mindstudio training tool (mstt) advisor [6]. Based on its built-in optimization rules learned from practice, it can automatically detect the causes of bottlenecks and provide optimization suggestions.

To show how to use *Hermes* for optimization, we present numerous cases, covering optimizations of classic bottlenecks and production tasks (§5). Our real-world cases include optimizing the 100B PanGu-α model [65], deploying MobileNetV1-SSD [35], and addressing performance fluctuations in MoE model training across over 9000 NPUs. These case studies show how to apply optimization based on bottleneck analysis and achieve speedups of 3.05×, 1.91×, and 1.19×, respectively, confirming the effectiveness of *Hermes*.

2 Background and Motivation

In this section, we present the goals and problems faced by different users in training and compare the differences and connections between Ascend NPU and NVIDIA GPU, which together motivate our systematic analysis and optimization.

[1] A basic mathematical operation (e.g., matrix multiply, convolution).

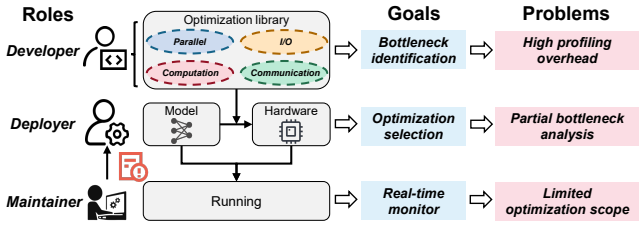

Figure 1: Different roles in model training.

2.1 Roles in Real-World Model Training

As shown in Figure 1, in real-world model training, three roles of users are involved: *developers*, *deployers*, and *maintainers*. Each role has specific responsibilities, challenges, and goals in optimizing training performance. (i) *Developers* are responsible for developing optimizations for different bottlenecks, such as I/O [24], computation [38],communication [46], or parallelism [25, 57, 67]. Therefore, developers must first *identify specific bottlenecks that limit training efficiency*, and then design targeted optimizations to mitigate them. (ii) *Deployers* deploy models on hardware and achieve high training efficiency. However, in practical deployment, users face constantly evolving models and hardware, leading to shifting training bottlenecks and rendering previous optimizations potentially unsuitable. Therefore, deployers must *analyze bottlenecks and select appropriate optimizations* to achieve the expected training performance. (iii) *Maintainers* monitor model training, ensuring smooth progress. However, in large-scale training, performance fluctuations [27] occur frequently and undermine training efficiency. In a 5-month cluster observation, an average of 2.4 incidents were recorded per month. In an 18,000-card cluster, single-card throughput ranged from 10 to 106 TFLOPs/s, with an average of only 85 TFLOPs/s, achieving only 84% of the expected throughput. Therefore, maintainers must *accurately capture performance fluctuations and identify the underlying causes*.

Training optimization usually consists of three key steps: 1) *Profiling* to collect key performance metrics; 2) *Analyzing* to identify training bottlenecks; and 3) *Optimizing* by applying suitable optimizations. Combining the goals of different roles, we summarize the requirements for training optimization.

- *Detailed but lightweight profiling.* Users should be able to collect detailed performance metrics, while profiling should be lightweight to monitor performance fluctuations.
- *Locating various bottlenecks accurately.* Users should be able to accurately identify I/O, computation, communication, and parallel bottlenecks.
- *Efficient optimization suggestions.* Users should be able to choose effective optimizations based on bottleneck causes. Although many technologies have been proposed to meet

these requirements, there are still some significant challenges.

Profiling: To capture transient performance fluctuations in long-term training, maintainers need to continuously monitor and collect detailed performance data for each step/NPU [50]. As shown in §4.1.3, simply profiling the single-step training of an 8B Llama-3 model on 8 NPUs incurs an overhead of 1.77× the original cost. Given the high per-step overhead, the cumulative cost of continuous profiling over thousands of steps in large model training becomes intolerable.

Analysis: Existing bottlenecks analysis are largely *manual*, users must explore all potential bottlenecks and compare the profiling results with the expertise [44]. Even if some auto-analysis can help users identify bottlenecks, they are limited to specific types, such as I/O [24] and RDMA bottlenecks [19, 34]. However, isolated analyses often miss the interdependencies between bottlenecks. For example, synchronization issues in communication bottlenecks may stem from uneven computational loads, while long computation times could result from slow operator compilation or dispatch on the CPU side. Therefore, the challenge lies in comprehensively identifying different types of bottlenecks.

Optimization: Although some tools like DayDream [70] and dPRO [22] can predict optimization effects based on task dependencies, their application is restricted to data parallelism [36]. In most cases, developers select optimizations without knowing the causes of bottlenecks, which can render the proposed optimization less effective. However, due to the complexity of the root causes and the diversity of optimizations, it is also challenging to match effective optimizations to different bottlenecks.

2.2 Comparison of NPU and GPU

Before addressing these challenges, it is necessary to learn the background of Ascend NPUs, especially the similarities and differences with NVIDIA GPUs.

Similar to GPUs, Ascend NPUs also follow the same hierarchical training paradigm. And NCCL, CUDA, and NVLink for GPUs correspond to HCCL (Huawei Collective Communication Library) [10], CANN (Compute Architecture for Neural Networks) [3], and HCCS (Huawei Cache Coherent System) [20] in Ascend, respectively. As shown in Figure 2, the training process on Ascend NPUs can be divided into the following layers: (i) *Application*. Users can train different types of models according to their needs, such as NLP, vision, recommendation, and multimodal. (ii) *Framework*. Ascend can support mainstream deep learning frameworks such as PyTorch, MindSpore, and TensorFlow [1] to convert model code into computation graphs. (iii) *Communication*. HCCL provides parallel communication in distributed training, supporting algorithms such as Ring and Mesh, and primitives such as AllReduce and AlltoAll. (iv) *Platform*. CANN is responsible for converting the computation graph into executable operators on Ascend NPUs, consisting of the operator

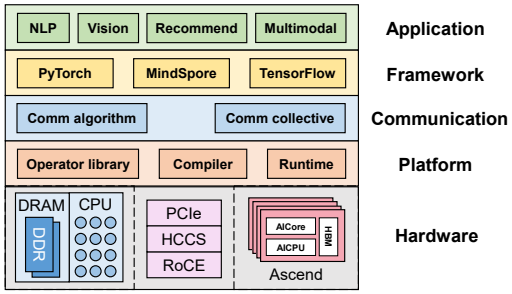

Figure 2: The training paradigm on Ascend NPUs.

library, compiler, and runtime (task scheduling). (v) *Hardware*. Finally, the operators are dispatched to NPUs for execution, while PCIe and HCCS for intra-node communication, and RDMA for inter-node communication. The detailed topology is given in Appendix A.

It is worth noting that there are some differences between the two in terms of chip architecture. In NPUs, AICore [31] is the computing core (similar to CUDA Core and Tensor Core in GPUs), responsible for performing computation-intensive tasks such as matrix and vector operations. However, unlike the GPU, there is another computing unit with slightly lower performance, AICPU [31], which is responsible for non-matrix computing tasks that AICore does not support.

Taking these into account, we can categorize training bottlenecks into two groups: (i) *Hardware-agnostic bottlenecks*. Since the consistent training paradigm and behaviors (data preprocessing, forward and backward computation, gradient update, and parallel strategies), common training bottlenecks, such as low parallelism, high I/O delays, inefficient computation, and slow communication synchronization, are universal regardless of whether the hardware is NVIDIA GPU or Ascend NPU. (ii) *Hardware-specific bottlenecks* refers to performance bottlenecks introduced due to Ascend's architecture characteristics that need to be analyzed separately, such as the inefficient AICPU operators, the overhead of private format for AICore, and the byte alignment requirements in HCCS.

Therefore, different bottleneck types lead to different profiling requirements. Compared to NVIDIA GPUs, the profiling of Ascend NPUs differs in two key aspects: (i) First, considering differences in architecture such as AICore, AICPU, and HCCS, dedicated profiling interfaces for these units are necessary to capture their performance metrics. (ii) Second, while NVIDIA Nsight [44] provides granular profiling interfaces for GPU kernels, network communication, storage, and more, it primarily treats these as isolated bottlenecks. The profiling of Ascend needs a holistic bottleneck analysis and actionable optimization recommendations.

3 Lessons and Insights

In this section, we will share the lessons learned from our practices and insights to achieve a holistic bottleneck analysis.

3.1 Lessons

We have summarized the following lessons from 135 training optimization cases on Ascend NPUs, including I/O, CPU, parallel, computation, and communication bottlenecks.

CPU scheduling bottlenecks dominate in practice but are often overlooked. As shown in Table 4, among all our optimization cases, host bottlenecks account for 45.9%, with CPU bottlenecks reaching 37.0%. This problem exists on both GPUs and NPUs. Although the executing streams of the CPU and device can operate asynchronously, synchronization and data transfers between the CPU and device can severely impact training efficiency. For example, recompilation of the operators can introduce the CPU bottleneck. Specifically, in the Pytorch framework, operators follow this compilation and execution logic. When an operator is invoked, the CPU first checks if it has been pre-compiled. If not, it undergoes just-in-time (JIT) compilation [49] to generate a binary executable dispatched to the device, which will introduce extra overhead.

Underutilization dominates computation bottlenecks. The computation bottleneck analysis reveals a significantly higher proportion of underutilized operators, ranging from 61.48% in 100B PanGu-α to 97.8% in ResNet50. And smaller models tend to exhibit a higher percentage of underutilization. When optimizing underutilized operators, it is essential to consider the characteristics of the Ascend hardware. The first possible cause is the AICPU operators. Due to the input type (not supported by AICore) or an implementation problem, the operators can only be executed on poorly performing AICPUs. In such cases, we should eliminate AICPU operators by converting data types (supported by AICore) or other substitutions. Similarly, replacing operators with better hardware affinity for AICore is another method to improve model FLOPs utilization (MFU). We define "good affinity" as whether the operator's shape meets the hardware's memory layout and alignment requirements (e.g., whether the inner axes of Cube computation are divisible by 256).

Contention between computation and communication. Parallel computing and communication can boost performance, but we observe that their concurrent execution may degrade performance in some situations. The root cause lies in resource contention, particularly the contention for HBM bandwidth. Specifically, communication tasks such as HCCS can access HBM via Direct Memory Access (DMA), whereas the primary computation matrix multiplication (MatMul) is often memory-bound. This leads to HBM bandwidth contention, resulting in lower-than-expected computing performance, often a drop of 20% to 40%. For example, in tensor parallelism, splitting the serial GEMM computation and communication into chunks [13, 27] can enable fine-grained overlap and greatly improve performance. However, overlapping computation and communication chunks can compete for HBM bandwidth, which affects individual performance. Thus, setting fine-grained priorities for HBM access can prevent such contention and further accelerate training.

Minimize remote access to alleviate I/O bottlenecks. I/O bottlenecks stem mainly from high data reading and processing overhead on the CPU side, which cannot overlap with NPU computations. In large-scale training, data reading bottlenecks are particularly prominent due to read/write on remote storage, including other remote access except for training data, such as checking file paths or writing logs. Therefore, unnecessary remote accesses should be minimized, for instance, by reading data only from the local card or DP domain. When unavoidable, like logging, data can be written to local storage first and periodically flushed to remote storage.

Port flapping and link failures dominate network issues. Based on our experience, network problems are mainly due to hardware, such as port flapping and link failures. Moreover, the closer these issues occur to the compute nodes, the greater their impact on the training performance of clusters. Thus, it is essential to promptly clean and replace optical modules and repair links with packet loss or error.

3.2 Insights

Based on these lessons, we have the following insights to achieve a holistic bottleneck analysis.

The training pipeline operates hierarchically, with different types of bottlenecks occurring in the corresponding components. As shown in Figure 2, the framework converts the program into a computational graph, with parallel strategies organized by HCCL, and finally, the graph is converted into executable operators on the hardware through the CANN. Specifically, data preparation is executed by CPU and DRAM storage on the host, while computation operators are mainly executed by AICore and AICPU on the device, and communication operators involve HCCS and RDMA on the network. Therefore, operator bottlenecks typically manifest in specific components, stemming from (i) issues in the operator's implementation and (ii) poor hardware efficiency.

In addition to bottlenecks in operators, the parallelism between operators can also become a training bottleneck. For example, Ascend supports multi-stream parallel execution in Pytorch, with the parallel efficiency between streams directly affecting the training. This includes not only the computation-communication parallel bottlenecks that the well-known parallel strategies (DP, TP, PP) aim to solve but also the parallelism between I/O and computation, as well as CPU and computation. Parallel bottlenecks, in turn, affect the execution of specific I/O, computation, and communication.

Considering parallel bottlenecks between operators and performance bottlenecks within each operator, we propose a hierarchical analysis. Specifically, bottleneck analysis is divided into two layers: inter-operator parallel analysis and intra-operator bottleneck analysis, covering all host, device, and network components. In this way, it provides a structured framework that can systematically decompose the complex

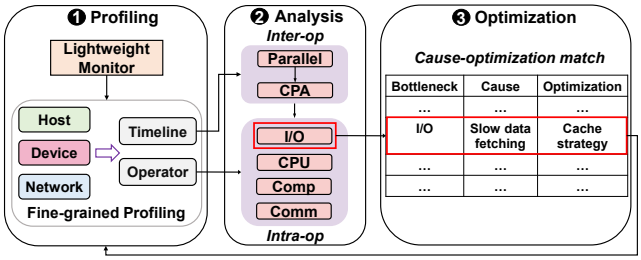

Figure 3: The workflow of *Hermes*.

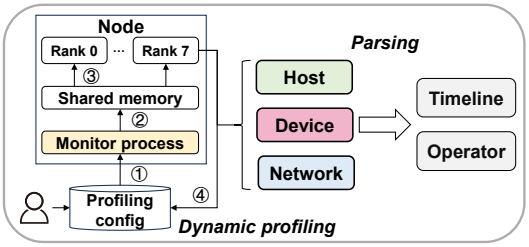

Figure 4: Fine-grained profiling.

training process into different layers and accurately identify bottlenecks in the most common locations.

4 System Design

In this section, we first introduce the main workflow of *Hermes*, then dive into the design of each core module. As shown in Figure 3, the main workflow consists of the following steps.

Coarse-to-fine profiling(§4.1): We observe that it only requires a few key metrics to determine the presence of performance fluctuations. Therefore, we propose a lightweight but fine-grained profiler to identify the problematic steps/devices and capture the necessary metrics.

Hierarchical bottleneck analysis(§4.2): We propose a hierarchical analysis model that first considers the inter-operator parallelism and then delves into the intra-operator implementation. In addition to identifying the bottleneck, we provide a set of mechanisms to trace the root causes.

Experience-guided optimization(§4.3): Based on our experience in bottleneck optimization, we propose an optimization advisor that automatically provides effective recommendations by establishing a match between bottleneck causes and corresponding optimizations.

Users can select the necessary steps based on their goals, e.g., the developer only needs to perform the profiling and analysis, and then directly develop their optimization strategy. The optimization workflow is iterative. After optimizing the current bottleneck, users can repeat the process until the desired performance is achieved.

4.1 Coarse-to-fine Profiling

As illustrated in Figure 3, the profiling module comprises a lightweight monitor and fine-grained profiling. The former collects key metrics in real-time to quickly identify problematic steps and devices with little overhead. Next, fine-grained profiling focuses on the problematic steps and devices, collecting detailed performance data without interrupting training while minimizing storage requirements and parsing times.

4.1.1 Lightweight Monitor

For model developers and deployers, it suffices to profile a selected step offline to analyze persistent slowdowns, as the performance of each training step is consistent. However, continuous online profiling is the only viable approach for maintainers who aim to pinpoint transient performance fluctuations. Therefore, to minimize the overhead of online profiling, this monitor collects only some coarse-grained key metrics during the whole training, including (i) the execution time of each step and (ii) overall performance such as throughput, MFU, and communication bandwidth, which are also the indicator of performance fluctuation.

Cluster Analysis. Based on the monitoring data, we use two steps to identify problematic steps and devices. (i) The first is to compare the execution time of the current step with the historical ones. If the current step is significantly slower, it indicates a performance fluctuation. (ii) We further need to determine which devices are experiencing issues in this step. Considering the various parallel strategies in training (e.g., data parallelism [30], tensor parallelism [41], and pipeline parallelism [23, 40]), the whole cluster is divided into different communication domains (devices involved in the same synchronization). Devices within the same communication domain theoretically have the same execution time. Therefore, we compare the execution times of devices within each communication domain to identify the slowest device, which is often the problem device and requires further profiling.

4.1.2 Fine-grained Profiling

After identifying the problematic steps and devices, we perform fine-grained profiling. We first profile the operator (the smallest execution unit) and collect metrics from various components: (i) *host operator*, including I/O operator queues, and CPU operator metrics related to the Pytorch framework and the CANN operator library; (ii) *computation operator*, computation performance (precision, frequency, FLOPs), and memory access performance (byte and bandwidth) on NPUs; (iii) *communication operator*, transfer time and bandwidth of PCIe, HCCS, and RDMA interconnect. Furthermore, we profile the timeline to illustrate the timing dependencies of operators across different components. However, there are two challenges when fine-grained profiling is applied.

Table 1: Profiling cost comparison of end-to-end training.

Model	#Para	#NPU	Time		Memory		CPU usage	
			Before	After	Before	After	Before	After
Bloom	7B	8	1300 s	1000 s	1650 MB	1800 MB	1%	5%
PanGu	230B	128	120 min	102 min	13.8 GB	16.2 GB	1%	5%

Dynamic profiling. Common profiling tools such as PyTorch Profiler [50] require users to pre-configure monitoring parameters (e.g., via torch.profiler.schedule) before training begins. This intrusive approach requires interrupting training, which incurs prohibitive overhead for large-scale jobs due to checkpoint reloading and warm-up costs. Recent works like Llama-3 [17] have recognized this limitation and enabled on-the-fly configuration changes [55]. On this basis, we propose a more specialized and lightweight dynamic profiling framework with the following features: (i) fully decoupled from the program; (ii) faster synchronization based on shared memory and thread-level updates; (iii) automatically perceives the context to activate profiling and adapts to Ascend-specific metrics. As shown in Figure 4, after modifying the configuration, each node uses a dedicated thread to monitor configuration changes (①) and places it in shared memory (②). Before the next step starts, each rank reads the updated configuration and begins executing profiling (③). Once the step ends, each rank outputs the profiling results for subsequent parsing and configuration adjustments (④). In addition, dynamic profiling can seamlessly integrate with the lightweight monitor, automatically triggering when performance fluctuations are detected.

Efficient parsing. Fine-grained profiling data must go through several parsing steps before being presented to users, including reading, calculating, and visualizing. Considering a cluster with 10,000 NPUs, the profiling data can reach several TBs, potentially requiring days for processing and causing visualization tools such as TensorBoard [21] and Chrome Trace Viewer [16] to slow down or crash. Therefore, we standardize the database format for all metrics, resulting in a 75% reduction in memory usage. We not only leverage multi-threading and high I/O concurrency to accelerate parsing but also utilize idle CPU resources across multiple machines like Canopy [28]. In addition, we can hide the parsing latency within the training phase by transitioning from synchronous to asynchronous parsing. Finally, the MindStudio Insight tool [5] can handle extremely large datasets (more than 10 GB) and reduce latency to under 30 seconds, even with 10,000 cards.

4.1.3 Profiling Cost

Our design balances the overhead associated with the lightweight monitor and fine-grained profiling. When training the 8B Llama-3 model on 8 NPUs, each step takes 85.19 s without profiling and 150.58 s with detailed profiling. With a lightweight monitor, the time is only 85.20 s. After end-to-end validation, our profiling significantly reduced training time compared to existing profiling methods, with minimal impact on resources. As shown in Table 1, when using coarse-to-fine profiling compared to detailed profiling, the end-to-end training time is reduced by 23% for the 7B Bloom model with 8 NPUs and 15% for the 230B PanGu model with 128 NPUs. Meanwhile, memory usage increased by only 9% and 5%, respectively, while CPU usage increased by only 4%.

4.2 Hierarchical Bottleneck Analysis

Hermes employs a hierarchical analysis, which begins with a parallel analysis across different operators and then delves deeper into each operator to identify its bottleneck causes.

4.2.1 Inter-operator Analysis

Inter-operator analysis consists of two steps: (i) identifying parallel bottlenecks among operators by multi-component parallel analysis; (ii) pinpointing bottleneck operators by critical path analysis [29]. The overlap between host, computation, and communication will directly affect the composition of operators on the critical path, causing shifts in the bottleneck operators. Consequently, two steps work together to first resolve parallel bottlenecks before optimizing specific operators (I/O, CPU, computation, or communication).

Multi-component Parallel Analysis. Since components can run in parallel, different types of operators can overlap to accelerate training. Conversely, shorter overlaps reduce component utilization, causing parallel bottlenecks. However, existing works (such as Syndicate [37]) focus solely on the overlap between computation and communication without considering the host operators. We perform a parallel analysis of operators across all components. A typical step time is divided into several segments: *overlap*, where computation and communication/host operators run simultaneously; *non-overlap computation/communication/host*; and *free time*. Therefore, if the overlap ratio is significantly lower than the threshold, it indicates the presence of parallel bottlenecks. Further, for the non-overlapping parts, we should identify the *critical operators* that are truly slowing down the training.

Critical Path Analysis. We extract the critical path [29] composed of operators from different components along the timeline, and accelerate training by reducing the execution time of operators on it. Specifically, we infer a dependency between two operators across different components when the completion time of one operator aligns with the start time of the subsequent operator. We validate this by the inter-operator relationships defined in the computation graph. Accordingly, we develop a traversal algorithm starting from the last operator and searching backward to identify the longest sequence of dependent operators that leads back to the initial operator. In this way, we can pinpoint the critical operators that significantly influence the execution time, reducing the number of operators to be analyzed by more than half. We then rank these critical operators by their execution times to identify the most time-consuming ones for cause analysis.

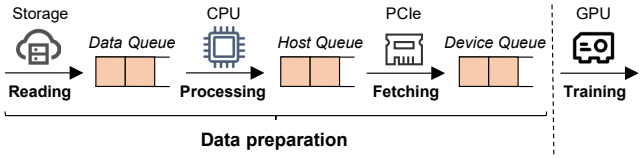

Figure 5: Queue-based I/O analysis.

4.2.2 Intra-operator Analysis

Based on practical experience, we have summarized the causes and detection mechanisms of various types of bottlenecks for critical operators, including host-side I/O and CPU, computation, and communication.

Queue-based I/O Analysis. To provide training data for computation, I/O usually consists of the following stages. As shown in Figure 5, the data first needs to be read from the storage (*data reading*) and then transferred to the CPU for processing (*data processing*). For example, the processing in language models involves tokenization, padding & truncation, and word vectorization [12]. Then, the processed data will queue up on the host side, waiting to be transferred to the devices (*data fetching*). All stages can lead to bottlenecks, and we can use the corresponding queue states to identify them. The Device Queue stores data transferred from the host to the device. If the device queue is not empty, it indicates that there is enough data to continue training, which does not happen in I/O bottlenecks. Conversely, we then move to the Host Queue, which stores processed data. If the host queue is not empty, it indicates a fetching bottleneck, often due to slow transfer between the host and device. Conversely, we need to trace back to the Data Queue, which holds the reading data. If the data queue is not empty, it indicates a processing bottleneck. Otherwise, it points to a reading bottleneck.

Based on Meta's I/O analysis [66], considering that data processing is mainly CPU-based in our practice, we have summarized the following common causes of I/O bottlenecks: (i) *Data reading.* Low disk I/O bandwidth, or restricted network bandwidth to access remote storage. (ii) *Data processing.* Extra overhead from data format conversions, such as with compressed files like zip and tar; no multiprocessing in the dataloader ($num_worker = 1$); other multiprocessing operations that may affect the *dataloader*, like the taskset command [33] for process CPU binding. (iii) *Data fetching.* PCIe transfer from host to device becomes a bottleneck. In this case, consider enabling the *pin_memory* option to transfer data directly to the device through DMA. Faced with complex causes of I/O bottlenecks, *Hermes* only lists potential causes corresponding to the current bottleneck to guide users in inspecting the targeted configurations manually.

CPU Causes Analysis. The CPU handles the compilation of operators and dispatches them to the device, and its performance directly impacts overall training. Based on extensive practice experience, we observe that various causes may result in CPU bottleneck and summarize their reasons in Table 2.

Table 2: CPU bottleneck causes.

Cause	Reason
Operator Compilation	Dynamic shape operators require recompilation
Operator Dispatch	Excessive dispatch or synchronous operations
Garbage Collection	Frequent garbage collection events
CPU Resource Contention	Interference of external CPU process
Environment Configuration	Unsuitable hardware or software configurations

- *Operator Compilation.* Operators must be compiled on the CPU to generate NPU-executable code. If an operator's shape changes, JIT compilation is triggered, adding extra compile time and causing a CPU bottleneck. Thus, *Hermes* detects compilation timeout operators, especially dynamic shape operators, and advises users to replace them or disable JIT compilation.
- *Operator Dispatch.* Dispatching compiled operators from the CPU to the NPU for execution can cause a CPU bottleneck. First, numerous small operators may be dispatched frequently. Thus, *Hermes* provides fusible operator analysis to show the sequence of operators with fusion value. It advises users to fuse these small operators into one, reducing dispatch times. Second, although dispatch is asynchronous, developers might introduce synchronous operations between CPU and NPU streams like *SyncBatchNorm*, *tensor.item*, and *reduce_all*, which slow down the process. Thus, *Hermes* detects the time-consuming synchronous streams and displays their stack, which helps users modify the code to eliminate these sync streams.
- *Garbage Collection (GC).* Python's garbage collection mechanism can automatically detect and free up memory that is no longer in use. However, during large-scale training, the significant fluctuation in memory usage can trigger garbage collection more frequently, which in turn leads to drastic performance degradation. Thus, *Hermes* provides a GC analysis to record the occurrences and durations of abnormal GC events. It suggests that users address GC problems by adjusting the threshold using $gc.set_threshold()$ or disabling GC using $gc.disable()$.
- *CPU Resource Contention.* Other CPU processes unrelated to training may compete for resources, which affects the training performance. In our experience, performance monitoring tools like Prometheus [18] often preempt CPU resources. So, *Hermes* periodically checks the CPU usage of common processes to prevent such contention.
- *Environment Configuration.* Both hardware and software configurations during training can affect performance. Hardware factors like the number of CPU cores, frequency, and computational power may be at play. Potential software issues include OS bugs, high logging levels, memory usage, and inconsistent driver versions. *Hermes* provides self-test scripts to troubleshoot these potential problems.

Computation Cause Analysis. We use the Roofline model [59, 64] to evaluate the computation performance. As shown in Figure 6, the solid line represents the peak perfor-

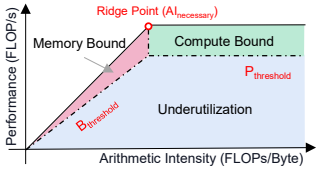

Figure 6: Roofline-based computation Analysis.

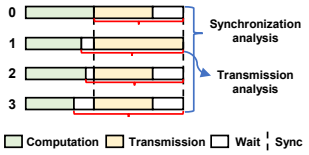

Figure 7: Time breakdown of AllReduce operator.

mance that an operator can achieve with a given arithmetic intensity. The height of the line reflects the arithmetic performance, while the slope of the line reflects the memory bandwidth. We add two dashed lines for the thresholds: the left one marks the bandwidth utilization threshold, and the right one marks the arithmetic utilization threshold. The red area upon the left threshold shows *memory bound*, while the green area upon the right threshold shows *compute bound*. The blue area below the two thresholds represents the *underutilization*. The operator's performance point falling in a specific region determines its computation bottleneck (Appendix B).

Different computation bottlenecks often have different causes. When compute bound, *Hermes* will check whether the node is downclocked over the threshold (often 5%) or has poor intrinsic arithmetic. When memory bound, *Hermes* will suggest operator fusion [43, 68], quantization [38, 56, 63], or using memory optimization techniques like ZeRO [51, 52]. In practice, most operators are underutilized due to various reasons, such as inefficient AICPU operators, operators with suboptimal hardware affinity with Ascend, or private data formats causing extra conversion overhead. For all of these, *Hermes* has the corresponding detection and optimization rules. For a more detailed analysis of operator performance, refer to [69] and the Ascend Optimization Engine [9].

Communication Cause Analysis. As shown in Figure 7, we analyze the causes of communication bottlenecks using the AllReduce operator as an example. Its execution consists of two synchronizations and one transmission. First, it waits for all devices to complete their computations before starting transmission, and synchronization occurs again after all devices have finished transmitting. Consequently, both synchronization and transmission can lead to communication bottlenecks, necessitating a separate analysis of each.

Synchronization analysis examines the wasted time when a device waits for others to complete. For example, in post-transmission synchronization[2] among n devices, we use T_i to denote the transmission time of i-th device. As each device needs to wait for the slowest device to finish its transmission, we use $T_{\max} = \max_{i=1}^{n} T_i$ to denote the slowest transmission time. Accordingly, the overall wait time can be modeled as:

$$T_{\text{wait}} = \sum_{i=1}^{n} (T_{\max} - T_i) = n\left(T_{\max} - \frac{1}{n}\sum_{i=1}^{n} T_i\right) = n(T_{\max} - T_{\text{avg}}) \tag{1}$$

[2]It can be seamlessly extended to synchronization after computation.

Table 3: Communication bottleneck causes.

Cause	Reason
Bandwidth Contention	Intra-node bandwidth contention for parallel computing and communication
RDMA Retransmission	Frequent RDMA timeout retransmission
Small Packet	Underutilization of bandwidth by small packet
Byte Alignment	HCCS data size misalignment
Network Configuration	Switch congestion or UDP port hash collisions

In addition, we have total time, where each device needs $T_{\max}$ including transmission and wait time, by summing them up, we obtain:

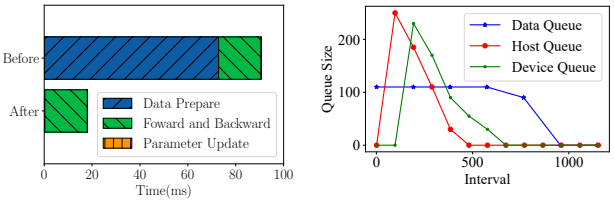
$$T_{\text{total}} = n \cdot T_{\max}, \quad R_{\text{wait}} = \frac{T_{\text{wait}}}{T_{\text{total}}} = 1 - \frac{T_{\text{avg}}}{T_{\max}}, \tag{2}$$

where R_{wait} is the ratio of wasted wait time. We set a threshold to determine whether slow synchronization is the cause.

Transmission analysis aims to identify the causes affecting transmission efficiency, including PCIe, HCCS, and RDMA links. *Hermes* first confirms whether the link bandwidth meets the expected threshold. If all links have reached their physical limit, it will advise users to upgrade the network. Otherwise, it will detect all the problems summarized in Table 3 to determine the true cause of the suboptimal bandwidth.

- *Bandwidth Contention.* The transmission of communication operators can be affected by computation operators, particularly due to the bandwidth contention from the intra-node interconnect (HCCS and PCIe). This problem is particularly pronounced when memory-intensive operators, such as MatMul, are executed concurrently. *Hermes* monitors whether the communication operator's intra-node bandwidth falls below the threshold. If so, it will recommend users to re-schedule operators.
- *RDMA Retransmission.* For inter-node transmissions, RDMA retransmissions are a significant cause of bandwidth degradation. *Hermes* compares the RDMA transmission time of communication operators to a retransmission threshold (often 4 seconds). If a retransmission occurs, *Hermes* will advise users to verify the retransmission duration and the network configuration of switches and servers.
- *Small Packet.* Small packet sizes can lead to multiple transmissions, reducing bandwidth utilization. *Hermes* has determined the packet size thresholds at which each link reaches its bandwidth limit in practice. Thus, *Hermes* checks for an excess of packets much smaller than the threshold. If found, it will advise increasing the batch size, gradient fusion [26, 46], or operator fusion.
- *Byte Alignment.* HCCS communication requires memory alignment; the data size must be a multiple of 512 bytes to avoid a drop in the transmission bandwidth. *Hermes* offers a byte alignment analysis for communication operators. It detects operators that do not meet this requirement and suggests adjusting their data size.
- *Network Configuration.* Other network misconfigurations

can also seriously affect communication. *Hermes* summarizes and automatically detects common ones, such as anomalies in HCCL environment variables, congestion from switch settings, or UDP port hash conflicts. Unfortunately, if these analyses fail to reveal the problem, manual intervention is essential.



4.3 Bottleneck Cause-Optimization Match

As of December 2024, we have addressed 223 training performance issues for over 40 clients, identifying 135 key cases for analysis and summarization. Among these, both CPU and computation bottlenecks account for over 30%. The former is often caused by system, hardware, or implementation issues and can be overlooked. The latter is mainly due to poor operator implementation, insufficient hardware affinity, and a lack of operator fusion. Based on these cases, we developed the mstt advisor [6]. By inputting profiling data, it will automatically identify the bottleneck through hierarchical bottleneck analysis. As shown in Table 4, the advisor has established many analytical rules for each bottleneck cause and provides all applicable optimization suggestions. Notably, the optimizations provided by the advisor mainly target hardware-agnostic bottlenecks, including parallel, CPU, and most communication bottlenecks. These bottlenecks inherently stem from unified training paradigms and frameworks, allowing the optimizations to be extended to other hardware platforms. However, bottlenecks directly tied to Ascend features, such as AICPU operators, API affinity conflicts, private data formats, and HCCS byte misalignment, cannot be extended.

In summary, using profiling data as input, the advisor can automatically generate a complete analysis report in HTML showing bottlenecks in current training. For example, when detecting AICPU operators whose execution time exceeds the threshold, the advisor will output *AICPU issues* and provide the following optimization suggestions: (i) *Convert the data type to those supported by AICore.* AICPU only executes operators if their data formats are not supported by AICore. Therefore, the advisor lists common operators' supported data formats on both AICPU and AICore. If the target operator is on the list, the advisor will recommend that users reformat the input to AICore compatible type, such as converting the Mul operator's input from int16 to int32. (ii) *Modify code to avoid AICPU operators.* For AICPU operators that cannot convert the format, the advisor suggests replacing them with equivalent operators in AICore or avoiding their use.

5 Case Study

In this section, we provide extensive case studies, including classic bottlenecks and real-world production problems, to demonstrate how *Hermes* guides optimizations.

(a) Time breakdown. (b) Queue size distribution.

Figure 8: I/O analysis and optimization of ResNet50.

5.1 Case Study of Classic Bottlenecks

Here, we present typical optimization cases for I/O, CPU, and communication bottlenecks, explaining the reasons behind the optimizations (more cases are in Appendix C and D).

5.1.1 Case Study of I/O Optimization

The single-card ResNet50 model training is an example of experiencing an I/O bottleneck. As revealed in Figure 8(a), before optimization, the execution time per step is approximately 90 ms, with data preparation taking around 72.8 ms, indicating an I/O bottleneck. Therefore, the advisor performed a queue-based I/O analysis, where the data distribution in different queues is shown in Figure 8(b). As training begins, the data, host, and device queues peak in sequence. Over time, the device and host queues gradually empty, while the data queue remains full. And the advisor concluded that the I/O bottleneck was attributed to slow data processing.

Optimization: Based on the suggestion of the mstt advisor, we found that only one CPU core was active during processing ($num_worker = 1$). To address this, we increased the number of concurrent threads to 12 to better utilize CPU parallelism.

Results: Although the parallelism only increased by 12×, this optimization enables overlap between data processing and subsequent NPU computation, allowing the processing time to be almost completely hidden within the computation time. As shown in Figure 8(a), the explicit data preparation time was reduced to 0.25 ms. The step time was reduced to 18.07 ms, achieving a speedup of 5.34×.

5.1.2 Case Study of CPU Optimization

During GPT-3 training on a single node with 8 NPUs, we observed an average step time of 444.40 ms, accompanied by significant performance fluctuations, with many steps exceeding 1000 ms and a maximum of 3027.6 ms. Cluster analysis identified the 153rd step as a major performance degradation, pinpointing rank-3 NPU as the slowest card. Further bottleneck analysis revealed a long non-overlap host time of 130.86 ms, indicating a severe host bottleneck, primarily due to the excessive execution time of the $aten :: mul$ operator.

Optimization: *Hermes* analyzed the CPU performance and found no issues with operator compilation, dispatch, synchronization, garbage collection, or SW/HW configurations.

Table 4: Cause-optimization match.

Bottleneck	Cause	Optimization	Ratio
Parallel	Poor Parallelism	Auto hybrid parallel [67] / Multi-shard parallel	5.2%
I/O	Slow Data Reading	Increase I/O bandwidth / Remote to local storage	8.9%
	Slow Data Processing	Improve CPU parallelism (num_workers)	
		Avoid compression formats (zip, tar)	
		Cancel the taskset process binding [33]	
	Slow Data Fetching	Cache strategy (pin_memory, data prefetcher) [24, 66]	
CPU	Operator Complication	Replace dynamic shape operators / Disable JIT compilation	37.0%
	Operator Dispatch	Operator fusion [43, 68] / Eliminate synchronization operations	
	Garbage Collection	Disable gc / Increase gc threshold	
	CPU Resources Contention	Disable other CPU process	
	Environment Configuration	Align software versions / Reduce logging level	
Computation	Compute Bound	Avoid decreasing computing frequency / Isolate slow nodes	31.9%
	Memory Bound	Operator fusion [43, 68] / Quantization [38, 56, 63] / ZeRO [51, 52]	
	Underutilization	Eliminate AICPU operators	
		Replace operators with affinity APIs	
		Forbid private format	
Communication	Bandwidth Contention	Avoid bandwidth contention by re-scheduling operators	17.0%
	RDMA Retransmission	Adjust RDMA network configurations of switch and server	
	Small Packet	Increase batch size / Gradient fusion [26, 46] / Operator fusion	
	Byte Alignment	Align HCCS data size	
	Network Configuration	HCCL environment variables / Switch congestion control / UDP hashing collision	

Table 5: Gradient fusion optimization of VGG16.

	Computation (ms)	Non-overlap Communication (ms)	Free (ms)	Total (ms)
Before	54.555	21.760	0.177	76.492
After	52.907	3.594	0.139	56.640

Eventually, CPU usage shows that a Prometheus monitoring program was deployed on this machine, consuming a massive 4000% of CPU resources. This plugin was originally intended for the master node but was mistakenly deployed on the worker node, leading to performance degradation.

Result. After terminating the Prometheus process, the average step time for GPT-3 training decreased to 374.88 ms, with only 4 of 4989 steps exhibiting performance fluctuations exceeding 10%, marking a significant improvement in stability compared to the original 128 steps.

5.1.3 Case Study of Communication Optimization

As shown in Table 5, the step time of VGG16 8-card training is 76.492 ms, with the non-overlap AllReduce operators taking 21.760 ms, resulting in a communication bottleneck. According to the synchronization analysis, the maximum value of R_{wait} is 0.3 and exceeds the threshold. Therefore, the bottleneck is caused by the slow transmission from Rank 7 NPU. This operator only involves HCCS communication, with a bandwidth utilization of only 53%. The average size of HCCS packets is only 12.81 MB, which is too small compared to the 32 MB threshold, resulting in bandwidth underutilization.

Optimization: Faced with this problem, *Hermes* suggests using gradient fusion [11] to improve bandwidth utilization,

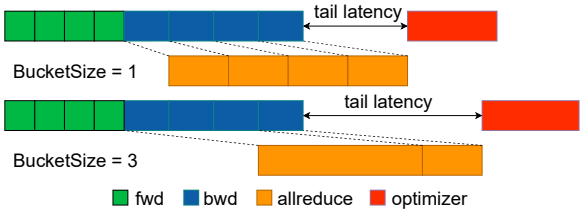


Figure 9: Inappropriate bucket size setting.

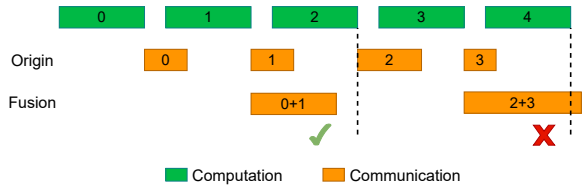
which fuses the gradients of multiple backward computations. However, existing frameworks like Pytorch and Horovod [53] only allow for fixed capacity or manual configuration. As shown in Figure 9, undersized capacity (BucketSize=1) cannot improve bandwidth utilization, while oversized capacity (BucketSize=3) can result in long-tail latency. Thus, we further integrate the profiling result to guide our fusion. Specifically, we simulate the AllReduce fusion for gradients of different sizes, which reveals the benefit (time reduction/bandwidth improvement). In addition, we collect execution information to predict the tail latency for a given fusion strategy, including 1) the size of each gradient, 2) the dependencies between operators, and 3) the duration of each computation operator. We model an optimization problem and introduce a greedy forward search algorithm to find a solution by maximizing bandwidth and minimizing tail latency. As shown in Figure 10, we can adaptively fuse the gradients according to the search algorithm. The details can be found in Appendix E.

Results. After this optimization, the non-overlap communication time decreased to 3.594 ms, and the step time subsequently dropped to 56.64 ms with a 1.35× speedup. In addition, we also evaluated common vision, NLP, and recommen-



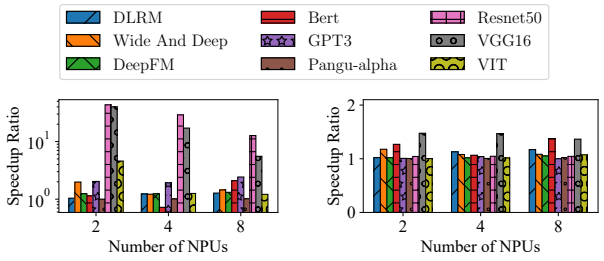


Figure 10: Forward search fusion.

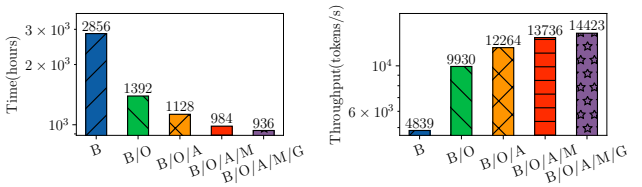
(a) Non-overlap communication. (b) Step time.

Figure 11: Speedup of communication optimization.

dation models. Figure 11 shows the speedup of non-overlap communication and step time before and after optimization. Specifically, *1) if a small packet size is not the root cause pinpointing by Hermes, then the corresponding optimization is limited.* DLRM [42] exhibits a limited improvement in Figure 11(a) because the packet size is large enough. *2) if one is not identified as a bottleneck by Hermes, then the improvement is limited.* For instance, in ResNet50, the optimization brings a significant reduction in non-overlap communication in Figure 11(a), but the step time is not significantly improved in Figure 11(b), since communication is not the bottleneck.



5.2 Case Study of Real-world Model Training

Our practices are conducted on the Ascend training clusters shown in Appendix A. Here, we present three real-world cases in diverse task scenarios, sharing our practical insights.

5.2.1 Iterative Optimization Development for PanGu

We present the iterative analysis and optimization by *Hermes* on the 100B PanGu-α model training. The process consists of three iterations corresponding to bottlenecks: (i) computation, (ii) parallel, and (iii) communication. We can address these bottlenecks by applying optimization recommendations, resulting in the 3.05× speedup in the overall training time.

Baseline: The 100 billion parameters PanGu-α language model is deployed on 128 Ascend NPUs. We selected 50 billion tokens from the original 1.1TB Chinese text corpus from [65] as the training dataset. The baseline configuration is from MindSpore's official SOTA models [4], which employs a re-computation and hybrid parallelism strategy, with data

(a) Overall training time. (b) Overall training throughput.

Figure 12: PanGu-α overall training performance, where B denotes Baseline, O denotes Operator optimization, P denotes Auto hybrid parallelism, M denotes Multi-shard parallelism, and G denotes Gradient fusion.

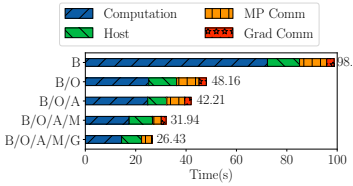


Figure 13: Step time of PanGu-α model.

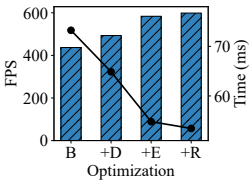

Figure 14: Deploy optimization.

parallelism is 2, tensor parallelism is 8, and pipeline parallelism is 8. The *batch_size* is 512, while the *micro batch_size* is 32. As shown in Figure 12, the total training time is 2856 hours, achieving a throughput of 4839 tokens/s.

Iteration 1: Computation Bottleneck. In the inter-operator analysis, the step time consists of three parts: computation (including overlap), non-overlap communication, and host. Considering the parallel strategy, non-overlap communication can be divided into model parallel communication (Send/Receive) and gradient communication (AllReduce). As shown in Figure 13, the computation time in the baseline accounts for a staggering 73.5% of the iteration time. Thus, even with a satisfactory overlap ratio (8.76%), the computation remains a bottleneck. According to the intra-operator analysis, the top 10 time-consuming computation operators totally consume 59.59 s, accounting for 83.57% of all computation operators. *Therefore, addressing these operators is our top priority.*

Facing the computation bottleneck, we have identified the primary cause of underutilization by Roofline analysis. Following the suggestions from *Hermes*, we have adopted operator optimization, such as replacing high-performance operator, operator fusion [43], and forbidding private formats to accelerate computations. The details can be found in Appendix C. Based on Figure 12, the operator optimizations reduce the step time from 98.01 to 48.16 s and the total time from 2,856 to 1,392 hours, a speedup of 2.05×.

Iteration 2: Parallel Bottleneck. After addressing the computation bottleneck, we observed a reduced computation ratio to a reasonable level of 52.2%. However, we noticed that the overlap between computation and communication only ac-

counted for 2.66% of the step time. The bottleneck has moved to *a significant parallel bottleneck*.

Based on the advice of the advisor, we have adopted two different optimizations to improve parallelism. (i) *Auto hybrid parallelism.* Encouraged by auto parallelism [67], we propose the pipeline parallel simulation to identify a more optimal parallel configuration. Based on the simulation results, we find that incremental *micro batch_size* within a certain range improves throughput, especially at higher pipeline parallelism. Furthermore, if the LayerNorm operator is used for data parallelism, reducing the tensor parallelism can enhance computation performance. Consequently, we adjust the parallel configuration by increasing *micro batch_size* from 32 to 64, setting the pipeline parallelism to 16, and halving the tensor parallelism. By applying the better parallel configuration, the step time decreased from 48.16 to 42.21 s. (ii) *Multi-shard parallelism.* In brief, we divide the task executed within an NPU into two parallel parts: one for computation and the other for communication (details in Appendix D). This approach has improved the overlap ratio and reduced the step time to 31.94 s. Together, the two optimizations accelerated the total time from 1,392 to 984 hours, a speedup of 1.41×.

Iteration 3: Communication Bottleneck. After enhancing the parallelism to 11.19%, we further analyzed the non-overlap communication, including Send, Receive, AllGather, and AllReduce. Among these, AllReduce accounts for 46.83% of the communication time and 22.55% of the step time. Therefore, we must focus on *the communication bottleneck from AllReduce operators*.

Through the communication analysis of AllReduce, *Hermes* has identified that the bottleneck originates from the small packet. Thus, we applied the adaptive gradient fusion in §5.1.3 to address it. As depicted in Figure 12 and Figure 13, the optimization reduced the step time from 31.94 to 26.43 s, with a 1.05× speedup in total time to 936 hours.

5.2.2 MobileNetv1 Deployment Optimization

The MobileNetv1-SSD [35] vision model is applied to object detection in autonomous driving. When migrating this model from an NVIDIA A800 GPU to Ascend NPU directly, users observed significant performance degradation (only achieved 43% of the former), requiring deployment optimization.

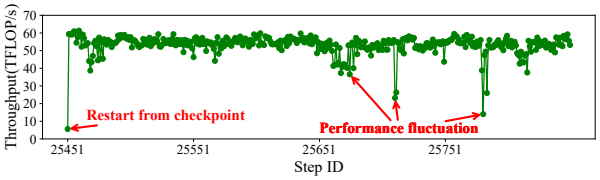
To simplify the analysis, we start with single-card training to identify bottlenecks in NPUs. In the baseline, the model already incorporates the hardware-affinity optimizer (NpuFusedSGD [8]) and mixed precision optimization [38], achieving a step time of 73.24 ms and 436.942 FPS (Frame Per Second) as shown in Figure 14. Using *Hermes* for analysis, the results indicate the presence of significant CPU bottlenecks and provide the following suggestions.

Disable JIT compilation. *Hermes* reveals that operator compilation time on the CPU is high, with a total of 762 operators, which consume a staggering 57.862 ms. This issue stems primarily from the dynamic shape [48] of operators. If the input and output shapes of an operator remain constant during training, enabling JIT compilation allows for fusion optimization based on existing operator information, generating more efficient operators online. However, the dynamic shape will invalidate prior operator information and bring re-compilation costs. Thus, the advisor recommends disabling online compilation ($jit_compile = false$) and dispatching the compiled binary operators to reduce time. After this, the step time decreased to 64.87 ms and the FPS increased to 493.332.

Eliminate synchronization. Secondly, a total of 18 synchronization operations between CPU and NPU were detected, and the two slowest operations accounted for 24.136 ms. The frequent synchronizations are often attributed to certain synchronous operators and environment variable settings. Eventually, the advisor shows that it is due to the frequent use of $tensor.item()$. By replacing this function, we achieved a step time of 54.82 ms and an FPS of 583.695.

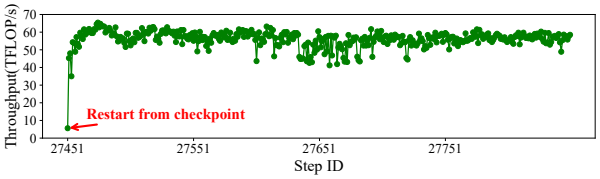
Replace affinity APIs. The advisor suggests that some APIs can be replaced with more hardware-friendly ones for Ascend. Specifically, tensor reshape and transpose functions in PyTorch like *view*, *permute*, *transpose*, and *contiguous* can be replaced with $npu_confusion_transpose$ [7]. This optimization brings a step time of 53.45 ms and an FPS of 598.716.

Unbind CPU process. When scaled up to 8-NPU training, we observed too high step time in the early steps of each epoch. *Hermes* revealed that there is an I/O bottleneck caused by a slow dataloader with 2857.845 ms, attributed to the taskset command that binds the CPU. This command is used to bind a process to specific CPU cores, reducing context-switching overhead, and improving cache utilization. However, incorrect CPU binding can cause the dataloader and other processes to be bound to the same core, resulting in memory bandwidth contention. Following the advice of the advisor, we unbind the CPU processes, recovering stabilized 8-NPU training performance. The training time decreased from 11.10 to 5.81 ms (1.91× speedup), and the FPS reached 90% of the GPU's performance (5921), meeting the performance goal.



Summary. Table 6 also summarizes the optimization results in deploying other models. Leveraging the optimization suggestions, we have achieved training speedups ranging from 1.08× to 5.34× for these vision, NLP, and recommendation models, demonstrating the effectiveness of *Hermes*.

5.2.3 Performance Fluctuation in Large-scale Training



When training a large model, even minor disturbances can lead to significant performance fluctuations, such as the decrease in MFU within MegaScale [27]. However, pinpointing the underlying causes is far from straightforward. Similarly, we frequently encounter performance fluctuations in large-scale training based on Ascend NPUs. Notably, 25% of our analyzed performance fluctuation cases were attributed to Python's garbage collection (GC) [47]. Here, we use a case

Table 6: Model deployment optimization results

Type	Model	Parameter	Optimization Speedup (-: not optimizable)						# of NPUs	Dataset
			I/O	CPU	Para.	Compu.	Comm.	Total		
Vision	ResNet50	25.6M	5.03	-	-	1.02	1.04	5.34	8	ImageNet2012

(a) Performance before optimization.

(b) Performance after optimization.

Figure 15: Performance fluctuations optimization.

study of 9,000-card MoE model training to share our experience in optimizing garbage collection.

As shown in Figure 15(a), after resuming training from the checkpoint, the throughput gradually increases to about 60 TFLOPs/s. However, during the 400 training steps, there are several significant performance fluctuations, dropping to a low of only 14.0 TFLOPs/s. Each of these drops persists for several steps, severely impacting overall performance. Bottleneck analysis revealed that, within the timeline of the slowest NPU, the non-overlap host time significantly exceeds that of other NPUs. Additionally, *Hermes* offers a GC detection interface to record its occurrences. The results indicated that the number of GC events far exceeded the threshold and performance fluctuations occurred whenever the GC was cleared. If the GCs are not synchronized between each stream, all GCs will execute sequentially within a step, slowing down training.

Although this issue stems from Python's GC mechanism and is currently unresolvable, *Hermes* provides alternative solutions to mitigate it. Firstly, disabling GC (*gc.disable*()) can prevent performance fluctuations but lightly increases training time (based on experience with 7B Llama-2, the cost is about 1%). Secondly, by using the *set_threshold* interface to appropriately increase the threshold, we can reduce the occurrence of fluctuations (with a cost of only 0.02%). Given the relatively low cost of the latter, this approach is commonly adopted in practice. Therefore, we appropriately increased the GC threshold and implemented periodic calls to the *gc.collect*() in the code (typically after saving checkpoints). The results of continued training after optimization, as shown in Figure 15(b), indicate a significant reduction in performance fluctuations. During the same 400 steps, the average throughput improved from 53.33 to 56.23 TFLOPs/s (1.05× speedup).

In addition to software issues, we also detected hardware-induced performance fluctuations when training models in the 18,000-card cluster. Training throughput ranged between 10 and 106 TFLOPs/s, with a high variance of 291, and an average of only 85 TFLOPs/s. Following the recommendations from *Hermes*, we made several optimizations, including switching log writes from remote storage to local storage, repairing four spine-leaf links, and isolating 30 compute nodes (due to port flapping, NPU memory failures, etc.). After these optimizations, training throughput stabilized between 63 and 108 TFLOPs/s, with a variance of 31, and the average improved to 101 TFLOPs/s (1.19× speedup).

6 Limitations and Future Work

We discuss the limitations and future directions of *Hermes*.

More model training techniques. Currently, *Hermes* is mainly used to analyze and optimize the training performance of the Transformer and MoE models. In fact, many new techniques are widely applied in the training of large models such as ChatGPT and Llama, including reinforcement learning (e.g. RLHF [15, 45]) and multimodal techniques [61]. However, *Hermes* currently cannot effectively analyze and optimize the bottlenecks introduced by them. For example, in RLHF, there are potential performance issues in iterative reward modeling, policy optimization, and environment interaction. In multimodal models, cross-modal data alignment (such as image-text fusion) is likely a performance bottleneck. Therefore, we plan to expand *Hermes* to support these emerging

model training technologies.

Diagnosing complex bottlenecks. In complex scenarios, it is still challenging for *Hermes* to diagnose the causes of bottlenecks. For example, in MoE model training, when the AlltoAll communication is severely unbalanced, a simple synchronization analysis is not sufficient to accurately determine whether it is a slow card or slow communication. There are also CPU bottlenecks caused by external environmental changes, which heavily rely on our current troubleshooting experience, currently limited to common monitoring software. As parallel strategies become more complex, including not only DP, PP, and TP but also expert parallelism and context parallelism, how to more accurately identify slow and fast cards becomes a challenge. Therefore, our goal is to improve *Hermes*'s ability to handle these complex situations, provide visualization functions, and more accurately identify bottlenecks.

Evolving cause-optimization mapping. *Hermes* has summarized the causes of bottlenecks and optimization mappings (Table 4) based on 135 actual cases, which already cover most of the bottlenecks and optimizations. However, it is foreseeable that new model training technologies and changing runtime environments will introduce new bottlenecks, and the corresponding new optimization techniques will continue to emerge. The existing mappings of *Hermes* cannot meet the needs and need to be continuously updated. In addition, we plan to move beyond rule-based heuristics by integrating training logs and even LLM-based agents to assist in more accurate root cause analysis and optimization suggestions.

7 Related Work

Performance Profiling. The most convenient way for users to obtain training performance is the built-in profiler of frameworks, such as PyTorch Profiler [50]. These profilers mainly collect information on specific operations within the training framework (e.g., execution time), but their support for hardware profiling is relatively limited (e.g., only GPU utilization and estimated SM efficiency). Furthermore, system-level performance analysis tools, such as Nsight Systems [44] for NVIDIA GPUs, not only provide detailed profiling metrics at the GPU kernel level but also capture the execution and resource utilization of the entire system in real-time, including CPU, GPU, NIC, and storage. However, with the popularity of large-scale training, frequent performance fluctuations [27] and the huge cost of long-term monitoring make it difficult for a single profiling tool to meet demand. In contrast, *Hermes* not only takes into account the architectural features of Ascend but also implements lightweight and online profiling similar to the Llama-3 training [17].

Bottleneck Analysis. After obtaining profiling data, users often need to manually identify bottlenecks based on their own experience. Although there are some automated analysis tools, they only target specific types of bottlenecks. For example, PRESTO [24] only focuses on I/O bottlenecks, SketchDLC [62] only focuses on communication bottlenecks, and some works [19, 34] only focus on RDMA bottlenecks. Even the most powerful Nsight System [44], which provides Expert Systems Analysis to automatically discover performance issues, only covers six rules, such as CUDA synchronous operation and low GPU utilization. In comparison, *Hermes* covers a wide range of common bottlenecks, not only saving a lot of time but also considering the relationships between different bottlenecks to find the real causes.

Training Optimization. Numerous optimizations have been developed to tackle the corresponding training bottlenecks. For example, PRESTO [24] accelerates data preparation by balancing storage capacity and I/O throughput. Mixed precision operation [38] speeds up the computation by reducing the input through compression. Schedulers such as ByteScheduler [46] enhance communication efficiency by controlling tensor splitting and fusion. Hybrid parallelism [57] and auto parallelism [25, 67] achieve a better overlap of computation and communication. When facing bottlenecks, it is also challenging to choose appropriate optimizations. Although tools such as DayDream [70] and dPRO [22] can predict optimization effects based on task dependencies, they are limited to data-parallel scenarios. The Expert Analysis of Nsight System [44] also provides only optimization suggestions for six rules. In contrast, *Hermes* can offer comprehensive optimization suggestions based on the root causes of bottlenecks.

8 Conclusion

In conclusion, *Hermes* addresses the critical issues of performance fluctuation detection, bottleneck analysis, and optimization strategy recommendation. By offering a lightweight profiler, a thorough hierarchical analysis framework, and matching bottleneck causes with optimizations, *Hermes* allows efficient training optimization. Our real-world case studies demonstrate the effectiveness of *Hermes*, leading to substantial improvements in training speed and stability. We believe that our insights from *Hermes* will help the community toward more efficient and stable large-scale model training.

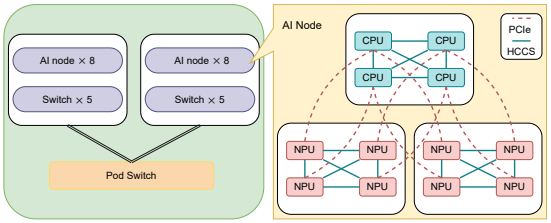

Figure 16: AI computing node topology.

Table 7: Per-node specification.

CPU Compute (TOPs)	1.96 (FP64) / 3.92 (FP32)
NPU Compute (TFLOPs)	2048 (FP16) / 4096 (INT8)
HBM	256 GB
DDR	2 TB
HCCS bandwidth	32 GB/s (uni-directional)
PCIe bandwidth	30 GB/s (uni-directional)
Network bandwidth	8 × 100 Gbps

A Environment details

Figure 16 shows the topology of the Ascend AI computing cluster in our experiments. Each cluster contains 16 NPU Pods, which are interconnected through high-speed aggregation switches. Each NPU pod comprises 8 AI compute nodes interconnected via high-speed access switches. In the single-node topology, every four NPUs are interconnected via HCCS, forming an intra-node cluster with a unidirectional bandwidth of 30 GB/s. The intra-node cluster and NPUs are connected to the CPUs through PCIe 4.0 with a unidirectional bandwidth of 32 GB/s. Each NPU has a 100G RoCE v2 direct outboard network port to establish interconnections with NPUs in other nodes.

Table 7 summarizes the aggregated capabilities of a single node with 4 CPUs and 8 NPUs. The 8 NPUs can provide 2048 FLOPs of half-precision peak computing power, 4096 TOPs of integer-precision peak computing power, and 256 GB of HBM. The four CPUs offer a total of 1.96 TOPs of single-precision peak computing power and 3.92 TOPs of double-precision peak computing power and share 2 TB of DDR4.0 general-purpose memory.

B Roofline Analysis

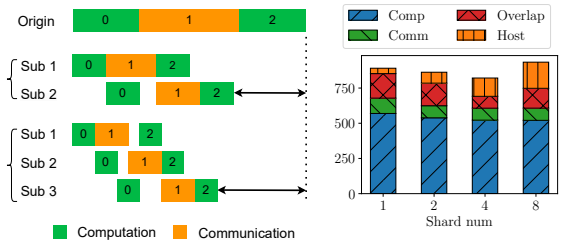
We define compute Arithmetic Utilization $U_{\text{arithmetic}}$(Memory Bandwidth Utilization U_{memory}) to measure the ratio of actual computational performance P_{actual} (bandwidth B_{actual}) to peak performance P_{peak} (bandwidth B_{peak}). A utilization threshold $U_{\text{threshold}}$ is first established based on practical experience to delineate underutilization. This leads to the establishment of performance threshold $P_{\text{threshold}} = U_{\text{threshold}} * P_{\text{peak}}$ and bandwidth threshold $B_{\text{threshold}} = U_{\text{threshold}} * B_{\text{peak}}$. We then introduce the following classification function.

$$f(P_{\text{actual}}, B_{\text{actual}}) = \begin{cases} \text{memory bound}, & \text{if } AI_{\text{actual}} \le AI_{\text{necessary}} \\ & \text{and } B_{\text{actual}} \ge B_{\text{threshold}}, \\ \text{compute bound}, & \text{if } AI_{\text{actual}} > AI_{\text{necessary}} \\ & \text{and } P_{\text{actual}} \ge P_{\text{threshold}}, \\ \text{underutilization}, & \text{otherwise.} \end{cases} \tag{3}$$

Following the roofline model, we use $AI_{\text{necessary}} = P_{\text{peak}}/B_{\text{peak}}$ in ridge point to classify the *memory bound* and *compute bound*. Operators that fail to meet either memory or compute thresholds fall into the underutilization category.

Referring back to Figure 6, the height of the line reflects the compute performance, while the slope of the line reflects the memory bandwidth. To visualize thresholds, two dashed lines can be added: the left line for $B_{\text{threshold}}$ and the right line for $P_{\text{threshold}}$. The area between these two threshold lines is shaded blue in the figure, marking the *underutilization* zone.

C Case Study of Computation Optimization



In 100B PanGu-α, the top 10 time-consuming computation operators mainly include MatMul/BatchMatMul, format conversion operators (TransData and Cast), and element-wise operators (Mul and Add). The roofline analysis shows that 61.48% of the bottlenecks were underutilized, while 34.02% were memory-bound, with compute-bound only 4.50%.

Optimization: For the underutilized operators, we chose the following optimization. 1) *FastGeLU.* We replace the inefficient GeLU operator with FastGeLU, which is a *high-performance operator*. 2) *Operator Fusion.* We fuse inefficient element-wise operators such as Mul and Add into the LayerNorm operator, which is suitable for parallel acceleration. We can also perform fusion on time-consuming MatMul operators, such as FastGeLU with MatMul or BatchMatMul with Add. 3) *Format Conversion:* Ascend's matrix compute unit (Cube [31]) only supports private formats (Appendix F), while tensor inputs often do not, leading to frequent format conversions during training. So we defaulted to using the private format to reduce the need for format conversion operators.

Results. After the optimizations, the computation time per step decreased from 72.31 s to 25.16 s. Specifically, regarding the distribution of computation bottlenecks, the ratio of underutilized operators decreased to 46.32%, and most of them shifted to the memory-bound.

D Case Study of Parallel Optimization

Taking the GPT3-13B model with 8-card 8-way tensor parallel training as an example, as shown in Figure 17(a), the single step time is 890.92 ms, 'Host', 'Comp' and 'Comm'

(a) Multi-shard parallelism. (b) Results on GPT3.

Figure 17: New optimization for parallel bottleneck.

are non-overlapping parts. The multi-component parallel analysis shows that the overlap time between computation and communication is only 38.149 ms, suggesting a parallel bottleneck.

Optimization: Inspired by finer-grained parallelism [14, 58], we propose the multi-shard parallel strategy to divide the computation and communication tasks within the same NPU, further enhancing the overlap. According to Figure 17(a), the computation and communication tasks are sequential and independently executed in the origin training, resulting in only one component being utilized while the other is idle. Our optimization tries to parallelize the computation and communication components by splitting the task along the *batch_size* dimension into two shorter tasks. Within the same device, one task focuses on communication, while the other performs computation. Moreover, increasing the number of partitions can theoretically achieve higher parallelism, but it also introduces additional overhead, which is a trade-off. Notice that multi-shard parallelism can be used as a standalone parallel strategy or combined with others like tensor parallelism.

Results: During tensor parallelism, AllReduce (AllGather and ReduceScatter) communication is typically involved before and after the computation of the self-attention and linear layers [54], which is consistent with multi-shard parallelism. As shown in Figure 17(a), we evaluated with shard numbers 2, 4, and 8. When num=2 or 4, the overlap time ratio increases, resulting in more overlapped computation and communication, and the step time decreases to 860.46 ms (1.04×) and 821.375 ms (1.08×), respectively. Surprisingly, when num=8, although the overlap time continues to increase, the step time increases instead of decreasing, reaching 933.968 ms. The reasons include the total computation time exceeding the computation time of the original task after partitioning, and the additional communication overhead. Therefore, we should better keep the number of partitions within a small range.

E Adaptive Gradient Fusion

Actually, the dual problem of fusion is how to segment a sequence of gradient synchronization operators. The origin is equal to that each operator constitutes a segment. Formally, we have a sequence of operator $O = [o_1, o_2, \ldots, o_n]$. For the operator o_i, we use v_i to denote the volume of gradients. As the gradients for the synchronization operator o_i will be generated from the corresponding computation operator, we use $d_{compute,i}$ to denote the corresponding duration time of computation. The segmentation is defined as $S = [\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_n]$ where $\mathcal{S}_i = [o_l, o_{l+1}, o_r]$ denotes a segment of the operator sequence. The optimization problem can be formulated as:

$$\begin{aligned} \arg\min_{S} \quad & e_{comm,m} \\ \text{s.t.} \quad & \mathcal{S}_1 \cup \mathcal{S}_2 \cup \cdots \cup \mathcal{S}_m = O, \\ & \forall 1 \le i < j \le m, \quad \mathcal{S}_i \cap \mathcal{S}_j = \emptyset, \end{aligned} \tag{4}$$

where $e_{comm,m}$ denotes that the communication end time of m-th fused gradients. The end time of i-th fused gradients can be obtained from the following recursive equation:

$$\begin{aligned} e_{compute,1} &= \sum_{o_i \in \mathcal{S}_1} d_{compute,i} \\ e_{comm,1} &= e_{compute,1} + f\left(\sum_{o_i \in \mathcal{S}_1} v_i\right), \\ e_{compute,k} &= e_{compute,k-1} + \sum_{o_i \in \mathcal{S}_k} d_{compute,i} \\ e_{comm,k} &= \max\left(e_{compute,k}, e_{comm,k-1}\right) + f\left(\sum_{o_i \in \mathcal{S}_k} v_i\right), \end{aligned} \tag{5}$$

where $f : \mathbb{R} \to \mathbb{R}$ maps volume to communication time according to our benchmark.

Forward search fusion is illustrated in Figure 10. Once the gradient computation is completed, the current AllReduce operator starts executing. At the same time, the next gradient computation continues until it is completed, triggering the next AllReduce. The algorithm aims to merge as many AllReduce operators as possible without increasing the overall communication time. The process begins by attempting to fuse the first and second AllReduce operators. It calculates the end time of the fused AllReduce and compares it with the start time of the next one. If the end time does not exceed the start time, the fusion is successful, and the fused operator is included in the strategy. Conversely, when attempting to fuse the third and fourth AllReduce operators, the end time of the fused operator exceeds the start time of the next AllReduce. Therefore, the fusion is abandoned, and the current operator is added to the strategy. This process is repeated, and ultimately, all the fused AllReduce operators are obtained.

F Private Data format

ND and NZ formats are common data formats in Ascend chips. The former is the arbitrary format that supports ex-officio Tensor data storage. It defaults to the NCHW format in Pytorch and MindSpore, while it defaults to the NHWC

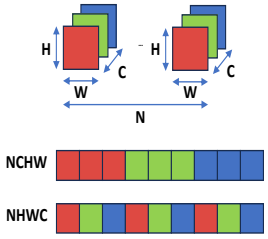


Figure 18: ND format.

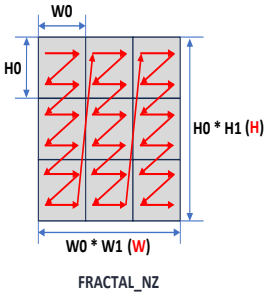

Figure 19: NZ format.

format in Tensorflow, where N is the batch size, C is the number of input channels, and H and W are the sizes of the input feature maps. Figure 18 shows a schematic of this data format and the mapping of its logical arrangement to its physical arrangement in memory.

The NZ format (*FRACTAL_NZ*) is an Ascend-specific fractal format, such as the data storage of featuremap. The data format, as shown in Figure 19 of the output matrix, is $NW1H1H0W0$ during cube unit calculation. The whole matrix is divided into $(H1 * W1)$ fractals, which are arranged according to column-major and have the shape of N, and $(H0 * W0)$ elements inside each fractal, which are arranged according to row-major and have the shape of z. Considering the format of the data layout, the $NW1H1H0W0$ data format is called the Nz format, where H0 and W0 indicate the size of a fractal.

CAFault: Enhance Fault Injection Technique in Practical Distributed Systems via Abundant Fault-Dependent Configurations.

Abstract

To ensure high reliability and availability, distributed systems are designed to be resilient to various faults in complex environments. Fault injection techniques are commonly used to test whether a distributed system can correctly handle different potential faults. However, existing fault injection testing is typically performed under a fixed default configuration, overlooking the impact of varying configurations (which can differ in real-world applications) on testing execution paths. This results in many vulnerabilities being overlooked.

In this work, we introduce CAFault (**C**onfiguration **A**ware **Fault**), a general testing framework for enhancing existing fault injection techniques via abundant fault-dependent configurations. Considering the vast combinatorial search space between fault inputs and configuration inputs, CAFault first constructs a fault-dependent model (FDModel) to prune the test input space and generate high-quality configurations. Second, to effectively explore the fault input space under each configuration, CAFault introduces fault-handling guided fuzzing, which constantly detects bugs hidden in deep paths. We implemented and evaluated CAFault on four widely used distributed systems, including HDFS, ZooKeeper, MySQL-Cluster, and IPFS. Compared with the state-of-the-art fault injection tools CrashFuzz, Mallory, and Chronos, CAFault covers 31.5%, 29.3%, and 81.5% more fault tolerance logic. Furthermore, CAFault has detected 16 serious previously unknown bugs.

1 Introduction

In a distributed environment, various faults can occur, such as network delays, packet loss, hardware failures, etc. To handle these faults and enhance system availability, distributed systems are designed with different kinds of fault tolerance mechanisms, such as replication [9], consensus protocols [11], and failover strategies [47]. In a practical distributed system, fault tolerance mechanisms guarantee one of the most fundamental properties called availability [5], ensuring that distributed systems can continuously provide functional services without interruption, even when faults occur.

Due to the complexity of fault tolerance mechanisms in distributed systems, it is challenging to avoid incorrect handling or implementation bugs in these fault tolerance logics. These bugs are referred to as **fault handling bugs**. Since fault tolerance mechanisms play a critical role in distributed systems, such bugs can have severe consequences, leading to service unavailability, data loss, and even compromising system security. To detect these bugs, several fault injection tools [6,17,46,56,59] have been developed to simulate and inject various faults into systems. These tools have successfully uncovered numerous bugs to date.

However, existing fault injection tools typically test distributed systems in fixed default configurations, ignoring how different configurations can impact the execution of fault tolerance mechanisms. In real-world applications, configurations can vary significantly, and existing tools overlook many execution paths, missing hidden bugs that might arise under different configurations. For example, in MySQL-Cluster [12], the default configuration for the data consensus mechanism is set to 'RAFT' [53], which ensures consistency across nodes. However, MySQL-Cluster also offers different consensus options, such as 'Paxos' [27] and 'Quorum-based' [35] mechanisms. The choice of consensus configuration can significantly impact the fault tolerance logic, such as how the system handles network partitions, node failures, and data consistency during recovery, potentially leading to different behaviors and vulnerabilities depending on the selected configuration.

To improve fault handling bug detection in distributed systems, an intuitive approach is to conduct fault injection testing under different configurations. However, since distributed systems typically have numerous configuration parameters, the configuration input space is often large [68], denoted as M. Similarly, the fault injection parameters, such as the time, location, and sequence length of the fault, create a vast input space [22], denoted as N. Consequently, exploring the combination of these two input spaces results in a total search space of $M * N$, which is significantly enormous.

*Fuchen Ma and Yu Jiang are the corresponding authors.

To effectively explore such a huge input space, there are two main challenges: (1) **The first challenge** is automatically analyzing the implicit dependencies between fault and configuration inputs to prune the configuration input space M. Many configuration items in distributed systems, such as log level settings, are unrelated to fault handling and can be excluded from testing. However, the vast number of configuration options and their complex semantics make it difficult to automatically identify these dependencies. Existing configuration testing tools [41, 42, 61, 65] rely on manual modeling to construct dependencies between configuration and workload inputs, which is labor-intensive and lacks scalability. (2) **The second challenge** lies in optimizing and pruning the exploration of the fault injection input space N. In each configuration input, fault injection can occur at any time and at any execution location, making the exploration space N infinite. Existing state-of-the-art (SOTA) fault injection tools typically use code coverage [17] or runtime behavior-guided [46] fuzzing strategies to explore fault input generation. However, these methods are time-consuming and tend to explore code unrelated to fault-handling logic, which result in ignoring bugs hidden in deep paths, leading to ineffective testing.

To address these challenges, we propose CAFault, a comprehensive testing framework aimed at detecting fault handling bugs in distributed systems across different configuration setups. First, CAFault introduces an FDModel that automatically identifies implicit dependencies between fault and configuration inputs, helping to prune and optimize the configuration input space. FDModel monitors the runtime behavior of the distributed system under test, observing which configuration items influence fault handling logic and how faults impact the system status. By tracking coverage changes and correlating them with configuration changes, the FDModel is dynamically constructed and updated throughout the testing process. Second, to effectively explore the fault input space and uncover bugs hidden in deep paths for each configuration input, CAFault employs a fault-handling guided fuzzing strategy. It performs static analysis to identify fault-handling code in the system and then leverages coverage data from this identified code to guide fault input generation during fuzzing. In this way, CAFault continuously conducts efficient fault injection testing with abundant fault-dependent configurations, effectively exercising fault tolerance mechanisms and detecting bugs in distributed systems.

We implemented CAFault and evaluated its effectiveness on four widely-used distributed systems: ZooKeeper [36], MySQL-Cluster [12], Hadoop Distributed File System (HDFS) [4], and IPFS [32]. In comparison to other state-of-art fault injection tools, e.g., CrashFuzz [17], Mallory [46], and Chronos [6], CAFault excelled in exposing more bugs and covering 31.5%, 29.3%, and 81.5% more fault tolerance logic, respectively. CAFault found 16 bugs in total, with 4 in ZooKeeper, 6 in MySQL-Cluster, 3 in HDFS, and 3 in IPFS. We also enhanced existing fault injection tools with the FDModel in CAFault. The results show that FDModel significantly improves testing performance, detects 6 more bugs, and covers 25% more fault tolerance logic on average.

In summary, we make three key contributions:

- We propose the FDModel that automatically analyzes implicit dependencies between fault and configuration inputs. Enhanced with this model, the performance of existing fault injection techniques has been significantly improved.
- We introduce fault-handling guided fuzzing to prune fault input space and effectively exercise fault tolerance mechanisms in distributed systems.
- We implement and evaluate CAFault on four widely used distributed systems. We will open-source CAFault[1].

2 Background of Fault Tolerance Mechanism

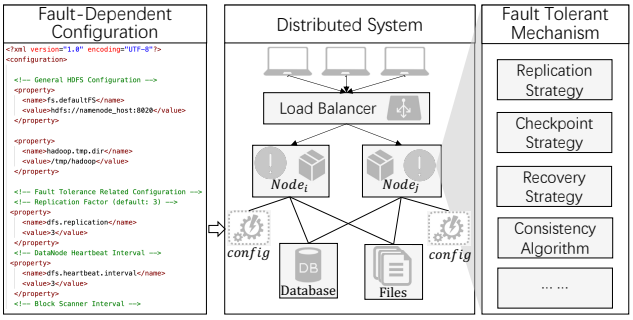

Figure 1: Typical fault tolerance mechanisms in Distributed Systems, that are affected by various configuration setups.

Fault tolerance mechanisms in distributed systems are essential for ensuring the reliability and availability of services in the presence of failures. Due to the complexity of distributed interactions, distributed systems are inherently more vulnerable to faults than standalone systems, with potential failures including network issues, hardware malfunctions, or software bugs. Fault tolerance mechanisms aim to detect, tolerate, and recover from these failures to ensure continuous operation. As shown in Figure 1, Mainstream fault tolerance techniques primarily include redundancy, checkpointing, recovery, and consistency strategies [38]. Replication strategy [26] involves adding extra resources to improve system reliability and fault tolerance, including hardware (e.g., redundant servers), data (e.g., replication across nodes), and computational replication (e.g., task replication or load balancing). Checkpointing [14] is a technique where the system periodically saves its state to allow recovery to a known good state after a failure. Recovery mechanism [60] can be cold recovery, where the system restarts from the last checkpoint and reloads data, or hot recovery, where the system resumes from a more recent state to minimize downtime and data loss. Consistency algorithms [19], such as Paxos and Raft, ensure that distributed systems maintain data consistency across nodes

[1] CAFault:https://anonymous.4open.science/r/CAFault-43A8/

despite faults, addressing issues like network partitions and concurrent updates that could cause data inconsistencies.

Fault-Dependent Configuration: System configuration is crucial to ensure that a distributed system operates reliably and efficiently under varying conditions [68]. It provides the flexibility for the system to adapt to different requirements. In distributed systems, configuration inputs are the parameters or settings that define how the system behaves [62]. These inputs can be divided into two main types: (1) *General configurations*, such as network settings and resource allocation, which are not related to fault tolerance mechanisms. (2) *Fault-dependent configurations*, which determine how the system responds to failures. These include settings like whether a service should be replicated, the frequency of recovery triggers, and thresholds for fault detection. The fault tolerance behavior of the system can vary significantly depending on these configurations, as they control critical aspects like timeout intervals, redundancy levels, and recovery strategies. For example, in a high-replication configuration, the fault handling logic may prioritize data consistency and integrity, triggering immediate recovery processes to synchronize all replicas. In contrast, a low-replication configuration might focus on minimizing downtime, quickly recovering a failed node without waiting for full synchronization across replicas [69]. Therefore, fault-dependent configuration inputs have a significant impact on fault injection testing. Unfortunately, existing fault injection tools overlook this aspect.

3 Motivation Example

Some bugs in fault tolerance mechanisms are difficult to detect because they can only be triggered under specific configuration settings, yet they can lead to severe consequences in distributed systems. One such example is a fault-handling bug in HDFS [8], caused by incorrect type sorting, specifically the failure to properly handle null values. This bug leads to HDFS node crashes, resulting in service unavailability for all applications relying on the system. Figure 2 illustrates the key steps to trigger this bug, while Figure 3 presents the core code snippet of it. In an HDFS cluster, the NameNode manages nodes, while the DataNode stores data. Once the HDFS cluster loads the configuration, the NameNode sets up the LoadBalancer ('balance.start=true' means that load balancing is enabled automatically) and heartbeat mechanism based on the configuration settings. When a DataNode fails to respond to heartbeat packets due to various faults (e.g., persistent network issues), the NameNode considers the DataNode to be offline. As a result, the LoadBalancer detects a storage imbalance and initiates the load reallocation process. The DataNodeManager then sorts the DataNodes based on their actual load. Since 'read.considerStorageType' is set to True, the DataNodeManager first sorts the DataNodes according to their storage types. However, if the previously offline DataNode has just restarted and reconnected, and at that moment the DataNodeManager is fetching its storage type, and the initialization thread responsible for that storage type has not yet completed, a null value will be returned. Subsequently, this bug is triggered because the default Comparator.comparing (line 5) cannot handle comparisons involving null values, causing the NameNode to crash. This fault handling bug is fixed by overriding the comparator and adding handling for null value comparisons, as shown in lines 6-14.

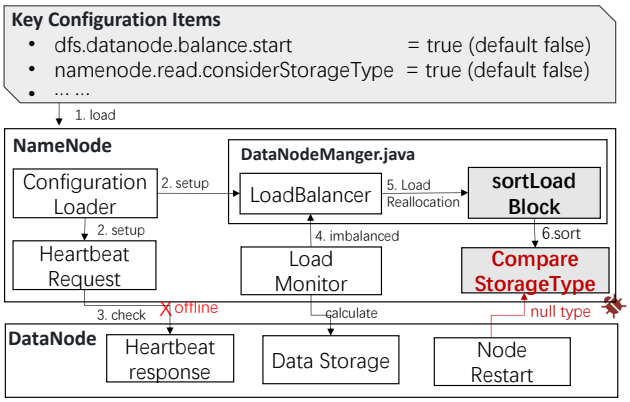

Figure 2: The HDFS-17098 breaks down the NameNode in HDFS, resulting in service unavailable.

```
1  private Consumer<...> sortLoadBlock() {
2     Consumer<...> loadSort = null;
3     if (readConsiderStorageType) {
4       Comparator<DatanodeInfoWithStorage> comp =
5  -       Comparator.comparing(getStorageType);
6  +       Comparator.comparing(getStorageType,
7  +           (s1, s2) -> {
8  +              if (s1 == null) {
9  +                return (s2 == null) ? 0 : -1;
10 +              } else if (s2 == null) {
11 +                return 1;
12 +              } else {
13 +                return s2.compareTo(s1);
14                }));
15      loadSort=list.Collections.sort(list, comp);
16    }
17 }
```

Figure 3: The core code snippet of HDFS-17098. Missing Null Type handling in'sortLoadBlock()'.

Fault tolerance mechanisms are commonly used in distributed systems, and bugs in their implementation are inevitable. Bugs in one node may affect the whole distributed system, thus causing severe consequences such as service hangs or node crashes. We can draw **three important lessons** from this case: 1) The execution logic of fault tolerance mechanisms is influenced by configuration inputs, a factor that existing fault injection tools often overlook. To address this, we propose CAFault, which focuses on enhancing these tools with high-quality configurations. 2) The dependency between configuration items and fault inputs is implicit. In this case, the activation of 'balance.start' and 'considerStorageType' affects the fault handling logic during the node reconnection process, yet they do not appear to have a direct dependency

relationship. If we naively enumerate and explore all combinations of configurations and fault inputs, it would lead to an explosion of the input space. To solve this problem, CAFault dynamically learns, optimizes, and refines the implicit dependencies between configurations and fault inputs by leveraging the runtime information of the distributed system under test. 3) Some fault handling bugs are hidden in deep paths, and triggering them requires a combination of multiple faults. In this case, triggering this bug requires at least one network failure causing a heartbeat timeout, which triggers the load balancing process, as well as a node failure, followed by the successful automatic restart of the node at the right moment. To handle this issue, CAFault employs fault-handling guided fuzzing, dynamically selecting high-quality fault combinations to explore as much fault tolerance logic as possible.

4 CAFault Design

Design goal: A practical configuration-aware fault injection framework should have the following properties.

- *General:* CAFault is designed to find fault handling bugs for most practical distributed systems, from distributed file systems, e.g., HDFS [3], to distributed configuration services, e.g., ZooKeeper [36]. From distributed database systems, e.g., MySQL-Cluster [12], to decentralized file systems, e.g., IPFS [32]. The tool can be deployed to different distributed systems with minor adjustments.
- *Automatic:* The entire testing process is automated, requiring minimal or no manual effort.
- *Efficient:* CAFault is able to constantly exercise the fault tolerance mechanisms and effectively detect more bugs in real-world distributed systems compared to SOTA tools.

4.1 CAFault Workflow

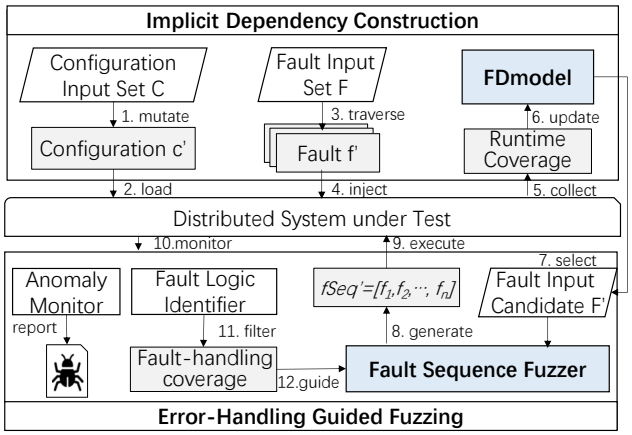

Figure 4: The workflow of CAFault. It includes two main phases: (1) Implicit Dependency Construction and (2) Fault-Handling Guided Fuzzing.

Figure 4 illustrates the workflow of CAFault, which consists of two main phases. The first phase focuses on the construction of the FDModel (fault-dependent model): (1) CAFault selects a configuration from the Configuration Input Set (initially containing the system's default configurations) and performs random mutations to generate a new configuration, c'. (2) The distributed system under test then loads the configuration c'. (3) CAFault iterates through each fault operation in the Fault Input Set (including IO timeout, node crash, etc.). (4) CAFault sequentially injects each fault input F into the system. (5) For each executed fault input F, corresponding coverage information is collected. (6) Based on real-time coverage changes, the FDModel is dynamically updated and refined. In this phase, if c' leads to new coverage improvements in the fault tolerance mechanisms, it is regarded as a high-quality fault-dependent configuration and added to Set C for further exploration. Note that this phase does not require precise attribution of coverage data to individual fault operations, only whether the coverage change needs to be observed. Finally, based on c', CAFault proceeds to the second phase.

The second phase is the fuzzing test process, consisting of the following steps: (7) CAFault uses the FDModel to select fault operations that are dependent on configuration c', creating the fault candidate set F'. (8) The Fault Sequence Fuzzer mutates and generates fault operation sequences $fSeq'$ based on the set F'. (9) CAFault then injects and executes $fSeq'$ in the distributed system under test. (10) Subsequently, CAFault monitors the runtime states of the system in real-time. (11) Finally, the Fault Logic Identifier analyzes the runtime states, filtering out fault-handling coverage information. Simultaneously, the Anomaly Monitor identifies if there are unexpected errors. The bugs are reported once they are detected. (12) Fault sequences that lead to new fault-handling coverage or expose new bugs are prioritized by the Fuzzer to guide the generation of subsequent fault sequences. Importantly, CAFault treats each fault sequence as a single fuzzing unit, collecting feedback at the sequence level rather than for individual faults. As a result, it does not require attributing precise feedback to each fault; instead, it evaluates the overall effectiveness of the entire sequence in exercising fault-handling logic. CAFault proceeds to the next fuzzing iteration (from step 8 to step 12) of the testing process until coverage converges (where newly generated fault sequences no longer yield additional fault-handling code coverage). Afterward, CAFault returns to the first phase, continuously alternating between exploring configuration inputs and generating fault inputs, until termination.

4.2 FDModel Updating

Both configuration inputs and fault inputs influence the execution logic of a distributed system's fault tolerance mechanisms. However, their dependency relationships are often implicit and difficult to uncover directly. CAFault leverages dynamic

runtime information to continuously learn these implicit dependencies, enabling the ongoing updating and optimization of the FDModel. A heuristic insight of this step is that, under the same fault input f_i, if changing a configuration item $item_j$ triggers a change in the execution coverage data, then we consider there to be an implicit execution dependency between item $item_j$ and fault f_i.

Definition of Implicit Dependency: Implicit dependency refers to long and complex control-flow and data-flow relationships between configuration items and fault-handling logic that are difficult to detect. First, we formally define the process of testing a distributed system as $\phi = \{C, F, Cov\}$. Specifically, $C = \{c_1, c_2, c_3, \ldots, c_n\}$ represents the set of configuration inputs to be loaded into the system. $F = \{f_1, f_2, f_3, ..., f_m\}$ represents the set of fault inputs to be injected into the system under test. $Cov = \{cov_{1,1}, \ldots, cov_{i,j}, \ldots, cov_{n,m}\}$ represent the coverage data, and $cov_{i,j}$ means represents the coverage data generated by executing configuration c_i and fault input f_j. For each c in C, $c = \{item_1, item_2, item_3, \ldots, item_l\}$ represents the actual settings of all items in c. Let $diff(c_i, c_j) = \{item_1, item_2, \ldots, item_k\}$ represent the differences between configuration c_i and configuration c_j, where the values of these k items are different. $\forall f_i \in F$, if $diff(c_a, c_b) = \{item_j\}$ and $cov_{a,i} \neq cov_{b,i}$, then we define that item $item_j$ has an implicit execution dependency with fault f_i, denoted as $d_{(item_j, f_i)}$.

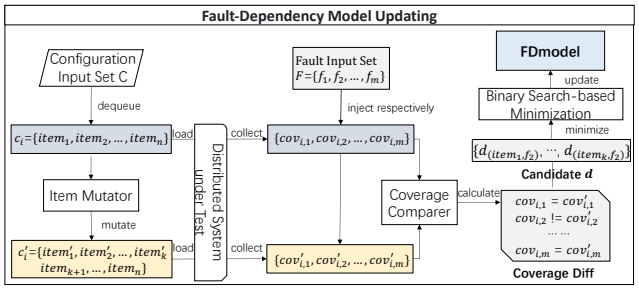

Figure 5: The process of Fault-Dependency Model updating. CAFault continuously learns implicit dependencies and refines the FDModel by analyzing coverage differences.

Figure 5 provides a detailed overview of the FModel update process. CAFault first dequeues a configuration c from the Configuration Input Set C. Then, an item mutator is employed to randomly mutate k items ($k \geq 1$ and $k \leq$ number of all items) based on the selected configuration, generating a new configuration c'. We assume that there are k items $\{item_1, item_2, \ldots, item_k\}$ that are mutated and differ between c and c'. CAFault loads configuration c, and then injects each fault f from the Fault Input Set F respectively, recording the corresponding coverage in fault tolerance mechanisms (will be introduced in section 4.3), denoted as $Cov = \{cov_{i,1}, cov_{i,2}, \ldots, cov_{i,m}\}$. Next, CAFault reloads c' and repeats the previous step, obtaining the coverage information $Cov' = \{cov'_{i,1}, cov'_{i,2}, \ldots, cov'_{i,m}\}$. Then CAFault utilizes a Coverage Comparer to calculate the coverage difference between Cov and Cov'. As shown in Figure 5, if $cov_{i,2} \neq cov'_{i,2}$, it means that changing these k items under the fault input f_2 affects the fault tolerance execution logic of the system under test. Therefore, these k items $\{item_1, item_2, \ldots, item_k\}$ may have an implicit execution dependency with fault f_2, resulting in a candidate dependency d. Considering that not every item in these k items will affect the execution logic of f_2, in order to precisely analyze the dependency between these k items and f_2, we use a binary search-based minimization algorithm to try to extract the smallest subset of items that can trigger the coverage difference. Finally, CAFault applies the minimized dependency d to update the FDModel.

Item Mutation: when mutating configuration items in distributed systems, we apply different strategies based on the type of the item. For boolean configuration items, we mutate their values by performing a logical NOT operation. For enum-type items, we randomly select one value from the available options. For numeric configuration items, we mutate them by adding or subtracting a random value, ensuring that the new value remains within a valid range. For string-type items, we mutate them according to their semantics. If the item represents a time value, we generate a random time in the correct format. For items representing IP addresses or file paths, we skip mutation operations, as arbitrary modifications to these values could disrupt the network topology and prevent the distributed system from functioning properly.

Algorithm 1: Binary Search-based Minimization.

```
Input : f: fault input
        d: dependency require to be minimized
fn binaryMinize(d, f):
    cov' = execute (d, f) ;
    if cov'==cov then
        d.removeAll () ;
    end
    else
        left = 0, right = len(d) - 1 ;
        mid = (left + right) // 2 ;
        if left < right then
            left_item = d[left:mid] ;
            right_item = d[mid:right] ;
            d_min.add (binaryMinize(left_item,f));
            d_min.add (binaryMinize(left_item,f));
        end
    end
```

Binary Search-based Minimization: Algorithm 1 illustrates the procedure for candidate dependency minimization. The inputs to the minimization algorithm consist of fault injection f and the set of fault-dependent configuration items d to be minimized. The function 'execute(d, f)' refers to the process of executing fault injection f on the configuration c with only the items in set d mutated, while the other items remain unchanged. Coverage is used to determine whether

each change in configuration items leads to a change in coverage. Specifically, the algorithm first splits the candidate item set into two parts: $left_{item}$ and $right_{item}$. It then recursively explores each subset of items (Lines 7-14). If the coverage produced by executing a particular item set is the same as the coverage of the original configuration c, it is considered that all items in that set have no execution dependency on fault f, and these items are removed (Lines 3-5).

4.3 Fault-Handling Guided Fuzzing

The fault injection input space remains vast for each specific configuration. A commonly used method, such as CrashFuzz, uses code coverage-guided fuzzing to explore fault input generation. However, an increase in code coverage does not necessarily equate to an increase in fault tolerance logic coverage, leading to the exploration of many non-fault-handling code paths. An intuitive insight of CAFault is to directly use code in fault tolerance mechanisms as feedback to guide the exploration of fault injection generation. To achieve this, we first need to automatically extract the code related to fault tolerance mechanisms from the coverage data.

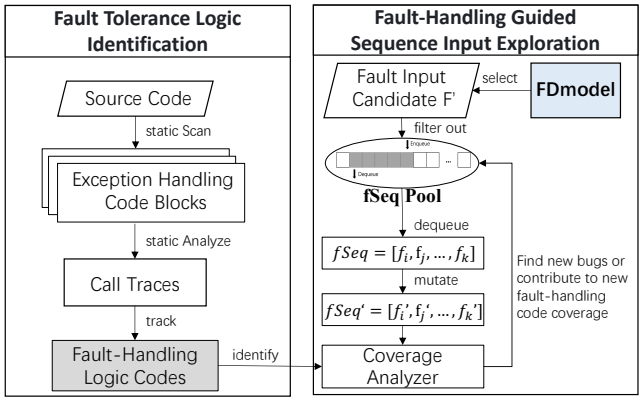

Figure 6: The process of Fault-handling code guided fuzzing. CAFault first constructs a fault-handling code identifier and then dynamically analyzes coverage based on it.

Figure 6 provides a detailed overview of the fault-handling guided fault input exploration process. Before testing begins, CAFault performs static analysis to identify and mark the code related to fault tolerance mechanisms, outputting the fault-handling code. During the testing process, CAFault first uses the FDModel along with the current configuration c of the system under test to select fault operations related to it, placing them into a candidate set F'. Then the fSeq pool is filtered to remove those sequences that include a fault f which does not belong to F'. During coverage analysis, CAFault calculates the fault-handling coverage based on the code sections marked by the Fault Mechanism Logic Identifier, using it as feedback to guide the fuzzing process. Once the fault-handling coverage converges, it indicates that the fault exploration for the current configuration c is complete. CAFault then switches back to the first phase, generating and loading a new high-quality configuration.

Fault Tolerance Logic Identifier. Considering that in most distributed systems, their fault tolerance mechanisms typically involve the capture and handling of various exceptions, the first step is to statically scan the source code of the system under test to identify all exception-handling code blocks. In Java language, this step is achieved by recognizing 'try', 'catch', and 'finally' blocks. In C++ language, this is done by identifying 'try', 'catch', and 'throw' statements. In Go language, this is achieved by identifying 'defer', 'panic', and 'recover' statements. Subsequently, for each exception handling code block, CAFault performs static analysis of its call traces. By tracking these call traces, CAFault identifies and marks codes related to the fault tolerance mechanism, generating a fault-handling code set for subsequent coverage analysis.

Algorithm 2: Fault-Handling Guided Fuzzing.

Input : $DSUT$: Distributed System under Test
c: current configuration loaded in the DSUT
Output : B: fault handling bugs

1 $DSUT$.load (c);
2 B={} $fseqPool$={};
3 $CovAnalyzer$ = setupCoverAnalyzer();
4 $fseqPool$.enqueue (randomInit ())
5 **while** *true* **do**
6 $fSeq = fseqPool$.dequeue() ;
7 $fSeq^{'}$ = mutate($fSeq$) ;
8 $CAFault$.inject($fSeq^{'}$);
9 **async:**
10 $Cover = DSUT$.execute($fSeq^{'}$) ;
11 $Cover_{fault}$ = idenitfy($Cover$) ;
12 **end async**
13 Bug_{new} = checkAnomaly();
14 B_n.append($newBugs$);
15 **if** ($Cover_{fault}$.isNew ()) *or* (Bug_{new} != *NULL*) **then**
16 $fseqPool$.enqueue($fSeq^{'}$);
17 **end**
18 **end**

Fault Sequence Exploration: Algorithm 2 illustrates the fault-handling guided fuzzing process. Before the fuzzing process begins, CAFault first sets up the Distributed System Under Test (DSUT) and loads the configuration c. Then, CAFault initializes a coverage analyzer to collect and calculate fault-handling coverage in real time. Next, CAFault initializes the fault sequence pool $fSeqPool$. If this is the first time entering the fuzzing phase, CAFault randomly selects some faults from the candidate set F' as the initial fault sequence. If it is not the first time entering the fuzzing phase, CAFault loads the fault sequences from the previous fuzzing phase's fSeqPool, as shown in Lines 1-4. Then, the fuzzing process starts.

In each fuzzing iteration, CAFault first dequeues a fault sequence $fSeq$ from the pool and applies mutation strategies commonly used in existing fault injection tools to mutate it into a new sequence $fSeq'$. The mutated fault sequence $fSeq'$ is then injected into the DSUT by CAFault (Lines 6-8). The $fSeq$ is executed asynchronously by the DSUT, and its fault-handling coverage information is analyzed in real time, as shown in Lines 9-12. Meanwhile, an anomaly detector monitors the system's runtime status and reports any new bugs if a fault-handling bug is detected (Lines 13-14). If the $fSeq'$ contributes new fault-handling coverage or leads to the discovery of new bugs, it is regarded as an interesting seed and is stored back in the fSeqPool to guide the next fuzzing iteration. In this way, CAFault continuously generates fault sequences, exploring as much fault tolerance logic as possible.

5 Implementation

We implemented CAFault in the four widely used distributed systems: HDFS, ZooKeeper, MySQL, and IPFS. The reasons we choose them are listed below:

System Popularity: HDFS, a core component of the Apache Hadoop project, is one of the most widely used distributed file systems for data storage [48]. MySQL Cluster is a scalable, real-time, ACID-compliant transactional database, favored for its low cost and multi-master architecture [40]. ZooKeeper is a popular distributed coordination service, enabling processes to synchronize through a shared namespace with high throughput and low latency [36]. IPFS is a widely used peer-to-peer file-sharing and distributed storage system that enables content addressing and efficient data retrieval [2].

Platform Diversity: These distributed systems come from different organizations and are implemented in different programming languages. HDFS and ZooKeeper are developed by Apache Software Foundation in Java language. MySQL-Cluster is developed by MySQL AB in C++ language. IPFS is developed by IPFS Org in the Go language. Implementation and evaluation of these distributed systems can demonstrate that CAFault is a cross-platform and language-independent testing framework with high generality.

Figure 7 presents the components of CAFault, which can be divided into three core parts. The first part is the Configuration Generator, which is implemented for synthesizing high-quality configurations that impact fault tolerance mechanisms in distributed systems under test. The second part is the Fault Injector, which effectively explores fault inputs under each fault-dependent configuration setup. The third part is the Interaction Adaptor, designed to interact with the target system, including standardizing the configuration input format of the distributed systems under test, sending workloads to them, and detecting anomalies within the systems. The rest of the section describes notable implementation details.

Coverage Collector: To collect runtime code coverage information, language-specific instrumentation tools are required for the distributed systems under test. For Java programs, we use Javacoco [33]. For C/C++ programs, we use gcov [18]. For Go programs, we use gtest [20].

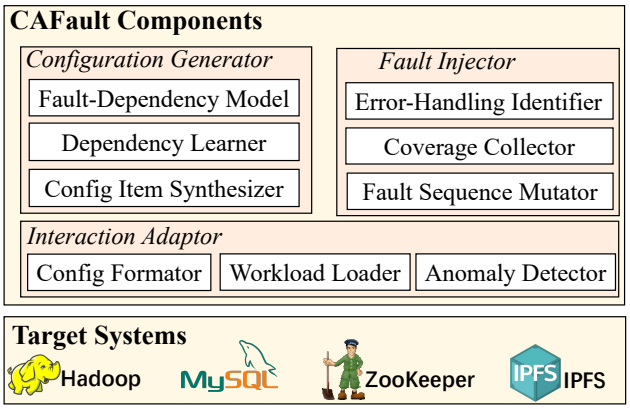

Figure 7: Components of CAFault, including Configuration Generator, Fault Injector, and Interaction Adaptor.

Workload Loader: In distributed system testing, workload refers to the set of tasks, requests, or operations sent to the system to simulate real-world usage. For HDFS, the workload is derived from Intel HiBench [29], a widely used benchmark suite for testing big data processing systems. For MySQL Cluster, the workload is generated using SQLancer [58], a popular SQL generator for testing the robustness and correctness of database systems. For ZooKeeper, the workload is loaded from Apache JMeter [25], a commonly used functional testing tool for performance and stress testing distributed systems, including ZooKeeper. For IPFS, we use ipfs-benchmark [31] to simulate multiple client requests and generate workloads.

Configuration Parameter Mutator: CAFault considers all exposed configuration items of each target system and mutates them using type-aware strategies (e.g., boolean negation, enum substitution, numeric shifting), consistent with existing configuration fuzzing tools such as ECFuzz [41]. The detailed mutation strategy is introduced in Section 4.2.

Fault Type and Detector: Due to the diversity of fault tolerance mechanisms in distributed systems, there are many types of fault handling bugs. Currently, CAFault adopts a set of commonly used faults, including delay, crash, restart, and packet loss, which is consistent with those used by SOTA fault injection tools (i.e., Chronos, Mallory, and CrashFuzz). We also integrate several mainstream bug detectors: For crash recovery bugs [16], we use the detector from CrashFuzz. For timeout bugs [10], we leverage the monitor from Chronos. For other common bugs (including memory vulnerability, inconsistency, etc.), we use three detectors (i.e., AddressSanitizer, log checker, and consistency checker) from Mallory.

Bug Reproducing and Analyzing: When reproducing bugs in distributed systems, especially those involving non-determinism, we follow the strategy adopted by previous fault injection tools such as Phoenix [45]. Specifically, when a bug is detected, we precisely log the execution context of each injected fault, including the fault type, injection timing,

Table 1: 16 new fault handling bugs detected by the tools within 48 hours. CAFault found all 16 bugs, including 3 in HDFS, 6 in MySQL-Cluster, 4 in ZooKeeper, and 3 in IPFS. In comparison, other SOTA tools detected fewer bugs: CrashFuzz found 3 bugs, Mallory found 4 bugs, and Chronos found 1 bug, respectively.

#	Platform	Version	The Root Cause Analysis	Identifier
1	HDFS	3.4.1	NameNode in Quorum-based Mode breaks down due to NullPointer in NameNodeRpcServer after multiple request timeout.	HDFS-202410312
2	HDFS	3.4.1	DataNode fails to recover caused by incorrect connect retries in the node restart process when using default configuration.	HDFS-202410318
3	HDFS	3.4.1	File fetching repeatedly hangs due to NullPointerException in BlockPlacementPolicy when setting dfs.replication=1	HDFS-202410319
4	MySQL-Cluster	8.4	Data loss in NDBD and failure to recover caused by incorrect index deletion when setting HAProxy.balance=roundrobin.	MySQL-S1825461
5	MySQL-Cluster	8.4	Bufferoverflow in sql_opt_exec_shared due to incorrect handling in data resynchronization when setting sync_binlog=0.	MySQL-S1825462
6	MySQL-Cluster	8.4	NDBD fails to recover caused by SEGV in Item_subselect which crashes the server node when using default configuration.	MySQL-S1827319
7	MySQL-Cluster	8.4	Continuous data write timeouts due to incorrect thread allocation in perfschema/pfs.cc When setting RedoBufferSize 1MB.	MySQL-S1827320
8	MySQL-Cluster	8.4	Data inconsistency among ndbds caused by incorrect STATUS in ndb_mgmd restarting when setting NoOfReplicas to 10.	MySQL-S1827321
9	MySQL-Cluster	8.4	SQL Query hangs and fails to recover due to wrong connection retry in conn_handler when using default configuration.	MySQL-S1830147
10	ZooKeeper	3.9	Leader node disconnects other nodes and fails to recover when meeting network faults in fast leader election mode.	ZooKeeper-2024532
11	ZooKeeper	3.9	Data corruption: Zookeeper client erroneously handling absolute path changes when resetting ZOOCFG.dataDir	ZooKeeper-2024550
12	ZooKeeper	3.9	NullPointerException in inputStream field crashes nodes and stops them restarting when using default configuration.	ZooKeeper-2024551
13	ZooKeeper	3.9	Request timeout due to missing ZooDefs.OpCode in RequestMetricsCollector when setting tickTime to 100	ZooKeeper-2024547
14	IPFS	0.33	Inconsistent repo size caused by incorrect calculation of resyncing repository when setting a small ipfs.cache.	IPFS-10252
15	IPFS	0.33	Resources accessing hangs incorrect IPNS address resolution after nodes restart when using the FUSE mounting mode.	IPFS-10573
16	IPFS	0.33	Kubo daemon crashes and fails to recover caused by incorrect pointer access under the default recovery configuration.	IPFS-10217

and executed code location at the time of injection. During the reproduction phase, we strictly replay these faults with the same context to maximize consistency with the original execution. To further mitigate the effects of non-determinism, we re-execute the fault sequence multiple times.

Adaptation to New Distributed Systems: The effort of adapting CAFault to other DFSes could be small. Modules in CAFault are well-encapsulated and loosely coupled. Hence, when adapting CAFault to a new distributed system under test, developers only need to implement three interfaces related to a specific target system. (1) The first interface is 'config.format()', which converts the configuration input format of the target system to CAFault's standard format (XML [37]) and vice versa. Currently, we support several mainstream configuration file formats, such as JSON [44], YAML [1], INI [15], and TOML [63]. If the distributed system uses one of these common file formats, no adaptation is needed. Otherwise, it is necessary to manually implement this format interface, though this situation is rare. (2) The second interface is 'Workloading()', which is used to load the workload required for testing the distributed system under test. Fortunately, most commonly used distributed systems have their own workload generation tools for testing and evaluation. As previously mentioned, we can directly integrate and use these existing workloads through this interface. (3) The third interface is 'statusMonitor()', which is responsible for monitoring key statuses and identifying bugs in the distributed system.

6 Evaluation

To evaluate the effectiveness of CAFault, we compared it with three SOTA fault injection tools: CrashFuzz, Mallory, and Chronos on four widely used distributed systems. These tools were chosen because they represent recent advances published in top-tier conferences. Each of them has been evaluated against a wide range of prior fault injection tools (e.g., Jepsen [34], ChaosMonkey [50], etc.) and has demonstrated superior performance in terms of bug detection and code coverage. We ran each distributed system in a cluster of 20 virtual nodes isolated by Docker [13]. Each Docker has a 2.25 GHz 6-core CPU, 16 GB of RAM, and a 480 GB SATA SSD. They all connect to each other with a 10 Gbps network bandwidth setup. They ran Ubuntu 20.04.2 with Linux kernel version 4.4.0. All Docker containers run in a physical machine, which is a 64-bit machine with 128 CPU cores (AMD EPYC 7742 64-Core Processor), and 512 GB main memory. All the experiments are conducted several times with the same workloads, and the average values are used in this paper. We designed experiments to address the following research questions:

- **RQ1:** Is CAFault effective in finding fault handling bugs of real-world distributed systems?
- **RQ2:** Can CAFault cover more fault tolerance logic in distributed systems compared to other SOTA tools?
- **RQ3:** How effectively does the Fault-Dependency Model enhance testing performance?
- **RQ4:** To what extent does fault-handling guided fuzzing improve the performance of testing?
- **RQ5:** What is the accuracy of CAFault?

6.1 Bugs in Real-World Distributed Systems

We applied CAFault to the latest versions of four distributed systems (HDFS 3.4.1, MySQL-Cluster v8.4, ZooKeeper v3.9, and IPFS v0.33) to evaluate fault handling bug detection. For comparison, we also ran CrashFuzz, Mallory, and Chronos on the same target systems using the same experimental setup. Furthermore, since these existing tools only perform testing on the fixed and default configurations of the distributed systems under test, to provide a fair comparison and validate whether FDModel can enhance the testing performance

of existing fault injection techniques, we also integrate FDModel into these tools, which we refer to as CrashFuzz$^+$, Mallory$^+$, and Chronos$^+$. Specifically, we first loaded fault-dependent configurations from the FDModel generated by CAFault. Then, we applied the existing fault injection techniques (i.e., CrashFuzz, Mallory, and Chronos) to each configuration to explore the fault input space. Once the fault injection test coverage converged for the current configuration, we moved to the next configuration (as described in Section 4.1). Each experiment is conducted for 48 hours. In total, CAFault identified 16 fault handling bugs on four target distributed systems with 3 in HDFS, 6 in MySQL-Cluster, 4 in ZooKeeper, and 3 in IPFS. The detailed information on these fault handling bugs is presented in Table 1.

As shown in Table 1, all 16 identified fault handling bugs have been confirmed and fixed by the corresponding vendors. Among these, except for 5 that were found solely through the default configuration of the system under test, the majority of the bugs (11/16) required testing under various configuration item settings with corresponding fault injection to be triggered. Specifically, most of the fault handling bugs (8/16) caused server nodes to crash, and due to errors in the fault tolerance mechanism, these distributed nodes were unable to recover automatically. Three bugs were caused by errors during the data synchronization process, resulting in data inconsistency across distributed nodes and even the loss of critical data. The remaining 5 bugs caused the distributed services to hang for an extended period, affecting system availability. Some of these fault handling bugs can lead to serious consequences. Take bugs #1, #4 and #10, and #16 for example, these bugs could allow attackers to deliberately crash or hang specific target nodes, disrupting their ability to handle requests or impeding the data synchronization process through the execution of specific fault operations. Such malicious activities could directly result in the loss of critical data or cause the outage of essential cloud services and ultimately lead to significant economic losses.

Table 2: Bugs found by CAFault and other SOTA methods. Existing fault injection tools detect no more than 5 bugs, while CAFault detects 16 unknown bugs.

Tool Name	Number	Bugs ID #
CAFault	16	#1 - 16
CrashFuzz	3	#2, 6, 12
CrashFuzz$^+$	9	#2, 3, 5, 6, 8, 11-14
Mallory	4	#2, 6, 12, 16
Mallory$^+$	12	#2, 3-9, 11-14, 16
Chronos	1	#9
Chronos$^+$	5	#3, 7, 9, 13, 15

Comparison with existing methods: In our 48-hour experiments, CrashFuzz only found 3 bugs, including bugs #2, #6, and #12. Mallory has successfully found 4 bugs, including bugs #2, #6, #12, and #16. Chronos only found 1 bug (#9). However, the remaining 11 bugs were not detected by these tools because these fault-handling bugs require specific fault-dependent configurations to be triggered. Therefore, with the enhancement of FDModel, CrashFuzz$^+$, Mallory$^+$, and Chronos$^+$ successfully detected 8 additional bugs. However, 3 bugs (#1, #4, and #10) were still not detected. This is because they are hidden not only in various specific fault-dependent configurations but also in deep execution paths. Triggering them requires conducting multiple fault interactions across different phases first. With the help of the fault-handling guided fuzzing strategy, CAFault successfully explored the fault tolerance logic hidden in deep paths and detected all 16 bugs, proving the effectiveness of CAFault in detecting fault handling bugs in real-world distributed systems, which adequately answers **RQ1**. Compared with other SOTA tools, CAFault found all the bugs that other tools found.

6.1.1 Case Study

Now we use one case to illustrate how the fault handling bugs detected by CAFault affect the whole distributed system, and how CAFault detects them. This case is the bug #1 listed in Table 1. This bug is a severe node crash, and attackers may utilize it to cause arbitrary distributed nodes to break down by conducting a certain delay strategy. It is caused by an implementation bug that incorrectly manipulates a NullPointer. It is found in version 3.4.1 of HDFS. It can only be triggered when running NameNode in Quorum mode. The code snippet in Figure 8 describes the detailed information.

```
1  private void tryReconnect() {
2      Preconditions.checkState(proxy == null);
3      proxy = createProxy();
4      ...
5      if (quorumEnabled) {
6        address = getConnect(NodeID, server);
7  +     Preconditions.checkArgument(detailedConnetTime
       != null, "Quorum mode enabled, detailed connect
       time metric +should not be null!");
8        detailedConnetTime.add(proxy, address);
9      }
10     updateProcessingDetails(Timing.LOCKWAIT, now -
           startNanos);
11 }
```

Figure 8: A NullPointer bug that crashes HDFS NameNode.

Root Cause: In HDFS, NameNode is designed for managing the filesystem metadata and keeping track of the locations of blocks across the cluster. The NameNode can be configured to run in various modes. To support the HDFS High Availability (HA) feature, the Quorum Journal Manager (QJM) is introduced to share edit logs between the Active and Standby NameNodes [24]. As shown in Figure 8, when heartbeat checks between distributed NameNode nodes fail due to various faults (e.g., network delays), the 'tryReconnect()' function is called to attempt re-establishing the NameNode quorum. In most cases, this code runs normally. However,

when another reconnect thread for the current NameNode is being re-spawned (due to multiple reconnect attempts exceeding the max_try setting), the 'detailedConnectTime' in that thread might not have been properly re-initialized yet. If the 'tryReconnect()' function is called in the current thread before this re-initialization, it triggers a null pointer issue, causing the node to crash and preventing it from recovering automatically. The developer has fixed this fault handling bug by adding a NullPointer checker (lines 7).

This crash bug was introduced when the quorum mode was added in HDFS v2.0.1. However, it remained hidden in the daily usage of HDFS until it was detected for the first time by CAFault. This is mainly because most of the previous fault injection testing tools were only run under HDFS's default configuration (i.e., Standalone Mode), which failed to trigger this bug. Additionally, even though existing tools (CrashFuzz$^+$, Mallory$^+$, and Chronos$^+$) were enhanced with our FDModel, they still did not detect it during our 48-hour experiment. This is because the bug is hidden deep within the fault interaction path: in addition to needing to run in quorum mode, it also requires that at least two connections on the NameNode be in a disconnected state, with one connection exceeding the maximum retry limit, while another connection attempts to reconnect at the same time. Such a scenario is quite rare. Fortunately, with the fault-handling guided fuzzing strategy, CAFault generates a wide range of fault inputs, enabling it to explore various fault-handling logic in the distributed system. This ultimately triggers the fault handling bug hidden in the deep path.

6.2 Fault Tolerance Logic Coverage

To evaluate the effectiveness of CAFault in covering fault tolerance logic in distributed systems, we set up a network for each target system and compared CAFault with other SOTA tools under the same experimental conditions. We measured the coverage of fault-handling code (which represents the fault tolerance mechanisms in the distributed systems under test, as detailed in Section 4.3) over a 48-hour testing period. The statistics are shown in Table 3. A 48-hour duration is commonly used in prior fault injection studies, offering a fair basis for comparison. Moreover, for most tools, code coverage tends to converge within this timeframe, with negligible gains observed beyond that point, as shown in Figure 9. In conclusion, CAFault consistently outperforms other SOTA tools across all four target distributed systems. Compared to CrashFuzz, Mallory, and Chronos, CAFault covers 31.5%, 29.3%, and 81.5% more fault-handling code, respectively, on average. The statistics adequately answer **RQ2**

Compared to their original versions (CrashFuzz, Mallory, and Chronos), the FDModel enhanced tools (CrashFuzz$^+$, Mallory$^+$, and Chronos$^+$) consistently achieve better coverage across all four target systems. Overall, with the help of FDModel, they improved fault tolerance logic coverage by

Table 3: fault-handling code coverage on four target systems in 48 hours. CAFault covers 81.52%, 31.55%, and 29.31% more fault tolerance logics compared with other SOTA tools.

	HDFS	MySQL-Cluster	ZooKeeper	IPFS	Improvement
CrashFuzz	9965	14624	4869	2393	-
CrashFuzz$^+$	13550	17982	6221	2969	↑ 27.69%
Mallory	10058	14951	5132	2361	-
Mallory$^+$	13012	18975	6065	2885	↑ 24.16%
Chronos	7776	10583	3656	1564	-
Chronos$^+$	9650	12953	4412	1962	↑ 23.15%
CAFault	**13684**	**19162**	**6254**	**3097**	↑ **29.31% - 81.52%**

27.69%, 24.16%, and 23.15%, respectively. The key reason for this improvement is that FDModel generates various high-quality, fault-dependent configuration inputs, which enrich the testing scenarios of existing fault injection tools and enhance testing efficiency. Among these existing fault injection tools, Chronos achieves the lowest coverage. This is because Chronos primarily focuses on timeout-related mechanisms in the distributed system under test, neglecting other fault-handling logic, such as crash recovery or failover, which results in lower fault-handling code coverage. In comparison to the FDModel enhanced tools (CrashFuzz$^+$, Mallory$^+$, and Chronos$^+$), CAFault consistently outperforms them across all four target systems. The main reason is that, with the help of fault-handling guided fuzzing,CAFault effectively explores the fault input space for each configuration, thus improving the efficiency of testing fault tolerance mechanisms.

To track the trends of coverage growth over time, we record the fault-handling code coverage every minute over 24 hours, as shown in figure 9. The data shows that the coverage of existing fault injection tools grows significantly during the first 300 minutes on all four target DFSes. The data shows that existing fault injection tools experience significant coverage growth within the first 5 hours across all four target distributed systems. After approximately 10 hours, their coverage gradually converges (only less than 1% branch coverage improvement is observed). In contrast, CAFault exhibits a gradual and steady increase in coverage over the 48-hour testing period, surpassing other state-of-the-art tools after around 8 hours. Specifically, during the first 8 hours, CAFault's test coverage is lower than that of these SOTA tools. This is mainly because CAFault continuously analyzes runtime coverage data during testing, particularly in the early phase, and updates the FDModel accordingly, which introduces some overhead. Additionally, the system under test incurs extra overhead when loading and running the high-quality configurations generated by CAFault. However, once the FDModel is completed (around 8 hours), CAFault's test coverage steadily surpasses that of other SOTA tools and remains consistently higher.

6.3 Effectiveness of Fault-Dependent Model

To evaluate the effectiveness of the FDModel, we also conducted the experiment that compares CAFault with *CAFault*$^-$, a version of CAFault that disables the FDModel and randomly

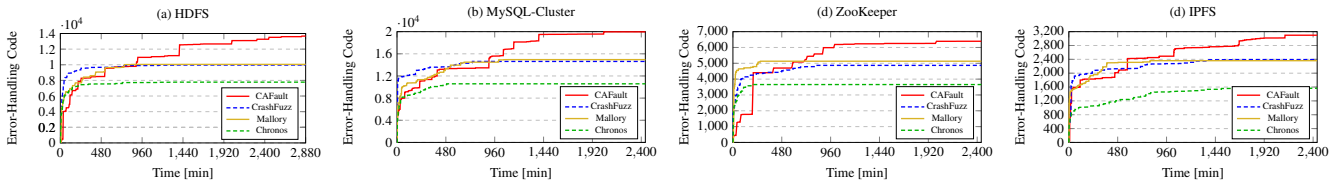

Figure 9: Coverage trends evaluated for CAFault, CrashFuzz, Mallory, and Chronos. Compared with them, CAFault with FDModel and the fault-handling guided fuzzing shows better fault tolerance logic coverage on all the target distributed systems.

generates configuration inputs instead. We collected the fault-handling code coverage and the number of bugs in 48 hours on all four target distributed systems.

Table 4: Comparison of $CAFault^-$ and CAFault on four target systems in 48 hours. CAFault with FDModel detects 128.5% more bugs and covers 29.19% more fault-handling codes.

	Number of Bugs		Fault Handling Coverage	
	$CAFault^-$	CAFault	$CAFault^-$	CAFault
HDFS	1	3	10443	13684
MySQL-Cluster	4	6	14996	19162
ZooKeeper	1	4	4902	6254
IPFS	1	3	2376	3097
Improvement	-	↑ 128.5%	-	↑ 29.19%

As shown in Table 5, with the help of FDModel, CAFault detects all 16 bugs within 48 hours, whereas $CAFault^-$ only detects 7 of them. Specifically, compared to $CAFault^-$, CAFault consistently achieves higher fault-handling code coverage across all four target distributed systems. In total, CAFault covers 9480 more fault-handling codes, resulting in a 29.19% improvement in fault tolerance logic coverage. This demonstrates that the FDModel significantly enhances both fault-handling code coverage and bug detection.

Take Bug #1 listed in Table 1 as an example. CAFault successfully detected this deep fault-handling bug within 48 hours, whereas CAFault$^-$ failed to do so. The key reason lies in the execution dependency between specific configuration and fault inputs required to trigger the bug – specifically, running in quorum mode while experiencing frequent network delays and reconnect attempts. Without the configuration-fault dependency information provided by the FDModel, CAFault$^-$ can only randomly generate combinations of configurations and fault inputs. Given the vast input space, it becomes highly unlikely for CAFault$^-$ to reach the precise conditions needed to expose this bug within the testing time window. Thus, we can conclude that FDModel effectively improves testing performance, which adequately answers **RQ3**.

6.4 Effectiveness of Fault-Handling Feedback

To evaluate the effectiveness of the fault-handling guided fuzzing strategy, we also conducted an experiment that compares CAFault with $CAFault_r$, a version of CAFault that randomly injects faults, and $CAFault_c$, a version of CAFault that utilizes traditional code coverage guided fuzzing. We collected the fault-handling code coverage and the number of bugs in 48 hours on all four distributed systems.

Table 5: Comparison of $CAFault_r$, $CAFault_c$ and CAFault. CAFault with fault-handling guided fuzzing detects 33.3%-77.8% more bugs and covers 11.46%-18.04% more fault tolerance Mechanism codes.

	Number of Bugs			Fault Handling Coverage		
	$CAFault_r$	$CAFault_c$	CAFault	$CAFault_r$	$CAFault_c$	CAFault
HDFS	2	2	3	11607	12316	13684
MySQL-Cluster	3	5	6	15958	17183	19162
ZooKeeper	2	2	4	5402	5657	6254
IPFS	2	3	3	2615	2749	3097

As shown in Table 5, with the help of the fault-handling guided fuzzing algorithm, CAFault detects all 16 bugs within 48 hours, while $CAFault_r$ and $CAFault_c$ detect only 9 and 12 bugs, respectively. Moreover, compared to these methods, CAFault consistently achieves higher fault tolerance logic coverage across all four target distributed systems, covering 18.04% and 11.46% more fault-handling codes in total. Besides, we also use Bug #1 in Table 1 as an illustrative example. Only CAFault successfully detected it, while $CAFault_r$ and $CAFault_c$ failed. This is mainly because the bug is deeply hidden and requires the execution of multiple complex exception-handling steps – specifically, a rare scenario involving simultaneous reconnect attempts under multiple disconnected NameNode connections. With the help of the fault-handling guided fuzzing strategy, CAFault efficiently explores fault-handling logic and ultimately triggers this bug. Therefore, we can conclude that fault-handling guided fuzzing significantly improves both fault tolerance logic coverage and bug detection, leading to a substantial enhancement in testing performance. This effectively addresses **RQ4**.

6.5 Accuracy of CAFault

Due to CAFault's alternating two-phase design, where the first phase uses a fixed set of fault operations to infer configuration-fault dependencies, some dependencies may be missed, particularly when certain configuration items only influence fault-handling behavior under complex fault combinations. To assess potential false negatives, we collected 10 historical bugs from the four target distributed systems, each of which was originally triggered under non-default configurations and specific fault conditions. We configured the systems to the corresponding historical versions and executed CAFault on each

for 48 hours. As shown in Table 6, CAFault successfully reproduced 9 out of the 10 bugs. The one missed case involved a configuration that only exhibited dependency behavior when subjected to a specific combination of multiple faults, a type of complex dependency that CAFault's current design does not yet support. Addressing such complex multifault dependencies to improve FDModel deserves future exploration.

Table 6: Historical bugs reproduced by CAFault.

HDFS	MySQL-Cluster	ZooKeeper	IPFS	Total
2/2	3/4	2/2	2/2	9/10

Considering that FDModel's dynamic dependency analysis is time-consuming, each test requires launching a cluster, running workloads, injecting faults, and cleaning up, efficiency becomes a key concern. A straightforward alternative is to use static analysis to pre-establish configuration-fault dependencies. Specifically, we first construct the Abstract Syntax Tree (AST) of the system's source code and analyze the reachability between nodes where configuration items are accessed and where fault-handling logic resides. If an execution path connects these two nodes, it is considered that an implicit dependency exists between them, thereby forming a coarse-grained FDModel. We then manually evaluated the accuracy of this static approach. However, it produced a high false positive rate of approximately 67%, mainly due to the extensive use of multithreading and asynchronous execution in distributed systems, which static analysis struggles to handle effectively. Thus, we use the dynamic analysis approach to construct the FDModel to avoid such false positives.

7 Discussion

Limitation of FDModel. Exploring both the fault and configuration input space inevitably introduces additional computational complexity. CAFault addresses this by dynamically learning the dependencies between fault inputs and configuration items using runtime coverage feedback to build an FDModel, which helps prune the vast input space. With the help of FDModel, CAFault successfully covers 29.19% more fault-handling codes and detects 128.5% more bugs in fault tolerance mechanisms. However, this dynamic learning process introduces runtime overhead, slowing down the initial testing speed, as observed in the coverage trends in Figure 9.

To mitigate this, future work may incorporate static analysis to quickly construct an initial FDModel by examining the reachability between configuration item nodes and fault-handling code in the source code. While static analysis is efficient, it often introduces a significant number of false positives. Based on our preliminary evaluation, approximately 67% of the inferred dependencies were incorrect, primarily because static analysis cannot accurately capture dynamic execution contexts such as multi-threading and asynchronous events common in distributed systems. How to effectively utilize CAFault's dynamic analysis to refine the initial model and reduce false dependencies remains an important direction for future research. Similarly, leveraging SMT solvers to infer configuration-fault dependencies is also a potential direction. If configuration parameters and control-flow paths can be symbolically represented, SMT solvers could help precompute feasible dependency paths, accelerating FDModel construction. While challenges remain in modeling accuracy and scalability for large codebases of distributed systems, integrating SMT into CAFault deserves future exploration.

Speculate on potential bugs. Given the vast configuration input space, being able to speculate on the potential range of undiscovered faults in unexplored configurations can help effectively prune the search space. While it is difficult to precisely quantify these faults, informed estimation is possible. A natural assumption is that fault-handling bugs are roughly evenly distributed across the fault-handling code. Based on this, we can estimate the bug exposure potential of an unexplored configuration by analyzing how much unique fault-handling logic it is expected to cover. This can be achieved through static or dynamic profiling of the fault-handling code paths activated by each configuration. Configurations likely to trigger more diverse fault-handling behaviors can then be prioritized during testing. We leave the design of such estimation models and prioritization strategies as an important direction for future work.

More bug types support. Currently, CAFault focuses on detecting bugs related to fault tolerance mechanisms, such as crash recovery failures and timeouts, by generating abundant high-quality configurations. However, distributed systems are also prone to many other types of bugs, such as fail-slow [23, 43, 54], race condition [55] bugs, load imbalance bug [7], etc. These tools share a common limitation: they typically test only the default configuration, missing many bugs.

Take load imbalance bugs as an example. These faults occur in distributed systems when uneven workload or data distribution degrades performance, wastes resources, and undermines reliability.. Themis [7] detects them by calculating the load differences between distributed nodes as an evaluation metric. A key insight of CAFault is its ability to generate high-quality configurations related to target bugs, thereby enriching the test scenarios of existing testing tools and improving their test coverage and bug detection capabilities. This approach is orthogonal to the above work. CAFault can first filter out configuration items related to system load, mutate them to generate high-quality configurations, and then use these load-dependent configurations to detect imbalance bugs effectively.

However, different from the fault handling bugs (e.g., crash, recover fail, or hang), which have precise and deterministic definitions, load imbalance bugs are harder to define accurately. 'Imbalance' is a qualitative rather than a quantitative concept, making it difficult to establish a precise definition of what constitutes an imbalance status. As a result, testing for

imbalance bugs often leads to false positives. To address this issue, a reliable and precise oracle for load imbalance bugs needs to be explored in future research.

8 Related Work

Fault injection technology: Fault injection is a widely-used technique for identifying and mitigating potential system failures by intentionally introducing faults or errors into a system [64]. In distributed system testing, there are three main types of fault injection [28]: (1) Implementation-level model checking: Typical tools such as MODIST [66] and SAMC [39] model fault operations (e.g., network delays, disk failures) and abstract system states (e.g., data storage, replication). They then simulate failures and enumerate sequences of nondeterministic events to detect bugs. However, these approaches suffer from the state space explosion problem, making it difficult to explore the vast and complex state spaces in real-world distributed systems. (2) Run-time fault injection: Techniques like chaos engineering inject random faults into a live system. Chaos Monkey [50] and Simian Army [51] from Netflix first simulate network faults in complex cloud environments. Alibaba's ChaosBlade [30] extends support to more fault injections, such as network disruptions and CPU scheduling issues, for comprehensive distributed system testing. Jepsen [34] tests distributed data management systems by performing fault injections using manually written test cases. However, these methods often lack fine-grained control and fail to account for the runtime context. (3) Compile-time fault injection [21, 49]: injecting predefined faults into the source code and testing how the system handles them during execution. CrashFuzz [17] utilizes code coverage guided fuzzing to dynamically optimizes the generation of fault injection inputs for cloud system testing. Mallory [46] constructs a "happen-before" graph to describe the causal relationships between behaviors, and then guides the generation of fuzz fault inputs based on key behavioral states. Chronos [6] proposes deep-priority guided fuzzing to explore fault inputs and detects timeout bugs hidden in deep paths. However, existing fault injection techniques overlook the impact of different configuration inputs on fault tolerance testing in distributed systems, leading to missed some bugs.

Configuration Testing technology: Configuration testing detects bugs in the configuration handling logic of distributed systems by generating a large number of high-quality configuration inputs [67]. Typical tools such as TEA-Cloud [52] and ChatT [57] focus on testing the system's configuration logic for computational resources, including the number of physical machines, CPU usage, network bandwidth, and disk storage capacity. They generate configuration files that cover various computational resource configurations through manually defined generation rules and evaluate system performance under different configurations to uncover potential bugs. Ctests [61] models the dependencies between configurations manually and generates multiple different configuration combinations for testing inputs based on this model using mutation techniques. ConfTest [42] analyzes the system's configuration options, syntax, and semantic constraints to create a detailed configuration model to identify configuration-related logical errors. ECFuzz [41] employs a multi-dimensional configuration generation strategy that formulates diverse mutation strategies based on parameter dependencies, and in each test round, selects and combines multiple parameters from the candidate set. However, existing configuration testing primarily models the dependencies between configuration and workload inputs, neglecting the relationship between configuration and fault inputs. Additionally, their modeling approach relies on manual effort, with accuracy depending on the domain knowledge of the modelers, making it both resource-intensive and time-consuming.

Main Difference: Different from the above work, CAFault focuses on enhancing existing fault injection techniques via abundant fault-dependent configurations to detect more fault handling bugs, thereby improving the resilience and stability of the system. To prune the input space and generate high-quality configurations, CAFault harnesses an FDModel to describe the implicit dependencies between configuration and fault inputs, dynamically optimizing and updating the model based on the runtime state of the system under test. To effectively explore fault injection inputs for each configuration setup, CAFault employs fault-handling guided fuzzing to continuously exercise the fault tolerance mechanisms in distributed systems. Moreover, due to the scalability of the testing framework, CAFault can be quickly adapted to test other distributed systems.

9 Conclusion

In this paper, we propose CAFault, a general testing framework for enhancing existing fault injection techniques with abundant fault-dependent configurations. CAFault first introduces the FDModel to construct implicit dependencies between fault and configuration inputs for pruning the test input space. Then, CAFault harnesses a fault-handling guided fuzzing strategy to effectively explore the fault input space under each high-quality configuration input. We implemented and evaluated CAFault on four widely used distributed systems. Compared with the SOTA tools, crashFuzz, Mallory, and CAFault, CAFault covers 31.5%, 29.3%, and 81.5% more fault tolerance logic. Our future work will consider enhancing CAFault by supporting more types of bug.

Abstract

Accumulation-based operations, such as summation and matrix multiplication, are fundamental to numerous computational domains. However, their accumulation orders are often undocumented in existing software and hardware implementations, making it difficult for developers to ensure consistent results across systems. To address this issue, we introduce FPRev, a diagnostic tool designed to reveal the accumulation order in the software and hardware implementations through numerical testing. With FPRev, developers can identify and compare accumulation orders, enabling developers to create reproducible software and verify implementation equivalence.

FPRev is a testing-based tool that non-intrusively reveals the accumulation order by analyzing the outputs of the tested implementation for distinct specially designed inputs. Employing FPRev, we showcase the accumulation orders of popular libraries (such as NumPy and PyTorch) on CPUs and GPUs (including GPUs with specialized matrix accelerators such as Tensor Cores). We also validate the efficiency of FPRev through extensive experiments. FPRev exhibits a lower time complexity compared to the basic solution. FPRev is open-sourced at https://github.com/peichenxie/FPRev.

1 Introduction

Today, floating-point computations are ubiquitous, with accumulation-based operations (AccumOps) such as summation, dot products, matrix-vector multiplications, and matrix multiplications playing fundamental roles in various domains. However, no general specification dictates the accumulation orders of AccumOps. Without well-defined requirements, AccumOps are implemented differently across software and hardware, leading to inconsistencies due to the non-associativity of floating-point addition [35]. For example, the half-precision (float16) sum of 0.5, 512, and 512.5 depends on the accumulation order: $(0.5+512)+512.5=1025$, while $0.5+(512+512.5)=1024$. Consequently, varying AccumOp implementations yield different results, complicating reproducibility in software development.

Numerical reproducibility is critical in scientific computing [12, 28, 33], high-performance computing [35], database management system [22], deep learning [4, 31], etc. Particularly, software without verified numerical reproducibility is deemed risky or disqualified when applied to safety-critical or rigorous scenarios like aerospace or banking, where even minor inconsistencies in data are unacceptable. Unfortunately, with the rapid evolution of heterogeneous hardware and the fast iteration of diverse software stacks, reproducibility of AccumOps has become increasingly challenging. Existing implementations rarely disclose their accumulation orders, hindering reproducible AccumOp development.

We propose FPRev, a diagnostic tool to help developers identify how AccumOps are implemented in software and hardware. FPRev reveals the accumulation order of an AccumOp implementation (AccumImpl) through numerical testing. This enables developers to reproduce an AccumImpl on a new system by using the revealed accumulation order as a specification and verify equivalence between two implementations by comparing their accumulation orders.

As a case study, we use FPRev to analyze popular numerical libraries on diverse hardware, uncovering their undocumented and undisclosed accumulation orders. On different CPUs, we apply FPRev to the NumPy library [11]. On different GPUs, we apply FPRev to the PyTorch library [27]. The results indicate that NumPy's summation functions are implemented equivalently across CPUs, and the same holds for PyTorch's summation functions across GPUs. However, other AccumOps relying on BLAS (Basic Linear Algebra Subprograms) backends like Intel MKL [15], OpenBLAS [26], and NVIDIA cuBLAS [24] exhibit non-reproducible behavior.

FPRev also visualizes the order with the summation tree, i.e., a full binary tree representing how an AccumImpl performs summation, to guide develeopment. For example, Figure 1 illustrates NumPy's summation of 32 single-precision (float32) numbers. It divides the 32 numbers into 8 ways, accumulates the summands with a stride of 8 on each way, and sums up the 8 ways together using pairwise summation. This 8-way accumulation order is friendly to CPU's SIMD instruc-

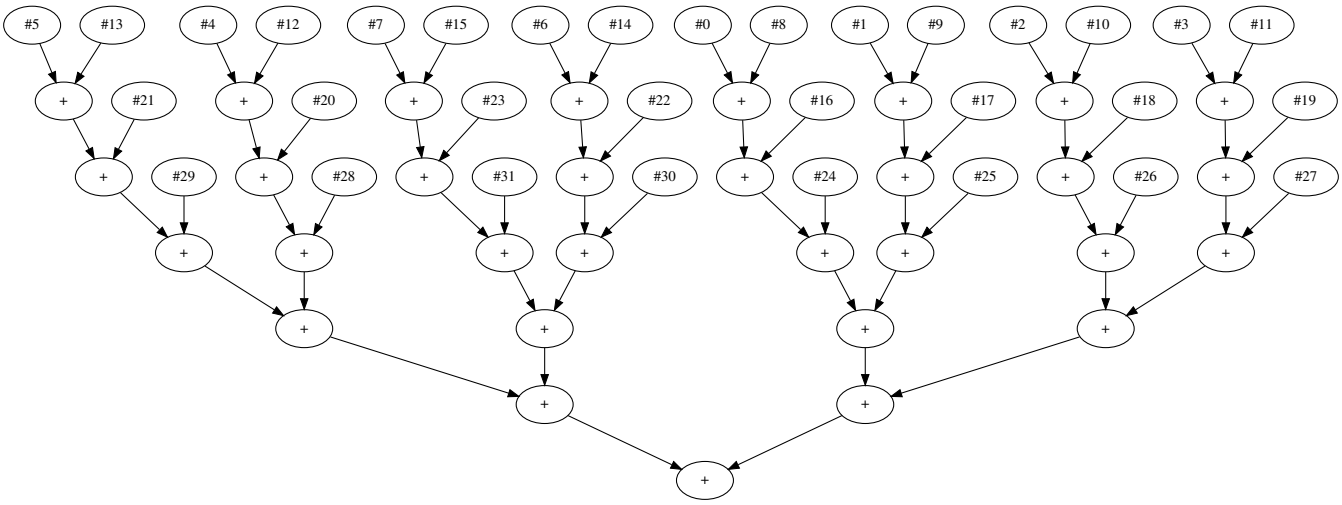

Figure 1: Visualizing the accumulation order of Numpy's summation function for $n = 32$ single-precision numbers with a summation tree. The numbers on the leaf nodes denote the indexes in the input.

tions. With this information, it is easy to replicate NumPy's numerical behavior in a new implementation.

Design overview. Determining the accumulation order of an AccumImpl is a challenging task. Static methods, such as analyzing the source code, are cumbersome and inapplicable to black-box implementations and compiler optimization. Dynamic methods, like scrutinizing the runtime traces, lack an automatic tool to analyze the traces. In addition, many software or hardware implementations are parallel, making the analysis more challenging.

We address these challenges through non-intrusive testing. Recall the example where $(0.5+512)+512.5 = 1025$ and $0.5+(512+512.5) = 1024$ in half precision. Different accumulation orders yield distinct results, making it possible to deduce the order from numerical outputs. However, the number of all possible accumulation orders is exponential, making the time complexity of the naive brute-force solution (NaiveSol) impractical.

To achieve practical time complexity, we propose a basic solution called BasicFPRev that uses specially designed inputs to facilitate the distinguishing process. We take the summation function for example. First, BasicFPRev set all n summands to 1.0. Then, two of the summands are replaced by a very large number (denoted by M) and its negative ($-M$), where M satisfies $(n-2)+M = M$. The summation output corresponds to an integer between 0 and $n-2$, depending on when M or $-M$ cancel each other during the accumulation. Specifically, when $\pm M$ is added to other numbers, it remains $\pm M$; when M is added to $-M$, it results in 0; after that, the remaining summands are accumulated without rounding errors because they are all 1.0. Therefore, the output equals the number of summands accumulated after $M+(-M)$.

BasicFPRev leverages this information to construct the summation tree. Using i and j to denote the indexes of M or $-M$ in the input, we note that the operation $M+(-M)$ corresponds to the lowest common ancestor (LCA) of node $\#i$ and $\#j$ in the summation tree, and the number of leaf nodes under the LCA equals n minus the summation output. Based on this finding, BasicFPRev enumerates i and j, collects the output for the corresponding input, and infers the size of subtree rooted at the LCA of node $\#i$ and $\#j$. BasicFPRev then constructs the summation tree bottom-up, starting with subtrees of two leaf nodes and progressively building larger subtrees until the entire tree is generated.

Based on BasicFPRev, FPRev further reduces time complexity by eliminating redundancy, and adds support for matrix accelerators such as Tensor Cores on recent NVIDIA GPUs [19]. Matrix accelerators are specialized hardware units on GPUs for high-performance matrix multiplication, but they perform non-standard multi-term fused summations [9]. FPRev models their accumulation orders using a multiway tree, where a node with multiple children represents a multi-term fused summation for a group of summands. The summands are aligned and truncated before they are accumulated, as if they are added in finite-precision fixed-point arithmetic.

FPRev has a time complexity of $\Omega(nt(n))$ and $O(n^2t(n))$, where $t(n)$ is the time complexity of the tested AccumImpl. This shows a significant improvement over the $O(4^n/n^{3/2} \cdot t(n))$ complexity of NaiveSol and the $\Theta(n^2t(n))$ complexity of BasicFPRev. Experimental results confirm FPRev's efficiency and scalability across diverse AccumOp implementations on three CPUs and three GPUs with distinct architectures.

In summary, the contributions of this paper include:

1. Design and development of FPRev: we introduce FPRev, a diagnostic tool that non-intrusively reveals the accumulation order of accumulation-based operations implemented in different software and hardware, enabling

developers to verify equivalence and maintain numerical reproducibility between implementations.
2. Empirical analysis of popular implementations: We demonstrate FPRev's capabilities by analyzing accumulation orders in popular libraries (e.g., NumPy and PyTorch) across CPUs and GPUs, providing reproducibility insights in backend implementations.
3. Algorithmic innovation: we describe the algorithm of FPRev for revealing accumulation orders and constructing summation trees, refine the algorithm to reduce time complexity, and extend it to handle modern GPU matrix accelerators (e.g., NVIDIA Tensor Cores), modeling their multi-term fused summation using multiway trees.
4. Performance evaluation: we evaluate FPRev's efficiency through comprehensive experiments, test diverse AccumOps implementations on various CPUs and GPUs, and demonstrate significant performance improvements over naive and basic solutions.

2 Related work

2.1 AccumOp implementations

2.1.1 On canonical CPUs and GPUs

Accumulation-based operations (AccumOps) are implemented diversely on modern systems. On most CPUs and GPUs, implementations use standard IEEE-754 addition or fused multiply-add (FMA) arithmetic [14] to accumulate floating-point numbers. However, they may perform accumulations in different orders without explicitly disclosing those orders.

First, there is diverse numerical software, including BLAS libraries such as Intel MKL [15] and NVIDIA cuBLAS [24], Python libraries such as NumPy [11] and PyTorch [27], and domain-specific compilers such as Numba [17] and Triton [34]. These libraries are developed without a unified specification, making it difficult to guarantee consistent accumulation orders.

Second, the same software may behave differently across different hardware. Different CPUs and GPUs vary in architecture, number of cores, SIMD width, cache size, etc. Consequently, for performance optimization, software may adjust the accumulation order based on the specific hardware characteristic. Specifically, library developers implement various techniques (e.g., different configurations of loop unrolling, block partitioning, cache optimization, and vectorization) for performance tuning, resulting in different accumulation orders. Additionally, auto-tuners (e.g., Triton [34] and TVM [5]) are often used to search for optimal configurations, given the complexity of performance factors such as instruction pipelining and dynamic frequency scaling.

Although order-independent algorithms have been proposed [6–8], which ensure consistent results regardless of the accumulation order, they are highly inefficient and thus rarely used in industry.

Our tool FPRev supports the AccumOp implementations on canonical CPUs and GPUs and can reveal their undisclosed accumulation orders.

2.1.2 On matrix accelerators

Matrix accelerators [19, 29] are specialized hardware components in modern GPUs designed for high-performance matrix multiplication. Developers can implement matrix multiplications using the APIs of matrix accelerators [23]. However, the numerical behavior and accumulation order of the APIs are undocumented and inconsistent across different GPUs.

FPRev supports the AccumOp implementations based on matrix accelerators and can reveal their undisclosed accumulation orders.

2.2 Revelation of numerical behaviors

FPRev achieves non-intrusive revelation of accumulation orders through numerical testing. Prior works [9, 18] have also employed numerical testing to study the numerical behavior of matrix accelerators. They design "corner cases" as test inputs and analyze the numerical behavior based on the outputs. They find that for float64 on NVIDIA Tensor Cores and AMD Matrix Cores, the matrix multiplication instruction is based on a chain of standard FMA arithmetic. In contrast, other instructions use a non-standard arithmetic where multiple terms (the exact number depends on the hardware) are accumulated after alignment and truncation.

FPRev is a general tool that applies to AccumOp implementations, including those based on matrix accelerators, while prior works focus exclusively on specific hardware.

2.3 Numerical reproducibility engineering

The inconsistent AccumOp implementations pose significant issues in numerical reproducibility [2, 35]. To help developers debug the issues, several testing-based tools have been proposed. For example, Varity [16] uses randomized testing to verify equivalence between implementations. Tools like pLiner [10] and its follow-up [20] employ differential testing to pinpoint non-reproducible parts of a program. In contrast, FPRev uses a deterministic testing method to identify the accumulation order of AccumOps.

Early works [12, 33] have emphasized the importance of reproducible AccumOps for ensuring numerical stability but lack practical solutions. A preliminary approach [1] adopts the aforementioned order-independent algorithm [7] to ensure reproducibility, but suffers from its inefficiency. In contrast, FPRev offers a more practical solution: replicating the accumulation order of existing efficient implementations.

3 Problem statement

3.1 Motivation

Accumulation-based operations (AccumOps) are fundamental in floating-point computing, but most implementations do not specify their accumulation orders. This lack of transparency motivates us to design a tool for revealing the accumulation order.

An example application of the tool is in developing reproducible AccumOps, which are key to software reproducibility and service consistency [12, 25, 33]. Developers must ensure that the accumulation order remains consistent across systems to maintain the reproducibility of AccumOps. If developers can determine the accumulation order, they can use it as a specification to guide their development process. In addition, when porting software to a new system, developers need a rigorous way to verify the equivalence of AccumOps between two systems. This can be achieved by comparing the accumulation orders of the AccumOps implemented on two systems.

3.2 Problem definition

For an AccumOp implementation (AccumImpl), we aim to design a diagnostic tool to reveal its accumulation order. For brevity, we focus on the summation function in the following discussion, since other AccumOps can be abstracted as calls to the summation function with the intermediate results as inputs. For example, dot product $\mathbf{x}\cdot\mathbf{y}$ can be treated as $\sum_{i=0}^{n-1} x_i y_i$. Thus, solutions for the summation function can be naturally applied to other AccumOps.

We formulate the summation operation as follows. The floating-point addition is performed $n-1$ times in a predetermined order to calculate the sum of n floating-point numbers. We assume that the accumulation order is unknown but is uniquely determined by the given implementation on specific hardware. Therefore, randomized implementations and those where the order depends on the values of the summands are out of scope[1].

The problem is how to reveal the accumulation order in an summation implementation, denoted by SUMIMPL. Specifically, the input of our revelation algorithm is SUMIMPL and the number of summands n. The output of the algorithm is the accumulation order of SUMIMPL.

Strictly speaking, the accumulation order is represented by a computational graph called the summation tree, which is a rooted full binary tree with n leaf nodes and $n-1$ inner nodes. Each addition operation corresponds to an inner node, which represents the sum of this operation. The two children of the node represent the two summands of this operation. For example, Figure 1 depicts the accumulation order of Numpy's summation function for $n = 32$ single-precision numbers.

[1]While randomized or input-dependent summation algorithms are possible, they tend to be inefficient. Similarly, algorithms using AtomicAdd are affected by thread scheduling, but we did not find popular libraries implementing such algorithms.

3.3 Inefficiency of the naive solution

We now introduce a naive solution (NaiveSol) to the problem, which is based on brute-force search. We design a recursive algorithm to enumerate every possible accumulation orders. For each order, we verify its correctness through randomized testing. Specifically, we generate multiple random inputs, compute the sums in the current order, and compare the results with those from SUMIMPL. If the results match, we accept the order.

The time complexity of NaiveSol is $O(4^n/n^{3/2}\cdot t(n))$, as the number of all possible orders is the $(n-1)$-th Catalan number $C_{n-1} = \frac{(2n-2)!}{n!(n-1)!} = O(4^n/n^{3/2})$. Here, $t(n)$ represents the time complexity of SUMIMPL. In addition to being inefficient, NaiveSol is not fully reliable because different orders can produce the same output for certain inputs. Although the probability is low and reliability can be improved by increasing the number of test inputs, a deterministic solution with full reliability is preferable, as we will achieve next.

4 Basic polynomial-time solution

The exponential complexity of the naive solution is highly impractical. To address the issue, we present our basic solution called BasicFPRev for revealing the accumulation order, which reduces the time complexity to polynomial. We design an algorithm to determine the accumulation order from the numerical results of the tested summation implementation (SUMIMPL) for specially designed testing inputs. The following parts detail the three steps of the algorithm.

4.1 Step 1: designing testing inputs

To facilitate distinguishing the accumulation order, we leverage the swamping phenomenon of floating-point addition [13]. When two floating-point numbers differing by many orders of magnitude are added, the smaller number is swamped and makes no contribution to the sum. For example, $2^{24}+1$ equals 2^{24} in single-precision (float32) arithmetic.

To induce and utilize this phenomenon, we construct various "masked all-one arrays" as testing inputs. Specifically, let n denote the number of summands, and let SUMIMPL represent an summation implementation with a predetermined but unknown accumulation order. Let M be a very large floating-point number that readily induces the swamping phenomenon. For example, we set $M = 2^{127}$ for float32 or $M = 2^{1023}$ for float64. Then, we define a masked all-one

array $A^{i,j}$ as $A^{i,j} = (A_0^{i,j}, A_1^{i,j}, ..., A_{n-1}^{i,j})$ such that

$$A_k^{i,j} = \begin{cases} M & \text{if } k = i \\ -M & \text{if } k = j \\ 1.0 & \text{otherwise} \end{cases}$$

where i and j denote the indexes of M and $-M$ in the array. In $A^{i,j}$, there exist exactly one M and one $-M$, with all other elements being 1.0.

We use $\pm M$ as masks. Specifically, $M + \sigma = M$ and $-M + \sigma = -M$ hold for $0 \le \sigma \le n-2$ in floating-point arithmetic, if $n \ll M$. Therefore, in SUMIMPL($A^{i,j}$), adding any summand or intermediate sum (except M and $-M$ themselves) to $\pm M$ yields $\pm M$. In other words, M and $-M$ can mask the summands or intermediate sums added to them.

As a result, the output of SUMIMPL($A^{i,j}$) depends on the accumulation order and we can distinguish the accumulation order from the output. For example, given $n = 3$ and $A^{0,1} = (M, -M, 1)$, sequential summation $M + (-M) + 1$ corresponds to 1, stride summation $M + 1 + (-M)$ corresponds to 0, and reverse summation $1 + (-M) + M$ corresponds to 0. If the output equals 1, then we can infer the accumulation order is sequential summation. If the output equals 0, we can determine the exact accumulation order by further testing with $A^{0,2}$ as the input.

4.2 Step 2: analyzing the accumulation order from the outputs

To analyze the accumulation order, we call SUMIMPL with $n(n-1)/2$ inputs, i.e., $A^{i,j}$ for $0 \le i < j < n$. Each output reveals information about the accumulation order. Specifically, since $\pm M$ mask the summands or intermediate sums added to them, these numbers make no contribution to the sum. In contrast, only those summands not masked by $\pm M$ contribute to the sum. Therefore, the output equals the sum of these summands. Since each of the summands equals 1.0, the output equals the number of the summands not masked by $\pm M$:

$$n^{i,j}_{\text{not masked}} = \text{SUMIMPL}(A^{i,j}).$$

Then, we can also obtain the number of the summands masked by $\pm M$ by calculating $n^{i,j}_{\text{masked}} = n - 2 - n^{i,j}_{\text{not masked}}$.

How does this information relate to the order, or specifically, the summation tree? Recall that i and j denote the positions of the masks, represented by node #i and #j in the summation tree. **We note that the neutralization of the two masks (i.e., the addition operation $M + (-M) = 0$) corresponds to the lowest common ancestor (LCA) of node #i and #j** . Then, observing the subtree rooted at the LCA, we find that all the summands masked by $\pm M$ are in the subtree, and all the summands not masked by $\pm M$ are out of the subtree. Therefore, the number of leaf nodes in the subtree (representing the size of the subtree) equals $n - n^{i,j}_{\text{not masked}}$, denoted by

$$l^{i,j} = n - n^{i,j}_{\text{not masked}} = n - \text{SUMIMPL}(A^{i,j}).$$

For brevity, we use $l^{i,j}$ to denote "the number of leaf nodes in the subtree rooted at the LCA of node #i and #j " in the rest of the paper.

Take Algorithm 1 as an example SUMIMPL, whose accumulation order is depicted in Figure 2.[2] If $i = 2$ and $j = 4$, then the array $A^{2,4}$ is $(1, 1, M, 1, -M, 1, 1, 1)$. Computing the sum of $A^{2,4}$ with the example SUMIMPL, the 3rd summand and the intermediate sum of the 0th and 1st summands are masked by M (the 2nd summand); the 5th summand is masked by $-M$ (the 4th summand). Therefore, in total, $n^{2,4}_{\text{masked}} = 4$. In contrast, the 6th and 7th summands and their intermediate sum are not added to M or $-M$, so $n^{2,4}_{\text{not masked}} = \text{SUMIMPL}(A^{2,4}) = 2$.

Algorithm 1 An example summation implementation.

```
float sum = 0;
for (int i=0; i<8; i+=2)
    sum += a[i] + a[i+1];
```

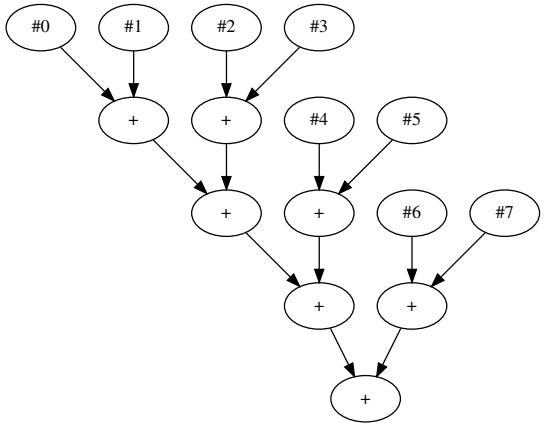

Figure 2: The summation tree of Algorithm 1. The numbers on the leaf nodes denote the indexes in the input.

The LCA of node #2 and #4 is the grandparent node of node #4, as shown in 2. It corresponds to the neutralization of the 2nd summand M and the 4th summand $-M$, i.e., $M + (-M) = 0$. Within the subtree rooted there, there are node #0, #1, #2, #3, #4, and #5 (6 leaf nodes in total), corresponding to the two masks and the summands masked by them. In contrast, node #6 and #7 (2 leaf nodes in total), which correspond to the summands not masked, are out of the subtree. Therefore, $l^{2,4} = 8 - 2 = 6$. Table 1 shows more examples of the output of SUMIMPL($A^{i,j}$) and $l^{i,j}$ for Algorithm 1.

[2] We compile it with different compiler versions and optimization flags, and note that they do not change the accumulation order, even if they might in theory. We suspect such changes can be found on more complex math expressions instead of summations.

Table 1: The order-related information $l^{i,j}$ inferred from the outputs of Algorithm 1 with different masked all-one arrays $A^{i,j}$ as inputs.

i	j	Input: $A^{i,j}$	Output	$l^{i,j}$
0	1	$(M,-M,1,1,1,1,1,1)$	6	2
0	2	$(M,1,-M,1,1,1,1,1)$	4	4
0	3	$(M,1,1,-M,1,1,1,1)$	4	4
0	4	$(M,1,1,1,-M,1,1,1)$	2	6
0	5	$(M,1,1,1,1,-M,1,1)$	2	6
0	6	$(M,1,1,1,1,1,-M,1)$	0	8
0	7	$(M,1,1,1,1,1,1,-M)$	0	8
		...		
2	3	$(1,1,M,-M,1,1,1,1)$	6	2
2	4	$(1,1,M,1,-M,1,1,1)$	2	6
		...		

4.3 Step 3: generating the summation tree

With the information $L=\{(l^{i,j},i,j)\}$ derived from the outputs, where $l^{i,j}$ represents the size of the subtree rooted at the LCA of node #i and #j, generating the summation tree from L is a tree algorithm problem.

Our solution employs a bottom-up approach to construct the tree. First, we sort L in ascending order. For each $l^{i,j}$, we locate the root of the existing subtree containing node #i and the root of the existing subtree containing node #j, and merge them by creating a new parent node for them. By repeating this process, we construct the entire summation tree, progressing from small subtrees to larger ones.

For example, consider the order-related information $L=\{(l^{i,j},i,j)\}$ shown in Table 1. To generate the summation tree, we start by initializing the tree with eight disjoint nodes labeled 0 to 7. Then, examining the smallest value in L, we have $l^{0,1}=2$. This implies that the subtree rooted at the LCA of node #0 and #1 should have 2 leaf nodes. Since the summation tree is a full binary tree, node #0 and #1 are exactly the two children of the root of this subtree. Therefore, we add a new node to the tree, label it with n plus the label of its left child (i.e., $n+0$ in this example), and add two edges from the two leaf nodes to the new node.

For $l^{2,3}=l^{4,5}=l^{6,7}=2$, similarly, we can construct the subtree containing node #2 and #3, the subtree containing node #4 and #5, and the subtree containing node #6 and #7. Now, we have four subtrees of size 2, where the size of a subtree is represented by the number of leaf nodes in it.

Next, the smallest unexamined value in L is $l^{0,2}=4$. This implies that the subtree rooted at the LCA of node #0 and #2 should have 4 leaf nodes. We note that node #0 and #2 are currently in two different subtrees (each has 2 leaf nodes), so we should merge the two subtrees. Therefore, we find the current roots of the subtrees containing node #0 and #2 respectively, i.e., node #i' and #j' where $i'=n+0$ and $j'=n+2$. Subsequently, we add a new node as the parent of node #i' and #j', label it with n plus the label of its left child, i.e., $n+i'=2n+0$, and add two edges from node #i' and #j' to the new node.

For $l^{0,3}=4$, we find that node #0 and #3 are already in the same subtree with 4 leaf nodes, so we just skip it. The same process is applied to $l^{1,2}=l^{1,3}=4$. Now, we have a subtree with 4 leaf nodes and two subtrees with 2.

The next smallest unexamined value in L is $l^{0,4}=6$, which implies that the subtree rooted at the LCA of node #0 and #4 should have 6 leaf nodes. Similarly, node #0 and #4 are currently in two different subtrees (one has 4 leaf nodes and the other has 2), so we should merge the two subtrees. Therefore, following the similar process, we find the current roots of the trees containing node #0 and #4 respectively, i.e., node #i' and #j' where $i'=2n+0$ and $j'=n+4$. Subsequently, we create a new node as their parent (labelled as $n+i'=3n+0$), and add two edges from node #i' and #j' to it.

For $l^{0,5}=6$, we find that node #0 and #5 are already in the same subtree with 6 leaf nodes, so we skip it. The same process is applied to $i\in\{1,2,3\}$ and $j\in\{4,5\}$. Now, we have a subtree of with 6 leaf nodes and a subtree of with 2.

Finally, in the similar way, the next smallest unexamined value in L is $l^{0,6}=8$, which implies that the subtree rooted at the LCA of node #0 and #6 should have8 leaf nodes. Since node #0 and #6 are currently in two different subtrees (one has 6 leaf nodes and the other has 2), we should merge the two subtrees. After we add the parent node of the current roots of the two subtrees and add the corresponding edges, the entire summation tree is generated.

To generalize and formulate the algorithm, we present BasicFPRev in Algorithm 2, where the GENERATETREE function encapsulates Step 3. It first initializes T with n disjoint nodes and no edges. Then, for each $l^{i,j}$, it finds the roots of the existing subtrees containing node #i and #j . If they are identical, then the i-node #i and #j are already in the same subtree. Otherwise, it combines them. The FindRoot function can be implemented by the disjoint-set data structure, resulting in an amortized time complexity of $O(\alpha(n))$ [32], where $\alpha(n)$ is the inverse Ackermann function.

4.4 Time complexity and correctness analysis

Let $t(n)$ denote the time complexity of SUMIMPL. The computation of L has a time complexity of $\Theta(n^2t(n))$. In GENERATETREE, the time complexity of sorting $n(n-1)/2$ elements is $\Theta(n^2\log n^2)=\Theta(n^2\log n)$. Therefore, the time complexity of GENERATETREE is $\Theta(n^2\log n+n^2\alpha(n))=\Theta(n^2\log n)$. Thus, the overall time complexity of BasicFPRev is $\Theta(n^2t(n))+\Theta(n^2\log n)=\Theta(n^2t(n))$.

The correctness of BasicFPRev is inherent in its design and can be proven as follows. For a given implementation SUMIMPL and n, we use T to denote the real summation tree and define $T'=\text{BASICFPREV}(\text{SUMIMPL},n)$. Assuming $T\neq T'$, there must exist i and j such that $l_T^{i,j}\neq l_{T'}^{i,j}$. Now we con-

Algorithm 2 BasicFPRev: our basic solution for revealing the accumulation order.

Require: Implementation SUMIMPL and the number of summands n
Ensure: Summation tree of SUMIMPL

```
function BASICFPREV(SUMIMPL, n)
    L ← ∅
    for i ← 0 to n − 1 do
        for j ← i + 1 to n − 1 do
            A^{i,j} ← (1, 1, ..., 1); A^{i,j}_i ← M; A^{i,j}_j ← −M
            l^{i,j} ← n − SUMIMPL(A^{i,j})
            L ← L ∪ {(l^{i,j}, i, j)}
    function GENERATETREE(L)
        T ← ∅
        for (l^{i,j}, i, j) ∈ L in ascending order do
            i' ← T.FindRoot(i)
            j' ← T.FindRoot(j)
            if i' ≠ j' then
                k ← i' + n                    ▷ assign a new label
                T ← T ∪ {(i', k), (j', k)}
        return T
    return GENERATETREE(L)
```

struct $A^{i,j}$ and compute its sum in the order T and T' respectively, resulting in s and s'. Then, $s = n - l^{i,j}_T \neq s' = n - l^{i,j}_{T'}$. However, since $s = \text{SUMIMPL}(A^{i,j})$, then $l^{i,j}_{T'} = n - s' \neq n - s = n - \text{SUMIMPL}(A^{i,j})$. This contradicts the statement $l^{i,j} \leftarrow n - \text{SUMIMPL}(A^{i,j})$ in Algorithm 2. Therefore, the assumption $T \neq T'$ is false, so $T = T'$.

5 Algorithm improvement in FPRev

This section introduces the full version of our tool FPRev, which is evolved from our basic solution BasicFPRev detailed in Section 4. First, we refine the algorithm to reduce its time complexity. Second, based on the refined algorithm, we add support for multi-term fused summation, which is used by matrix accelerators, and finalize FPRev.

5.1 Reducing time complexity

5.1.1 Removing redundancy

By analyzing BasicFPRev, we observe that Algorithm 2 requires $n(n-1)/2$ different $(l^{i,j}, i, j)$ tuples, even though many values of $l^{i,j}$ are identical. However, only $n-1$ new nodes and $2(n-1)$ new edges are constructed. Since computing multiple $l^{i,j}$ by calling SUMIMPL is the primary source of the method's time complexity, reducing redundancy in $l^{i,j}$ (i.e., the cases corresponding to $i' = j'$ in Algorithm 2) can significantly improve efficiency.

To achieve this, we calculate $l^{i,j}$ on demand. Specifically, we do not calculate all $l^{i,j}$ ahead of the tree generation. Instead, we directly start to generate the summation tree, and calculate $l^{i,j}$ when needed. Following the bottom-up idea, we still construct subtrees from leaf to root.

Step 1. We use the set $I = \{0, 1, ..., n-1\}$ to denote the labels of the leaf nodes for which we are going to construct a summation tree. Let i represent the leaf node with the smallest label in I. The sibling node of node #i is either a leaf node or an inner node. If it is a leaf node, there exists a unique j such that $l^{i,j} = 2$. Otherwise, if it is an inner node, then $l^{i,j} > 2$ for all j such that $j \neq i$. Therefore, to distinguish the two cases, we need to calculate $l^{i,j}$ for all other js, denoted by the set $L_i = \{l^{i,j} : j \in I - \{i\}\}$. We examine the minimum value in L_i, which is denoted by $l = \min(L_i)$.

If l equals 2, let j be the one that satisfies $l^{i,j} = 2$. Then, node #j is the sibling node of node #i, so we add a new node to the tree, and add two edges from node #i and #j to the new node. Now, the currently constructed subtree has 2 leaf nodes.

Otherwise, if l is larger than 2, the sibling node of node #i must be an inner node. The subtree rooted at this inner node must have $l-1$ leaf nodes. Let $J_l = \{j : j \in I - \{i\} \wedge l^{i,j} = l\}$. Then, the number of members of J_l must be $l-1$, and the members of J_l are exactly the leaf nodes of this subtree. This can be proven by contradiction. Now, constructing this subtree is a subproblem for the set J_l. Suppose that we have constructed this subtree by a recursive algorithm. We shall add a new node to the tree, and add edges from node #i and the root node of this subtree to the new node. Now, the currently constructed subtree has l leaf nodes.

Summarizing the two cases, we can treat both cases as the same pattern: finding $J_l = \{j : j \in I - \{i\} \wedge l^{i,j} = l\}$ and solving the subproblem for J_l. The first case ($|J_l| = 1$) just leads to the stop condition of the recursion ($|I| = 1$).

Step 2. Now we have constructed a subtree with l leaf nodes. Let r be the root of this subtree. Similarly, to find the sibling node of r, we examine the minimum value in the rest of L_i, which is denoted by l' here. Then, we solve the subproblem for $J_{l'} = \{j : j \in I - \{i\} \wedge l^{i,j} = l'\}$, and get a subtree whose leaf nodes are $J_{l'}$. The root of the subtree, whether a leaf node or an inner node, is the sibling node of r. Therefore, we shall add a new node to the tree, and add edges from r and the root node of the subtree to the new node. Now, the currently constructed subtree has l' leaf nodes.

Remaining steps. We repeat the above step until all values in L_i are examined and the entire tree is constructed. We implement this method with a recursive algorithm, as shown in Algorithm 3.

5.1.2 Demonstration with example

Consider the example SUMIMPL in Algorithm 1, whose summation tree is illustrated in Figure 2. We call Algorithm 3 with this SUMIMPL and $n = 8$. First, the set of leaf nodes is

Algorithm 3 Refinement of BasicFPRev (Algorithm 2).

Require: Implementation SUMIMPL and the number of summands n
Ensure: Summation tree of SUMIMPL
  function BASICFPREVREFINED(SUMIMPL, n)
    function BUILDSUBTREE(I)
      $T \leftarrow \varnothing$
      if $|I| = 1$ **then** ▷ stop condition
        return T
      $i \leftarrow \min(I)$; $L_i \leftarrow \varnothing$
      for $j \in I - \{i\}$ **do** ▷ calculate $l^{i,j}$ on demand
        $A^{i,j} \leftarrow (1,1,...,1)$; $A^{i,j}_i \leftarrow M$; $A^{i,j}_j \leftarrow -M$
        $l^{i,j} \leftarrow n - \text{SUMIMPL}(A^{i,j})$
        $L_i \leftarrow L_i \cup \{l^{i,j}\}$
      $r \leftarrow i$ ▷ current root of the subtree
      for $l \in L_i$ in ascending order **do**
        $J_l \leftarrow \{j : j \in I - \{i\} \wedge l^{i,j} = l\}$
        $T' \leftarrow \text{BUILDSUBTREE}(J_l)$
        $T \leftarrow T \cup T'$
        $T \leftarrow T \cup \{(r, r+n), (\text{GetRoot}(T'), r+n)\}$
        $r \leftarrow r+n$
      return T
    return BUILDSUBTREE($\{0,1,...,n-1\}$)

$I = \{0,1,...,7\}$, where the smallest label is $i = 0$. Next, the set $L_i = \{l^{i,j} : j \in I - \{i\}\} = \{2,4,4,6,6,8,8\} = \{2,4,6,8\}$ is computed. Examining the smallest value in L_i, we have $l = 2$ and $J_l = \{j : j \in I - \{i\} \wedge l^{i,j} = l\} = \{1\}$. Therefore, BUILDSUBTREE($\{1\}$) is called, reaching the stop condition. Then, the subtree with node #0 and #1 as its leaf nodes is constructed. The root of this subtree is denoted by r.

Next, examining the smallest value in the rest of L_i, we have $l = 4$ and $J_l = \{j : j \in I - \{i\} \wedge l^{i,j} = l\} = \{2,3\}$. Therefore, BUILDSUBTREE($\{2,3\}$) is called, where we have $I = \{2,3\}$, $i = 2$, and $L_i = \{2\}$, and BUILDSUBTREE($\{3\}$) is called there. BUILDSUBTREE($\{2,3\}$) returns the subtree with node #2 and #3 as its leaf nodes. We then designate its root as the sibling node of r, and construct the parent node of this root and r. Then, the subtree with node #0, #1, #2, and #3 as its leaf nodes is constructed. r is updated by the root of this subtree.

The next smallest value is $l = 6$. We have $J_l = \{4,5\}$. Similarly, BUILDSUBTREE($\{4,5\}$) is called, and it returns the subtree with node #4 and #5 as its leaf nodes. We merge its root with r, and construct the subtree with node #0, #1, #2, #3, #4, and #5 as its leaf nodes. r is updated by the root of this subtree.

Finally, $l = 8$ and $J_l = \{6,7\}$. BUILDSUBTREE($\{6,7\}$) is called, and it returns the subtree with node #6 and #7 as its leaf nodes. We merge its root with r. Then the entire tree is constructed.

5.1.3 Time complexity

The time complexity of Algorithm 3 is $O(n^2 t(n))$ and $\Omega(nt(n))$. The worst-case scenario occurs when adding n summands in the right-to-left order. In this case, BUILDSUBTREE will be invoked with all suffixes of $\{0,1,...,n-1\}$, and $l^{i,j}$ for all $0 \le i < j < n$ will be calculated. The worst-case time complexity is $\Theta(n^2 t(n))$. In practice, this order is cache-unfriendly, and thus no library uses it.

The best-case scenario corresponds to the sequential summation, where the summation tree will be constructed in one pass, and only $l^{0,j}$ for all $0 < j < n$ will be calculated. The best-case time complexity is $\Theta(nt(n))$. In practice, many libraries use similar orders, because these orders are cache-friendly and efficient.

5.2 Adding support for matrix accelerators

5.2.1 Multi-term fused summation

Matrix accelerators such as NVIDIA Tensor Cores are specialized hardware components in modern GPUs. Matrix accelerators enable assembly instructions that take a matrix $A = (a_{ij})_{M\times K}$, a matrix $B = (b_{ij})_{K\times N}$, and a matrix $C = (c_{ij})_{M\times N}$ as input, and produce a matrix $D = (d_{ij})_{M\times N}$ such that $D = A \times B + C$. The data types of A and B are identical. The data types of C and D are also identical, and their precision is no lower than the precision of A and B.

The numerical behavior of these assembly instructions remains undisclosed. Specifically, the computation of $d_{ij} = c_{ij} + \sum_{k=0}^{K-1} a_{ik} b_{kj}$ is executed in an undocumented way. Through delicate numerical experiments, prior works [9,18] have found that for double-precision input, the computation is executed in a chain of standard FMAs; for low-precision input (specifically, when the precision of A and B is lower than float32), the computation of $d_{ij} = c_{ij} + \sum_{k=0}^{K-1} a_{ik} b_{kj}$ is executed based on multi-term fused summation:

- The products are computed exactly, and the results are maintained in full precision without rounding after the multiplication.
- The summation of a group of summands is performed in a fixed-point manner. Specifically, the significands are aligned to the largest exponent of the summands, and then truncated to 24+ bits (i.e., no less than the precision of float32). The number of bits and the truncation method vary depending on the GPU architecture.
- Then, the sum is converted to the floating-point number in the output data type of the instruction.

Note that the size of the group w, the width of the accumulator, and the detailed conversion method vary depending on the GPU architecture. In addition, previous works do not target the high-level APIs and libraries, so the accumulation orders of them remains unknown.

Our proposed solutions can work for standard FMAs. However, multi-term fused summation requires a new method, be-

cause it is executed in a non-standard, IEEE-754-incompliant way. Specifically, in multi-term fused summation, w summands (e.g., $x_0 = c$, and $x_i = a_{i-1}b_{i-1}$ for $1 \le i < w$) are summed in a fixed-point manner, thus making the result independent of the summation order. To represent this operation in the summation tree, we should use a node with w children instead of a node with two children. Therefore, the summation tree should be an w-way tree.

5.2.2 Constructing the multiway summation tree

To adapt to the multiway tree, we first revisit BasicFPRev in Section 4. The first two steps still work because we find that the key equation $l^{i,j} = n - \text{SUMIMPL}(A^{i,j})$ remains valid in multi-term fused summation. Thus, the values of $l^{i,j}$ can be obtained in the same way, and we only need to redesign the tree construction algorithm in the third step.

Then, we revisit the tree construction algorithm in Algorithm 3. In BUILDSUBTREE(I), we calculate $l^{i,j}$ for a fixed i and all $j \in I - \{i\}$, enumerate them in ascending order, and maintain r as the root of the largest constructed subtree containing node #i. For some $l \in L_i = \{l^{i,j} : j \in I - \{i\}\}$ and $J_l = \{j : j \in I - \{i\} \wedge l^{i,j} = l\}$, the return value of BUILDSUBTREE(J_l) is the subtree with J_l as its leaf nodes. The root of this subtree must be the sibling node of r, so we can create a new node as their parent node and update r. However, this relation is not always true for the multiway tree.

In addition to being sibling node, the root of the subtree may also be the parent node of r in the multiway tree. For example, suppose a 5-way tree with leaf nodes $I = \{0,1,2,3,4\}$ as the children of the root. Then, when $r = 0$, $l = 5$, and $J_l = \{1,2,3,4\}$, solving the subproblem for J_l should return a partial subtree with J_l as its leaves. The root node of the subtree is the parent node of r.

To distinguish the two cases, we observe the return value of BUILDSUBTREE(J_l), denoted by T', and the complete subtree rooted at the root of T', denoted by T_c. In the first case, the root of T' should be the sibling of r, and $T' = T_c$. In the second case, the root of T' should be the parent of r, and $T' \subset T_c$. Therefore, we can compare the size of T' (denoted by $n^{T'}_{\text{leaves}}$) with the size of T_c (denoted by $n^{T_c}_{\text{leaves}}$). We note that $n^{T'}_{\text{leaves}} = |J_l|$, and $n^{T_c}_{\text{leaves}} = \max\{l^{j,k} : j,k \in J_l\} = \max(L_{\min(J_l)})$. Therefore, if $\max(L_{\min(J_l)}) = |J_l|$, then the root of T' should be the sibling of r, so we should create a new node as their parent node and update r with the index of this new node. Otherwise, $\max(L_{\min(J_l)}) > |J_l|$, so the root of T' should be the parent of r, and thus we should add an edge from r to the root of T', and update r with the root.

Through this modification, the multiway tree can be correctly constructed. We elaborate on the above process in Algorithm 4, i.e., the algorithm of FPRev. It has the same time complexity as Algorithm 3 (note that Algorithm 3 just corresponds to the case where $\max(L_{\min(J_l)}) = |J_l|$), and supports multi-term fused summation.

Algorithm 4 The algorithm of FPRev.

Require: Implementation SUMIMPL and the number of summands n
Ensure: Summation tree of SUMIMPL

```
function FPREV(SUMIMPL,n)
    function BUILDSUBTREE(I)
        T ← ∅
        if |I| = 1 then                                  ▷ stop condition
            return (T, 1)
        i ← min(I); L_i ← ∅
        for j ∈ I − {i} do                  ▷ calculate l^{i,j} on demand
            A^{i,j} ← (1,1,...,1); A^{i,j}_i ← M; A^{i,j}_j ← −M
            l^{i,j} ← n − SUMIMPL(A^{i,j})
            L_i ← L_i ∪ {l^{i,j}}
        r ← i                                  ▷ current root of the subtree
        for l ∈ L_i in ascending order do
            J_l ← {j : j ∈ I − {i} ∧ l^{i,j} = l}
            (T', n^{T_c}_leaves) ← BUILDSUBTREE(J)
            T ← T ∪ T'
            if |J_l| = n^{T_c}_leaves then                ▷ T' = T_c
                T ← T ∪ {(r, r+n), (GetRoot(T'), r+n)}
                r ← r+n
            else                                          ▷ T' ⊂ T_c
                T ← T ∪ {(r, GetRoot(T'))}
                r ← GetRoot(T')
        return (T, max(L_i))
    (T, n^{T_c}_leaves) ← BUILDSUBTREE({0,1,...,n−1})
    return T
```

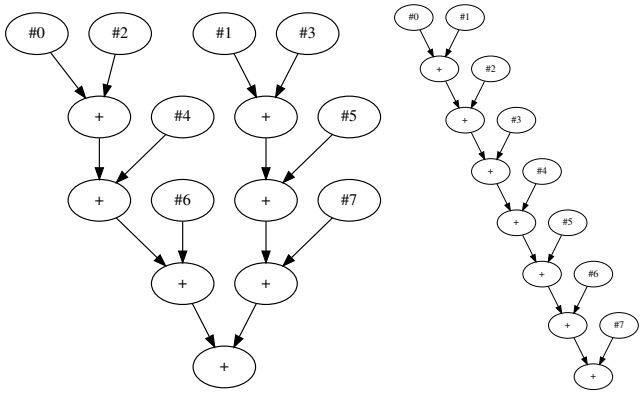
5.3 Time complexity and correctness

Following the same analysis in Section 5.1.3, the time complexity of FPRev is $O(n^2t(n))$ and $\Omega(nt(n))$, and the probability of the worst-case time complexity $O(n^2t(n))$ is low. The correctness of it is also guaranteed by design and can be proven following the same process in Section 4.4.

6 Case study

In this section, we apply FPRev to two prevalent numerical libraries: NumPy [11], the most popular Python library for numerical computing on CPUs, and PyTorch [27], a very popular Python library for numerical computing on GPUs. We successfully identify and analyze the undocumented accumulation orders in these libraries.

6.1 NumPy's implementation on CPUs



We use FPRev to test NumPy (version 1.26) on three CPUs:

- CPU-1: Intel Xeon E5-2690 v4 (24 v-cores)
- CPU-2: AMD EPYC 7V13 (24 v-cores)
- CPU-3: Intel Xeon Silver 4210 (40 v-cores)

Summation. On these CPUs, we find that NumPy implements identical accumulation order for the summation function in single precision. Therefore, Numpy's summation is verified to be reproducible across these systems, and can be used in software requiring numerical reproducibility.

The accumulation order is sequential for $n < 8$. For $8 \leq n \leq 128$, NumPy implements an eight-way summation. Each way i sums up $a_i, a_{i+8}, a_{i+16}, \ldots$ sequentially, and the sums of eight ways are summed using pairwise summation. For example, Figure 1 shows the accumulation order for $n = 32$. This accumulation order implies that developers can leverage the eight-way SIMD instructions in the CPU to accelerate computation. For $n > 128$, NumPy increases the number of ways, thus leveraging multi-threading for large-scale summation.

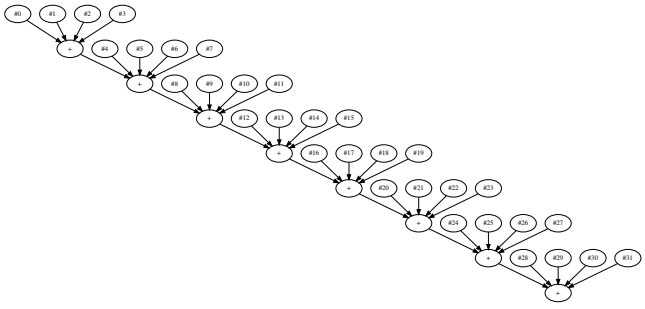
Other AccumOps. We also test NumPy's dot product, matrix-vector multiplication, and matrix multiplication functions in single precision. We observe discrepancies in the accumulation order across the tested CPUs. For example, Figure 3 shows the accumulation orders of Numpy's $n \times n$ matrix-vector multiplication for $n = 8$ on the CPUs. We note that on CPU-1 and CPU-2, the 32 products of each output element are accumulated using 2-way summation, whereas on CPU-3, which has more cores than CPU-1 and CPU-2, the products are accumulated sequentially.

(a) On Intel Xeon E5-2690 v4 and AMD EPYC 7V13 (24 v-cores).

(b) On Intel Xeon Silver 4210 (40 v-cores).

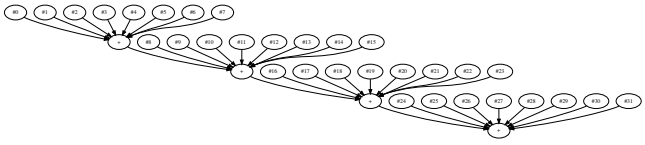
Figure 3: The accumulation orders of NumPy's 8×8 matrix-vector multiplication on different CPUs.

In summary, NumPy's summation function is safe for developing reproducible software for these CPUs, while other AccumOps of NumPy should not be used in software requiring numerical reproducibility.



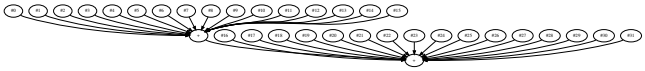
6.2 PyTorch's implementation on GPUs

We use FPRev to test PyTorch (version 2.3) on three GPUs:



- GPU-1: NVIDIA V100 (5120 CUDA cores)
- GPU-2: NVIDIA A100 (6912 CUDA cores)
- GPU-3: NVIDIA H100 (16896 CUDA cores)

On these GPUs, we observe findings similar to those for NumPy: PyTorch implements identical accumulation orders for the summation function in single precision but not for the BLAS operations. Therefore, PyTorch's summation function is safe for developing reproducible software for these GPUs, while other AccumOps of PyTorch should not be used in software requiring numerical reproducibility.



Matrix multiplication on Tensor Cores. To enable Tensor Core computation, we apply FPRev to half-precision matrix multiplication in PyTorch, which is implemented using the cuBLAS backend. The results show that the summation tree is a 5-way tree on NVIDIA V100, a 9-way tree on A100, and a 17-way tree on H100, corroborating the conclusion in [9, 18], which states that the Tensor Cores on NVIDIA Volta, Ampere, and Hopper architectures use (4+1)-, (8+1)-, and (16+1)-term fused summation respectively. For example, Figure 4 shows the summation trees for $n = 32$ on these devices.

(a) On NVIDIA V100.

(b) On NVIDIA A100.

(c) On NVIDIA H100.

Figure 4: The accumulation orders of PyTorch's half-precision $32 \times 32 \times 32$ matrix multiplication on Tensor Cores.

We also examine the SASS assembly instructions they use, and observe that V100 uses the `HMMA.884` instruction, and both A100 and H100 use the `HMMA.16816` instruction. **Interestingly, an `HMMA.16816` instruction on A100 indicates the shape of the inputs where the accumulation dimension $K = 16$, but it is implemented through (8+1)-term fused summation by the A100 Tensor Core hardware.**

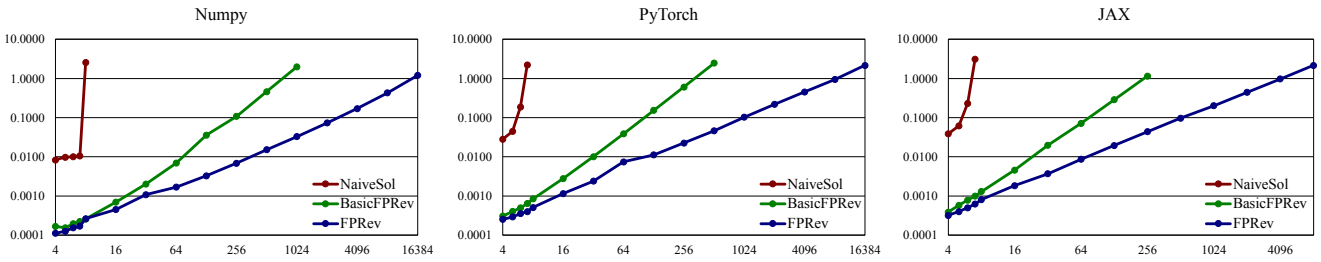


Figure 5: Execution time of applying NaiveSol, BasicFPRev, and FPRev to the summation functions in NumPy, PyTorch, and JAX. The vertical axis represents execution time in seconds. The horizontal axis represents the number of summands n.

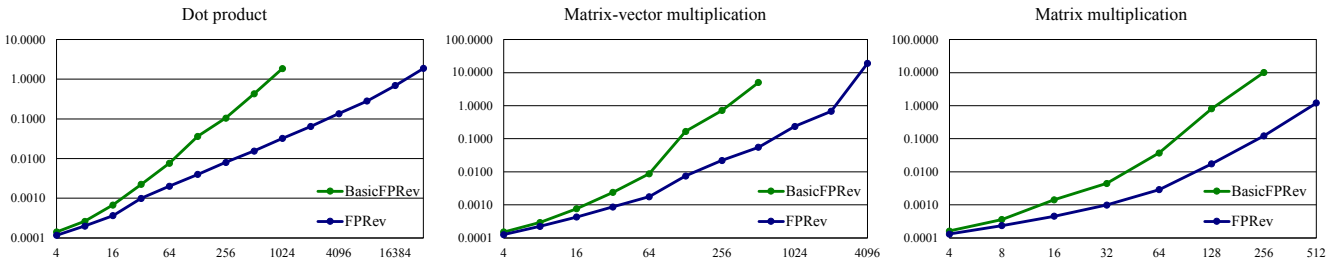

Figure 6: Execution time of applying BasicFPRev and FPRev to the dor product, matrix-vector multiplication, and matrix multiplication functions in NumPy. The vertical axis represents execution time in seconds. The horizontal axis represents the number of summands n.

7 Performance evaluation

7.1 Experiment design

In this section, we evaluate the efficiency of FPRev. Specifically, we aim to answer the following research questions (RQs):

- RQ1: how efficient is FPRev when applied to different libraries?
- RQ2: how efficient is FPRev when applied to different operations?
- RQ3: how efficient is FPRev on different CPUs and GPUs?

To answer the RQs, we measure the execution time (wall-clock time) of applying our solutions to tested libraries and operations. We implement FPRev (Algorithm 4) in Python (version 3.11). For comparison, we also implement the basic solution (Algorithm 2), denoted by BasicFPRev.

7.2 RQ1: How efficient is FPRev when applied to different libraries?

For RQ1, we test the single-precision summation function in three libraries: NumPy (version 1.26) [11], PyTorch (version 2.3) [27], and JAX (version 0.4) [3]. We run the experiments on Intel Xeon E5-2690 v4 with 24 v-cores. In these experiments, we also implement the naive brute-force solution (Section 3.3), denoted by "NaiveSol", to show its extremely low efficiency. For remaining RQs, we omit the naive solution because it is proven to be too inefficient.

We begin with the number of summands $n = 4$, and increment n until the execution time exceeds one second. Each experiment is carried out 10 times, and the arithmetic mean of the 10 results is reported in Figure 5. The red curves indicate that the execution time of NaiveSol grows exponentially as n grows. The results substantiate the $O(4^n/n^{3/2} \cdot t(n))$ time complexity of NaiveSol. The green and blue lines show that the execution time of BasicFPRev and FPRev grows polynomially. The different slopes also demonstrate that the execution time of BasicFPRev is longer than that of FPRev, and increases more rapidly as n increases. This is because the time complexity of BasicFPRev is $\Theta(n^2 t(n))$, while that of FPRev is $\Omega(nt(n))$ and $O(n^2 t(n))$.

These trends suggest that the scalability of BasicFPRev is much better than that of NaiveSol, and the scalability of FPRev is even better. For example, when $n = 16$, NaiveSol can take over 24 hours to produce an output, but BasicFPRev and FPRev only take less than 0.01 seconds. If $n = 8192$, BasicFPRev will take over 100 seconds to produce an output, but FPRev only takes about 1 second.

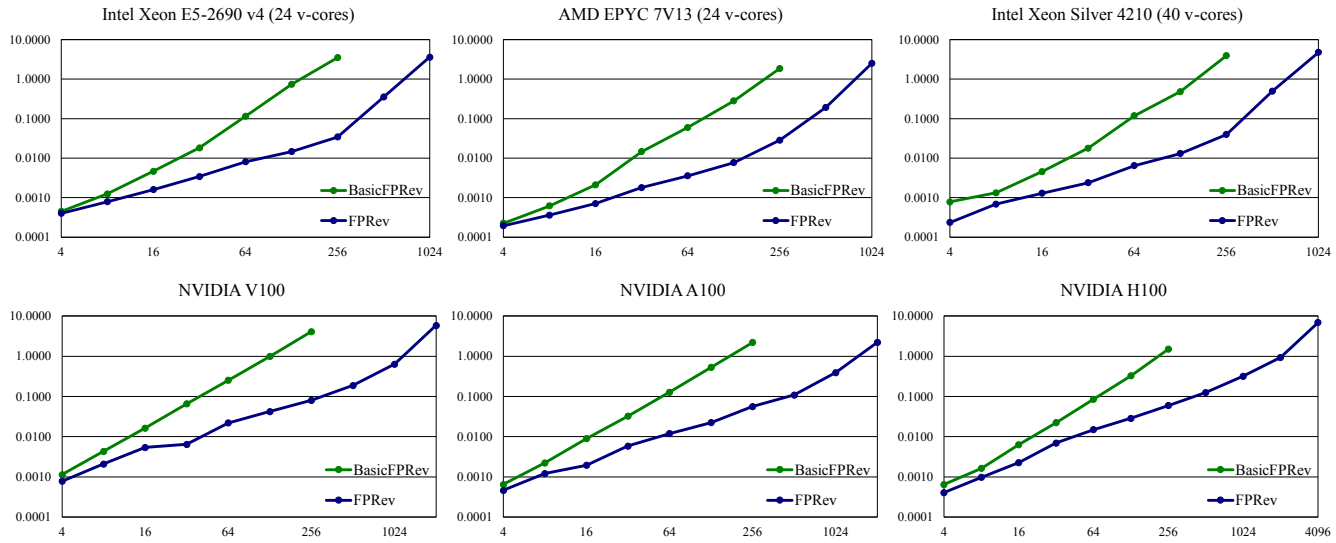

Figure 7: Execution time of applying BasicFPRev and FPRev to the matrix multiplication functions in PyTorch on different CPUs and GPUs. The vertical axis represents execution time in seconds. The horizontal axis represents the number of summands n.

7.3 RQ2: How efficient is FPRev when applied to different operations?

For RQ2, we test the single-precision dot product, matrix-vector multiplication, and matrix multiplication functions in NumPy on Intel Xeon E5-2690 v4. The time complexity of these functions is $O(n)$, $O(n^2)$, and $O(n^3)$, respectively.

Similarly, we begin with $n = 4$, and increment n until the execution time exceeds one second. Each experiment is carried out 10 times, and the arithmetic mean of the 10 results is reported in Table 6. The different slopes indicate that the time complexity of BasicFPRev is higher than that of FPRev. In addition, as the time complexity of the workload increases, the growth speed of the runtime with regard to n accelerates. Therefore, the speedup of FPRev over BasicFPRev is more pronounced as the workload is more complex. For example, for $n = 256$, FPRev is 13.0× as fast as BasicFPRev for dot product, 32.3× for matrix-vector multiplication, and 82.1× for matrix multiplication.

7.4 RQ3: How efficient is FPRev on different CPUs and GPUs?

For RQ3, we test the single-precision matrix multiplication in PyTorch on the CPUs and GPUs listed in Section 6. Similarly, we begin with $n = 4$, and increment n until the execution time exceeds one second. Each experiment is carried out 10 times, and the arithmetic mean of the 10 results is reported in Figure 7. The results demonstrate consistent improvements in the runtime of FPRev compared to BasicFPRev. Therefore, FPRev is consistently more efficient than BasicFPRev on different devices.

8 Discussion

8.1 Limitation and mitigation

8.1.1 Dynamic range of the input data type

When applying FPRev to data types with low dynamic range, the mask M may be too small to effectively mask the sum of ones. For example, the maximum value of the 8-bit floating-point number with 4 exponent bits (FP8-e4m3) defined in [21] is 1.75×2^8, so the condition $M \gg n$ may not hold, and $\pm M + \sigma \neq \pm M$ for $0 \leq \sigma \leq n-2$. To mitigate the issue, we can replace the ones in the masked all-one arrays with smaller numbers (e.g., $2^{-9} \times 2^{-9}$ for FP8-e4m3 matrix multiplication), and scale the sum back to an integer between 0 and $n-2$ when calculating $l^{i,j}$. This solution does not affect efficiency.

8.1.2 Precision of the accumulator

The precision of the floating-point accumulator can limit the input size that FPRev supports. For example, float32 has a precision of 24 bits, so the maximum number of summands (n) that FPRev supports is $2^{24} + 1 = 16777217$ for float32 accumulation operations. For larger numbers, the sum of $n-2$ ones cannot be represented precisely in float32, so the sum of masked all-one arrays may be incorrect. This issue can be mitigated by dynamically replacing the multiple ones corresponding to a constructed subtree with one and multiple zeros, as if compressing the constructed subtree into one node.

Specifically in the BUILDSUBTREE(I) function of FPRev (Algorithm 4), the computation of $\text{SUM}(A^{i,j}) = 0$ is accurate for js such that $l^{i,j} = n$, so we can build the subtree for them in the end. We extract those js to $J = \{j : l^{i,j} = n\}$ after computing $L_i = \{l^{i,j} : j \in I - \{i\}\}$. Then, we set the values at J to 0, and build the subtree for $I - J$ recursively (which results in a smaller subproblem). After the subtree for $I - J$ is constructed, we set the values at J back to 1.0, and set the values at $I - J - \{i\}$ to 0. Now, the constructed subtree (containing $I - J$) is treated as a node, represented by node #i. Next, we run the original tree construction algorithm (the last iteration of the for-loop, i.e., $l = |All|$) for J, and then the whole tree is constructed.

Combining the two mitigation techniques, the modified version of FPRev is shown in Algorithm 5. This version is applicable to data types with low dynamic range and low accumulation precision, such as 16-bit and 8-bit floating-point formats (including BF16, FP16, FP8-e5m2, and FP8-e4m3 on recent Tensor Cores).

Algorithm 5 The modified version of FPRev.

Require: Implementation SUMIMPL, the number of summands n, large value M, and tiny value e
Ensure: Summation tree of SUMIMPL
  function MODIFIEDFPREV(SUMIMPL, n, M, e)
    function BUILDSUBTREE(I, All)
      $T \leftarrow \varnothing$
      if $|I| = 1$ **then** ▷ stop condition
        return T
      $i \leftarrow \min(I)$; $L_i \leftarrow \varnothing$
      for $j \in I - \{i\}$ **do** ▷ calculate $l^{i,j}$ on demand
        $A_k^{i,j} \leftarrow e$ for $k \in All$; $A_i^{i,j} \leftarrow M$; $A_j^{i,j} \leftarrow -M$
        $l^{i,j} \leftarrow |All| - \text{SUMIMPL}(A^{i,j})/e$
        $L_i \leftarrow L_i \cup \{l^{i,j}\}$
      $J \leftarrow \{j : l^{i,j} = \max(L_i)\}$
      $A_k^{i,j} \leftarrow 0$ for $k \in J$ ▷ Ignoring J
      $(T, n_{\text{leaves}}^{T_c}) \leftarrow$ BUILDSUBTREE($I - J, All - J$)
      $r \leftarrow \text{GetRoot}(T)$
      $A_k^{i,j} \leftarrow e$ for $k \in J$
      $K \leftarrow I - J - \{i\}$
      $A_k^{i,j} \leftarrow 0$ for $k \in K$ ▷ Treating $I - J$ as $\{i\}$
      $(T', n_{\text{leaves}}^{T_c}) \leftarrow$ BUILDSUBTREE($J, All - K$)
      $T \leftarrow T \cup T'$
      if $|J| = n_{\text{leaves}}^{T_c}$ **then** ▷ $T' = T_c$
        $T \leftarrow T \cup \{(r, r+n), (\text{GetRoot}(T'), r+n)\}$
      else ▷ $T' \subset T_c$
        $T \leftarrow T \cup \{(r, \text{GetRoot}(T'))\}$
      return $(T, \max(L_i))$
    $All \leftarrow \{0, 1, ..., n-1\}$
    $(T, n_{\text{leaves}}^{T_c}) \leftarrow$ BUILDSUBTREE(All, All)
    return T

8.2 Extensibility and future work

Section 6 has demonstrated that FPRev can be applied to popular numerical libraries like NumPy and PyTorch. FPRev can be applied to other accumulation implementations as long as they fall within the scope detailed in Section 3. In practice, we find most popular libraries have deterministic reduction orders and fall into the scope. FPRev also works for accumulation operations in collective communication primitives, such as the AllReduce operation, if their accumulation order is predetermined.

To further extend our tool to other functions based on special summation algorithms, the algorithms must satisfy the property $l^{i,j} = n - \text{SUMIMPL}(A^{i,j})$ or its variant in Algorithm 5. For example, the next generation of Tensor Core will support the microscaling data format [30], including the 4-bit and 6-bit formats MXFP4 and MXFP6. If their dynamic range and accumulator precision permit and the property holds, our methods can reveal the accumulation order within a block of microscaling numbers. Then, we can treat a block as one summand, and use FPRev to construct the summation tree for the summation of the blocks, and then expand each block to a subtree.

In addition to revealing accumulation orders, we plan to extend our methods to detect more floating-point behaviors in matrix accelerators. For example, we can determine the rounding mode and the precision of the accumulator of Tensor Cores by enumerating $n = 1, 2, ...$ and checking the result of $2^n + 1.75 - 2^n$. We are designing more numerical experiments to identify how the block fused multiply-add is conducted. Then, with the information detected, we can model the exact behavior of the hardware matrix accelerators.

Another direction is further optimizing the efficiency of FPRev. For example, we can randomize the selection of $i \in I$ in the FPRev algorithm, as if selecting the random pivot in quick sort. This might reduce the expected time complexity of FPRev.

9 Conclusion

In this paper, we introduce FPRev, a diagnostic tool for revealing the accumulation order in software and hardware implementations through numerical testing. It can help verify and facilitate the development of reproducible software. As a case study, FPRev reveal the undisclosed accumulation orders of prevalent numerical libraries such as NumPy and PyTorch on different CPUs and GPUs. We also demonstrated the efficiency FPRev through experiments covering various implementations and devices. Our source code is available at https://github.com/peichenxie/FPRev, encouraging further investigation and improvement by the research community.

A Artifact Appendix

Abstract

The repository includes the source code of FPRev and the source code for reproducing the experiments of the paper. The following content includes main claims that can be verified via experiments, and instructions to reproduce the experiments.

Scope

The main claims include:

1. FPRev is functional to reveal the floating-point accumulation orders in common implementations. This claim is detailed by Section 6 "Case study" in the paper. To verify this claim, run `python experiments/casestudy.py` and check the output files in the `outputs` directory.
   (a) `outputs/Numpy*.pdf` represents the revealed accumulation orders for NumPy, as discussed in Section 6.1 "NumPy's implementation on CPUs". Among them, `outputs/NumpyGEMV8.pdf` corresponds to Figure 3 of the paper, if the CPU models are consistent to those in the paper.
   (b) `outputs/Torch*.pdf` represents the revealed accumulation orders for PyTorch, as discussed in Section 6.2 "PyTorch's implementation on GPUs". Among them, `outputs/TorchF16GEMM32.pdf` corresponds to Figure 4 of the paper, if the GPU models are consistent to those in the paper.
2. FPRev is efficient. This claim is detailed by Section 7 "Performance evaluation" in the paper. To verify this claim, run `python experiments/rq1.py`, `python experiments/rq2.py`, and `python experiments/rq3.py`, and check the output files in the `outputs` directory.
   (a) `outputs/rq1.csv` provides the results of Section 7.2 "RQ1: How efficient is FPRev when applied to different libraries?". It corresponds to Figure 5 if the CPU model is consistenst to that in the paper.
   (b) `outputs/rq2.csv` provides the results of Section 7.3 "RQ2: How efficient is FPRev when applied to different operations?". It corresponds to Figure 6 if the CPU model is consistenst to that in the paper.
   (c) `outputs/rq3.csv` provides the results of Section 7.4 "RQ3: How efficient is FPRev on different CPUs and GPUs?". It corresponds to Figure 7 if the CPU and GPU models are consistenst to those in the paper.

Contents

Installation

```
sudo apt install graphviz
git clone https://github.com/peichenxie/FPRev.git
cd FPRev
pip install .
pip install -r experiments/requirements.txt
```

Running experiments

- To reproduce the results in Section 6 (Case study), run `python experiments/casestudy.py` on different hardware models.
- To reproduce the results in Section 7.2 (RQ1: How efficient is FPRev when applied to different libraries?), run `python experiments/rq1.py`.
- To reproduce the results in Section 7.3 (RQ2: How efficient is FPRev when applied to different operations?), run `python experiments/rq2.py`.
- To reproduce the results in Section 7.4 (RQ3: How efficient is FPRev on different CPUs and GPUs?), run `python experiments/rq3.py` on different hardware models.

Then, check the output files in the outputs directory. See `outputs/README.md` for more information.

Hosting

https://github.com/peichenxie/FPRev

Requirements

The artifact requires the following platform:

- GPU: NVIDIA V100 or newer
- OS: Ubuntu 22.04
- Software: Python (version 3.11)

If you wish to reproduce the results in the paper, please use the identical CPU and GPU models:

1. CPU: Intel Xeon E5-2690 v4 (24 v-cores), GPU: NVIDIA V100 (5120 CUDA cores)
2. CPU: AMD EPYC 7V13 (24 v-cores), GPU: NVIDIA A100 (6912 CUDA cores)
3. CPU: Intel Xeon Silver 4210 (40 v-cores), GPU: NVIDIA H100 (16896 CUDA cores)

Inferring Likely Counting-related Atomicity Program Properties for Persistent Memory

Chun Jason Xue
MBZUAI

Abstract

Persistent Memory (PM) technologies provide fast, byte-addressable access to durable storage but face crash consistency challenges, motivating extensive work of testing and verification of PM programs. Central to PM testing tools is the specification of program properties for object persistence order and atomicity. Although several methods have been proposed for inferring PM program properties, most focus on ordering properties, offering limited support for atomicity properties. This paper explores a class of important atomicity properties between the container-like arrays and their logical size variables, referred to as the counting correlation, which are common in PM programs but exceed the capability of existing approaches. We propose invariants to capture the necessary behaviors of counting-correlated variables, utilize symbolic range analysis to extract PM program behaviors, and encode them into SMT constraints. These constraints are checked against the invariants to infer likely PM program properties. We demonstrate the utility of the inferred properties by leveraging them for PM bug detection, which discovers 14 atomicity bugs (including 11 new bugs) in real-world PM programs.

1 Introduction

DRAM technology is facing significant challenges in density scaling and power leakage [37]. Alternatively, Persistent Memory (PM) technologies, such as Intel Optane [18] and CXL-SSD [2, 35], open a new paradigm that allows for byte-addressable interfaces like DRAM and avoids the overhead of the storage stack. However, PM-based systems are error-prone due to the crash consistency issue. A store to PM is first written to a volatile cache and then flushed to the durable media, during which data is reordered [32, 33]. Programmers need to explicitly use hardware instructions like `clflush` and `sfence`, or transaction interfaces provided by libraries to ensure crash consistency. Yet appropriate usage of these instructions or interfaces demands expertise, beyond the reach of most programmers. As a result, PM programs are found to have many crash consistency bugs by emerging PM testing tools [9, 11, 15, 24, 30].

Due to the explosive program state and the arbitrary crashes that need to be explored, most existing PM testing tools rely on manual annotation [5, 5, 16, 23, 24], which can be tedious, or PM *program properties* specified by developers [9, 30] to inject crashes in a way that efficiently triggers potential bugs. Consequently, there is a persistent need for specifying PM program properties to detect crash consistency violations. To relieve the burden of programmers, PM program property inference approaches, such as Witcher [9] and Huang et al. [15], have been proposed to infer likely program properties based on control and data dependencies. While these methods show promise in *ordering properties*, they face challenges when dealing with the diverse *atomicity properties* of common PM data structures.

This paper examines a crucial category of atomicity properties that pertain to the relationship between container-like PM data structures and the integer variables that represent their semantic sizes–a relationship we refer to as *counting*. For instance, in a tree node, the children array is counting-correlated with its length variable, which records the number of appended pointers to child nodes. Without ensuring atomic persistence of updates to the children array and its length variable, the crash could result in the program reading a dangling pointer or losing ingested data. This counting correlation is also present in other persistent data structures and PM-based systems, such as hash tables [22, 28, 41] and ring buffers [14, 36, 39]. Unfortunately, systematically inferring properties related to counting correlation is out of reach of dependency-based atomicity property inference approaches, which rely on assumptions about access patterns rather than directly analyzing the program semantics of counting.

This paper studies the inference approach of the counting-related atomicity properties, aiming to complement the existing atomicity inference methods and thereby expand the scope of violations that the PM testing tools can detect. However, identifying the counting correlation among variables is not as

straightforward as its simple definition suggests. The semantic sizes, as a logical concept derived from the programmer's intent, are not explicitly revealed through program behavior. To handle it, we first propose the invariants for describing the necessary behaviors of counting-correlated variables based on their access ranges. We leverage symbolic range lattice [29] to extract these behaviors from the program, then encode them into SMT (Satisfiability Modulo Theories) [4] constraints, which are checked against the invariant with an SMT solver, thereby validating the likely counting-related atomicity properties. To show the effectiveness of the proposed inference approach, we leverage the inferred properties to detect PM bugs and successfully detect 14 atomicity violations, including 11 previously unknown bugs.

In summary, this paper makes the following contributions.

- We identify an important class of atomicity properties, termed counting, which are crucial for ensuring the crash consistency of PM programs. We also propose invariants to capture the behaviors of counting-correlated variables.
- We propose a framework that infers the counting correlation in PM programs by combining the symbolic range analysis with SMT constraint solving to validate the invariant.
- We evaluated the effectiveness of our approaches on real-world PM programs and found 14 atomicity bugs.

2 Background and Motivation

2.1 Background

Applications accessing PM could directly perform byte-addressable load/store operations, instead of system calls, as with traditional storage devices. Store requests to PM are first buffered in a volatile cache and then wait an arbitrary amount of time before the cacheline containing the data is evicted to PM. As a result, the reordering of writes to different memory locations may occur [34], causing the data persistence order may differ from the original execution order in the program. When a crash occurs, durable data in PM is prone to unexpected inconsistency.

PM programming delegates the task of ensuring crash consistency to the programmers, by using low-level instructions like `clflush` (or `clwb`) to flush cache lines and `sfence` to enforce the order, as well as high-level transaction (TX) interfaces [17, 19, 38] to provide all-or-nothing semantics. Despite these explicit flush and fence instructions, PM programs suffer from crash consistency issues [5, 9, 24, 30], including correctness bugs (e.g., improper or missed flush/fence) and performance bugs (e.g., extra flush/fence). This work focuses on the correctness issues.

2.2 Related Work

While earlier PM testing tools discussed the detection of durability bugs (i.e., missing flush for a particular store)–the simplest form of correctness bug in PM programs [20, 24, 30], recent works focus more on discovering application-specific bugs that require an understanding of the program logic. In particular, application-specific testing frameworks are designed to detect (i) *ordering bugs* that violate the must persist-before requirements between writes, i.e., without properly using fences, and (ii) *atomicity bugs* that violate the must persist-together requirements of writes, i.e., without enclosing the writes in a transaction.

The main challenge faced by application-specific PM testing tools is the explosive PM state space [12, 20, 30] due to the arbitrary write reordering and crash point in PM programs. To overcome it, existing tools use manual annotation [5, 5, 16, 23, 24], known bug pattern [10, 30], or in a more general way, PM *program properties* specified by developers [9, 30] to inject crashes such that potential bugs are triggered efficiently.

However, relying on manual efforts to specify the PM properties is time-consuming and demands expert knowledge of program semantics and the PM hardware model, making it not within reach of most developers. Although a black-box approach [11] has been proposed to bypass the need for program properties by focusing on the recovery procedure–specifically, examining whether the crashed program states are recoverable–the recovery code itself is often buggy and unreliable [24]. As a result, existing PM testing tools still have a common requirement for PM program properties to identify violations effectively.

To help programmers specify PM program properties, Witcher [9] and Huang et al. [15] propose to infer likely program properties based on the control dependency and data dependency patterns. For example, from a single control dependency relationship `if(x) then y=0`, where the write to `y` is control dependent on the read from `x`, an ordering PM program property is inferred that a store of `x` should be persisted before an update of `y` to ensure crash consistency. Through static analysis or dynamic analysis of data and control dependencies in program traces, Witcher and Huang et al. have demonstrated their ability to infer several ordering and atomicity PM program properties and detected potential bugs by checking whether these properties are satisfied.

Limitations. While dependency analysis can easily infer a *persist-before* requirement from a single data or control dependency relationship, it is limited to capturing the *persist-together* requirements for common data structures in PM programs. Table 1 presents the control dependency patterns that two existing works rely on to infer the potential atomicity properties in PM programs. Witcher observes that the updates of two or more guardians should be persisted atomically; the guardian is the flag variable at the condition statement controlling the access to other variables, e.g., `x` in `if(x)`. In contrast, Huang et al. regard a set of guardians that guard each other as atomic variables. The logic is that since each guarding relationship produces an ordering requirement, the

Inferred Likely Atomicity Property	ATOMICITY(x, y)	ATOMICITY(x, y)

Table 1: Existing dependency-based atomicity PM program property inference approaches.

only way to reconcile the conflicting requirements between interdependent variables is to persist them together.

Consider an atomicity bug found by our work from P-ART [22], a persistent adaptive radix tree (ART), shown in Figure 1 (b). In this code, a `children` array that collects the valid elements from the node_4 of ART, along with a variable `childrenCount` that indicates the size of valid elements in `children`, are expected to update atomically. Failing to ensure atomicity upon crash could result in irrecoverable data loss if only the array update is persisted, or the return of stale values if only the size update is persisted.

However, neither of the aforementioned dependency patterns could be identified in the accesses to `children` and `childrenCount`. In Figure 1 (a), `childrenCount` guards the access to `children`, but the testing tools fail to detect any instances where `children` guards `childrenCount` (to form the pattern in Huang et al.) or other variables (to form the pattern in Witcher). Unlike a single variable acting as a guardian, the `children` array functions as a *container* with different semantics. It stores multiple user data and ensures their durability in PM to serve future queries. These container-like structures are common in PM use cases, such as database indexes [22, 27, 28, 41] and file systems [7, 40]. Without a guardian role, these structures are hardly captured by the dependency analysis to infer their related atomicity properties.

Besides, work on detecting atomicity violations in concurrent programs [25, 31], such as MUVI [25], might potentially uncover certain counting-related bugs. However, these methods lack the capability for systematic detection and employ runtime techniques that are not straightforward for adoption in PM. For instance, controlling thread interleaving [31] is challenging in the context of PM due to the costly PM writes, as well as arbitrary crashes, which alter the interleaving space.

2.3 Counting-related Atomicity Property

We now introduce the counting relationships between container-like structures and their size attributes commonly found in PM programs. These relationships form a new atomicity property pattern, complementing existing dependency-based ones. Formally, an integer variable *SZ* tracks a numerical value about the *logical size*[1] of one or multiple arrays *ARR*s in the following three scenarios:

[1]The physical size could be regarded as a special case of the logical size.

```
73  Tree::lookupRange (…) {
74      ...
99      for (uint32_t i = 0; i < childrenCount; ++i) {
100         const N *n = std::get<1>(children[i]);
101     ...}
    }                          (a) Tree.cpp

109 N4::getChildren (…) {          They should be
116     ...                        in the same TX
117     children[childrenCount] = std::make_tuple(key, child);
118     childrenCount++;
119     ...
    }                          (b) N_4.cpp
```

Figure 1: An example atomicity bug outside the reach of dependency-based inference approaches.

- the logical size of an array, and
- the sum of the logical sizes of multiple arrays, and
- the complementary size of an array to a constant.

If a *SZ* and one or more *ARR*s exhibit any of the above relationships, an atomicity property ATOMICITY(*SZ*,*ARR*) should be satisfied in PM programs to ensure the crash consistency.

Despite their intuitive semantics, counting-related atomicity properties are often violated in many software storage stacks, which are among the primary targets PM is expected to reshape. For example, in btrfs, `i_size` that indicates the file size was found to be inconsistent with the actual file size when appending data. This inconsistency arises when the log of `i_size` is delayed as improper flags are set by other operations, and then a fsync flushes the data with the value of `i_size` smaller than the actual data size [26]. And in ext4, `i_disksize` indicating the size of data stored on disk is found inconsistent with the real data size when a delayed end-of-file write back meets a crash while a direct non-end-of-file write succeeds [13]. Although only a limited number of atomicity PM bugs are found due to the lack of testing tools aside from Witcher [9] and Huang et al. [15], there is a counting-related PM atomicity bug [6]. In this bug, `size` that indicates the allocated size of an array becomes inconsistent with the array when a crash happens between their updates.

3 Property Inference

3.1 Overview

This work aims to infer counting-related atomicity properties from PM programs. Rather than relying on *causation relationships*, as dependency-based inference approaches do, we resort to a *correlation relationship*, in which variables maintain a semantic relation throughout the program. We expect our approach to complement the work of Witcher [9] and Huang et al. [15], thereby broadening the range of inferred atomicity properties and related bugs covered by testing tools.

Problem. Although the concept of counting is intuitive, discovering the counting correlation is not straightforward. As a

programmer's intent, an array's logical size, which indicates the number of valid elements in its allocated space, is unknown to the analysis tools. Furthermore, the variable that represents the array's logical size may not consistently align with the array's true size throughout the program's execution. Consider an array insertion example in List 1. After executing lines 2 to 5, which insert an element into the middle of the `array`, the real size of `array` after line 2 is `size+1`, different from the value of `size` until its update at line 6. Here, `size` is intended to be counting-correlated with `array`. But the definitions of counting cannot be used to identify counting-correlated variables.

```
1  // insert an element at position p
2  for(i = size - 1; i >= p; i--){
3      array[i + 1] = array[i];
4  }
5  array[p] = 20;
6  size += 1;
```

Listing 1: Array insertion example (`0 <= p < size`).

Main Idea. Our solution to the above problem is based on our observation that *the read access to the array must remain within the range of valid elements constrained by the real size*, where the range of valid elements is accessible by analyzing program behaviors. As a result, we propose that the likely PM atomicity property ATOMICITY(`array, size`) is identified if any read access to `array` could be proved to be restricted by `size`. We refer to this as the *read range invariant*. Later, we will show why write access to the array may be beyond the valid element range and how to leverage this fact to form an (optional) *write range invariant*.

Inference Approach. To infer the counting-related atomicity property, we need to discover the counting-correlated variable pairs that satisfy the above access range invariants. A possible solution is to employ dynamical analysis such as Daikon [8], which monitors the indices of all pointer accesses and the values of all integers, subsequently verifying each pair in traces against the invariant individually. However, due to the inequalities in access range invariants, dynamic analysis often yields highly inaccurate results and is hard to scale in the presence of loops. Instead, we resort to Symbolic Range Analysis (SRA) [29], which over-approximates the access ranges for array indices and offers a more reliable analysis of program behaviors.

3.2 Invariants for Counting Correlation

Since the definition of counting about the logical/real size of an array does not characterize the real behaviors of correlated variables, we propose two access range invariants as the necessary conditions to infer likely counting-related atomicity properties. The invariant refers to the assertion about the correlated variables that are always held to be true in the program. We denote the program with P in this section.

Invariant 1: Read Range. We observe that a read access, which incorporates the programmer's intent for acquiring the valid elements of a container, has its index always lie in the region restricted by the container's logical size. Thus, we propose to use read range invariants to capture the relationship between the access behavior to an array and its counting-correlated size variable. We first introduce the invariant for the first correlation pattern, which is the base of the two other correlation patterns, as shown below:

$$\forall \rho \in P,\ Read_\rho(ARR, idx) \implies idx < Val_\rho(SZ). \quad (1)$$

$Read_\rho(ARR, idx)$ indicates there is a read to ARR at line ρ with access index being idx, and $Val_\rho(SZ)$ is the value of the logical size variable SZ at line ρ. We assume $idx \geq 0$. Consider the example in Listing 1, where the program shifts all elements starting from the insertion position towards the right, the index of read to `array` is $[p, size-1]$, which could be proved to be contained by the range $[0, size)$.

We also motivate the access range invariants by demonstrating an alternative class of correlation-based atomicity invariants based on access-together-times (MUVI [25]). This invariant is originally designed for testing concurrent programming atomicity bugs, in which accessed-together times exceeding a threshold should be updated atomically. From Listing 1, we notice the access-together-times invariant does not hold unless a tiny threshold is set, since this piece of code accesses `array` $size - p + 1$ times, while accessing `size` once.

By leveraging the basic read range invariant defined in Eq. (1), our approach could be extended to handle the two additional correlation patterns related to the logical size, given certain specifications from users. In the second pattern, the variable SZ_s tracks the cumulative logical sizes of multiple arrays. Provided N, the number of arrays considered by the user, the read range invariant is:

$$\forall \rho \in P, \sum_{i \in [1,N] \wedge Read_\rho(ARR_i, idx_i)} idx_i < Val_\rho(SZ_s). \quad (2)$$

Here, the sum of the indices of accesses to a number of ARRs at line ρ is compared against the integer value of $Val_\rho(SZ_s)$, enabling the inference of the cumulative size variable by programmer intent. We set $N = 2$ as the default configuration. In the third correlation pattern, the variable SZ_c is used to represent the complementary size of the array relative to a constant. Provided the constant C from the user, the read range invariant under this scenario is:

$$\forall \rho \in P,\ Read_\rho(ARR, idx) \implies idx < C - Val_\rho(SZ_c). \quad (3)$$

Here, the read access index is checked against the complementary value $C - Val_\rho(SZ_c)$.

We use the read index to establish the range invariant because writes may exceed the region restricted by the logical size variable, e.g., during insertion. In Listing 1, the write

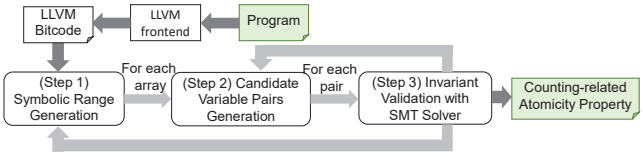

Figure 2: The workflow of our work.

indices to `array` are within the range $[p, size]$. As the insertion extends the logical size at the final step, writes access the index outside of the existing valid element region intended to be represented by `size` to include new elements.

Invariant 2: Write Range. According to the above observation regarding the write behaviors of arrays in programs, the write access range cannot be directly used for inferring the programmer's intent concerning the logical size of arrays. However, we can refine this approach by relaxing the condition on the maximum allowable write index. This adjustment allows us to incorporate an optional invariant, thereby enhancing the accuracy of our inferences. For example, under the assumption that each insertion function only adds one element, the write range invariant for the first pattern is:

$$\forall \rho \in P,\ Write_{\rho}(ARR, idx) \implies idx \leq Val_{\rho}(SZ), \quad (4)$$

where $Write_{\rho}(ARR, idx)$ indicates there is a write to ARR at line ρ with index idx. A constant term c could be added after the integer variable value to allow for different index relaxation limit assumptions. We set c as 0 by default.

3.3 Atomicity Property Inference

The workflow of inferring counting-related atomicity properties is shown in Figure 2. Our tool accepts the programs in C and translates them into LLVM bitcode IR [21]. We employ a symbolic range lattice [29] to abstract the symbolic access indices (**Step 1**) and identify candidate variable pairs for invariant validation (**Step 2**). Finally, we encode the symbolic information of array indices and the integer variables into SMT constraints and use an SMT solver to verify whether the invariants are satisfied (**Step 3**). For each variable pair that satisfies the invariant, an atomicity property is generated.

Step 1. Symbolic Range Generation. Before generating symbolic accesses to arrays, we first prepare all the candidate arrays. We use an LLVM pass to identify all pointer variables, including those that are members of structures. Since C conflates arrays with pointers, we differentiate the array variables from regular pointers by checking the pointer's operand. We collect the pointers that represent arrays into the set $\{ptr\}$. For each ptr, the symbolic range analysis is then employed to compute symbolic bounds for all accesses to ptr. Formally, the symbolic range of an access index int_v, denoted as $[\![int_v]\!]$, consists of a pair of symbolic bounds denoted by $[l, r]$, where

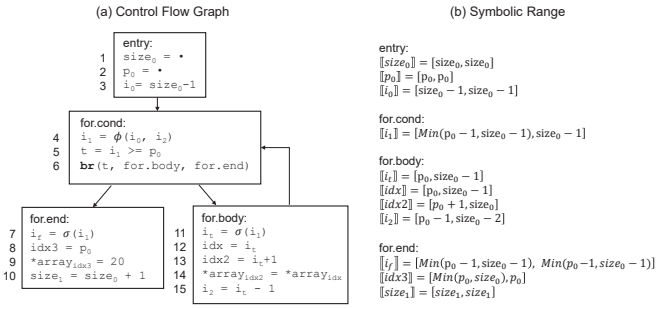

Figure 3: The control flow graph and the symbolic ranges of integer variables in Listing 1.

$l \leq r$. Here, l represents the lower bound, denoted as $[\![x_v]\!]_{\downarrow}$, and r represents the upper bound, denoted as $[\![x_v]\!]_{\uparrow}$. If the symbolic value is undecidable, the range is $[None, None]$.

Example. We use the program in Listing 1 to illustrate the computed symbolic ranges of integer variables, including the access indices. We show the control flow graph in Figure 3 (a). The program is transformed to Extended SSA form [1] before the analysis, where a ϕ-function is created when the value of a variable depends on multiple predecessor blocks, and a σ-function is a copy created for the splitting at a conditional. Before the analysis, all integer variables are initialized with a degenerate-interval symbolic range, i.e., $[\![\cdot]\!] = [\cdot, \cdot]$. The program inputs, which include the potential integer variables, are treated as symbols during SRA, also known as the symbolic kernel [29], to compute other symbolic ranges.

SRA computes the symbolic ranges of integer variables as follows. The assignment instructions after reads rewrite both bounds of the symbolic range, e.g., i_0 is assigned $[\![size_0]\!] - 1 = [size_0 - 1, size_0 - 1]$. Besides, the ϕ-function computes a union of two symbolic ranges from two blocks. In Line 4, $[\![i_1]\!] = [Min([\![i_0]\!]_{\downarrow}, [\![i_2]\!]_{\downarrow}), Max([\![i_0]\!]_{\uparrow}, [\![i_2]\!]_{\uparrow})]$ And σ-function computes the interval intersection of the operand's symbolic range and the condition. For example, i_t is in the condition $i_1 \geq p_0$ satisfied branch; its symbolic value becomes $[Max(p_0, [\![i_1]\!]_{\downarrow}), [\![i_1]\!]_{\uparrow}]$. Following these rules, SRA converges after iterations and finally yields the results in Figure 3 (b). Note that the symbolic range results provide over-approximation of the variable ranges [29], which means the actual values during program execution must fall within these ranges.

Step 2. Candidate Variable Pairs Generation. The next step is generating the candidate variable pairs to be checked against the counting invariants. The naive method enumerates all integers to form a pair with a candidate array. Instead, we only select the integer variables that appear in the symbolic range of any accesses to ptr. Specifically, we collect all integer-type IR instructions but exclude the integers unrelated to the computed symbolic ranges into the set $\{int\}$. The candidate variable pairs are $\{(ptr, int)\} = \{ptr\} \times \{int\}$. We

Table 2: Tested PM Programs.

then validate the invariant for each candidate pair.

Step 3. Constraint-based Invariant Validation. To determine whether an integer variable *int* is counting-correlated with *ptr*, we encode *int* and the accesses to *ptr* into the SMT constraints of the invariant, e.g., the invariants shown in Eq. (1) and Eq. (4) for the first correlation pattern. Then, the SMT solver is used to check if the constraints are *always* satisfied, representing that the accesses to *ptr* are restricted by *int* across user (function) inputs. Specifically, for each access index *idx* to *ptr*, an SMT constraint $[\![idx]\!]_{\uparrow} < [\![int_v]\!]_{\downarrow}$ is built for read invariant, and $[\![idx]\!]_{\uparrow} \leq [\![int_v]\!]_{\downarrow}$ is built for write invariant. For the read index range that is undecidable or has an infinite value in any of the bounds, we directly add `False` to the constraints set. Then we make the conjunction of constraints for all accesses to form the invariant constraint.

Taking the first counting correlation pattern as an illustrative example, if we let all SSA forms of *int* constitute V_{int} and the read indices to *ptr* forms U_{ptr}, a read invariant INV is:

$$\bigwedge_{idx \in U_{ptr}} \bigvee_{v \in V_{int}} [\![idx]\!]_{\uparrow} < int_v. \tag{5}$$

Here, the disjunction among multiple SSAs of *int* ensures that the indexes are checked against a specific assignment of *int*. Thus, we don't need to distinguish which assignment manually. An SMT solver Z3 [3] is utilized to check whether the constraints are satisfied *across all possible values of int*. Since SMT solvers only find a specific satisfaction for given constraints, we make the negation of Eq. (5) ($\neg$INV) and ask the solver to prove its UNSAT, i.e., no values could be found to make the invariant unsatisfied. If the proving is successful, a likely counting-related atomicity property ATOMICITY(*ptr*, *int*) is generated.

To encode the invariant in the second correlation pattern, the sum of indices to each accessed ptr_i is checked. Similarly, encoding the invariant in the third scenario requires only replacing an SSA of the integer variable int_v with $C - int_v$.

4 Evaluation

4.1 Methodology

The program analysis stage of our work is implemented as LLVM [21] compiler passes with a symbolic range analysis pass modified from the open-source Nazaré et al. [29] [2]. The invariant validation is implemented in Python with Z3 [3] as the SMT solver.

Experimental Setup. We conduct all experiments on a machine equipped with 2× Intel Xeon Gold 5317 CPUs, 128GB DRAM, and 512GB Intel Optane DC Persistent Memory. The PM consists of four 128GB Optane memory through interleaved mode. To demonstrate the utility of our counting-related atomicity property inference approach, we leverage the inferred properties to detect PM bugs. For each identified property, ATOMICITY(`x`,`y`), we confirm the atomicity violations by manually checking whether the updates of `x` and `y` are protected by a transaction, e.g., between TX_BEGIN and TX_END of `libpmemobj` [17]. Integrating our property inference approach into an established property-checking procedure to confirm bugs through trace analysis (e.g., Huang et al. [15]) is left in our future work. Table 2 shows the tested real-world PM programs in this evaluation, including popular PM data structures such as hash tables (CCEH and Level-hashing) and trees (P-ART and P-BwTree).

4.2 Results

Table 3 summarizes 14 atomicity violations in the tested problems, where 11 of them are new bugs, and the rest have been reported [9]. Among the detected bugs, 4 bugs (#10, #12, #13, and #14) violate the atomicity properties between an array and its correlated allocation size (a special case of logical size), producing a fault when the post-crash program reads the unallocated memory space. All the rest of the bugs violate the atomicity property between an array with its logical size. The impact of these bugs varies due to the diverse element types within the array. Bug #8 involves a value array failing to update atomically with its logical size, causing invalid reads or user data loss after a crash. In other bugs, the pointer arrays are not atomically updated with the integer variable indicating the number of valid pointers, leading to stale pointer reads in post-recovery programs. These different impacts of atomicity violations highlight the varied scenarios where an atomicity bug can occur.

Next, we compare our tool with a correlation inference tool MUVI [25]. Since Huang et al. [15] relies on the dual-dependent relationship that does not exist in any pair of array and integer, we compare with another dependency-based atomicity property inference approach Witcher [9]. Among the 14 bugs detected by our tool, MUVI successfully identified 4 of them, while Witcher identified 3. MUVI works effectively when the array and the size variable are closely tied to each other. We observe that this detection strategy struggles to identify counting-correlated variables in two main scenarios. First, when an array has more than one size variable, e.g., one for allocated size and one for logical size, the frequency of access to the array and its size variable tends to be random. Second, when the elements of the array are structures with multiple variables that might be accessed individually, the program

Table 3: Atomicity bug detection results of our tool and related work.

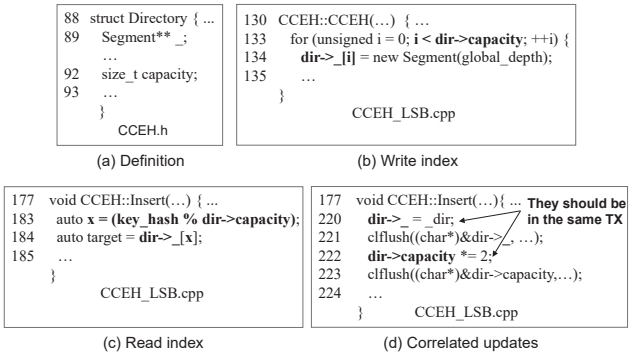

Figure 4: An example of a pair of counting-correlated variables (a), the example write to the array (b), the example read to the array (c), and an atomicity bug detected by our tool (d).

has more frequent access to the array than to its size variable. Witcher is unable to detect most counting-related atomicity violations, since few arrays serve as guardians within condition statements. However, there are three exceptions: bugs #2, #6, and #13, in which the pointer element in the array is used to control the read of the pointed-to structure.

False Positives. Our approach may produce false positives by incorrectly identifying variable pairs as counting-correlated. We have manually inspected the inferred properties and found the existence of such incorrect properties around the misidentified temporary loop variables. The temporary loop variables that control the instructions for accessing the array have the same analyzed behaviors as the logical size variable, leading to the wrong inference. Fortunately, such cases can be easily filtered by manual post-processing (e.g., checking whether the reported integer variable is in PM or DRAM).

A detected bug example. Figure 4 shows the bug #9, where a pointer array `dir->_` and its logical size variable `dir->capacity` is counting-correlated. Our tool could detect this atomicity property, as the read and write access to `dir->_` are restricted by `dir->capacity`. MUVI could detect it due to the symmetric access to the array and the size variable, while Witcher fails since `dir->_` is not a guardian.

Running Time of Property Inference. We recorded the runtime overhead of our tool's workflow on the benchmark programs for inferring PM properties, finding it is between 0.2 and 0.6 seconds. Our tool's static analysis method avoids exploring program states, resulting in a short analysis time. In contrast, Witcher spends 11 minutes to more than 1 hour to detect ordering and atomicity bugs [9]. Yet SMT solvers may become the bottleneck when applying our approach to large-scale PM systems with complex constraints to be checked. This issue could be mitigated by restricting the checked SSAs of an integer variable to the ones in the same block as the array access, reducing the number of constraints. Additionally, optimizations like constraint caching or lightweight approximations could prevent worst-case SMT solver behavior in larger PM systems, which we plan to explore in future work.

5 Conclusion

This paper presents an observation and inference approach for a class of important atomicity properties about the counting relationship between the array and its logical size variable in PM programs. We first propose the necessary conditions for the behaviors of counting-correlated variables among diverse array operations as invariants. We then use symbolic range analysis combined with an SMT solver to discover the variables satisfying the invariants, generating likely atomicity properties. The evaluation shows that using our inference method, 14 bugs are detected in real-world PM programs.

Abstract

Ensuring the reliability and security of an operating system (OS) kernel is a critical and challenging task. To this end, *coverage-guided kernel fuzzing* has been employed as an effective technique for finding kernel bugs. Specifically, in kernel fuzzing, *input minimization* is one critical stage to provide short, coverage-preserving seeds for improving the efficacy of fuzzing. However, we observe that the cost of the minimization — taking over half of the fuzzing resources — significantly limits the potential of kernel fuzzing.

To the best of our knowledge, no prior work explores and mitigates the preceding problem in kernel fuzzing. To this end, we introduce and design two general and novel optimization strategies — *influence-guided call removal* and *type-informed argument simplification* — for reducing the minimization cost. The *key idea* of these two strategies is to reduce the number of dynamic program executions needed for verifying whether the new coverage achieved by the inputs is always preserved.

We optimized the input minimization stage by our strategies in Syzkaller, the most popular and representative kernel fuzzer, resulting in a prototype named SyzMini. Our evaluation shows that SyzMini can significantly reduce the minimization cost by 60.7%. Moreover, SyzMini improves branch coverage by 12.5%, and finds 1.7~2X more unique bugs. On the latest upstream kernel version, Syzmini has found 13 previously unknown bugs, all of which have been confirmed and four have already been fixed. Our optimization strategies also show the general applicability for improving the effectiveness of other kernel fuzzers. We have made our implementation of SyzMini publicly available at [1].

1 Introduction

The reliability and security of an operating system (OS) kernel are of paramount importance. The bugs in the OS kernels could potentially lead to serious system-wide consequences, such as crashes [6, 16, 29], privilege escalation [2, 31] and arbitrary code execution [25, 48]. To this end, coverage-guided kernel fuzzing [8, 9, 19, 22, 38, 40, 44] has emerged as one of the most effective approaches for discovering kernel bugs. Indeed, Syzkaller [15], the most popular and representative coverage-guided kernel fuzzer, has been integrated into the testing pipeline of the Linux kernel. It has successfully uncovered over five thousand bugs in Linux [43].

Generally, coverage-guided kernel fuzzing usually includes two major stages in its core fuzzing loop: (1) *mutation* and (2) *minimization*. The mutation stage mutates the seeds to find interesting input programs (in the form of system call sequences) that can cover new code of the tested kernel. Since the new inputs are randomly generated, they are likely cluttered with redundant system calls or arguments. Therefore, an important stage, minimization, is adopted. The minimization stage compresses these interesting programs into a more streamlined and higher-quality set containing only essential calls and arguments while preserving the new coverage. Minimization, in turn, improves the efficacy of subsequent mutations, thus being critical in the fuzzing campaign [35].

Take Syzkaller as an example, it adopts a *one-by-one minimization strategy* [15] to minimize interesting programs. Given an interesting program P in the form of a system call sequence, the minimization attempts to reduce P by (1) removing each call in P one by one, and *later* (2) simplifying each argument in the remaining calls one by one. Crucially, each minimization attempt must be verified that the original coverage achieved by P is always preserved by *dynamically* executing the reduced program; otherwise, the attempt is rolled back. Take Figure 1 for instance. Given a program P that contains five system calls, with the last call c_5 achieving the new coverage, this stage first removes c_1 and executes the reduced sequence. The attempt is rolled back as the coverage of c_5 is altered due to the removal. This procedure is applied to each of the other calls, thus four executions are required (Figure 1(a)). Similarly, the minimization then considers each call argument, where three executions are conducted for a_1,

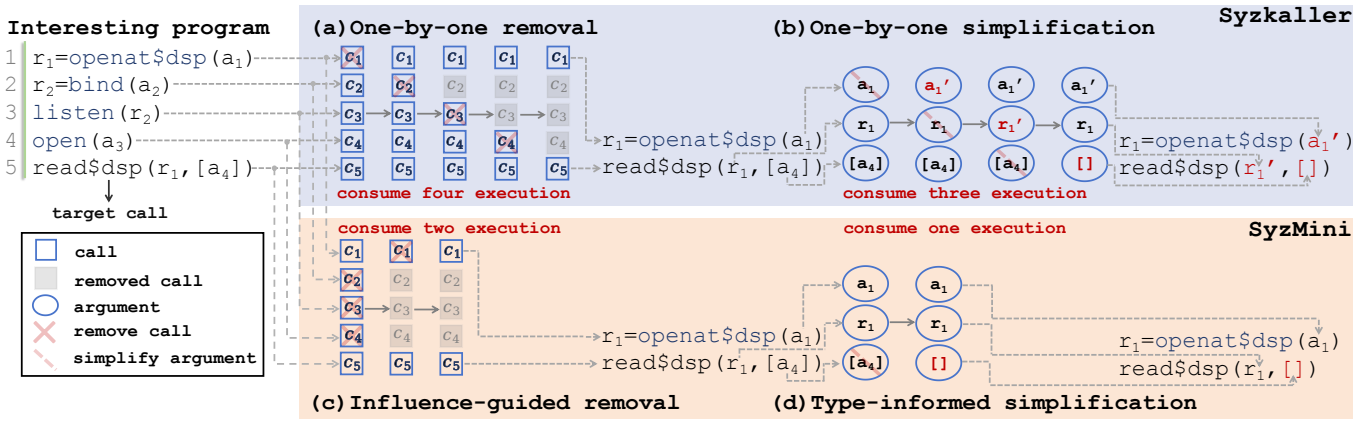

Figure 1: Illustrative example of input minimization between Syzkallar and our approach Syzmini.

r_1 and $[a_4]$ from the remaining calls $[c_1, c_5]$ (Figure 1(b)). In total, seven program executions are needed to minimize P.

However, we observe a significant *tension* exists between the benefits and the cost of the preceeding minimization in kernel fuzzing. On the one hand, the minimization stage improves the efficacy of subsequent mutations by providing short, coverage-preserving inputs. Our experiment on Syzkaller (detailed in Section 3) shows that omitting the minimization, the coverage and the number of found bugs would decrease by 27.5% and 40.4% respectively within a 48-hour fuzzing campaign; moreover, the gap continues to widen with prolonged fuzzing. Indeed, this minimization stage is critical for the effectiveness of kernel fuzzing.

On the other hand, the minimization stage incurs significant costs. For example, the one-by-one minimization in Syzkaller requires *dynamic* program execution to verify the preservation of coverage at each attempt to remove calls or simplify arguments. However, each program execution is expensive because it involves context switching between the user and kernel spaces. Our experiment (detailed in Section 3) reveals that, during a 48-hour fuzzing campaign, 57.5% of program executions are expended in the minimization stage, while the remaining 42.5% of program executions are used by the mutation stage. It is overwhelming that the minimization takes over half of the fuzzing resources.

However, to the best of our knowledge, no prior work explores and mitigates the preceding tension in kernel fuzzing. This paper aims to fill this gap. The key challenge is how to significantly reduce the minimization cost of reducing interesting programs. At the high level, our *key idea* is to reduce the number of program executions needed for verifying whether the new coverage is preserved—the fewer the program executions are, the lower the cost is.

To this end, this paper introduces two *general* and *novel* strategies to optimize the minimization by respectively reducing the number of program executions during removing calls and simplifying arguments. In the scenario of removing calls, let P be an interesting program and c be the target call in P which achieves new coverage. Our *key insight* is that removing the irrelevant calls in P (which have no execution influence on c) will not affect the new coverage achieved by c. Therefore, we could substantially reduce the number of program executions needed for verifying the coverage by removing these irrelevant calls *at one time* rather than *one by one*. Indeed, whether a call can affect c's coverage depends on their inherent dependencies. For example, if a call does not share any global kernel state with c, then this call has no execution influence on c_j and can be safely removed. In practice, this form of execution influence–often referred to as *influence relation* [8, 13, 17, 35, 40]–can be inferred through a combination of static and dynamic analysis on the system calls. In this paper, we term this optimization strategy as *influence-guided call removal strategy*.

Figure 1(c) illustrates this strategy. Based on the inferred influence relation, we could identify that the calls c_2, c_3, c_4 do not impact the execution of c_5, and then attempt to remove these calls at one time. If this attempt is successful (*i.e.*, the new coverage achieved by c_5 is preserved), P will be reduced to $[c_1, c_5]$ by only one program execution. Later, we attempt to remove c_1, which however fails to preserve the new coverage. As a result, our strategy only consumes two executions to minimize P, which reduces the minimization cost to half.

In the scenario of simplifying arguments, one-by-one minimization is conservative and minimizes every argument. As a result, it leads to a large number of program executions due to the numerous arguments and their sub-fields involved. Our *key insight* is that we only need to simplify those redundant arguments or their sub-fields that truly matter for the subsequent mutations. For example, removing superfluous elements from an array argument could significantly reduce the space for subsequent mutations, while investing similar effort in simplifying a simple scalar argument leads to marginal benefits. In this way, we could substantially reduce the number of program executions needed for verifying the coverage without sacrificing the benefits of minimization.

Based on the preceding insight, we design a *type-informed argument simplification strategy* to optimize the minimization. Given an interesting program P, this strategy analyzes the

type information of each argument and its sub-fields in P. If an argument or a field is fixed-size, the strategy skips the simplification; the strategy only attempts to simplify those variable-size arguments which may have redundant mutation space. For example, in Figure 1(d), this strategy does not simplify the fixed-size arguments a_1 (*Integer* type) and r_1 (*Resource* type, a 4-byte file descriptor). It would simplify the variable-size argument $[a_4]$ (*Array* type) to an empty array while ensuring the coverage is preserved. As a result, the type-informed strategy only consumes one program execution, while the original minimization requires three executions.

To evaluate the effectiveness of our approach, we integrated our proposed optimization strategies into Syzkaller, resulting in a prototype named SyzMini [1]. Our evaluation demonstrates that SyzMini significantly reduces the cost of minimization: the number of program executions in minimization is reduced by 60.7%. Compared to vanilla Syzkaller, SyzMini achieves a 12.5% improvement in branch coverage and a 1.7× speedup, while discovering 1.7–2× more unique bugs. Furthermore, SyzMini uncovered 13 previously unknown bugs in the latest upstream Linux, all of which have been confirmed, and four have already been fixed. To further illustrate the generality and benefits of our approach, we enhanced three distinct kernel fuzzing tools by optimizing the minimization: SyzVegas (employing reinforcement learning for scheduling fuzzing tasks), CountDown (accelerating finding memory-related kernel bugs), and SyzDirect (directed fuzzing for reproducing kernel bugs). With our enhancements, SyzVegas increases branch coverage by 14.5% and discovers 50% more bugs, CountDown identifies 66.7% more memory bugs, and SyzDirect reproduces 1.5× more bugs within the same time budget.

This paper has made the following contributions:

- To our knowledge, we are the *first* to explore and mitigate the significant tension between the benefits and cost of input minimization in kernel fuzzing.
- We introduce two general and novel optimization strategies respectively for removing system calls and simplifying arguments in minimization.
- We implement our optimization strategies for minimization in Syzkaller and three distinct kernel fuzzers. The extensive evaluation results demonstrate the effectiveness, general applicability, and benefits of our approach.

2 Background

Fuzzing is an automated software testing technique first introduced by Miller [34]. It aims to uncover bugs by repeatedly sending random inputs to the target program [14, 33]. Kernel fuzzers, domain-specific fuzzing tools for OS kernels, continuously generate system call sequences to find kernel bugs.

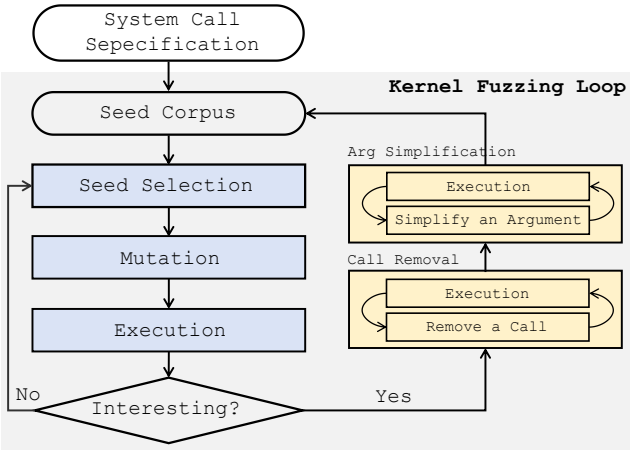

Figure 2: Overall workflow of Syzkaller

Figure 2 shows the workflow of Syzkaller [15], a state-of-the-art coverage-guided kernel fuzzing tool. Syzkaller first loads system call descriptions written in the declarative language *Syzlang* [42] as well as the initial seed corpus, and then conducts a fuzzing loop to explore interesting programs and find new bugs. The fuzzing loop includes two major stages, *i.e.*, *mutation* and *minimization*.

Mutation Stage. The mutation stage randomly selects a seed from the corpus (the programs that previously found new coverage), and then performs a series of random mutations on the seed (*e.g.*, inserting/removing a call, or changing the value of an argument or its sub-fields) to generate more diverse programs. Each program will be executed on the tested kernel and the achieved coverage for each call in the program is collected independently. For instance, given a call sequence $[c_1, c_2, ..., c_n]$, the coverage of each call is collected separately in n branch arrays, *e.g.*, cov_c_1, cov_c_2, ..., cov_c_n. The total coverage achieved so far is maintained in another global set. Hence, the fuzzer can identify the call that achieves new coverage by simply comparing each branch array with the global set, *e.g.*, comparing cov_c_1 with the global set determines if the call c_1 achieves new coverage. When the program achieves new coverage, each call contributing to this new coverage is treated as a target call for the next minimization.

Minimization Stage. The minimization stage minimizes an interesting program as a new seed for subsequent mutation. It first attempts to remove irrelevant calls and later simplifies arguments in the program. It employs a one-by-one minimization strategy. We explain the process as follows.

① *Removing Calls*. Given an interesting program $P = [c_1, c_2, ..., c_n]$, where c_i is the ith call in P. Let the last call c_n be the target call in P which achieves the new coverage. In the minimization stage, Syzkaller first removes the first call c_1 and executes the reduced program $[c_2, c_3, ..., c_n]$ to verify whether the new coverage is preserved. If the coverage is preserved, c_1 will be removed from P. Because c_1 is an irrelevant call *w.r.t.* c_n which does not affect the execution of

Table 1: Argument simplification methods in Syzkaller

Data Types		Simplification Methods
Primitive Type	Integer Flag Protocol Resource	Replace the current value with the default value of this type
Derived Type	Array Buffer	Minimize the number of elements
	Pointer	Simplify the pointed-to object
User-defined Type	Struct Union Enum	Simplify each sub-fields

c_n. In this case, P will be reduced to $[c_2, c_3, ..., c_n]$. Otherwise, P remains unchanged. Later, Syzkaller attempts to remove the next call c_2. This process continues until each call c_i in P (except c_n) has been attempted.

② *Simplifying Arguments*. Assuming after the call removal there are m arguments $[a_1, a_2, ..., a_m]$ in P. Syzkaller would first attempt to simplify the first argument a_1 to a_1' and execute the simplified program to verify whether the new coverage is preserved. If the coverage is preserved, a_1' replaces a_1; otherwise, a_1 remains unchanged. Each argument will be attempted one by one to minimize P.

It is worth noting that simplifying arguments depends on the argument types. Table 1 lists the simplification methods for different argument types in Syzkaller. For the argument of primitive type (*e.g.*, *Integer*, *Flag*, *Protocol* or *Resource*), Syzkaller replaces the argument by the default value of this type. For the argument of derived type (*e.g.*, *Array*, *Buffer*), Syzkaller attempts to minimize the number of elements by binary search. For the argument of user-defined data type (*e.g.*, *Struct*, *Union*), Syzkaller recursively simplifies each sub-fields of this argument one by one.

3 Motivation and Observation

In this section, we demonstrate and characterize the tension between the benefits and cost of minimization in kernel fuzzing. To this end, we selected Linux 5.15, the widely-used and stable long-term Linux version, as the fuzzing target; Syzkaller [15], the most popular kernel fuzzing tool, as the kernel fuzzer. Specifically, we implemented a version of Syzkaller without the minimization stage (named as Syzkaller⁻). For each tool, we allocated 48 hours for one fuzzing campaign to fuzz the kernel, and repeated each fuzzing campaign for ten times to mitigate the randomness.

Observation 1: The minimization stage is crucial in improving the effectiveness of kernel fuzzing in terms of code coverage and number of found bugs.

We compared the branch coverage and the number of found unique bugs of Syzkaller to those of Syzkaller⁻. As shown in Figure 3, compared to Syzkaller, the branch coverage and

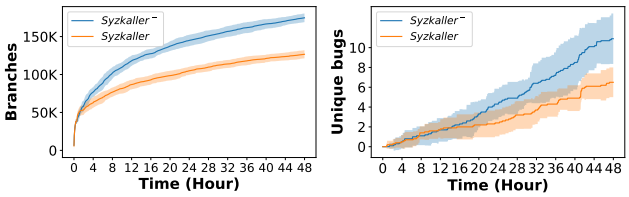

Figure 3: Syzkaller⁻ *vs.* Syzkaller on average coverage and bug finding (shaded area: mean ±1 standard deviation)

the number of found unique bugs of Syzkaller⁻ decrease by 27.5% and 40.4% respectively. Moreover, the gap gradually widens over time. The results show that minimization plays a crucial role in improving the effectiveness of kernel fuzzing.

Observation 2: The proportion of program executions during the minimization stage accounts for 57.5%, leading to significant costs.

We recorded the number of programs executed during the mutation and minimization stages respectively to measure the cost. Figure 4 shows the proportions of the numbers of program executions between mutation and minimization. We can see that the minimization stage consumes more program executions than the mutation stage. The minimization stage reaches a peak of 68.1% at the time of 4.5 hours. The portion gap gradually decreases over time but still accounts for 57.5% at the time of 48 hours. In particular, removing calls accounts for 34.0% and simplifying arguments accounts for 66.0%.

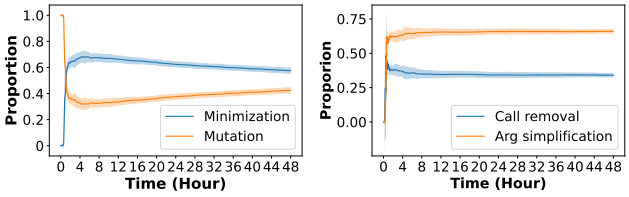

Figure 4: The proportion of program executions during minimization and mutation over time (shaded area: mean ±1 standard deviation).

The reason for this trend is that the fuzzer initially generates a large number of interesting programs with new coverage. Minimizing these programs requires a considerable number of program executions. As a result, the proportion of program executions in minimization rapidly increases in the first four hours. Over time, although the number of interesting programs gradually decreases, these programs become more complex (*e.g.*, involving more calls and arguments) due to the subsequent mutation. These complex programs requires more program executions to conduct the one-by-one minimization. Overall, the proportion of program executions in the minimization stage decreases slowly, but still surpasses that of the mutation stage (after the 48 hours), leading to significant cost.

Summary: The preceding observations indicate that the minimization stage is crucial for the effectiveness of kernel

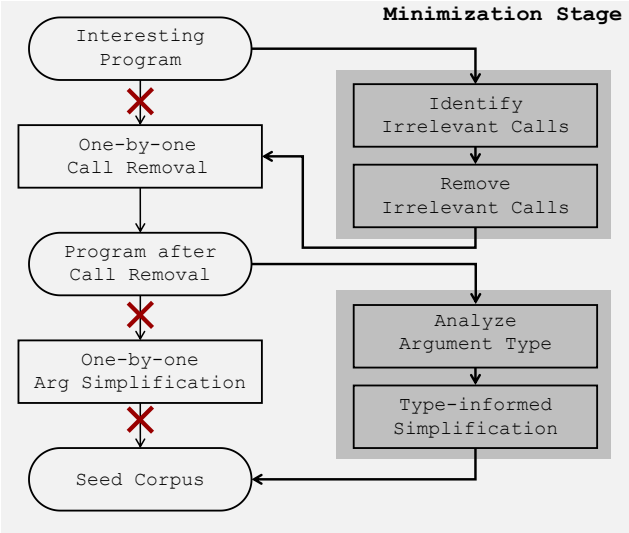

Figure 5: Overview of the influence-guided call removal and the type-informed argument simplification strategies.

fuzzing, but introduces significant cost in terms of program executions. Our goal is to reduce this minimization cost, thereby unleashing the potential of kernel fuzzing.

4 Approach and Implementation

Figure 5 shows the overview of our optimization strategies (*i.e.*, influence-guided call removal and type-informed argument simplification). These two strategies extend the default one-by-one minimization in Syzkaller. Specifically, the influence-guided call removal leverages the influence relations between system calls to identify irrelevant calls and remove these calls at one time. Later, the reduced program undergoes the one-by-one minimization to guarantee the number of calls in P is minimal (detailed in Section 4.1). The type-informed argument simplification analyzes the types of each argument and its sub-fields to identify which argument is fixed-size or variable-size. It would skip the simplification of the fixed-size arguments and only attempts to simplify the variable-size arguments (detailed in Section 4.2).

4.1 Influence-guided Call Removal Strategy

We define the influence relation between two system calls:

***Influence Relation**: For two system calls c_i and c_j, c_i has an influence relation with c_j if executing c_i can change the execution path of c_j by modifying the kernel's internal state that c_j depends on.*

The definition describes the relation between system calls based on the execution path. The relation exists when one call c_i can modify the global kernel state that the behavior of another call c_j depends on, thereby changing the execution path of c_j. In practice, the influence relation can be inferred by the static and dynamic analysis on system calls [40]. We will

Algorithm 1: Influence-guided Removal Strategy

Input : Interesting Program: $P = [c_1, c_2, ..., c_n]$, Influence relation matrix: M

   // Step 2. Remove irrelevant calls
13 P' ← P.remove_calls(irrelevant_calls)
14 target_call_cov ← execute(P)
15 target_call_cov' ← execute(P')
16 if target_call_cov ∈ target_call_cov' then
17     P ← P'
   // Step 3. One-by-one call removal
18 one_by_one_call_removal(P)
```

describe how to collect the influence relations in Section 4.3. In this section, we focus on explaining how to leverage these collected influence relations to reduce the minimization cost. Thus, we assume the influence relations have been collected for n calls and stored in M—a two-dimensional matrix $R^{n \times n}$.

Identify Irrelevant Calls. The strategy aims to identify all the calls that are irrelevant to the target call based on the collected influence relations. In algorithm 1, let $P = [c_1, c_2, ..., c_n]$ be an interesting program (assuming the last call c_n in P is the target call which achieves new coverage) and M be the influence relation matrix. The strategy first obtains all the calls that have *direct* influence relations with c_n (lines 2-4), and then identifies the calls that have indirect influence relations with c_n based on the transitivity of influence relation (lines 5-11). Specifically, on line 3, when $M[c_i][c_n]$=1 (denoting that c_i has direct influence on c_n), c_i will be saved into the list *relevant_calls* (which stores all the relevant calls). On line 9, when $M[c_k][c_j]$=1 (denoting that c_k has indirect influence on c_n through c_j), c_k will be also saved into the list *relevant_calls* (line 10). Specifically, the strategy uses a worklist algorithm to iteratively identify all the calls that have indirect influence on c_n. Finally, we obtain the set of irrelevant calls (stored in *irrelevant_calls*) *w.r.t.* P by filtering these collected relevant calls from the set of the calls from P (line 12).

Example. In Figure 6, the program P is an interesting program and c_6 is the target call. According to the influence

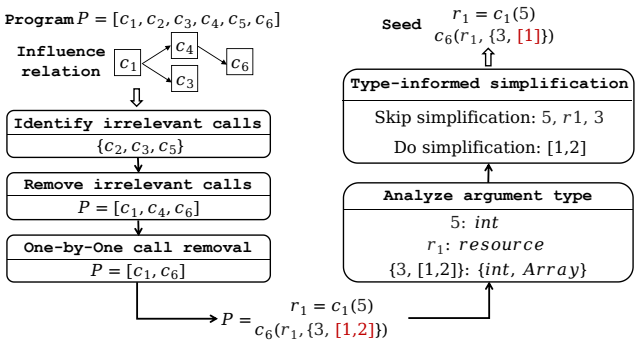

Figure 6: An Example for Influence-guided Removal and Type-informed Simplification

relation, c_4 has direct influence on c_6, and c_1 has indirect influence on c_6 through c_4. Thus, $\{c_1, c_4\}$ are the relevant calls and the other calls $\{c_2, c_3, c_5\}$ in P are identified as irrelevant.

Remove irrelevant calls at one time. When the irrelevant calls are identified, the strategy attempts to remove these calls at one time from P (line 13). If the new coverage of the target call is preserved by P', this attempt is successful and P is reduced to P' (line 17). Otherwise, the attempt will be rolled back — some calls in *irrelevant_calls* actually influence the execution of c_n. No matter whether this attempt is successful or not, the remaining relevant calls in P may not contribute to the new coverage. Thus, P needs to undergo the one-by-one call removal (*i.e.*, the default one-by-one minimization for removing calls) to ensure that each remaining call is truly associated with the new coverage of the target call and the number of calls in P is minimal (line 18). Compared to the default one-by-one minimization in Syzkaller, this influence-guided strategy is likely to remove many calls at one time and thus reduce the minimization cost.

Example. After identifying $\{c_2, c_3, c_5\}$ are the irrelevant calls, the strategy attempts to remove all these calls at one time. Assuming this attempt is successful, P is reduced to $[c_1, c_4, c_6]$ by only requiring one program execution. Later, the one-by-one minimization consumes two program executions to check whether c_1 and c_4 would influence the execution of c_6 and finally P is reduced to $[c_1, c_6]$ (assuming c_4 actually does not influence the execution of c_6). As a result, the optimization strategy only takes three executions to remove calls, while the default minimization requires five executions.

4.2 Type-informed Arg Simplification Strategy

We define fixed-size or variable-size arguments as follows.

*For an argument a, a is a fixed-size argument if a only involves fixed-length data types (*e.g.*, Integer, Flag, Protocol and Resource); a is a variable-size argument if a involves any variable-length data type (*e.g. *Array and Buffer).*

Analyze Argument Type. We detail how we analyze an argument type as follows. Given a program P after call removal, the strategy analyzes the type of each argument a from the

Algorithm 2: Type-informed Arg Simplification Strategy

```
   Input  : Program after call removal: P = [c_1, ..., c_n]
   Output : Final minimized program P
1  for i from 1 to n do
2      for arg in c_i.args do
3          Analyze arg's type
4          P ← type_informed_simplification(P, arg)
5  Function type_informed_simplification(P, arg)
6      if arg is a fixed-size argument then
7          continue
8      else
           // arg is a variable-size argument
9          if arg.type is Array or Buffer then
10             P ← simplify_variable-size_arg(P, arg)
11         if arg.type is Pointer then
12             P ← type_informed_simplification(P, arg.point_to_obj)
13         if arg.type is User-defined type then
14             for sub_field in arg.sub_fields do
15                 P ← type_informed_simplification(P, sub_field)
16     return P
17 Function simplify_variable-size_arg(P, arg)
18     P' ← P.remove_element_by_binary_search(arg)
19     target_call_cov ← execute(P)
20     target_call_cov' ← execute(P')
21     if target_call_cov ∈ target_call_cov' then
22         P ← P'
23         P ← simplify_variable-size_arg(P, arg)
24     return P
```

calls in P based on Table 2 (lines 2-3 in Algorithm 2). Specifically, if a belongs to primitive type (such fixed-length data types as *Integer*, *Flag*, *Protocol* and *Resource*), a is classified as a fixed-size argument. If a belongs to derived type (such variable-length data types as *Array* and *Buffer*), a is classified as a variable-size argument. If a belongs to *Pointer*, the strategy will recursively analyze the type of the pointed-to object of a to decide a's argument type according to the preceding definition. If a belongs to *user-defined* type, the strategy will recursively analyze the type of each sub-fields of a to decide a's argument type according to the preceding definition. If any point-to object or sub-field is a variable-length data type, a is a variable-size argument. Otherwise, a is classified as a fixed-size argument. In this way, any argument from the calls in P can be classified into either fixed-size or variable-size.

Example. Taking the program $P = [c_1, c_6]$ after call removal in Figure 6 as an example, assuming c_1 takes an argument 5 and returns r_1; c_2 takes r_1 and $\{3, [1,2]\}$. The strategy can identify 5 as *Integer* type and r_1 as *Resource* type. Since *Integer* and *Resource* are fixed-length data types, both of these two arguments 5 and r_1 are classified as the fixed-size arguments. For the argument $\{3, [1,2]\}$, the strategy will recursively ana-

Table 2: Argument type classification in Linux kernels

Primitive type	Category	Derived type	Category	User-defined type	Category
Integer Flag Protocol Resource	Fixed-size argument	Array Buffer	Variable-size argument	Struct Union Enum	Classify each sub-field
		Pointer	Classify the pointed-to object		

lyze the type of each sub-field. As a result, 3 is identified as *Integer* type and $[1,2]$ is identified as *Array* type. Since the field $[1,2]$ involves a variable-length data type, the argument $\{3,[1,2]\}$ is classifed as a variable-size argument.

Type-informed Simplification. After obtaining the type information of the arguments, in Algorithm 2, this strategy skips the simplification of fixed-size arguments (lines 6-7) and only simplifies the variable-size arguments (lines 9-10). For a variable-size argument *arg*, if the type of *arg* is *Array* or *Buffer*, the strategy will iteratively remove elements from *arg* to minimize the number of elements in the array by binary search while ensuring the coverage is always preserved (lines 18-24). When the type of *arg* is *Pointer* or *User-defined*, the strategy recursively checks the pointed-to object ($point_to_obj$ for *Pointer* type) or each sub-field (sub_field for *user-defined* type) in *arg* and adopts the same method to do simplification (lines 11-15). After traversing all the arguments, the simplified program will be returned and added to the seed corpus.

Example. According to the type analysis result of each argument in Figure 6, since 5 and r_1 are fixed-size arguments, the strategy will skip their simplifications. For the variable-size argument $\{3,[1,2]\}$, the strategy will skip simplifying the sub-field 3 but simplify the sub-field $[1,2]$. It would consume two executions to simplify $[1,2]$ to $[1]$ (assuming the argument $[1]$ can affect the execution of c_6). Finally, the simplified P becomes a seed. Overall, the strategy only takes two executions to simplify the arguments, while the default minimization requires five executions. The reason of skipping the simplification of those fixed-size arguments is that such simplification does not help reduce redundant mutation space.

4.3 Implementation

We implemented the two optimization strategies (*i.e.*, the influence-guided removal and the type-informed simplification) in Syzkaller (commit 1759857fa9bd [15]). We chose Syzkaller because it is the most popular and representative kernel fuzzing tool, and is a standard baseline used by many recent work [3,8,9,20,41,44]. We name the version of Syzkaller enhanced by the two optimization strategies as SyzMini.

Specifically, the influence-guided strategy needs the influence relations between the system calls as input. To this end, we collected the influence relations by following Healer [40]. In practice, we use both static and dynamic analysis to infer and collect the influence relations. In static analysis, given two system calls c_i and c_j, c_i has the influence relation with c_j if (1) c_i returns a resource type r, and at least one of the parameters in c_j is the resource type r, or (2) c_i has a pointer parameter a that points to one resource type r with an outward data flow direction, and c_j has the resource type r with an inward data flow direction. To collect static influence relations, we analyze the type information of each parameter specified by *Syzlang* [42]. In dynamic analysis, we leverage the default minimization process in Syzkaller to infer dynamic influence relations. Specifically, during minimization, if removing a call c_i affects the execution path (*i.e.*, the coverage) of the next call c_{i+1}, then c_i influences c_j. We ran Syzkaller until the branch coverage saturated and collected the dynamic influence relations, which took about four days. We collected a total of 74,865 influence relations including 44,966 static influence relations and 29,899 dynamic influence relations.

SyzMini uses the default branch coverage supported by Syzkaller to record the execution information of each call. To check whether one minimization attempt is successful, SyzMini verifies whether the branch coverage of a target call is preserved. If the coverage is preserved, this attempt is considered as successful.

5 Evaluation

This section evaluates the effectiveness of the two optimization strategies for minimization (*i.e.*, the influence-guided and type-informed strategies) implemented in SyzMini. we aim to answer the following research questions:

RQ1. How effective is SyzMini (which incorporates the two optimization strategies for minimization) in terms of code coverage and bug finding?

RQ2. What are the respective contributions of the influence-guided and type-informed strategies in improving kernel fuzzing?

RQ3. Why are the influence-guided and type-informed strategies effective in improving kernel fuzzing?

RQ4. How effective are the two optimization strategies when they are integrated into other distinct kernel fuzzers?

RQ5. What factors affect the effectiveness of the influence-guided and type-informed strategies?

5.1 Evaluation Setup

All the experiments were conducted on a machine running 64-bit Ubuntu 20.04 LTS and equipped with an AMD 3995WX 64-core CPU and 128G RAM. We selected Linux 5.15, 6.1, and 6.11 as the target kernels to be tested. Specifically, Linux 5.15 and 6.1 are the stable long-term versions and are the most widely used kernel versions by many distributions. Linux 6.11 is the latest upstream version at the time of our work. All these three kernel versions were compiled with the same configuration, *i.e.*, enabling the KCOV and KASAN features to collect code coverage and detect memory-related bugs. During the fuzzing campaign, each kernel runs on a virtual machine instance allocated with a 4-core CPU and 4GB RAM.

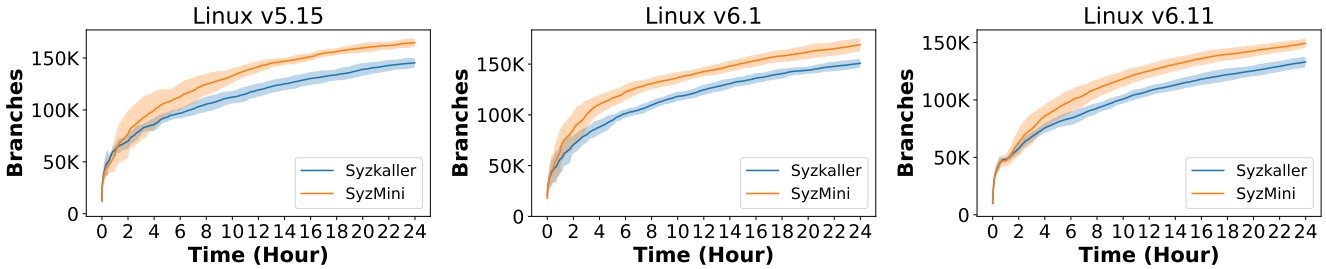

Figure 7: Average branch coverage growth of SYZMINI on v5.15, v6.1 and v6.11 over 24 hours compared to those of SYZKALLER (shaded area: mean ±1 standard deviation)

Table 3: Coverage statistics of Syzkaller *vs.* SyzMini

	v5.15	v6.1	v6.11	Overall
Syzkaller	145.371K	150.677K	133.172K	143.073K
SyzMini	164.724K	169.015K	149.311K	161.017K
Improvement	+13.3%	+12.2%	+12.1%	+12.5%
Speed-up	+1.83×	+1.61×	+1.62×	+1.69×

Table 4: Bug statistics of SyzMini and Syzkaller

Fuzzer	#Unique Bugs v5.15	v6.1	v6.11	Total	Bug Distribution v5.15	v6.1	v6.11	Total
SYZKALLER	14	12	6	27	18 10 4	12 8 4	8 4 2	32 18 9
SYZMINI	28	20	12	50				

[1] The blue and yellow regions in the venn diagrams denote #bugs found by SyzMini and Syzkaller, respectively; the gray regions denote #bugs found by both tools.

The influence-guided strategy is equipped with 74,865 entries of influence relations (detailed in Section 4.3). Each tool uses the same initial seeds as Syzkaller by default across the trials.

5.2 RQ1: Effectiveness of SyzMini

Setup of RQ1. We aim to evaluate the end-to-end effectiveness of SyzMini which incorporates the two optimization strategies. Thus, we compared SyzMini with Syzkaller in terms of code coverage and the number of bugs found. Following the general guidelines for fuzzing evaluation [24, 37], we allocated 24 hours for each kernel fuzzing tool (SyzMini and Syzkaller) for one round of fuzzing campaign and repeated such a fuzzing campaign for 10 rounds to reduce potential randomness. We also measured the *hitting-round* and *time-to-exposure* (*TTE*) for each found bug. These two metrics are widely used in evaluating fuzzing techniques [4, 7, 41]. Specifically, *hitting-round* represents the number of times a fuzzer triggers a target bug in repeated experiments. *TTE* is the time that a fuzzer triggers the target bug at the first time. We computed the arithmetic average of *TTE* (denoted by μTTE) for repeated experiments. If a fuzzer fails to trigger a target bug in a given time duration (24 hours in our setting), the *TTE* of this bug is treated as 24 hours. Additionally, to study the long-term effectiveness, we ran SyzMini and Syzkaller respectively for three days on the latest upstream kernel version Linux 6.11. We collected branch coverage and the number of found bugs.

Code Coverage. Figure 7 plots the branch coverage achieved by Syzkaller and SyzMini during the 24-hour fuzzing. Overall, SyzMini outperforms Syzkaller on the three kernel versions. Specifically, in the first 5 minutes, both tools generate and execute the initial seeds, so they achieve similar coverage. Later, a large number of interesting programs that require minimization are generated. However, performing minimization on these programs does not lead to coverage increases. Thanks to our optimization strategies, SyzMini avoids a large number of unnecessary program executions during minimization. It allows SyzMini to spend more time on mutation. As a result, SyzMini achieves the coverage improvement over Syzkaller after 1.5 hours, and this improvement has been maintained throughout the subsequent fuzzing. The shaded area denotes the average branch coverage ±1 standard deviation. The overlap between the shaded areas of SyzMini and Syzkaller is small, indicating a significant difference.

Table 3 gives the detailed coverage statistics. For example, on v5.15, SyzMini covered an average of 164.724K branches in the 10 rounds of a 24-hour fuzzing campaign, while Syzkaller covered an average of 145.371K branches. As a result, SyzMini achieved 13.3% improvement in branch coverage (see Row "Improvement"). Column "Overall" gives the average number of covered branches on the three kernel versions. Row "speed-up" presents the average speed-up of SyzMini when achieving the same coverage as Syzkaller. On average, SyzMini achieved 12.5% improvement in branch coverage compared to Syzkaller with a speed-up of 1.69×. The results indicate that the optimization strategies can significantly improve the effectiveness of kernel fuzzing in terms of code coverage.

Bug Detection. Table 4 lists the bug statistics. For example, on v5.15, SyzMini found a total of 28 unique bugs in the 10 rounds of 24-hour fuzzing, while Syzkaller found a total of 14 unique bugs. SyzMini found 2× more bugs than Syzkaller. Specifically, on v5.15, SyzMini found 18 bugs that Syzkaller missed, while Syzkaller only found 4 bugs that SyzMini missed. Column "Total" counts the total number of unique bugs found in the three kernel versions. SyzMini found a total of 50 unique bugs, while Syzkaller only 27 unique bugs. Specifically, SyzMini and Syzkaller found a total of 22 common bugs on the three kernel versions (accumulating the common bugs shown in the three venn diagrams of v5.15,

Table 5: *μTTE* and *hitting-round* of each bug

ID	*hitting-round* SK/SM	*μTTE* (h) SK/SM	ID	*hitting-round* SK/SM	*μTTE* (h) SK/SM
1	3 / 6	22.2 / 12.2	12	3 / 5	16.8 / 14.0
2	1 / 2	23.9 / 19.7	13	7 / 10	12.5 / 3.5
3	4 / 8	15.8 / 10.8	14	1 / 2	23.5 / 20.9
4	1 / 3	23.1 / 20.9	15	2 / 4	19.4 / 15.9
5	5 / 5	17.0 / 13.8	16	1 / 4	22.3 / 18.9
6	7 / 9	19.4 / 15.8	17	2 / 8	22.4 / 13.1

9	1 / 2	22.3 / 20.1	20	10 / 10	4.2 / 2.0
10	1 / 2	22.0 / 20.8	21	1 / 3	23.9 / 19.4
11	9 / 9	11.9 / 7.5	22	8 / 10	5.2 / 2.8

[1] SK and SM are Syzkaller and SyzMini, respectively. 1~10, 11~18 and 19~22 are the common bugs on v5.15, v6.1 and v6.11, respectively.
[2] The green one indicates which tool achieves the higher *hitting-round* or the lower *μTTE*.

v6.1, and v6.11 in Column "Bug Distribution").

Table 5 gives the *hitting-round* and *μTTE* for each common bug. On any of these bugs, SyzMini found them faster and more frequently than Syzkaller. Taking the bug with ID 1 as an example, the *μTTE* of Syzkaller is 22.2h, which is 1.8× more than that of SyzMini (12.2h); moreover, SyzMini successfully found this bug in 6 out of 10 rounds of fuzzing, while Syzkaller only found it in 3 rounds. These strong results show that SyzMini significantly outperforms Syzkaller in bug finding.

Long-term Effectiveness. In the 10 rounds of a three-day fuzzing campaign, SyzMini covered an average of 199.4K branches, which is 5.6% more than that of Syzkaller (188.9K). In terms of bug finding, although Syzkaller has been continuously deployed to find bugs in the upstream kernel version, SyzMini has still found 13 previously unknown bugs. We reported each bug (with the corresponding reproducer and kernel configuration) to the kernel maintainers. All these 13 bugs have been confirmed and 4 have already been fixed. Table 6 lists these bugs. Therefore, SyzMini is also effective in long-term fuzzing for improving coverage and finding bugs.

Table 6: Previously unknown bugs found by SyzMini.

ID	Subsystem	Function	Risk	Status
1	Block	bio_put_slab	use after free	confirmed
2	Gfs2	gfs2_quota_init	kernel bug	confirmed
3	NTFS3	end_buffer_read_sync	out of bounds	confirmed
4	Reiserfs	update_stat_data	kernel bug	confirmed
5	Net	netlink_unicast	general protection fault	confirmed
6	MM/pat	get_pat_info	inconsistent lock state	fixed
7	Net	cleanup_net	use after free	fixed
8	Bpf	btf_name_valid_section	out of bounds	confirmed

11	Bpf	build_id_parse_nofault	paging fault	fixed
12	Bluetooth	sco_sock_close	use after free	confirmed
13	Jfs	jfs_statfs.cold	out of bounds	confirmed

In summary, our optimization strategies not only improve branch coverage by 12.1~13.3% and found 1.7~2.0× more unique bugs, but find kernel bugs faster and more stably.

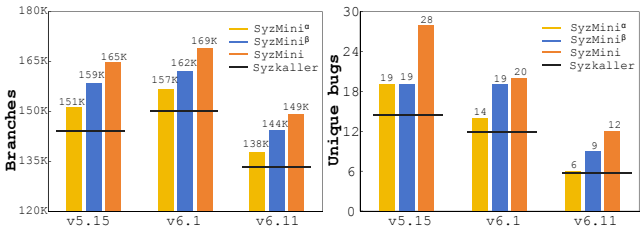

Figure 8: Numbers of covered branches and found unique bugs by Syzkaller, SyzMini$^{\alpha}$, SyzMini$^{\beta}$ and SyzMini.

5.3 RQ2: Contributions of Optimizations

Setup of RQ2. To investigate the respective contributions of the two optimization strategies in improving kernel fuzzing, we implemented two versions of SyzMini: SyzMini$^{\alpha}$ and SyzMini$^{\beta}$. SyzMini$^{\alpha}$ only includes the influence-guided strategy while SyzMini$^{\beta}$ only includes the type-informed strategy. We compare the code coverage and the number of found unique bugs between Syzkaller, SyzMini$^{\alpha}$, SyzMini$^{\beta}$ and SyzMini to analyze the contributions of the two optimization strategies. Following the setup of RQ1, we ran each tool for 24 hours and repeated 10 rounds.

Results. Figure 8 shows the numbers of covered branches and the numbers of found unique bugs by Syzkaller, SyzMini$^{\alpha}$, SyzMini$^{\beta}$ and SyzMini. For example, on v5.15, equipped with the influence-guided strategy, SyzMini$^{\alpha}$ achieved an average of 4.0% branch coverage improvement (from 145K to 151K) and found 5 more unique bugs (from 14 to 19), compared to Syzkaller. By comparing SyzMini$^{\beta}$ and SyzMini, without this influence-guided strategy, SyzMini$^{\beta}$'s branch coverage dropped by 3.7% (from 165K to 159K) and missed 9 unique bugs (from 28 to 19). Thus, the influence-guided strategy is useful in improving kernel fuzzing.

For the type-informed strategy, on v5.15, SyzMini$^{\beta}$ achieved an average of 9.1% more branch coverage (from 145K to 159K) and found 5 more unique bugs, compared to Syzkaller. By comparing SyzMini$^{\alpha}$ and SyzMini, without the type-informed strategy, the branch coverage achieved by SyzMini$^{\alpha}$ dropped by 8.2% (from 165K to 151K) and missed 9 unique bugs. The results indicate that the type-informed strategy is also important in improving kernel fuzzing. We also note that SyzMini$^{\beta}$ achieved more improvement than SyzMini$^{\alpha}$. We will explain this phenomenon in Section 5.4.

It is worth noting that the optimization effects of these two strategies are orthogonal. Because these two strategies act on two different steps (*i.e.*, removing calls and simplifying arguments) in minimization. Thus, SyzMini achieved the highest coverage and found the most number of bugs compared to Syzkaller, SyzMini$^{\alpha}$ and SyzMini$^{\beta}$.

In summary, the influence-guided strategy improves the coverage by 3.5~4.6% and increases the number of found unique bugs by 1~1.35×, while the type-informed strategy enhances coverage by 8.3~9.1% and increases the number of found unique bugs by 1.2~1.5×. The optimization effects of

Table 7: Numbers of program executions under different minimization strategies in removing calls and simplifying args.

Minimization	Number of Program Executions		
	Removing Calls	Simplifying Args	All
one-by-one	140,620	260,239	400,859
influence-guided	60,372 (57.1%↓)	–	320,611 (20.0%↓)
type-informed	–	96,896 (62.8%↓)	237,516 (40.7%↓)
both optimizations	60,372 (57.1%↓)	96,896 (62.8%↓)	157,268 (60.7%↓)

the two optimization strategies are orthogonal.

5.4 RQ3: Reasons of Effectiveness

Setup of RQ3. We designed a controlled experiment to explain why the two optimization strategies can improve the effectiveness of kernel fuzzing by reducing the cost of minimization. To this end, We ran Syzkaller for 24 hours and collected 16,266 interesting programs that need minimization. We applied the default one-by-one minimization strategy in Syzkaller, the influence-guided strategy and the type-informed strategy in SyzMini respectively to minimize these interesting programs. We counted the number of program executions needed for verifying the coverage to approximate the cost required by these different minimization strategies. Additionally, we also measured the portions of program executions between mutation and minimization before and after applying the two optimization strategies to explain the effectiveness.

Results. Table 7 gives the numbers of program executions under different minimization strategies. Compared to the one-by-one minimization, the influence-guided strategy reduced 57.1% program executions when removing calls (see Column "Removing Calls"), while the type-informed strategy reduced 62.8% program executions when simplifying arguments (see Column "Simplifying Args"). Overall, the influence-guided and type-informed strategies respectively avoided 20.0% and 40.7% of the total program executions required by the one-by-one strategy. Moreover, when both strategies are enabled, they can reduce a total of 60.7% program executions. These results show that the two optimization strategies can avoid a large number of program executions during minimization. As a result, SyzMini can allocate more time to the mutation stage and execute more diverse programs. It explains why SyzMini can achieve higher coverage and find more bugs than Syzkaller.

It is also worth noting that the type-informed strategy reduces 40.7% program executions, which is about 2X more than that of the influence-guided strategy (20.0%). The former strategy can reduce more cost of minimization than the latter. This result explains why SyzMini$^{\beta}$ can achieve more improvement than SyzMini$^{\alpha}$ for kernel fuzzing in RQ2.

Figure 9 shows the portion of program executions between the minimization and mutation stages in a 24-hour fuzzing campaign *before* and *after* applying the optimizations on the three kernel versions (*i.e.*, comparing between Syzkaller and SyzMini). Compared to Syzkaller, SyzMini

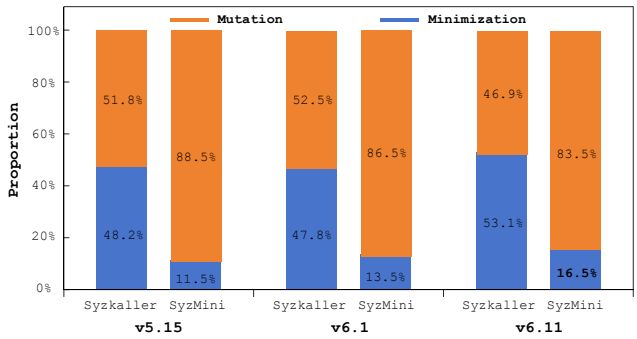

Figure 9: Proportion of program executions between mutation and minimization in SYZKALLER and SYZMINI

significantly reduce the proportion of program executions in minimization, while substantially increases the proportion of program executions in mutation. Taking v5.15 as an example, Syzkaller's minimization occupies 48.2% program executions, while SyzMini's minimization only occupies 11.5% (reduced by 75.7%); on the other hand, Syzkaller's mutation occupies 51.8% program executions, while SyzMini's mutation occupies 88.5% (increased by 70.5%). The results show that SyzMini does reduce the minimization cost and more time is allocated to mutation.

In summary, the influence-guided and type-informed optimization strategies reduce 60.7% of program executed during the minimization and more time is allocated to the mutation, thereby enhancing the effectiveness of kernel fuzzing.

5.5 RQ4: Applicability of Optimizations

Setup of RQ4. We aim to evaluate the generability and applicability of our optimization strategies on other distinct kernel fuzzers. To this end, we conducted a survey of research work on kernel fuzzing which was published in the recent five years (2019-2024) in relevant top venues (S&P, USENIX, CCS, NDSS, OSDI, SOSP, Eurosys, ATC). We collected 11 papers. We excluded 3 papers that did not open-source their tools, and 5 papers whose tools had not been actively maintained anymore. We finally obtained SyzVegas [44], CountDown [3] and SyzDirect [41] as the target fuzzers, all of which are built on Syzkaller but are designed for different purposes.

Specifically, SyzVegas targets adopting reinforcement learning for better scheduling seed selection, mutation and generation. CountDown targets detecting memory-related kernel bugs by a reference counter-guided mutation operator. SyzDirect is a direct kernel fuzzing tool which targets reproducing kernel bugs. These three tools are the state-of-art with different application scenarios. We implemented our optimization strategies in SyzVegas, CountDown and SyzDirect, and obtained their enhanced versions SyzVegas^{+}, CountDown^{+} and SyzDirect^{+}. We investigate whether their performance could be further improved.

To ensure fairness, we followed the default setups and evaluation metrics of these tools described in their papers. To

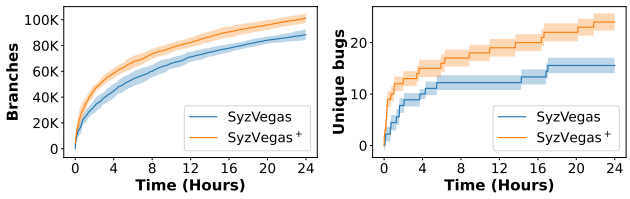

Figure 10: SyzVegas *vs.* SyzVegas$^+$ in term of branch coverage and number of unique bugs (shaded area: mean ±1 standard deviation).

compare SyzVegas and SyzVegas$^+$, we measured code coverage and number of found bugs. To compare CountDown and CountDown$^+$, we counted the number of found KSAN bugs (memory-related errors reported by Kernel Address Sanitizer). To compare SyzDirect and SyzDirect$^+$, we used *µTTE* and *hitting-round* to evaluate the directed fuzzing abilities. Specifically, SyzDirect provides a list of 100 kernel bugs as its evaluation dataset. Considering the experimental cost, we selected the first 10 bugs as the evaluation dataset in this paper. To prepare the dataset, we compiled the corresponding ten versions of Linux kernels with the configuration recommended by SyzDirect. We ran each tool 24 hours and repeated each experiment 10 rounds to migrate randomness. Thus, this evaluation for the three kernel fuzzing tools and their respective enhanced versions took 5,760 machine hours.

SyzVegas vs SyzVegas$^+$. Figure 10 shows the achieved code coverage and the number of found unique bugs on Linux v5.15. With the help of the two optimization strategies, SyzVegas$^+$ improves branch coverage by 14.5%. SyzVegas$^+$ found 24 unique bugs, while SyzVegas only found 16 unique bugs. It is clear that our optimization strategies enhances SyzVegas in code coverage and bug finding.

CountDown vs CountDown$^+$. Table 8 lists the number of KASAN bugs found by CountDown and CountDown$^+$ on Linux v5.11. During the 10 rounds of a 24-hour fuzzing campaign, CountDown$^+$ found a total of 43 KASAN bugs, while CountDown only found 27 bugs. CountDown$^+$ also achieved 4.5% more branch coverage. CountDown leverages the memory relation between system calls to guide the mutation of seeds for finding memory-related bugs. However, all the seeds in the corpus require minimization to improve mutation effectiveness. Our optimization strategies reduce the minimization cost, thereby allowing CountDown to have more time in performing memory-related mutations for finding KASAN bugs.

Table 8: CountDown *vs.* CountDown$^+$ on the KASAN bugs

Tool	All KASAN Bugs			Branch Coverage		
	Min	Max	Total	Min	Max	Avg
CountDown	0	5	27	116.9k	120.7k	119.0k
CountDown$^+$	1	7	43	119.7k	130.1k	124.3k
Improvement	1↑	2↑	66.7%↑	2.4%↑	7.8%↑	4.5%↑

SyzDirect vs SyzDirect$^+$. Table 9 gives the *µTTE* and *hitting-round* for reproducing each target bug. SyzDirect$^+$ successfully reproduced 9 bugs, while SyzDirect reproduced 6 bugs.

Table 9: SyzDirect vs SyzDirect$^+$ on bug reproduction

Bug ID	Commit ID	SyzDirect *µTTE*∼*hitting-round*	SyzDirect$^+$ *µTTE*∼*hitting-round*
1	3f2db250099f	×	16.0h∼4/10
2	c9a2f90f4d6b	21.6h∼2/10	20.0h∼4/10
3	b1a811633f73	×	21.2h∼1/10
4	2fd10bcf0310	21.2h∼2/10	10.1h∼8/10
5	b648eba4c69e	×	×
6	20aaef52eb08	13.6h∼10/10	12.8h∼10/10
7	3b0c40612471	18.8h∼4/10	17.6h∼6/10
8	ffb324e6f874	×	22.1h∼1/10
9	01faae5193d6	18.7h∼4/10	14.4h∼6/10
10	b2a616676839	20.4h∼6/10	14.10h∼8/10

The 6 bugs reproduced by SyzDirect were all reproduced by SyzDirect$^+$. Moreover, for these 6 bugs, SyzDirect$^+$ achieved higher *hitting-round*s and lower *µTTE* compared to SyzDirect. The results shows that our optimization strategies can enhance the directed fuzzing ability of SyzDirect. Given a bug location, SyzDirect prioritizes the mutations of seeds that are close to the bug location. But it still requires minimization to improve the quality of seeds. Our optimization strategies save the minimization cost, and give SyzDirect more time to mutation for increasing the probability of reproducing bugs.

In summary, the influence-guided and type-informed optimization strategies are orthogonal to the optimization strategies of existing kernel fuzzing tools. They improve SyzVegas by covering 14.5% more coverage and finding 1.5× more unique bugs, help CountDown identify 66.7% more KASAN bugs and enhance SyzDirect by reproducing 1.5× more kernel bugs.

5.6 RQ5: Factors affecting Optimizations

Setup of RQ5. We aim to analyze the factors that could affect the effectiveness of our optimization strategies. Specifically, the influence-guided optimization strategy leverages the influence relations between system calls to reduce the minimization cost. Thus, the number of influence relations is a critical factor affecting the strategy's effectiveness. To this end, we conducted a controlled experiment to study the impact of different numbers of influence relations on the effectiveness of this strategy. In our experiment, we have 74,865 influence relations in total. We selected the first 10%, 20%, …, 100% respectively from the list of these 74,865 influence relations as the input of the influence-guided strategy and observe the number of program executions during minimization.

The type-informed strategy reduces the minimization cost by skipping simplifying the fixed-size arguments. Thus, the number of fixed-size parameters (including the pointed-to objects if the parameters are *Pointer* type and the sub-fields if the parameters are *user-defined* type) in the system calls affects this strategy's effectiveness. However, obtaining all the system calls in the Linux kernel is difficult. We note that Syzkaller regularly updates the tested system calls when the Linux kernel has new updates. To this end, we analyzed the tested system calls provided by Syzkaller in the recent five

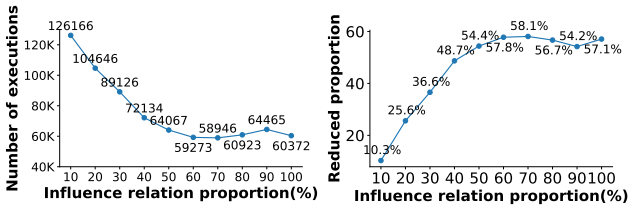

Figure 11: Number of program executions used for removing calls in minimization, and the reduced proportion of program executions compared to the one-by-one minimization.

years (2019-2024). We developed a script to scan all the tested system calls based on the *Syzlang* syntax [42], and counted the numbers of fixed-size and variable-size parameters according to the analysis method in Section 4.2.

Influence-guided Strategy. Figure 11 shows (1) the numbers of program executions used for removing calls in minimization, and (2) the reduced proportions of program executions compared to the one-by-one minimization (calculated by the similar method in Table 7) under different proportions of influence relations. We can see that when the proportion of influence relations increases, the number of program executions used for removing calls gradually decreases (see the left subfigure), and the reduced portion of program executions gradually increases (see the right subfigure). When the proportion of influence relations reaches 60%, the number of program executions and the reduced portion of program executions gradually stabilize. The reason is that, when the number of influence relations increases, the number of irrelevant calls identified by the influence-guided strategy in the program to be minimized gradually saturates. It also indicates that the number of collected influence relations in our experiment is enough for the strategy to take effect.

It is worth noting that this evaluation has also implied the relationship between such precision and optimization effectiveness. The reason is that proportion adopted essentially approximates the precision of influence relationship. When a smaller proportion of influence relation is given, the type-informed strategy will erroneously identify more irrelevant calls in the interesting program, reducing the precision of inferring irrelevant calls. The final result in Figure 11 shows that when the proportion of influence relation increases, the optimization effect increases; however, when the proportion reaches beyond 60%, its effect on the optimization strategy is negligible.

Type-informed Strategy. Table 10 shows the numbers of fixed-size and variable-size parameters in the system calls provided by Syzkaller. Indeed, we can see that the number of fixed-size parameters account for a large portion. Taking the version of Syzkaller in Dec. 2020 as an example, the proportion of fixed-size parameters is 80.5%, while the proportion of variable-size parameters is only 19.5%. The results shows that the tested system calls in Linux kernels are composed of a large number of fixed-size parameters. The type-informed strategy can avoid simplifying many unnecessary arguments which cannot benefit reducing the redundant mutation space. As a result, the number of program executions needed for verifying the coverage could be significantly reduced.

Table 10: Numbers of fixed-size and variable-size parameters in the system calls provided by Syzkaller.

Date	Commit ID	Fixed-size Parameter	Variable-size Parameter
2020-12	79264ae39c1e	101,897 (80.5%)	24,679 (19.5%)
2021-12	36bd2e486525	103,442 (80.1%)	25,643 (19.9%)
2022-12	ab32d50881df	107,575 (80.2%)	26,557 (19.8%)
2023-12	fb427a078200	112,523 (80.6%)	27,145 (19.4%)
2024-12	d7f584ee3c24	285,517 (74.0%)	100,631(26.0%)

In summary, for the influence-guided strategy, within the threshold of 60% influence relations, increasing the number of relations can improve its effectiveness and its optimization effect gradually stabilizes as the number of relations continues to grow. For the type-informed strategy, the fixed-size parameters occupy a high proportion in tested system calls, which help reduce the cost of simplifying arguments.

6 Discussion

SyzMini optimizes the minimization stage in kernel fuzzing and does not affect other parts of a coverage-guided kernel fuzzer. Figure 5 shows the extension implemented by SyzMini on top of Syzkaller. In the literature, a number of research work has been conducted to improve different aspects of kernel fuzzing (*e.g.*, generating system call description [8, 9, 39], mutating the seeds [13, 40] and scheduling the fuzzing tasks [20]). SyzMini is orthogonal to these existing work and would not affect any of these improvements. Thus, our optimization strategies are not limited to Syzkaller. Our extensive evaluation in Section 5.5 has also shown the significant effectiveness improvement when integrating our strategies into three kernel fuzzers (SyzVege, Countdown and SyzDirect) for different application scenarios. We believe integrating our optimization strategies to other kernel fuzzers will boost their effectiveness as well.

7 Related Work

Kernel Fuzzing. Since the success of Syzkaller [15], there has been much research work to improve the effectiveness of kernel fuzzing. A number of research work [5, 8, 9, 11, 17, 18, 39, 45] has been devoted to obtaining more comprehensive system call specifications for producing high-quality seeds. Moonshine [35] aims to generate high-quality initial seeds by distilling the collected system call sequences, thereby enhancing the mutation effectiveness. Other work [10, 13, 17, 23, 40] utilizes the relationship between system calls to narrow the mutation space. SyzVegas [44] leverages reinforcement learning to better schedule the fuzzing tasks such as program generation, mutation and minimization. Different from these existing work, our work SyzMini aims to reduce the cost of

minimization in kernel fuzzing, which has not been explored before.

Kernel Fuzzing Acceleration. There are some research work to accelerate kernel fuzzing. Horus [32] improves the communication speed between the host machine and the virtual machine running the tested kernel by replacing the remote procedure calls (RPCs) with direct memory access. Agamotto [12] observes that the kernel driver fuzzers frequently execute similar test cases, so it dynamically creates multiple checkpoints for these test cases to skip redundant parts. Different from these work, our work SyzMini accelerates kernel fuzzing by reducing the minimizaiton cost.

Input Minimization. Zeller *et al.* [47] first propose the concept of delta debugging to minimize the failure-inducing input. Delta debugging has been adapted in many scenarios. For example, AFL-family tools [28, 30, 46] use afl-cmin [26] and afl-tmin [27] to respectively minimize the seed corpus and an input file for improving the effectiveness of fuzzing. Specifically, afl-tmin [27] takes an input file and tries to remove as much data as possible while maintaining the same coverage as observed initially. In compiler fuzzing, C-Reduce [36] is used to reduce the bug-triggering C program by removing redundant code. In GUI testing, SimplyDroid [21] simplifies crash-triggering UI event traces for Android apps. However, these existing minimization techniques based on delta debugging cannot be directly applied to minimize the system call sequences from OS kernels. Because they do not consider the dependencies between the system calls and the type structures of arguments.

8 Conclusion

We have proposed two general and novel optimization strategies to reduce the cost of minimization stage in kernel fuzzing. The influence-guided strategy leverages the influence relation between system calls to optimize the call removal and the type-informed strategy utilizes the argument type information to avoid unnecessary simplification. Our evaluation shows that the minimization cost can be greatly reduced, compared to Syzkaller. The optimization strategies also help improve branch coverage and find more unique bugs. We believe our optimization strategies are general and could benefit many other kernel fuzzers.

IRHash: Efficient Multi-Language Compiler Caching by IR-Level Hashing

Abstract

Compilation caches (CCs) save time, energy, and money by avoiding redundant compilations. They are provided by means of compiler wrappers (Ccache, sccache, cHash) or native build system features (Bazel, Buck2). Conceptually, a CC pays off if the achieved savings by cache hits outweigh the extra costs for cache lookups. Thus, most techniques try to detect a cache hit early in the compilation process by hashing the (preprocessed/tokenized) source code, but hashing the AST has also been suggested to achieve even higher end-to-end savings, as the increased accuracy outweighs the additional parsing costs. Technically, all these CCs are currently limited to C or C-style languages.

In this paper we take the conceptual question of the "right" lookup level for compiler caches one step further onto the IR level. We provide IRHash, an IR-level CC for LLVM that not only offers higher accuracy than the previous works but can also support all languages with an LLVM backend.

We evaluate IRHash against Ccache and cHash based on the development history of 16 open-source projects written in C, C++, Fortran, and Haskell. With an average build time reduction of 19% across all C projects, IRHash provides better end-to-end savings than Ccache (10%) and cHash (16%), while additionally supporting more languages.

1 Introduction

Software development involves the frequent (re-)compilation of *translation units (TUs)* throughout the development cycle, consuming a considerable amount of time and energy (for both the developer and the machine).

To reduce these costs, content-based *compilation caches (CCs)*, such as Ccache [1] or sccache [2], aim to reuse build artifacts from previous builds. Both tools calculate a hash fingerprint of the TU (source file and included headers) and query their object-file cache. While effective, the resulting hash is sensitive to *any* source-code change, even superficial changes (i.e., formatting, coding style, comments) in any of the involved files result in a cache miss and the reinvocation of the compiler, even though the resulting object file would not be different. For higher accuracy, Ccache offers an option to calculate the hash after the C preprocessor has run, which normalizes the TU regarding *some* changes (on token level, e.g., white space formatting or commenting), but many superficial changes still lead to a cache miss, resulting in costly compiler invocations.

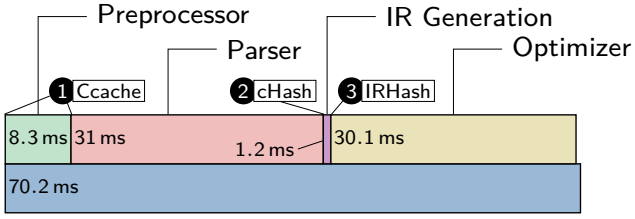

Figure 1: Build-time breakdown for a clean build of OpenSSL, which takes about 187 s and invokes the compiler 2 406 times. A single compiler invocation takes 70.2 ms on average, mainly comprising the duration for preprocessor, parser, IR generation, and optimizer. The markers show when different caching methods would detect redundant recompilations and stop the compiler invocation.

cHash [3] aims to overcome this issue by further normalization of the TU by calculating the hash after parsing, that is, on the level of the *abstract syntax tree (AST)*, where syntactically irrelevant changes are eradicated, and changes in unreferenced AST nodes can simply be ignored (e.g., an unreferenced type declaration). Due to its improved detection accuracy, cHash outperforms Ccache in most cases [3], even though the CC decision overhead is much higher: Fig. 1 shows this for OpenSSL, for which AST generation takes about four times longer than preprocessing. Apparently, further normalization to increase detection accuracy pays off.

About This Paper

In this paper we propose to go even further and solve the CC-problem on the level of the *intermediate representation (IR)*. Modern compilers, such as GCC or LLVM, generate a register-level IR from the AST to decouple language- and target-specific code generation and optimizations. As we can see in Fig. 1, this step takes only negligible extra time after AST generation (at least for OpenSSL). On the other hand, it might provide significant benefits: Besides providing higher *accuracy* (more superficial changes are eradicated), the IR is also relatively simple and language-agnostic: An IR-level CC approach thereby provides *generalizability* over all programming languages supported by the compiler suite. This is in stark contrast to the existing approaches, which are either bound to the C preprocessor (Ccache and sccache) or even the concrete AST-node types emitted by the compiler frontend (cHash). In particular, we claim the following contributions:

- We identify the IR-level as the most suitable level for CC with respect to *effectiveness* (end-to-end savings), *generalizability* (across languages), and *maintainability* (implementation effort).
- We propose IRHash, an IR-level compilation cache for LLVM IR and demonstrate its applicability for four front-end languages (C, C++, Fortran, Haskell).
- We demonstrate its accuracy and end-to-end savings in comparison to Ccache and cHash on the development history of 16 open-source projects. With an average build time reduction of 19% across all C projects, IRHash provides better end-to-end savings than Ccache (10%) and cHash (16%), while additionally supporting more languages.

The remainder of the paper is structured as follows: Sec. 2 describes the problem and limitations of existing caching mechanisms. Sec. 3 outlines the design and implementation of our IR-based caching approach. Sec. 4 evaluates its performance and versatility. Sec. 5 discusses the implications of our findings and potential improvements. Sec. 6 reviews related work, and Sec. 7 concludes this paper.

2 Problem Description

Source-code changes, whether during interactive development or condensed in a patch, are usually local and affect only a small portion of the program. Therefore, it is close at hand to recompile only the changed parts of the program while retrieving the rest from a *compilation cache (CC)* populated by previous compiler invocations. We define the *build-artifact reuse (BAR)* problem as the task of avoiding or speeding up unnecessary compilation steps by querying a CC.

However, in most programming languages, local changes can have a non-lexical, non-local impact on the compilation result. For example, changes to a C `struct`, which is declared in a header file, influence the resulting binary at every usage site. Also, if the BAR is too costly it can outweigh the savings of avoiding compilation steps.

Timestamp-based BAR, as introduced by `make` [4], addresses the problem at the TU level: For each TU, the file system timestamp of all compiler inputs is compared to the timestamp of the last compilation result. If all inputs are older than the last output, the compiler invocation is skipped and the last output is reused. This BAR method induces very low overheads, is entirely language agnostic, and has a high saving potential. However, it comes with two important downsides: (1) it is very sensitive to changes, especially with dense input-dependency graphs, and (2) it is a local strategy that is not able to reuse results across repositories or machines.

Content-based BAR [1]–[3], [5]–[7] addresses both shortcomings by calculating a fingerprint hash of the program that changes whenever the result would change. By keeping and querying a fingerprint–build-artifact CC we can skip compilation (steps).

For example, the Ccache [1] tool hashes either the original (direct mode) or the preprocessed source code (preprocessor mode). These modes differ in their *accuracy* and their *saving potential*: While the direct mode can skip the entire compiler invocation (70 ms for OpenSSL, see Fig. 1), it is sensitive to all textual changes. On the other hand, the preprocessed mode can ignore changes in inactive CPP blocks but requires executing the preprocessor, which takes 8.3 ms. More generally, the relative *end-to-end saving* of a BAR methods is:

$$\frac{T_{\texttt{saved}}}{T_{\texttt{total}}} = \frac{P_{\texttt{opt}} \cdot P_{\texttt{acc}} \cdot T_{\texttt{rem}} - T_{\texttt{over}}}{T_{\texttt{before}} + T_{\texttt{rem}}} \tag{1}$$

The BAR method will run after $T_{\texttt{before}}$ in the compilation process, and it will always introduce an overhead of $T_{\texttt{over}}$. If it can reuse a previous build artifact, it can skip the remaining $T_{\texttt{rem}}$ of the compilation, thereby saving time. However, it can only do so: (a) if the build artifact was produced before, which we introduce by $P_{\texttt{opt}}$, the probability that an optimal BAR[1] strategy with perfect accuracy would show, and (b) if the changed fingerprint does actually indicate a changed compilation result, for which we use the accuracy probability $P_{\texttt{acc}}$. Please note, that $P_{\texttt{opt}}$ depends on the project, the encountered change, the usage scenario, and the CC configuration (cache size). Only $P_{\texttt{acc}}$ is specific to the used BAR method.

A relevant question is, at which point in the compilation process should a BAR method run to maximize the end-to-end saving? For example, cHash [3] occupies another spot in this trade-off space: By hashing at the AST level, cHash can ignore changes to type declarations (e.g., in a header file) if that type was not referenced. However, for OpenSSL, its average $T_{\texttt{rem}}$ is only 31.3 ms per TU, while Ccache's $T_{\texttt{rem}}$ is at 62 ms per TU (89 %).

As the compiler progresses, $T_{\texttt{rem}}$ naturally decreases; however, as we get closer to the final binary, we expect $P_{\texttt{acc}}$ to

[1] Assuming reproducible builds, an optimal BAR method would invoke exactly those compiler runs that would result in a changed binary program.

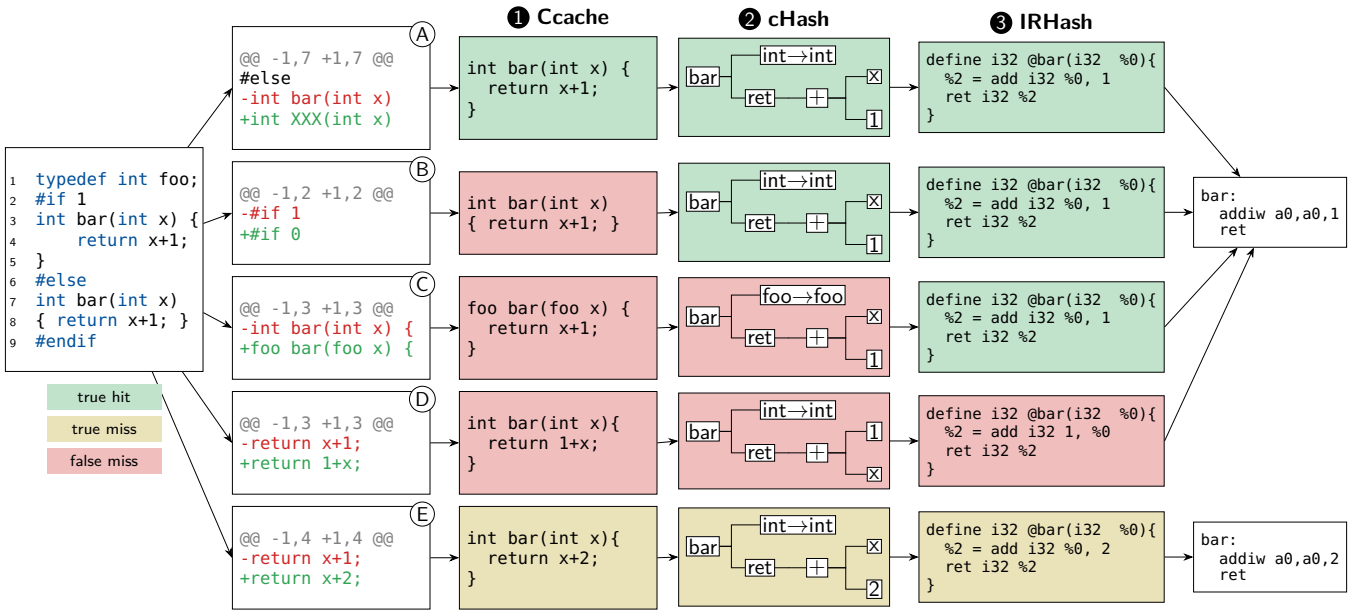

Figure 2: Examples for capabilities and limitations of BAR methods when confronted with different source-code changes

improve accordingly. Therefore, $T_{\texttt{over}}$, which scales with the amount of data and the complexity of the hash procedure, is quite important.

Directly tied to the hash-procedure complexity, and also deciding on its widespread adoption, is the language dependence of a BAR method. For example, Ccache's direct mode only has to hash a byte array, while cHash requires a hash rule for every language-specific AST-node type. This might also be why cHash has not gained widespread adoption and still only supports the C language.

3 IRHash: An IR-Based Compilation Cache

With IRHash, we solve the BAR problem at a different step of the compilation process, right after the IR generation. In the following, we will highlight the conceptual benefits, illustrate situations where IRHash can outperform the other BAR techniques, and touch on the implementation of our prototypical LLVM plugin.

3.1 Conceptual Benefits

Using a hash of a program's IR as a fingerprint to predict changed compilations comes with four key benefits:

Negligible smaller $T_{\texttt{rem}}$ than cHash. Preprocessing and parsing take a considerable share of the compilation process, as we can see in Fig. 1. In comparison, as done by a single tree traversal, generating the IR from the AST is quite fast, reducing $T_{\texttt{rem}}$ only slightly. For example, for OpenSSL, $T_{\texttt{rem}}$ is at 30.1 ms for the IR level and 31.3 ms for the AST-level. We will discuss this in more detail in Sec. 4.3.

Higher $P_{\texttt{acc}}$ At the IR level, many language constructs that are only syntactic sugar (C: `typedef`) or act as type-level safeguards (C++: `explicit`) are removed by IR code generation. The IR generation can also perform some ad-hoc optimizations (e.g., constant folding). Therefore, IR-level should have a higher $P_{\texttt{acc}}$ than AST-level hashing, which already outperforms source-level hashing. We will quantify this higher $P_{\texttt{acc}}$ in Sec. 4.2.

Low $T_{\texttt{over}}$ overhead The data structures that store the IR are designed for frequent traversal to speed up the optimization steps. Also, they are conceptually simpler as they are a sequential program (list of lists) for a virtual machine compared to the AST, which captures the syntactic structure of the program recursively (as a tree). Unlike source-level hashing, which has to hash all (preprocessed) compiler inputs, IR-level hashing can also be faster as only the relevant parts of the input are hashed. In Sec. 4.3, we will demonstrate that IR-level hashing actually has a lower $T_{\texttt{over}}$.

Simple and widely-applicable implementation Due to the conceptual simplicity of the IR, which is comprised of only a few instruction types, IR-level hashing is simpler to implement than AST-level hashing. Since the IR is a language-*independent* abstraction that connects language front-ends, optimization steps, and machine-specific back-ends, IR-level hashing is directly usable for different programming languages. We will argue for IRHash's simplicity in Sec. 3.3 and justify our applicability claim with four programming languages and 16 open-source projects (see Tab. 2).

Given these arguments, we believe that IR hashing is conceptually the most suitable point in time to perform BAR.

C++ Classes	Source Lines

Table 1: Implementation effort for IR-level hashing

3.2 Reasons for Better Accuracy

To give a better understanding of $P_{\texttt{acc}}$, we will exemplify the capabilities and limitations of the different BAR methods with the five source-code changes Ⓐ-Ⓔ in Fig. 2. We assume that the original code on the left was already compiled and inserted into the CC and we compile for RISC-V, as RISC-V allows us to show a limitation of CCs. Please note, that $P_{\texttt{acc}}$ is $(1 - \frac{\#\text{false miss}}{\#\text{runs}})$.

Ⓐ is a change to the dead preprocessor block (line 6-9). If used in preprocess mode, Ccache can ignore the change and correctly have a cache hit, reusing the previous result. Naturally, all the following steps also have a cache hit.

Ⓑ toggles the `#if` and selects the previously dead block. Since the `bar()` function is formatted differently, Ccache will falsely have a cache miss and continue compilation. As such syntactic differences are not visible in the AST, cHash has a cache hit.

Ⓒ replaces the `int` type with the equivalent `foo` type alias. While C `typedefs` are mere syntactic sugar, they are still visible in the AST, provoking a false cache miss with cHash. Due to type-alias erasure during IR generation, IRHash correctly has a cache hit.

Ⓓ swaps the terms of the sum. This change persists until the IR level, provoking a cache miss for IRHash. However, this is a false miss, as the RISC-V backend uses the add-with-immediate instruction and swaps the operands to the original order.

Ⓔ is an actual semantic change that results in a different binary output, requiring the full compilation process.

The different BAR methods remain, to a differing degree, stable hashes in the presence of irrelevant changes.

3.3 Implementation

Our IRHash prototype comes as an LLVM plugin that introduces a new IR-level compiler pass that has access to LLVM's internal data structures. Thus, IRHash can be loaded into all LLVM-based compilers and our IRHash pass can be scheduled at any point of the compilation process. For BAR, IRHash should run directly after the IR generation to maximize $T_{\texttt{rem}}$. Conceptually, the plugin consists of two parts: IR hashing and CC logic.

IR Hashing LLVM IR captures the program semantic as a set of per-function control-flow graphs with basic blocks as nodes. The IR code generation already flattens all language-level logic constructs (methods, lambdas, co-routines,...) into LLVM functions. Therefore, IR is stored as a shallow hierarchy of nested C++ objects (see Tab. 1): A TU is a list of functions and global variables. A function is a list of basic blocks, which themselves are lists of instructions. Each instruction has an opcode and multiple operands. As LLVM IR is always in SSA format [8], operands are either a literal constant or (the result) of another instruction. Global variables, functions, instructions, and constants have types, which only describe the data layout.

In Tab. 1 we see that it only takes a few hundred source lines to implement the necessary hash operators: For the TU hash, we include the hash of global variables and functions. The global-variable hash includes name, type, initializer, and attributes. For functions we hash the name, the prototype, attributes, and the hash of basic blocks and subsequently instructions. Besides opcode and operands, the instruction hash also includes certain attributes that influence the binary (e.g., allocation alignments, atomicity). With inline assembler we hash the string representation, and complex types are hashed recursively down to their scalar components.

We deliberately chose not to hash a serialized version of the IR (in textual or LLVM bitcode form), as this has two significant drawbacks: (1) We would lose the fine-grained control over the data included in the hash. For example, IRHash by default does not include debug information in the hash, which means purely syntactical changes do not trigger a rebuild. However, in scenarios where up-to-date debug information is required, this could be adjusted easily.

(2) IR serialization takes a considerable amount of time and is not necessary for many compiler runs. Nevertheless, if LLVM serializes the IR anyway, for example, for ThinLTO [9], an IR hash could be calculated using that.

Caching Logic With the IR hash at hand, the IRHash pass performs the CC lookup: Like Ccache, IRHash stores build artifacts (i.e., object files) in a cache directory with the file name matching the hash. On a hit, the cached build artifact is hard linked to the target location and the compilation is terminated. Also, the timestamp of the object file is updated to allow timestamp-based BAR methods to avoid downstream operations (like linking). On a cache miss, the compilation continues, and the resulting object file is put into the cache.

IRHash is implemented with a total 561 lines of C++ code, while cHash requires 1200 source lines for the hash operator alone [3]. Please note that IRHash supports multiple front-

end languages, while cHash only supports C. As Ccache is a production-ready CC with a multitude of features, its 19 000 source-code lines are not comparable. However, IRHash can be combined with Ccache (see Sec. 4.5) or could act as a fingerprinting module.

4 Evaluation

In the evaluation we demonstrate that IRHash works correctly and efficiently across languages on the development history of 16 open-source projects written in C, C++, Fortran, and Haskell. We also show that the IR level is best suited to solve the BAR problem by comparing IRHash with tools working at the source code and AST levels. For this purpose, we chose Ccache for the source-code level due to its popularity and cHash for the AST level, as it is the only tool known which works at this level. We determine the parameters of Equation 1 for these CCs and projects and conclude with a real-world end-to-end-performance benchmark.

4.1 Test Cases

For our evaluation we selected the open-source projects listed in Tab. 2. This selection spans a wide range of project sizes, from smaller codebases, like ShellCheck (16 kLOC) and LAPACK (779 kLOC) to larger ones, such as PostgreSQL (1 019 kLOC) and Linux (26 256 kLOC). These projects also represent diverse domains, including interpreters (Bash, CPython, Lua), database systems (PostgreSQL, SQLite), cryptography libraries (Mbed TLS, OpenSSL), static analysis tools (Clazy, GammaRay, ShellCheck), frameworks and toolkits (Asio, SDL), a mathematical library (LAPACK), a lightweight C library (musl), an x86 emulator (Bochs), and the Linux operating system kernel. For comparison with the textual and AST level, our evaluation focuses on C but to demonstrate applicability to other languages, some of these projects are written in C++ (Bochs, Asio, Clazy, GammaRay), Fortran (LAPACK) and Haskell (ShellCheck).

For our experiments we examined the development history of the projects up to the described version as a source of real-world changes required for incremental builds. The number of commits considered was limited to the 100 most recent ones. Together with the selection of projects, this should result in a diverse and representative set of changes. Commits failing to build in the baseline (without any caches) were filtered out. All measurements were performed on a system with an Intel® Core™ i7-12700 processor with Turbo Boost disabled for reproducibility and 32 GB of memory. The size of the CCs was not limited. All projects were tested using their default configurations, except for replacing the compiler with Clang and enabling the tested CCs. For SQLite we disabled amalgamation[2], a process in which all source code is concatenated into a single file. Amalgamation is mainly done for deployment and optimization purposes and is not intended for development. Asio as a header library is not compilable itself, which is why we have compiled the example code, the default target of the project. For LAPACK, written in Fortran, we compiled using Flang, LLVM's Fortran frontend [10]. ShellCheck, a project written in Haskell, was compiled using the LLVM backend of GHC 9.12.1 [11]. Due to an incompatibility with newer GHC versions of the earlier commits in its history, ShellCheck has only 59 successfully building (and therefore analyzed) commits. In contrast, there are usually no failing (clean) builds for the other projects and at most six for GammaRay. All in all, based on this diverse selection of projects and commits, we are confident that our results are representative of a wide range of software projects.

[2] https://sqlite.org/amalgamation.html

Table 2: Overview of Evaluated Projects

Project	Language	Version	LOC
Linux [12]	C	6.11	26 255 658
OpenSSL [13]	C	3.4.0	621 158
SQLite [14]	C	3.47.0	297 234
Lua [15]	C	5.4.7	21 879
PostgreSQL [16]	C	17.0	1 018 762
CPython [17]	C	3.13.0	672 595
Bash [18]	C	5.2	130 759
Mbed TLS [19]	C	3.6.2	166 172
SDL [20]	C	2.30.8	351 683
musl [21]	C	1.2.5	95 034
Bochs [22]	C++	2.8	289 270
Asio [23]	C++	1.32.0	182 108
Clazy [24]	C++	1.12	25 035
GammaRay [25]	C++	3.1.0	101 798
LAPACK [26]	Fortran	3.12.0	779 202
ShellCheck [27]	Haskell	0.10.0	15 672

4.2 Validation (P_{opt}, P_{acc})

First, we validated the implementation of IRHash by performing clean builds for 100 commits each across 16 projects. We compared the predictions of Ccache, cHash, and IRHash against object file hashes and measure the compilation time with caching disabled to determine the overhead. In total, 1 289 086 translation units were compiled.

Most importantly, IRHash, like the other tools, did not cause any false hits, which means that whenever an object file changed, the IRHash was also different. The property of correctness is mandatory for a CC. If developers cannot be sure that their changes have been compiled, i.e., a CC leads to incorrect results, it is practically useless. Consequently, Ccache and cHash also offer this property. Full completeness, i.e., no false misses ($P_{\mathsf{acc}} = 1$), on the other hand, is desir-

Table 3: The average accuracy ($P_{\texttt{acc}}$) and $P_{\texttt{opt}}$ per commit for the evaluated projects, commits, and CCs. Values not available due to lack of language support by a CC are marked with "-".

		$P_{\texttt{acc}}$ (%)		
Project	$P_{\texttt{opt}}$ (%)	Ccache	cHash	IRHash
Linux	99.91	97.89	98.14	99.99
OpenSSL	99.96	97.63	99.01	100.00
SQLite	98.86	93.66	99.01	99.82
Lua	97.23	85.26	97.03	99.21
PostgreSQL	99.88	97.99	100.00	100.00
CPython	98.97	98.74	99.48	99.78
Bash	97.09	93.23	99.58	99.97
Mbed TLS	99.37	93.62	99.76	99.97
SDL	99.31	95.78	99.94	99.93
musl	98.98	99.35	99.91	100.00
Average (C)	98.96	95.32	99.19	99.87
Bochs	98.95	97.29	-	98.81
Asio	96.08	59.92	-	96.72
Clazy	99.41	95.83	-	99.93
GammaRay	99.55	99.74	-	99.99
Average (C++)	98.50	88.20	-	98.86
LAPACK	99.80	-	-	99.99
ShellCheck	75.26	-	-	100.00

able but not claimed by any approach. As Tab. 3 shows, the accuracy $P_{\texttt{acc}}$ varies; the reasons are discussed in Fig. 2.

The results show that IRHash is generally one to two orders of magnitude more accurate than Ccache, cHash is in between but closer to IRHash. For example, for Mbed TLS with Ccache, 6.38% redundant builds are performed, with cHash 0.24%, and with IRHash only 0.03%. It is noticeable that both Lua and Asio have a high rate of false misses. In the case of Lua this is due to the fact that it was refactored frequently, sometimes in such a way that the code was only the same after optimization. Asio as a header library often introduces functions that are not used, a weakness of Ccache. Also, in the commit range we examined, implicit constructs were made explicit, and `std::move()` was inserted in places where the optimizer already had done so, leading to false misses for IRHash. The fact that many of the false misses are caused by semantic changes, which are only eliminated by optimizations, underlines the high suitability of the IR level for the accuracy of caching.

Another interesting observation is that cHash is more accurate for SDL than IRHash. This is due to an optimization of cHash: Unlike IRHash, cHash does not hash the types of structs themselves but their use only, i.e., the offset of the accesses and the size (for `sizeof()`). If a new field is added at the end of a struct that is not used and the size of the struct is not used or changed in a TU, the hash does not change either. In the future this optimization could be implemented in IRHash as well.

In contrast to the other CCs, IRHash also supports languages apart from C/C++. The last two experiments confirm that IRHash works for other compilers with an LLVM backend (Fortran and Haskell). With a $P_{\texttt{acc}}$ of 99.99% and 100.00%, it performs equally as well as for C/C++.

Note that $P_{\texttt{opt}}$ for ShellCheck (75.26%) is remarkably low. There are two reasons for this. Firstly, ShellCheck has relatively few translation units (27), thus modifying only a few files is already a significant share. Secondly, the compiler does not always work fully deterministically for each TU. The main problem is that internal identifiers are made globally unique (across all TUs). This process is nondeterministic. In addition, the identifiers are enumerated, which can lead to changes in one TU changing identifiers in another. This is further exacerbated in incremental builds where the number of TUs to be compiled varies. The GHC maintainers confirmed this behavior as a known bug and are, at the time of writing, working on a fix. [28]–[31]

All in all, the results demonstrate that the IRHash approach works correctly, effectively, and significantly more accurately than Ccache, especially for C++ projects. Compared to cHash, the difference in accuracy is less pronounced. This is primarily due to two factors: (1) changes in the AST frequently result in changes to the IR, and (2) the evaluated changes, derived from the projects' development history, often genuinely alter behavior. Nonetheless, the experiment confirms the expectation of IR Hashing providing a higher $P_{\texttt{acc}}$.

4.3 Performance Characteristics ($T_{\texttt{over}}$, $T_{\texttt{rem}}$)

We performed clean builds with deactivated caching for the same commits as before to quantify each CC's overhead. Similarly, 1 289 086 translation units were compiled. The resulting $T_{\texttt{over}}$ and $T_{\texttt{rem}}$ are summarized in Tab. 4.

The measurements show that Ccache's overhead is consistently the highest, with an average of 548.8 ms per commit for Linux, followed by cHash (236.1 ms) and IRHash (2.0 ms). The results for Linux highlight the limitations of Ccache. It invokes the preprocessor during cache misses, which in Linux entails resolving a multitude of complex and deeply nested macros. By contrast, cHash benefits from the fact that the macros are already resolved and a lot of code discarded. In the code generation phase, further complexity is resolved, enabling IRHash to process the IR code much faster. This pattern is observed consistently across all tested projects, though the specific performance characteristics vary.

However, it is noticeable that the absolute overhead of IRHash for the C++ projects Asio (14.5 ms) and Clazy (26.1 ms) is higher compared to C projects of their size, e.g., SDL (1.1 ms). This difference stems from the extensive code generated due to the use of templates. For instance,

Table 4: The average overhead ($T_{\texttt{over}}$) and time remaining after hash calculation ($T_{\texttt{rem}}$) per TU for the evaluated projects, commits, and CCs. Values not available due to lack of language support by a CC are marked with "-".

	$T_{\texttt{over}}$			$\frac{T_{\texttt{over}}}{T_{\texttt{total}}}$			$\frac{T_{\texttt{rem}}}{T_{\texttt{total}}}$

GammaRay	272.5 ms	-	2.4 ms	11.4%	-	0.1%	88.6%	-	12.1%
Average (C++)				10.2%	-	0.3%	89.7%	-	37.9%
LAPACK	-	-	0.5 ms	-	-	0.2%	-	-	41.7%
ShellCheck	-	-	60.7 ms	-	-	1.5%	-	-	85.5%

Asio (182 kLOC) generates 387 MiB of IR code, while SDL (352 kLOC) generates only 28 MiB. As this greatly increases the total compiler runtime, it is not reflected in the relative overhead, both for Ccache and for IRHash. Instead, it mainly affects the compiler frontend, which has to expand the templates. The overhead for Asio is 6.9% and 0.2% respectively, for Clazy 5.3% and 0.7% respectively, and for SDL 31.9% and 0.2% respectively. ShellCheck is special in that Haskell's GHC generates textual LLVM IR and then calls LLVM's `opt` to optimize the generated IR. With 439 MiB even more code is generated than with Asio, which explains the high overhead. In addition, IRHash only runs as part of `opt`, which leads to a $T_{\texttt{total}}$ that consists mainly of optimizations, since the compiler frontend has been executed already and the lowering happens in a later step. This leads to a comparatively high relative overhead and the fact that only the optimization phase (not the lowering) can be cached.

Regarding the saving potential $T_{\texttt{rem}}$, Ccache performs best because it starts the hash calculation the earliest. Interestingly, IRHash often completes hash computation earlier than cHash despite the latter starting earlier (as soon as the AST is generated). For example, for OpenSSL $T_{\texttt{rem}}$ is 61.8% when using Ccache, for cHash it is 36.1%, and for IRHash 38.9%. This behavior is due to an implementation detail in modern compilers, particularly Clang: To reduce memory usage, the compilation process handles each top-level declaration independently and sequentially. As a result, the code generation phase for the first declaration begins even before the AST for subsequent declarations is generated. Consequently, cHash starts exactly as much earlier as the code generation phase for the last top-level declaration takes and IRHash often compensates for this by completing the hash computation more quickly. Again, ShellCheck is special: Because its $T_{\texttt{total}}$ consists only of `opt`, the hashing pass runs directly at the beginning, leading to a high $T_{\texttt{rem}}$.

Overall, IRHash offers a trade-off: the hash is calculated later than when using Ccache but is significantly more accurate. Compared to cHash it is equally fast but more precise and not limited to C. The low overhead of the hash calculation also shows that our implementation is sufficiently fast, although there is still plenty of room for improvement. These results are a strong indicator for IR being better suited to solve the BAR compared to the AST.

4.4 End-to-End Performance ($T_{\texttt{total}}$, $T_{\texttt{saved}}$)

The end-to-end performance benchmark is intended to reflect the use case of a typical developer who frequently changes and builds the project. To simulate this scenario, we incrementally built 100 (+1 initial) commits from the development history of each of the evaluated projects. Non-building commits, along

Table 5: The optimization level, number of successfully building commits (in baseline) together with the average build time ($T_{\texttt{total}}$) and relative end-to-end savings per commit for the evaluated projects, commits, and CCs. The fastest cache for each project is highlighted in green. If a combination of caches is faster than this cache for a project, it is highlighted in gray. Values not available due to lack of language support by a CC are marked with "-".

				$\frac{-T_{\texttt{saved}}}{T_{\texttt{total}}}$				
Project	Opt	Commits	$T_{\texttt{total}}$	Ccache	cHash	IRHash	Ccache+cHash	Ccache+IRHash
Linux	O2	100	25.1 s	0.1%	3.0%	−3.1%	3.2%	−3.4%

GammaRay	O3	94	5.8 s	−20.2%	-	−10.6%	-	−26.4%
Average (C++)				−6.0%	-	−19.4%	-	−22.6%
LAPACK	O2	100	1.7 s	-	-	−12.4%	-	-
ShellCheck	O2	58	142.7 s	-	-	0.8%	-	-

with their subsequent commits used for a new clean build, were excluded from the evaluation. Tab. 5 presents the average performance improvements per commit for Ccache, cHash, and IRHash, compared to builds without any CC.

Across all 16 projects, regardless of optimization level, project size, or programming language, the results show that, with few exceptions, IRHash consistently achieves the fastest build times. In four of these exceptions, the fastest CC is only marginally faster. For SQLite and musl, Ccache, with improvements of 4.8% and 6.8%, is slightly faster than IRHash (4.4% and 5.3%). For Bash and Mbed TLS, cHash marginally outperforms IRHash (29.5% vs. 26.4% and 25.2% vs. 23.3%). In one other case, GammaRay, Ccache can utilize its higher $T_{\texttt{rem}}$ and offer more pronounced improvements (20.2% vs. 10.6%).

ShellCheck with a 0.8% slowdown is the only project where IRHash cannot improve the average build time. As mentioned in Sec. 4.2, GHC is not fully deterministic, which is amplified in incremental builds. This leads to frequent changes and cache misses. In addition, GHC uses fingerprints for the recompilation decision [29], which further increases the probability that a compiler call will actually result in a changed object file. Although IRHash still works absolutely correctly, it does not make sense to use it under these circumstances. Due to very few cache hits, the savings cannot outweigh the overhead.

In the end, it always depends on the time behavior of the cache and whether it is accurate enough for a specific change. If a change can be cached by a technique with higher $T_{\texttt{rem}}$, this will always be the fastest option. However, our evaluation has shown that, for a wide range of software projects and changes, caching at the IR level is the better choice. From these three CCs, IRHash provides competitive results most consistently.

4.5 Combining Approaches ($T_{\texttt{total}}$, $T_{\texttt{saved}}$)

Since a low $T_{\texttt{rem}}$ is a weakness of IRHash, combining it with Ccache by using both Ccache's compiler wrapper and the IRHash compiler plugin at the same time might lead to even better results. Therefore, Tab. 5 also presents the average performance improvements per commit for the combinations of Ccache with IRHash and, for comparison, Ccache with cHash. We did not measure the combination cHash+IRHash, as IRHash is superior to cHash both in terms of $P_{\texttt{acc}}$ and $T_{\texttt{rem}}$. The following applies to the combined cache: A miss in the first cache (Ccache) results in a query for the second cache (cHash or IRHash), which means that the data is stored in both

caches. If there is a cache hit in the first cache, the second cache is not queried.

The results show that whenever IRHash was faster than cHash, the combination with Ccache is also faster. Interestingly, this also applies to Bash, where cHash is faster.

In six out of 16 cases, Ccache+IRHash's improvements are the best compared to all other CCs and combinations thereof. In five of these cases (Linux, Lua, musl, Asio, Clazy) the improvement is small, for example, 3.4% over 3.1% with IRHash alone for Linux.

An interesting case is GammaRay, as Ccache alone speeds up the build by 20.2% and IRHash only speeds up the process by 10.6%, but together these tools achieve a speedup of 26.4%. While the speedup is more pronounced, this behavior is fundamentally no different to the other cases in which the combination is faster than the individual caches. However, when combining caches, only the speed can increase, not the hit rate. This is because a cache hit with Ccache means that after preprocessing the compiler input has not changed. Consequently, a deterministic compiler must always produce the same AST and IR code so that a hit in Ccache must also always mean a hit for cHash and IRHash. The advantage must therefore be that in cases where Ccache has a hit, calculating the more precise hash of cHash or IRHash is skipped. In cases where Ccache has a miss, the other methods may still save time due to their higher accuracy.

In cases where Ccache+IRHash delivers the best improvement, IRHash alone is often already highly effective and, therefore, a safe bet to use. Depending on the project and the change patterns ($P_{\texttt{opt}}$), it may make sense to use Ccache additionally.

4.6 Result Summary

At this point we want to conclude that IR-level hashing is (a) effective (end-to-end savings), (b) generalizable across languages, and (c) easy to implement and maintain.

IRHash outperforms Ccache and cHash or comes close for most projects (see Tab. 5). The reason for this is its higher $P_{\texttt{acc}}$ (see Tab. 3). While it has a comparable $T_{\texttt{rem}}$ than cHash, its $T_{\texttt{over}}$ is significantly lower, allowing it to outperform Ccache (see Tab. 4).

Our evaluation with 16 open-source projects across four programming languages demonstrates its easy and broad applicability. As we argued in Sec. 3.3, IR-level hashing is also easier to implement, for example, in the case of IRHash with a few hundred lines of code.

All in all, we think that IR-level hashing should become a standard extension to modern compiler frameworks.

5 Discussion

We have now described IRHash, our CC operating at the IR level, and have demonstrated the advantages over approaches operating at the source code and AST levels. In this chapter, we will discuss potential threats to the validity of our results, the generalizability of our approach, and open aspects in more detail.

5.1 Threats to Validity

To help ensure the internal validity of our study, we evaluated IRHash using the development histories of 16 open-source projects. The projects were chosen from different application domains: interpreters, database systems, cryptography libraries, static analysis tools, frameworks and toolkits, a mathematical library, a lightweight C library, an x86 emulator, and an operating system kernel. They are implemented in C, C++, Fortran, and Haskell.

Due to the significant differences between them, a large coverage of language constructs is given. In addition, IRHash operates on IR, which is intentionally kept simple, thereby considerably improving coverage further. In combination with the number of 1 289 086 compiled TUs, a diverse set of IR constructs was generated. IRHash has not missed a single change as verified against the most exact metric of binary equivalence.

To ensure external validity, we used the same variety of projects for the performance measurements. The experiments consistently yielded strong results, with IRHash not only being more precise than Ccache and cHash but also more effective in reducing compilation time. Moreover, due to the significant differences between C/C++, Fortran, and Haskell, we successfully demonstrated that the approach is language independent.

Overall, we are confident that our results are both correct and transferable to other projects and languages.

5.2 Open Questions

While we evaluated IRHash thoroughly, there are still possibilities for further research.

Source-code changes have different extents and impacts (reflected in different $P_{\texttt{opt}}$ values). For interactive development, developers will benefit even more from IRHash's faster turnaround times, as usually only a few lines are changed before recompilation. Commits or patches naturally require more recompilation effort (medium $P_{\texttt{opt}}$ values) and induce their costs, most importantly, on continuous-integration servers [32]. While we expect even lower $P_{\texttt{opt}}$ values between software versions, IRHash could help to reuse results between the different variants of statically-configured software product lines [33]. For our evaluation we deliberately chose to test IRHash with commits from existing Git histories. These changes have a medium scope and give us realistic change sets developed by independent third-party developers.

Multiple IR levels are gaining importance in current compiler design. For example, Rust's `rustc` compiler uses

three IR levels (High-, Medium-IR, and LLVM-IR) to perform incremental lowering. With MLIR [34], LLVM now also provides a general means to express different IR levels. However, with multiple IR levels, the gap between AST generation and LLVM-IR hashing increases, reducing $T_{\texttt{rem}}$. Therefore, the question arises at which IR level should results be cached. We consider this a topic for further research.

More fine-grained caching We also considered whether more fine-grained caching (i.e., function level) could lead to even better results. While IRHash currently fingerprints and caches the entire TUs, it can also provide per-function hashes. However, per-function caching is challenging, as interprocedural optimizations, which LLVM's fix-point optimizer schedules early, cause information to flow between functions. For example, if the compiler inlines function A into function B, a change to A will also change the binary form of B. Without fine-grained tracking of such dependencies, per-function caching, as already proposed by Sathyanathan *et al.* [35], risks incorrect compilation results. Such tracking, however, requires substantial compiler modifications, that are not necessary for IRHash, which is less intrusive and easier to validate.

IR normalization Another interesting direction to explore could be to combine *IR normalization*[3] with IRHash. By normalizing the IR (e.g., topological sorting of basic blocks) before hashing, even more non-semantic changes could be equalized, potentially leading to a higher $P_{\texttt{acc}}$. We refrained from enabling normalization as (1) bugs in the IR normalization would result in caching incorrect results, (2) normalization itself induces considerable overhead ($T_{\texttt{over}}$), and (3) our observed $P_{\texttt{acc}}$ was already quite high (see Tab. 3).

6 Related Work

Reducing the end-to-end costs of software recompilation by incremental builds is a decades-old mission that was even once considered a motivating factor towards modularization [36]. Yet the question which modules actually need to be recompiled based on a change in some other module remains an ongoing challenge: C and its descendants delegate modularization to an idiomatic usage of the preprocessor as well as the file system and the task of incremental builds to a language-agnostic build system (e.g., make [4]). Hence, changes are only detected and handled on the granularity of whole files, leading to many redundant recompilations. This has been identified as particularly problematic for so-called "God" header files, which trigger many other modules to be (redundantly) recompiled in case of a change [37], [38].

CCs, such as Ccache [1] and sccache [2] mitigate such recompilation costs by stepping in as a proxy compiler that detects a redundant build early in the compilation process. FASTBuild [39] goes one step further and incorporates a CC directly into the build system. All of these systems work on (preprocessed) C/C++ source-code level and can skip redundant builds only for irrelevant lexical changes. For languages with true module support (i.e., modules as first-class syntactic entities), several solutions have been proposed to prevent redundant builds at higher accuracy [40]–[42] by tracking the actual symbol-level interactions between exporting and importing modules. cHash [3] achieves this for C by shifting the detection onto the AST level. With IRHash, symbol-level dependencies are basically dealt with automatically in a language-independent way, as all symbol-level interactions have already been resolved on the IR level.

Parallelizing the compilation process is another common approach to reduce end-to-end build times. Systems like distcc [43], Icecream [44], CloudBuild [7], Bazel [5], and Buck2 [6] distribute compilation tasks over the local network or cloud. While parallelization reduces waiting times, it does not reduce the overall workload and energy costs. Therefore, all of these systems also provide means to integrate hash-based CCs, usually with the option to share the cache across branches, projects, and developers. It would be relatively easy to integrate IRHash into these settings if the respective compiler uses an IR.

For such larger *continuous integration (CI)* settings, AST-based (i.e., symbol-level) redundancy detection has also been suggested as a means to reduce the post-compilation overhead by preventing redundant regression testing [45]. Here, IRHash might further increase the accuracy and language support.

7 Conclusion

Compilation caches (CCs) reduce the costs of incremental software builds by interrupting redundant compilations early in the process in favor of a cached result from a previous build. Where exactly in the multi-stage process of modern compilers such caches should be implemented is a trade-off between effectiveness (end-to-end savings), generalizability (across languages), and maintainability (implementation effort).

In this paper, we have conceptually and experimentally analyzed (with 16 open-source projects in four different languages) that implementing a CC on the level of the *intermediate representation (IR)* is beneficial for all three properties in comparison to the previous approaches, which work either on source-code level (Ccache) or AST level (cHash).

IRHash, our implementation of IR-level caching for LLVM, provides, with 19% end-to-end savings, not only better effectiveness than Ccache (10%) and cHash (16%) across the analyzed C projects but also generalizability over other languages supported by LLVM (we have shown this for C++, Fortran, and Haskell) out of the box. Due to the structural simplicity of the IR language, the implementation of caching at this level can, furthermore, be kept simple and maintainable. In the case of IRHash, we needed less than 600 lines of code for the complete LLVM plugin. Overall, our results show that

[3] LLVM: `llvm/lib/Transforms/Utils/IRNormalizer.cpp`

the IR level is the most beneficial level for implementing a CC.

> *Please refer to the published artifacts to verify and replicate the experiments [46]. The IRHash source code is also available on GitHub [47].*

A Artifact Appendix

Abstract

IRHash is a multi-language compilation cache that operates at the IR level. The artifact contains all the source code for IRHash as well as its evaluation and the scripts to reproduce the results of the paper. This comprises all measured values in the paper, including validation and performance measurement. For this purpose, 100 commits are built for each of the 16 projects, both incrementally and as clean builds. This process runs fully automatically. As the procedure can take a very long time (over a week), there are also instructions to reduce the extent of the experiments. To ensure reproducibility, there are also OCI images provided that can be easily executed.

Scope

The artifact is intended to reproduce all findings of the paper by automatically executing the complete evaluation. Specifically, it concerns the results in Fig. 1, Tab. 3, Tab. 4, and Tab. 5, thereby validating the implementation of IRHash, analyzing its performance characteristics compared to Ccache and cHash, and executing the end-to-end-performance benchmark.

Contents

The artifact includes instructions, the source code for IRHash, its evaluation and scripts to reproduce the results of the paper. OCI container images are also included so that the experiments can be executed directly. Alternatively, Dockerfiles are provided to build the images.

Hosting

The artifact together with detailed instructions is available under the DOI 10.5281/zenodo.15367568 on Zenodo.

Requirements

Only the ability to run OCI image container is necessary, e.g., Podman or Docker, since all steps run in containers for reproducibility.

A.1 Installation

There is no installation required. A detailed guide on how to obtain and run the containers can be found together with the artifact.

On-Demand Container Partitioning for Distributed ML

Abstract

As machine learning (ML) models grow in complexity and scale, distributed deployment across multiple devices has become essential for ensuring performance and scalability. However, the dynamic nature of distributed ML, where models must be frequently retrained, partitioned, and updated, exposes severe limitations in the current de-facto container-based model deployment. Specifically, the layered architecture of container filesystems is not well-suited for handling fine-grained model updates and partitioned ML deployments, leading to inefficient rebuilds and long delays. In this paper, we present 2DFS, a novel two-dimensional filesystem that enables independent updates, caching, and distribution of ML model components. We design and develop a complete ecosystem, including a builder, registry, and cache hierarchy, to streamline the build and deployment processes of ML models leveraging 2DFS. Our comprehensive evaluation of 14 real-world ML models demonstrates that 2DFS achieves up to 56x faster build times, 25x better caching efficiency, while providing on-demand image partitioning with negligible overhead. 2DFS is fully OCI-compliant and integrates seamlessly with existing infrastructures and container workflows.

1 Introduction

In recent years, machine learning (ML) has emerged as a dominant paradigm in modern applications, from real-time video analytics [40, 42, 80, 82, 92] to intelligent transportation/operations [14, 51], and has radically transformed the field of computing [5, 48, 64, 65]. The increasing complexity and size of the models powering these applications has created a demand for high-performance warehouse computing infrastructures offering significant resources [18, 67, 104]. As the applications become more nuanced, latency has emerged as a driving operational factor, which has led to the development of distributed ML frameworks [1, 15, 20, 74], ML model optimizations [22, 34, 51, 89, 92], and split computing [3, 32, 39–41, 43, 50, 54–56, 63, 66, 95], also enabling executions on relatively constrained devices outside of traditional data center environments [7, 51, 103]. ML models can be partitioned and distributed independently to fit real-time hardware availability. This also guarantees improved resource utilization in shared infrastructures as well as better scalability to fulfill increasing user requests.

Despite all the advances, *the practical deployment and management of these "optimized" models across distributed infrastructures remains a challenge* [9, 19, 23, 66, 68, 81]. Popular Machine Learning Operations (MLOps) frameworks, such as MLflow [71], TFX [94], and KubeFlow [52], offer robust support for the training, versioning, and lifecycle management of models. However, when it comes to actual deployment, these frameworks typically rely on container-based virtualization (more specifically, Docker) to package models and their dependencies. That is because containers encapsulate both runtime environments and application dependencies in a lightweight and portable manner [14, 21, 40, 40, 51, 88, 94, 108]. We argue that while containers, backed by the Open Container Initiative (OCI) [45], provide portability and isolation, they limit the real-world applicability of many distributed ML optimizations and model partitioning techniques. In fact, when model weights are embedded in the container images, model updates caused by continuous re-training require a new image build every time [14, 21, 51]. This limitation also affects solutions based on live model partitioning. These approaches optimize inference by splitting and parallelizing the model based on real-time infrastructure changes. Unfortunately, new containers must be built for each generated partition and each partition update [40, 108]. Solutions managing model parameters using on-demand download via MLOps frameworks are extremely difficult to cache and optimize in edge environments. Instead, approaches using container volumes require considerable manual effort to provision the necessary external storage. These solutions are expensive to realize in edge infrastructures, where hardware availability is scarce, networking is limited, and infrastructure ownership is heterogeneous.

In this work, we address these limitations by introducing `2DFS`, a two-dimensional container filesystem tailored to dis-

* Both authors contributed equally to this research.

tributed ML model packaging and deployment. The proposed solution exploits the well-consolidated container registries and runtimes technologies for caching and distribution of the image layers, the ML model parameters, and further any large file required by the container. This prevents developers from reinventing the wheel with no need to manually provision and manage their own storage solutions or use third party tooling. `2DFS` introduces a new `2dfs.field` container image layer type that decouples model weights and partitions from the traditional container layered filesystem. By organizing data into a two-dimensional matrix of independent "allotments", `2DFS` enables model components to be built, cached, and updated independently. Furthermore, it also enables on-demand partitioning of the images, enabling flexible split-computing deployments. Specifically, our contributions are as follows.

I. We propose `2DFS`, a novel extension to the OCI container format. It adopts a two-dimensional filesystem design where model components, encapsulated as `2dfs.field` layer, can be processed, cached, and updated independently. This eliminates the inefficiencies of traditional hierarchical layering, where even minor updates would trigger expensive rebuilds across the entire container.

II. We design and develop the complete `2DFS` ecosystem that includes several core components: a builder utility for construction of `OCI+2DFS` images, a partitioning operator for on-demand image partitions, and an OCI-compliant registry supporting the new layer type and functionalities.

III. We conduct a comprehensive evaluation of `2DFS` using 14 real-world ML models. The results demonstrate significant improvements in build times and caching efficiency compared to traditional OCI images built with Docker. Specifically, `2DFS` achieves up to **56× faster** build times and a **25× faster** image updates; and in some cases, such as with large EfficientNet-V2L model which allows 82 splits, 2DFS builds were up to **120× faster**.

Note that while `2DFS` is well-suited to distributed ML, it is not limited to such but has broader applicability in distributed computing field. For example, it can be used to efficiently package binaries in container images §5. The `2DFS` project is open-source and available on GitHub [10].

2 Background and Motivation

Containers have emerged as a de facto standard for packaging applications and dependencies and have seen widespread adoption in the industry. Furthermore, with the increasing sophistication of container management platforms, thanks to Open Container Initiative (OCI) standardization [46], the creation, execution, and sharing of container images has become more streamlined. Even in the context of ML applications, containers have become the preferred method for packaging and deploying ML models [13, 101, 102], as they provide a consistent runtime environment and simplify management, especially when dealing with diverse hardware and software configurations at the edge [24, 77, 88]. However, the current containerization methods have significant overhead for supporting distributed/split ML model deployment – particularly for model partitioning and continuous model updating tasks. To grasp these limitations, we first provide a brief overview of containers under the hood.

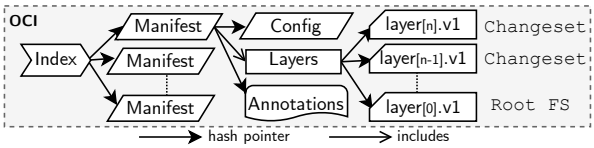

Figure 1: Cross-section of OCI image format.

2.1 Container Dissection and Lifecycle

Figure 1 shows the cross-section of an OCI image, which contains all necessary files to run a container. Internally, the image is structured as a Directed Acyclic Graph (DAG) composed of an `index`, a set of `manifests`, `config` files, and `layers`. A `manifest` represents an image tailored to a specific platform and contains references to the filesystem `layers` and a `config` file. A layer describes a filesystem change; starting from the `RootFS`, each layer updates, adds, or removes files from the previous layer. Layers are stacked on top of each other and joined together to form the container filesystem (e.g., OverlayFS [30]) A layer is stored as a compressed tarball called *blob* and referenced via a hash of their contents (the `digest`). When multiple containers are created from images that use identical layers, the layers are shared, reducing the storage overhead. Every change in a layer invalidates its hash, causing a cascade effect that propagates up to the `index`. The `config` file holds the container's configuration details, such as execution parameters and environment variables, along with the root filesystem changes expressed as a list of `DiffIDs`. A `DiffID` is the hash of an uncompressed image layer, not to be confused with the `digest` mentioned above.

A container image build process is handled by a builder component, which is composed of a front end and a back end. The front end parses the build file descriptor and converts it into a set of instructions that can be used by the backend. Let us take the example of Docker's builder component, `buildx`, which uses BuildKit [72] as the default backend. The `dockerfile` frontend takes Docker's build descriptor file (called Dockerfile [27]) and translates it to high-level `LLB` definitions. The BuildKit backend then creates the image's build graph from the definitions, and the `solver` component builds the container by executing the graph nodes one after another. At this stage, container layers are created as a result of file operations in the definition, such as copying files from the host to the container. Note that despite BuildKit being known for its optimized builder backends that can parallelize image builds, the process of layer generation is still sequential due to the nature of the filesystem operations.

2.2 The Rise of Distributed ML

Deploying ML applications can be challenging due to the high computational resources required by their underlying ML models [77, 82]. This challenge is more pronounced in edge computing environments, where machines are of heterogeneous hardware configurations and multiple applications share the resources [58, 61, 69, 92]. As a result, large ML models with several layers and parameters are often found unsuitable for edge infrastructures [68, 80, 91].

One approach focuses on designing compact models that are smaller and more efficient than their larger counterparts. Such models are developed using a combination of techniques such as using fewer network blocks/layers, blocks with fewer parameters, reducing the precision of model weights through quantization, removing unnecessary connections through pruning, and transferring knowledge from large models to smaller ones through distillation [14, 60, 66, 87, 89]. However, compact models often struggle to adapt to dynamic data distributions as effectively as larger models, making them susceptible to data drift and requiring regular updates [14, 22, 51, 81]. As such, these models require *frequent periodic retraining and updating* (as often as 30-50 seconds [51, 92]) to ensure they remain accurate and adaptable to edge environments.

Another approach is to split the large ML model into multiple parts and distribute them across multiple devices for parallel execution [39, 40, 50, 54, 66]. More specifically, the model is partitioned into several slices, each of which is deployed on a separate machine, forming an execution pipeline. An "early-exit" head can optionally be added to some of the splits [98, 100], providing the possibility of not processing all the splits until the end, trading accuracy with better response time. Table 2 shows the splitting potential of popularly used ML models, where some models can be split into as many as 82 layers. Recent work has explored its applicability in edge-cloud computing, where privacy or performance concerns dictate that the first few splits be processed at the edge, and intermediate information is sent to nearby and distant cloud infrastructure for further processing [54, 79, 95, 96]. However, model partitioning introduces new challenges, particularly in dynamic edge environments where the number of available devices can change over time due to failures, poor connections, or resource sharing with multiple applications [7, 61, 99]. Furthermore, since the hardware configurations of these devices are heterogeneous, the subset of model partitions that can be deployed on a device can vary [40, 103] – requiring flexible methods for distribution and deployment.

2.3 Containers for Distributed ML?

Almost all popular ML management frameworks, such as MLflow [71, 102], Flower [13], and SkyPilot [101], rely on containers for model deployment due to their agility and ability to replicate the runtime environment across different hardware configurations. The typical packaging process involves frameworks creating a container image that includes the ML model and its dependencies, which is then pushed to a central storage (registry) for distribution [13, 17, 44, 49, 51, 70, 71, 73, 76]. Each device periodically connects to the registry and fetches the updated images specific to their requirements.

# Images	Build Time (s)
1	81.67
20	113.78
41	157.64
62	149.92
82	242.66

Table 1: Docker build time with increasing splits of EfficientNet (`ENv2L`) across different images.

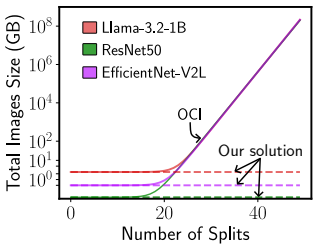

Figure 2: OCI image size explodes with increasing model splits, unlike our solution.

However, model optimization and partitioning techniques noted earlier do not function well for containerized models. Let's consider how split ML models can be distributed using containers. The obvious approach is to create a separate container image for each model partition (e.g., a model with 60 splits can be stored as 60 images). However, bigger devices might be able to compute larger chunks of the model or might provide better hardware acceleration for specific layers, therefore requiring a special image configuration. An ML cluster may also experience resource losses, and the splits must be re-computed to reduce the model fragmentation. The number of possible image configurations can grow exponentially with the number of splits. Additionally, computing these images for AI models can be an extremely time-consuming operation.

To demonstrate this, we conducted an experiment with the EfficientNetv2L (`ENv2L`) model, where we built an increasing number of Docker images while increasing the number of splits of a model. For example, 2 splits would result in 2 images, 3 splits would result in 3 images, and so on. Table 1 shows a significant increase in Docker image build time with increasing model splits – leading up to a 3× longer build compared to the 1 split use case. To combat this, one option could be pre-building all possible container images, ensuring that any requested subset of partitions is readily available for devices to pull from the registry. However, this approach becomes prohibitively expensive in terms of build time as well as the required storage space at the registry, as illustrated in Figure 2. Assuming we can map each model layer to a container image layer $l_i \in L$. Then, a model split is a container image where for each i, layer l_i is either included in the image or not. Each combination is an image manifest referencing the included layers, leading to 2^n combinations, where n is the number of splits. Thus, the combination of manifests required, as shown in the figure, explodes, leading to significant space overhead. We leave it to the reader to imagine the build time necessary to compute such a set of images. Moreover, if the build time is not enough of a concern, these models are also

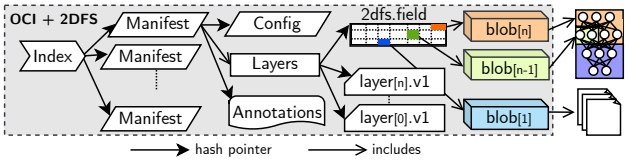

Figure 3: Cross-section of a 2DFS image.

frequently re-trained and updated – thus, the image build procedure must be repeated.

Alternative state-of-the-art solutions distribute model parameters by (a) independently storing and then mounting them to the containers as volumes or (b) downloading them on the fly. The former approach prevents data sharing across untrusted parties and requires considerable engineering efforts in edge environments where object stores are not widely available. The latter approach is transparent to the container runtimes, preventing efficient parameters caching and sharing across workloads but instead forcing the applications to download the parameters at startup every time. Local model registry caches can be used to mitigate bandwidth usage at the cost of additional resource usage.

2.4 Why 2DFS?

We believe that the limitations of containerized ML model distribution lie in the layered filesystem structure of container images, which is well-conceived for code and dependencies but not intended for large files, libraries, and drivers, resulting in severely bloated images [105]. This structure prevents the retrieval of on-demand data subsets and forces continuous container image rebuild for fine-grained file updates, which is expensive and time-consuming. For example, driver and library updates usually invalidate the cache of entire container images even if the underlying code did not change. On the other hand, by addressing content by digest, container registries offer an excellent mechanism for object retrieval. With this work, we aim to extend the OCI image format to recycle the well-known and commonly used container image registries to distribute not only code and dependencies but also binaries, model parameters, and any large file without affecting the complexity of the CI/CD pipelines. By building a specialized container layer offering independent file pointers, the ML model splits, drivers and dependencies can be independently cached in image registries and downloaded on-demand by container runtimes. Registries can then provide each client with image partitions, including only the necessary files, to avoid downloading bloated images.

3 2DFS System Design

2DFS is a two-dimensional filesystem build and distribution framework for containers. The first building block is the extension of the conventional layered filesystem used in container architectures, which often restricts optimization due to the linked nature of layer changesets. 2DFS introduces an additional layer type called 2dfs.field. Figure 3 shows a cross-section of an OCI container image with the new 2dfs.field layer type (OCI+2DFS). A field is a sparse hash-pointer matrix of *allotments* representing a self-contained, non-overlapping, and independent filesystem space. Each allotment links one or more files or, for instance, a split of a neural network. This design relaxes intra-layer dependencies, enabling more efficient filesystem distribution (see §3.1) and fast image builds with extremely high parallelism (see §3.2). The second important building block of the proposed system is the image partitioning operation, supported by the 2DFS compliant registry (see §3.5). This operation allows field partitions that can be retrieved independently. The sub-fields are serialized as regular OCI layers and are compliant with any existing container runtime. The two-dimensional design is well suited for flexibly partitioning ML models, allowing for more efficient and on-demand "best-fitting" deployments (see §3.4).

Figure 4 shows the end-to-end workflow of 2DFS container image specification, build, and distribution. At step ①, the developer specifies a base image and the allotments content (e.g., different model splits) with their position in the field via 2dfs.json descriptor file. For instance, model splits s1 and s2 are assigned to the allotments <0.0> and <0.1>, respectively. 2DFS builder (§3.2) extends a regular OCI image with a 2dfs.field (§3.1) layer and is responsible for (i) creating the filesystem, (ii) filling the field with allotments, (iii) attaching field to the image and (iv) caching the allotments. The extended image format, referred to as OCI+2DFS, is stored locally in the builder cache (§3.3) and can be pushed to a 2DFS-compliant registry (§3.5) in step ②. Developers can fetch partitioned images from the registry on-demand (step ③) by specifying the semantic tag in the pull request (§3.4). Note that the registry image partitioner only performs manifest operations on the pre-built allotments, restricting the partitioning overhead as much as possible. Upon receiving the image partition pull request (step ④), the registry serializes the image partition into a fully OCI-compliant image and serves it to the runtime *which can be used by any OCI-compliant runtime without modifications*.

3.1 2dfs.field layer

We extend the OCI Image Specification [46] to introduce 2dfs.field layer type as a new media type. As previously discussed, 2dfs.field is represented as a sparse matrix that organizes allotments in a grid structure. Among all the possible geometrical structures, this work represents a field as a 2-dimensional plane to simplify the definition of partitions and to easily map the structure of neural networks. In such a plane, allotments can be easily defined to contain model splits or can be graphically organized based on different use cases. Check §5 and Appendix A for further details. Inside the field, each allotment contains: (i) an index in the form of <row.column>, (ii) a digest, which serves as a hash-pointer reference to an OCI artifact, and (iii) the DiffID, represent-

  "owner": str
```

Listing 1: Description of the 2dfs.field manifest

ing the hash of the uncompressed content as defined by the OCI specification. Listing 1 illustrates the manifest description of 2dfs.field inside an image. OCI artifacts referenced by allotments are standard .tar.gz blobs that contain user-defined compressed content and are indistinguishable from regular OCI layer objects. The 2DFS builder (see §3.2) makes sure these blobs satisfy the following three properties: (i) they are commutative and can be applied in any order to a container filesystem without altering the final state, (ii) they can be cross-referenced across multiple fields, supporting efficient data sharing and caching across images, and (iii) they can be serialized as conventional OCI layers, ensuring seamless integration with existing OCI runtimes. Changeset operations in 2DFS closely resemble those in OCI layers. When a blob referenced by an allotment is updated, a cascade of hash invalidations occurs, requiring reconstruction of the field data structure. However, unlike intermediate layers in conventional container systems, where linked changesets force rebuilding all dependent layers, only allotments referencing modified files are updated, while the rest are served from the cache (see §3.3). For instance, if model split s1 in Figure 4 is updated, s2 allotment remains unaffected and will not be rebuilt in the new image. The next section details the 2DFS builder.

3.2 2DFS Builder

Starting from a regular OCI image and a 2dfs.json file descriptor, the builder composes the 2-dimensional field to create an extended OCI+2DFS image. The 2DFS builder consists of several components: (a) CLI utility, (b) image manager, (c) 2DFS filesystem serializer/deserializer, (d) cache manager, (e) exporter, and (f) compression utility. *CLI Utility* provides a range of commands to build, push, and manage both OCI and OCI+2DFS images locally. The core of the utility is the following build command:

```
tdfs build [base-image] [target-image] [flags]
```

Here, the base-image is a fully-compliant OCI image descriptor in the format registry/repository/image:tag. In case the registry or the tag is omitted, the tool defaults to Docker registry and latest, respectively. The command expects a descriptor file called 2dfs.json. The descriptor file contains a list of allotments defined by the user. For each allotment, the user describes the source files list and the destination path in the target image, as well as the row and column of the allotment in the field (see fig. 4).

The *OCI Manager* component is responsible for the lifecycle of an image within the builder – from its initial state as base-image to its final form as extended OCI+2DFS image. The build command utilizes the *OCI Manager* to retrieve the base-image, either from the local cache or from a remote registry, and then extend it with the 2dfs.field layer.

The *Cache Manager* handles the storage of image indexes, manifests, and blobs in the local caches, detailed in §3.3.

The 2DFS component generates the field data structure and its allotments based on the 2dfs.json descriptor. Its descriptor is parsed, and the referenced files are copied into temporary directories, which are structured according to the path hierarchy defined by the user. Each temporary directory is first hashed to generate a DiffID—the digest of the uncompressed layer, as per the OCI specifications.

The *Compression Utilities* compress the directories generated by the filesystem component into a .tar.gz file (referred to as a blob), which is cached and hashed. The blob hash, along with the DiffID, column, and row information, is used by the 2DFS serializer to create the allotments for the 2dfs.field layer. After the 2dfs.field layer is serialized, and the referenced blobs are successfully cached, the layer is appended to

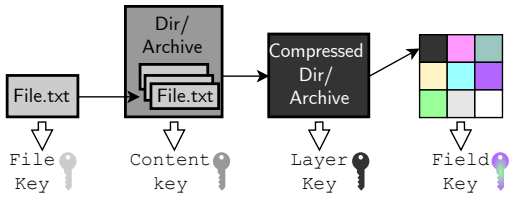

Figure 5: Caching layers architecture.

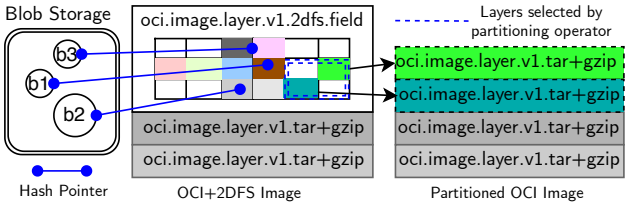

Figure 6: Example showcasing image partitioning.

each manifest referenced by the index. Since allotment generation is a platform-independent operation, the builder appends the new field structure to all manifest variants, regardless of OS or architecture – ensuring cross-platform compatibility. The corresponding `config` for each image is also updated to include all the `DiffIDs` for the allotments as if they are layered. This step is necessary to ensure compliance with the OCI runtime specification. If certain layers are removed from the image, e.g., due to image partitioning, the `config` is updated accordingly to reflect the modified image structure. The builder dynamically re-computes new config files using the `DiffIDs` embedded in the field's allotments. Modifying the manifest's layers and config file invalidates its hash-pointer reference at the index level, so the builder generates a new index file for the `OCI+2DFS` image to maintain integrity.

The *OCI Manager Exporters* use the updated index files to retrieve cache entries and package the new image. `2DFS` supports two exporters: tarball and registry. The tarball exporter can package either a full extended `OCI+2DFS` image or a partitioned image in plain `OCI` format. The registry exporter, on the other hand, pushes all image layers, fields, allotments, and blobs to a remote registry as OCI artifacts, utilizing standard REST API calls defined in the OCI distribution spec [45] to ensure compatibility with existing registries.

One key advantage of the `2DFS` build process is that it removes the need to mount the files into a running container to build and extract layers. This is possible because the `2dfs.field` layer only references static files used at runtime. As a result, the build process is significantly faster and scalable, particularly for large files, while minimizing disk I/O. Additionally, due to the independence of each file (allotment), the blobs can be built in parallel, further accelerating the build process.

3.3 Cache Hierarchy

The builder employs a multi-layer cache system to efficiently store files, allotments, and fields. Every time the *Cache Manager* modifies or creates an object, a hash of its bytes is generated, known as a cache *key*. This *key* uniquely identifies the object, allowing the builder to skip upcoming build stages if the *key* already exists. At each stage, the builder works with dedicated caching layers, generating or interacting with objects from previous stages.

Definition 1 *In a caching hierarchy, ranging from C_0 to C_j, the following rules apply when building a generic object o_i^k for each caching layer i with $0 < i < j$:*

R1. *o_i^k and key K_i^k are built from at least one object of C_{i-1}.*

R2. $$\begin{cases} C_i \leftarrow C_i \cup \{K_i^k : o_i^k\}; i \leftarrow i+1 & \text{if } K_i^k \notin C_i \\ i \leftarrow j & \text{otw} \end{cases}$$

For allotment generation, the build stages and corresponding cache operate as shown in Figure 5. At any level i in the hierarchy, a change has a cascade effect on the layers above. For instance, if a file within an allotment is updated, the following steps occur: (i) the file's *key* is invalidated, the builder copies the new file in a temporary directory used for the allotment build and the *key* of the uncompressed folder is generated (ii) the updated directory is compressed into a blob, generating another *key*; and (iii) the field is re-constructed. If a *key* matches an existing one during this process, the builder skips to the last cache layer and proceeds with the final stages of the build. Since allotments can be built independently, the `2dfs.field` is constructed from separate parallel build processes. Changes in the file structure trigger reconstruction of only affected allotments, resulting in significant build performance improvements (see §4).

The *Cache Manager* module is used by the *OCI Manager* component of `2DFS` builder. It employs *three* different cache storages for different object categories. The *Key Cache* stores intermediate keys for the file copying, allotment creation, and compression, which only serve as metadata for cache hierarchy. Note that the cache only stores the *keys* and hash-pointers referencing the blobs, which are instead stored in the *Blob Cache*. This cache contains every object in the builder except for the image indexes. Each object in this cache is named based on the `sha256sum` of its content, ensuring efficient content validation and easy retrieval using hash pointers. The media type for each blob in this cache is defined by its hash-pointer reference. This means that when a blob is retrieved from the cache, its media type is already known for deserialization, avoiding the need to duplicate this information elsewhere. Finally, the *Index Cache* stores the OCI index of all the images that are referenced via the hashed fully-qualified OCI name: `sha256sum(registry/repository/image:tag)`. Extended `OCI+2DFS` images are annotated with the name of the base image and a `"2dfs"` label indicating that the `2dfs.field` layer is present in the image DAG hierarchy.

3.4 Image Partitioning

The design of `2DFS` focuses on flexibility and ease of use. In a two-dimensional space, users are free to arrange ML models, files, libraries, and other resources to fit any area of

the field (Appendix A discusses this further). This design makes it easy for the user to select a subset of the field with only the desired functionalities. We call this process image partitioning, and it must allow retrieving only the necessary parts of an image on-demand, without needing to re-build or re-push any additional manifest. In 2DFS, partitions from the two-dimensional field can be easily extracted and serialized as regular OCI layers.

Definition 2 *Given a field F composed of allotments A where $F = A^{m \times n}$, a partition P is the union of subfields $P = \bigcup_i f_i$ where $f_i = A[f_i^{x_1} : f_i^{x_2}, f_i^{y_1} : f_i^{y_2}]; i, x, y \in \mathbf{N}; x \leq m, y \leq n$.*

Given a partition P, a 2DFS exporter can create an OCI bundle where the allotments composing the union of the subfields f_i are flattened into regular OCI layers. Figure 6 illustrates an example of the operation. The center shows the selected partition P of the 2DFS+OCI image composed of subfield $A[1:2, 4:5]$ spanning from <row 1.column 4> to <row 2.column 5>. This subfield only has two allotments (shown as different green shades). The image partitioning operation (i) fetches the corresponding allotment's blob from the local blob store, (ii) serializes the blob as regular OCI layers in the image manifest, and (iii) updates the manifest config file with the layer's DiffIDs. The result is the base image from the 2DFS build phase, without the special 2dfs.field layer, but with additional flattened allotments selected by the partitioning operator. To enable seamless image partitioning without additional registry endpoints, we define the partitioning operator as a semantic image tag, i.e., a string containing a special suffix defining the image operation.

```
registry/repository/image:tag--x1.y1.x2.y2
```

x1 and y1 are the coordinates of the top-left corner, and x2 and y2 the bottom-right corner of sub-field f_i (e.g., tag for fig. 6 partition is tag−−1.4.2.5). While only a 2DFS compliant registry can correctly parse the semantic tag, any runtime can use semantic tags to retrieve a partitioned image. The partitioning operators can be concatenated, allowing for an unlimited number of sub-fields for each partition. The sub-fields are parsed by the exporter or a compliant registry and transformed into the actual partition. The partition is processed to generate the requested image.

3.5 2DFS Registry

2DFS registry is an OCI compliant registry with support for .2dfs.field media type and partitioning operator. Starting from the open-source OCI implementation, we introduced the following updates:

1. *Partitioner*: Serializes the partition of an OCI+2DFS into an OCI manifest.
2. *Partitioning Operator Support*: Enables parsing of smantic tags for partitioning at the image/pull endpoint.
3. OCI+2DFS *Deserializer*: Provides support the 2dfs.field media type.

The *partitioner* efficiently generates OCI-compliant manifests and configs by fetching the OCI+2DFS image, decoding the 2dfs.field layer, and applying the selected allotments as OCI layers. It then removes the 2dfs.field layer, replacing it with standard layer descriptors, and it applies the layers DiffIDs to the rootfs of the image's config file. Finally, the new manifest is cached. When a semantic tag with a partition is detected at the /v2/<name>/manifests/<reference> endpoint, the tag parser triggers the *partitioner*, which fetches the manifest and generates the new partitioned image based on the requested subfields. The OCI+2DFS *Deserializer* extends the registry to handle 2dfs.field media types, leveraging distribution.UnmarshalFunc [25] type to deserialize and access the manifest content.

4 Evaluation

We evaluate the performance of 2DFS and compare it against Docker – the most popular container-building tool [28]. Since 2DFS is a completely new approach to layering, in most scenarios, multiple Docker images were used to simulate the same functionality of an OCI+2DFS image. For example, for *three* partitions of 2DFS image, we require *three* separate Docker images. In this evaluation, we focus on the continuous model updating and split computing use cases, where a ML model is stored as several partitions or splits. We compare the performance of 2DFS while varying the amount of splits of a model.

4.1 Experimental Setup

Build Infrastructure. All the build experiments are carried out with Docker runtime version 27.3.1 with containerd snapshotter and all default settings, such as buildx builder and BuildKit backend. The base image used for all the builds is the tensorflow/tensorflow image version 2.17.0. The image build is performed on a bare-metal server with 2× AMD EPYC 7302 16-Core Processors, 256GB DDR4 RAM, and 2TB 12Gb/s Solid State Drive. For the build, we compare the 2DFS builder (in §3.2) against the default Docker build command. The 2DFS compliant registry is hosted on a server running 1× Intel Core i9-9820X CPU, 128GB DDR4 RAM, 1TB NVMe 3.5Gb/s Solid State Drive. The machines are interconnected with a 1Gb/s Ethernet connection.

Edge Infrastructure. We created a distributed edge computing infrastructure consisting of 10 Raspberry Pi 4B (RPi) devices, each equipped with four ARM Cortex-A72 cores and 8GB of RAM. Additionally, we utilized a Linux PC with an Intel Core i7-4790 4-Core Processor and 16GB RAM as the gateway for our experiment in §4.5. All machines were interconnected via a 1Gb/s Ethernet switch. The gateway served as the controller for dynamically deploying different model splits on varying numbers of RPis, generating load, and aggregating output to calculate end-to-end response time. Notably, the gateway did not execute any model splits itself. The RPis rely on the remote server for cross-device clock synchronization.

Model	Label	Application	#Parameter	Total Size (MB)	#Splits	Avg #Params per Split $\pm\sigma$

Table 2: Overview of our Model Zoo which includes popularly used models for different application categories.

To ensure accurate timing measurements, we deployed a network time protocol (NTP) server on the gateway. This setup results in a maximum clock offset of approximately $\pm 100\mu s$ and a jitter less than $\pm 100\mu s$, allowing for precise device-to-device response time reporting. We perform all experiments 10 times and report the median across runs.

Model Zoo. Table 2 presents the model zoo utilized in our evaluation, comprising 14 models across three diverse application scenarios, including Object Recognition, Detection, and Segmentation. These models offer varying splitting options based on their architectural characteristics (cf. §4.1.1). The number of splits per model ranges from 18 to 82. The results are obviously expected to generalize to much larger models.

4.1.1 Generating Model Splits

To accommodate a wide range of models and offer a general solution, we employ the Keras API due to its ability to leverage multiple backends, such as PyTorch, TensorFlow, or JAX, catering to different hardware needs. We automatically generate the `2dfs.json` descriptor as a direct output of the model split generation. For all the models in the zoo, a descriptor shows the position of splits' weights and architecture in the two-dimensional structure. Our approach draws inspiration from previous work [40, 54, 92] on model slicing and is guided by three key principles:

1. **Minimizing output size.** We avoid slicing at branch or shortcut points, as this would require passing multiple tensors to the next device. Instead, we identify inherent information bottlenecks, typically located after aggregation layers (e.g., Add or Concatenation), which serve as suitable split points.
2. **Maximizing flexibility.** By introducing as many splits as possible while adhering to the first principle, we increase deployment flexibility and enable more efficient utilization of available resources.
3. **Balancing split inference times.** While not as critical as the first two principles, we strive to achieve a fair distribution of inference time across each split, ensuring that no single device is disproportionately burdened. Our end-to-end results on `MNv2L` (fig. 14) supports this goal.

Guided by these principles, our slicing strategy targets bottleneck layers whenever possible or, alternatively, those with relatively smaller output sizes compared to their neighbors as candidate split points. Each split was designed to contain two or three computationally expensive operations, such as various forms of convolution or fully connected layers. In certain applications, like object detection, the output of multiple splits may need to be transmitted and utilized in a later stage. We restructured these model graphs to transmit the necessary information directly to the specific split(s) that require it, thereby avoiding unnecessary data passing through all splits. Furthermore, whenever possible, we identified opportunities for parallel computation without tensor sharing and created separate splits to leverage these possibilities. For instance, a few blocks in `YOLOv3` have such a characteristic. By exploiting parallelism in the model graph, we can accelerate inference and improve scalability.

Our model slicing approach yields a varying number of splits across the 14 models in our Model Zoo (Table 2), ranging from 18 (e.g., `RN50`) to 82 (e.g., `ENv2L`). Each split can be deployed and containerized as a standalone application, enabling flexible deployment scenarios. We include in fig. 18 the parameter count and size distribution of different splits, showing the variability among models. Note that each split comprises multiple model layers. Each layer potentially has weights and biases that may change values after model updates or have distinct versions (e.g., `FP32`, quantized `INT8`) to accommodate diverse use cases. To comply with this dynamic nature, we detangle the split model architecture (computation graph) from the weights themselves to improve flexibility. We then apply `BZip2` compression to the splits and store them as separate allotments in the `OCI+2DFS` format.

4.2 Image Build

We begin by measuring the build performance of 2DFS and Docker builder. For each model in the zoo, we define a split capacity ranging from 0% to 100%. We define split capacity as the percentage of the splits we divide the model compared to the maximum allowed splits. For example, at 50% split capacity for ENv2L, we only generate 82×0.5=41 splits and divide the model into 41 portions instead of 82. With 0% split capacity, we do not split the model at all resulting in *one* large "split" representing the entire model. Each split is allocated in a separate 2DFS allotment or OCI layer. Therefore, an image containing YOLOv3 at 100% split capacity features 37 layers (RootFS + 36 splits), while an image with 100% split of ENv2L has 83 layers. We perform the experiments for all the models in the zoo, but only report results for a subset for brevity. We refer interested readers to Appendix B for the remaining results.

Figure 7 shows the results of build-time of 1 image with respect to split capacity %. On average, 2DFS builds OCI+2DFS images 16× faster than Docker with standard OCI images. Even in the base case of 0% split capacity, 2DFS is already outperforming Docker. For deep models with larger layer sizes, such as ENv2L, we observe a counterintuitive pattern in the Docker build. The build is slower when either the layers are too big (e.g., 0% split capacity) or the layers are too many (e.g., 100% split capacity), with a sweet spot at 50% split capacity. For smaller models, instead, Docker build time decreases somewhat linearly with the number of layers. This behavior hints that there is a tradeoff between layer size and layer number. Generally, it looks faster to build smaller layers until they are confined in numbers (E.g., less than 50 layers.). With 2DFS, we observe that the more we split, the faster the build time. The performance gap between the two build systems is related to how Docker handles the layer creation. Docker uses a build container to which all the files are copied during the build. Mounting the model weights into the build container and extracting a layer changeset is an expensive and time-consuming operation. Moreover, each layer operation is executed using the input mount point from the previous phase sequentially since Docker cannot know if the layer's applications are commutative. On the other hand, 2DFS exploits the allotment independence to parallelize the build process, thus escalating the cache hierarchy described in §3.3 for all the allotments simultaneously. The 2DFS builder runs under the assumption that a `2dfs.field` layer is immutable and only contains static files. Therefore, a build container is not necessary, and the allotments are computed locally, minimizing disk I/O utilization also for the 0% split capacity scenario.

With OCI+2DFS image format, we can retrieve on-demand any possible image split with a random partitioning. In fig. 8, we compare the build time needed to pre-compute multiple OCI images for each split. Because the total number of split and partition combinations would be unfeasible to build, we simplify the experiment by only building a small subset of possible image splits for Docker. In particular, we compute one Docker image for each split based on the Split Capacity. E.g., ENv2L50% split capacity in the context of this plot means that we partition the model in 41 splits, and we generate 41 different Docker images, one for each split, while only one OCI+2DFS image with 41 equal partitions from the original 82 allotments. Note that an OCI+2DFS image can actually generate up to 2^{82} different partitions with such split capacity, but it would be unreasonable to build so many Docker images as demonstrated in fig. 2. The results show an average of 56× faster build time for 2DFS, with a peak of 120× faster builds for the ENv2L model with 100% split capacity. The build time of OCI+2DFS in this experiment is constant and does not depend on the split capacity because we always build one image including all the allotments, while to achieve the same result with traditional OCI images, we need to build a new image for each split, increasing the build time manyfold.

Figure 9 shows the CPU and Memory usage of the builder machine measured during the experiment shown in fig. 7. The results show that while 2DFS and Docker have similar memory usage, 2DFS has higher CPU consumption, especially with higher image split capacity. With 0% split capacity, we observe similar consumption. The more we increase the split capacity, the higher the values of CPU usage. While 2DFS builder computes each allotment's DiffID and blob simultaneously, which are both CPU-intensive operations, Docker performs these operations in sequence, resulting in lower CPU usage but longer builds. It is worth noting that even if, in this experiment, Docker shows up to 20% lower CPU consumption over the build time, 2DFS build time was on average 16*x* faster, resulting in an overall lower total CPU time.

4.3 Image Download and Partitioning

We now evaluate the overhead caused by the partitioning operation at the registry compared to pull of traditional OCI images. Figure 10 compares the download time of four different partitions for the ENv2L and RN50 images, each containing respectively 25, 50, 75, and 100% of the total splits. For Docker, we pre-compute the splits, and we push all four images to the registry independently. For 2DFS, we just push to the registry a single OCI+2DFS image and ask for an on-demand partition every time. The pull requests are performed on a separate worker machine using the Docker CLI. We observe how the on-demand partitioning is performed by the registry with minimal overhead, leading to a comparable total download time with on average only 20 *ms* additional latency.

Figure 11 shows the bandwidth usage at the client side during the download of the pre-computed OCI images built using Docker versus the OCI+2DFS partitioned image. The result shows comparable bandwidth usage across the two approaches. Therefore, serialized allotments bring negligible overhead in terms of download time and data rate.

Figure 12 shows the CPU usage at the registry side during the download of traditional OCI images built using Docker and

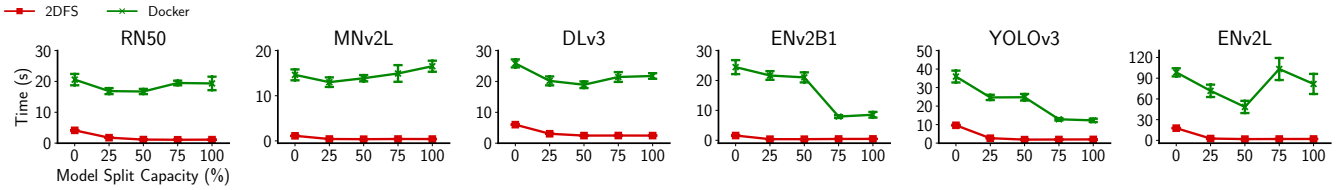

Figure 7: Build time for a single image with increasing number of splits per layer.

(a) Top-down update strategy.

(b) Bottom-Up Update Strategy.

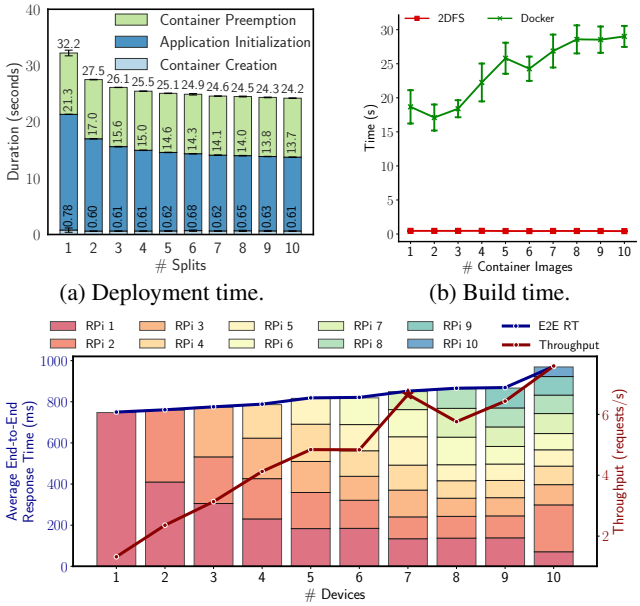

Figure 13: Build time after model updates with image caching.

2DFS images. With these measurements, we try to quantify the computational overhead of the on-demand partitioning operation compared to the download of pre-computed images. The results show that the registry CPU usage is comparable across the two approaches, with a slight increase for the 2DFS images of 1% after the 50-th percentile. This gap represents the CPU overhead of the on-demand partitioning operation and the serialization of the field's allotments into OCI layers. We also measure the memory overhead at the registry, but we omit the results as we do not observe any significant difference between the two approaches.

4.4 Model Updates

As mentioned in §2.2, some parts (i.e., splits) of a model, particularly in smaller models, may receive frequent updates to comply with the accuracy demands as they experience distribution drift. In this section, we evaluate the effect of model updates on the image rebuild. For each image in the model zoo, we build a baseline version where each split is placed on a different layer. Then, we update increasingly 25%, 50%, 75%, and 100% of the model splits with newer versions and re-perform the build of the images. This operation commonly happens after model re-training. This experiment measures the caching efficiency of each builder. Better caching strategies lead to lower build times. In 2DFS, the position of the allotment that needs to be updated does not affect the build time due to the independence property. Each allotment that has not been updated will skip the cache hierarchy as described in §3.3. On the other hand, in Docker, the position of the layer that needs to be replaced affects the cache invalidation and drastically increases the build time. Therefore, we compare two different configurations, one where the updated layers are placed at the top of the image and one where they replace the bottom layers of the image.

Figure 13 shows the results of the experiment. On the left side, we have the results obtained by starting the updates from the top layers, while on the right, the results while updating the layers from the bottom. As expected, Docker build time is relatively more efficient when updating the layers from the top, as Docker is able to cache the bottom layers successfully. However, the build time is, on average, 25× slower than 2DFS. The worst case scenario for Docker is when the layers are updated from the bottom, resulting in a 75× slower build time compared to 2DFS. Interestingly, in this latter scenario,

(a) Deployment time. (b) Build time.

(c) Response time & throughput.

Figure 14: Performance of distributed `MNv2L` over increasing number of devices and model splits.

the more layers we update, the faster the build gets. This is related to the way Docker invalidates the cache for the layers above and re-computes one layer after the other. We observe that for the bottom-up update scenario, the compression time increases with the number of updated layers while the layering time decreases. The layering time includes all the operations prior to the layer compression, such as cache invalidation, content copy, and changeset computation. We conclude that in the current Docker implementation, it is faster to rebuild the image from scratch than to perform a bottom-up update. When updating the image layers from the top, the compression and layering time grows linearly as expected. The `2DFS` build time is growing linearly with the number of updated layers but at a slower pace, showing a better caching efficiency.

4.5 Split Computing Performance

Another scenario of interest besides continuous model updates is the split computing phenomenon §2.2, where due to different reasons such as privacy and/or scalability, a model is split into multiple parts, and each device serves only a subset of the model. This inherently provides an opportunity for pipeline parallelism as we enable it by default. In this section, we evaluate the performance of the `MNv2L` model in a distributed Edge Computing testbed. We deploy the model on a set of Raspberry Pi devices, ranging from 1 to 10, each running a different split of the model. Every time a device joins the experiment, the image splits are re-computed uniformly to fit the new number of devices. For each new device, a new image split must be computed for traditional `OCI` images, while for `OCI+2DFS` images, we can simply request the new partition from the registry. We measure (i) E2E RT, which refers to the average end-to-end response time, (ii) throughput of the deployed system, which is the number of requests per second that it is able to fulfill, (iii) deployment time and (iv) build time of the images for the different splits.

Figure 14c shows the inference performance results. `RPi x` refers to the average time a particular Raspberry Pi device takes to process its split, including the communication and queuing delay. Observe how the end-to-end response time increases linearly with the number of devices. The model fragmentation and the additional networking overhead are the main contributing factors. On the other hand, the total throughput of the system increases steeply from less than 1.3 to 7.6 requests/s. Model fragmentation allows constrained devices to compute their splits, avoiding CPU throttling and memory exhaustion issues. Moreover, model splitting can improve the overall system scalability.

Figure 14a is showing the overall deployment time breakdown for the `MNv2L` model. This experiment does not include the download and partitioning time as it assumes that Docker images were pre-computed. The results show a logarithmic decrease in build time, mainly caused by the application initialization and the container creation. Smaller model sizes are faster to decompress, especially on constrained hardware, resulting in an overall speed-up of the deployment process.

Figure 14b shows the time to build the new image split for each device joining the experiment. Build time for `2DFS` is constant as only one image is generated at the beginning, and the new splits are requested on-demand. On the other hand, the build time for the Docker use case increases based on the number of images that need to be generated every time we need a new split. On some occasions, such as when generating images for 2 and 6 devices, the build time results are lower than expected, probably related to a discrepancy in the split sizes, which can lead to faster build times. The relative build time difference between the two approaches shows that `2DFS` build is 55.9× faster. We omit the total build time because it is not comparable across the two approaches; in fact, for this simple example, we had to build 55 OCI images but only a single image for `2DFS`.

5 Discussion and Future Directions

While our primary focus is on providing an efficient and standard packaging framework for the mainstream distributed ML, there are additional application scenarios for `2DFS` that are available straight out of the box. Conducting separate evaluation experiments of these applications is unlikely to provide new insights beyond those already presented in the previous section; thus, we discuss them here and refer to relevant evaluations when applicable.

Other ML Architectures. `2DFS` is not limited to the models provided in the Model Zoo. Indeed, it is a general solution, and one can use any model or set of models together with `2DFS` to streamline data propagation and parallel executions in a standard containerized way. This includes autoencoders, recurrent neural networks, and generative AI such as diffusion models

and large language models (LLMs). For instance, LLMs heavily rely on distributed inference infrastructure across several machines [4, 35, 83, 84, 107], a practice essential for scalability and for supporting massive models like Llama 3.1 with up to 405 billion parameters [38]. Integration of `2DFS` and LLM libraries like vLLM [53], DeepSpeed [4, 86, 93] and the Kubernetes-native `llm-d` [62] comes with foreseeable advantages such as facilitating LLM distributed serving pipelines by leveraging (i) `OCI+2DFS` images for efficient packaging of inference code and model parameters, and (ii) on-demand partitioning for distributing model shards. This combines LLM serving with the simplicity and scalability of self-contained microservice applications.

Additional ML Usecases. In the context of ML applications, several scenarios emerge where `2DFS` is advantageous. For instance, in ML serving systems, dynamic application demands (e.g., varying latency and accuracy requirements), different backends, and numerous model sizes lead to thousands of *variants* of the same base model and corresponding Docker images [88]. This calls for a more efficient packaging framework that can decouple these different models; this is where `2DFS` excels. In fact, each variant can be treated as a separate set of allotments, and significant gains can be achieved as demonstrated in §4.4.

Along similar lines, the concept of bloated vs. debloated ML containers [105] highlights the issue of oversized Docker containers with potential vulnerabilities due to the inclusion of various packages and toolchains during different stages (design, training, serving) of an ML application's lifecycle. `2DFS` offers a straightforward solution by facilitating the separation of these stages into distinct partitions. Appendix A illustrates ML packaging in more detail.

Further, another line of work [7, 85, 97] aims to reduce the communication overhead in tensor parallelism by constructing sparsely distributed sub-models. These works along with multi-model pipelines where an application is constructed of multiple ML tasks present another compelling use case for `2DFS`. Instead of relying on several docker images, or worse, a bulky image with redundant blobs, it packages everything into a single image. Each device only pulls the needed parts, resulting in reduced build, download, and deployment times §4.3.

Frequent ML Model Updates. One of the most critical aspects of containerized ML is the container build time, hindering the propagation of ML model updates. Often, platforms prefer to rely on object stores [36], just to avoid frequent container re-builds, which are slower. However, this practice requires customized release pipelines and has severe limitations in edge environments, as discussed in §2. Khani et al. [51] show how real-world continuous re-training for object-detection models such as MobileNetV2(`MNv2`) and ResNet50(`RN50`) can lead to model updates arriving every 30 seconds or even faster. For `RN50`, a relatively small model, in fig. 13, we show how traditional container updates on production-grade hardware can span between 6 and 20 seconds, depending on where the layer update happens, slowing the effectiveness of continuous re-training manyfold. On the other hand, `2DFS`, is able to build such images in 1 to 1.5 seconds, up to 13*x* faster. For larger models such as EfficientNetV2L(`ENv2L`), the gap increases further up to 75*x* faster rebuild. These results highlight how `2DFS` opens an unprecedented opportunity to utilize containers for model packaging and caching even in highly dynamic environments with frequent model re-train.

Broader Applications. By design, `2DFS` is a general-purpose solution applicable to diverse scenarios that require flexible and efficient packaging. An interesting use case is the management of fat images [2], where containers are built with extensive binaries, libraries and other application requirements, e.g. analytics utilities to full-blown networking libraries like ServiceRouter [90]. In traditional systems, any update to a single binary requires rebuilding the entire container, which is not only a resource-intensive process but can also take several hours to complete. With `2DFS`, separate allotments can contain different binaries and libraries, allowing teams to update specific components independently, while improving deployment efficiency. This capability significantly accelerates the DevOps workflows, enabling continuous integration and deployment practices to operate at a much finer granularity.

Future Directions. In addition to the above-mentioned scenarios, `2DFS` has potential operational benefits in microservice packaging/deployment in edge computing environments [12] and for federated learning workloads [13]. However, `2DFS` also has several limitations to be considered. `2DFS` is currently limited to supporting only OCI images, which, despite being an established standard, restricts its compatibility with other formats such as the conventional `vnd.docker`. While the number of `2DFS` allotments is potentially unlimited, leaving developers total freedom in how to architect the field, traditional OCI runtimes can only handle a maximum of 127 container layers. Therefore, to maintain compatibility with runtimes like Docker, the `2dfs.json` descriptor must be designed in a way that limits `2DFS` partitions to a maximum of 127 allotments per partition. This still allows fine-grained parameter caching but can be a limitation for developers dealing with extremely large models. In the future, we plan to address these limitations and extend the system by (i) exploring alternative field form factors and layouts to optimize both performance and usability, (ii) developing a `2DFS` storage driver to overcome the layer limitations imposed by current file systems, and (iii) designing a system-specific runtime that dynamically retrieves model partitions based on file system access patterns. For instance, a future direction can aim at extending container runtimes to better support use cases requiring more than 127 layers and optimize how allotments are handled within the container runtime storage driver [29].

6 Related Work

Distributed ML serving needs model partitioning. Related work on distributed ML serving can be categorized into two main avenues. One focuses on splitting models between edge devices and cloud servers to reduce data transmission latency and improve privacy [3, 32, 39–41, 43, 50, 54–56, 63, 66, 95]. Techniques vary in their partitioning strategies, often driven by specific objectives such as energy efficiency [50, 59], bandwidth, latency, or privacy [47, 79]. Some works employ early-exit mechanisms for generating predictions on edge devices [63, 92, 95]. Others propose creating multiple versions of partitions to adapt to changing network conditions [22, 43] or utilize idle machines over the Internet for large language models [16]. The second line of research targets deploying small models on distributed edge computing devices, often considering scenarios like self-driving cars [14, 51] or multiple audio and video analytics applications [22, 92]. These works address the capacity gap between smaller and larger models through model adaptation. Some proposals involve deploying models or splits on various devices and aggregating results to achieve desired accuracy [6, 7, 97, 100, 103], while others focus on efficient model update strategies, such as training only the final layers of models [51], freezing 70-90% of layers during retraining [14, 22], or dynamically selecting a portion of model partitions to process and applying early-exit to maintain Service-Level Objectives (SLO) requirements [92].

ML Serving meets containers. Containers have become ubiquitous as they offer isolated runtime environments, ensuring consistent behavior across different dependencies and platforms [14, 21, 40, 51, 88, 108]. However, most MLOps frameworks overlook the unique challenges of Distributed ML [8, 9, 11, 13, 19, 31, 33, 37, 57, 71, 75, 78, 106]. These frameworks assume that packaging is a solved problem, neglecting the complexities of dividing ML models into multiple parts for efficient adaptation and distribution across devices.

Our work highlights the need for a more comprehensive and efficient approach to packaging in Distributed ML. While there are numerous proposals addressing various aspects of Distributed ML, we found no existing packaging tool that natively supports its requirements. This gap underscores the importance of our solution.

7 Conclusion

In this paper, we introduced `2DFS`, a two-dimensional filesystem build and distribution framework designed to address the inefficiencies of existing container-based systems for distributed ML. Our design enables independent updates of model partitions by decoupling them from the traditional layered structure, offering substantial improvements in both build and deployment efficiency. Through our comprehensive evaluation, we demonstrated that `2DFS` provides significant performance gains – achieving on average *56× faster build times* and *25× better caching efficiency* compared to Docker and regular OCI images.

Appendix A Packaging ML Models

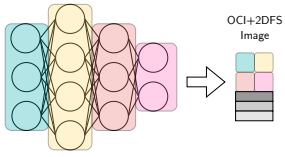

Figure 15: ML Model Packaging Example.

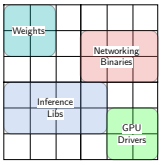

Figure 16: High Level Space Partitions.

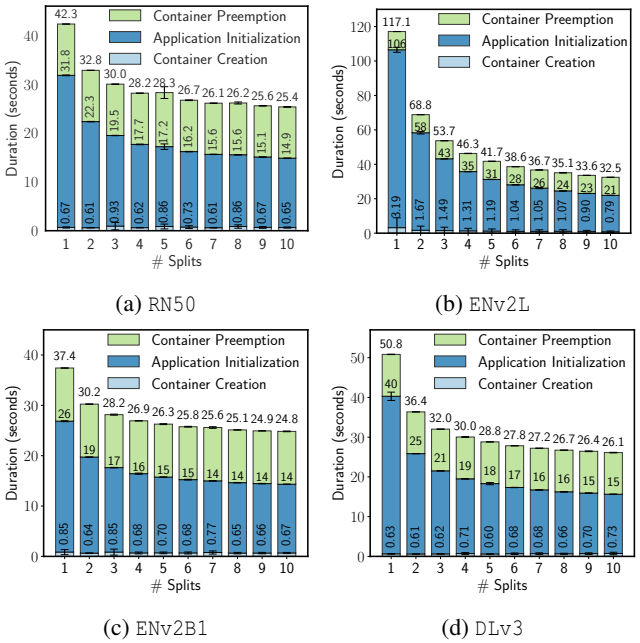
As for traditional containers, also in 2DFS the build and caching efficiency depends on the best practices on how to design the 2D space. When building a traditional Docker image the user uses a Dockerfile to define the operations composing the layers of the image. The order of the instruction heavily impacts the performance of the build as well as the wasted space in the final image. Docker provides a set of best practices to follow when designing a Dockerfile [26]. 2DFS performance heavily on the allotment sizes. The smaller the alltoments, the better the parallelization at build time and caching efficiency. For large models, we suggest splitting the model layers into separate files even if the model does not support partitions. This way, selective model updates invalidate only part of the 2D field, speeding up the build process. Figure 15 shows an example of a very simple model split technique that can significantly improve the 2DFS performance. By simply splitting the fully connected layers into separate files, we can package these files as independent allotments.



In more advanced usecases, the 2D space can be organized into scope-based partitions. E.g., in fig. 16, we place the model weights in the top-left corner, the networking binaries in the middle, the inference libs in the bottom left, and the GPU drivers in the bottom-right corner. Suppose the model is executed on a device without GPU; the bottom right corner can be left out of the partition. Alternatively, during training, we can remove the inference libs and networking binaries.

Appendix B Additional Results

		Split Capacity %				
Model	Format	0	25	50	75	100
ENv2L	Docker	451.84	451.88	451.92	451.97	452.00
	2DFS	451.68	451.69	451.70	451.72	451.73
RN50	Docker	124.87	124.88	124.89	124.89	124.90
	2DFS	124.64	124.64	124.65	124.65	124.65

Table 3: Exported Image Sizes Comparison with Different Split Capacities.

Figure 18 shows the parameter count and size distribution of different splits, showcasing the variability among the models of the zoo (Table 2). Note that although the splits closer to the end of a model comprise more parameters, this does not translate 1:1 to additional computation.

(a) RN50 (b) ENv2L (c) ENv2B1 (d) DLv3

Figure 17: Deployment time breakdown for different numbers of splits / available devices for two small (RN50 and DLv3), one medium (ENv2B1) and one large (ENv2L) models.

Figure 17 complements the experiments in §4.5 and it's showing the deployment time of RN50, ENv2L, ENv2B1 and DLv3for different numbers of devices. The number of splits equals the number of devices, and the image layers are homogeneously distributed across the splits. The deployment time is broken down into the time required to download the image, the time required to unpack the image, and the time required to start the application. The deployment time decreases logarithmic with the number of splits as shown also in fig. 14a. ENv2Lis showing a steeper performance improvement because, on the constrained Edge devices, the initialization phase is much slower when too many parameters are handled in a single node. With ten splits, we observe a 3.5× faster deployment time.

Figure 19 complements the results from fig. 7 with the models omitted for brevity. The results show the same Docker trends, with the small models showing little variation, the medium-sized models showing a build time decrease with a higher number of splits, the large model showing their best build performance at around 50% split capacity, and then higher build times towards 75% and 100%. As explained in §4.2, for Docker, the is a tradeoff between the number of layers and the size. 2DFS performance improves consistently with the number of allotments, plateauing at around 50%, hitting the I/O disk capacity.

Figure 20 complements the results from fig. 8 with the models omitted for brevity. The results show the same Docker trends, with build time consistently increasing when more

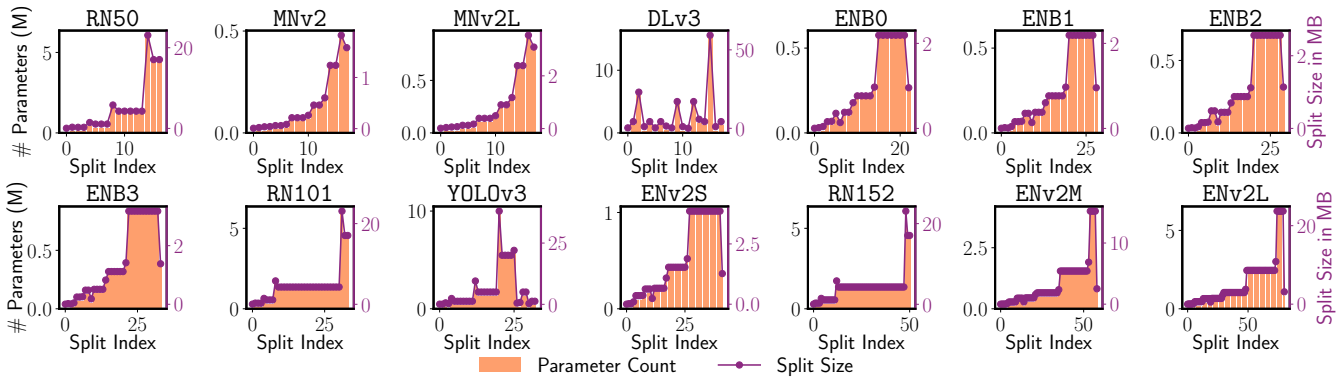


Figure 18: Per-Split Parameter Count and Byte Size.

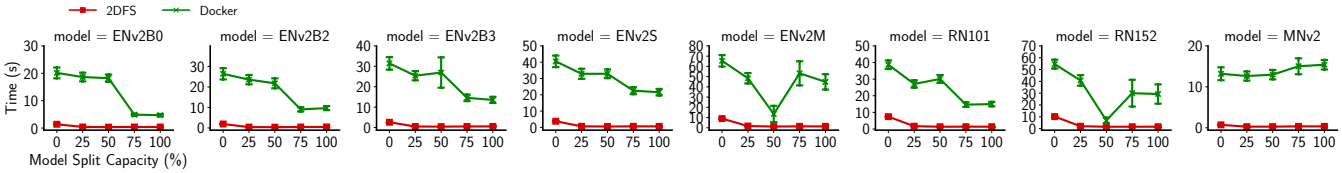

Figure 19: Build Time of 1 Image with Different Amount of Splits per Layer

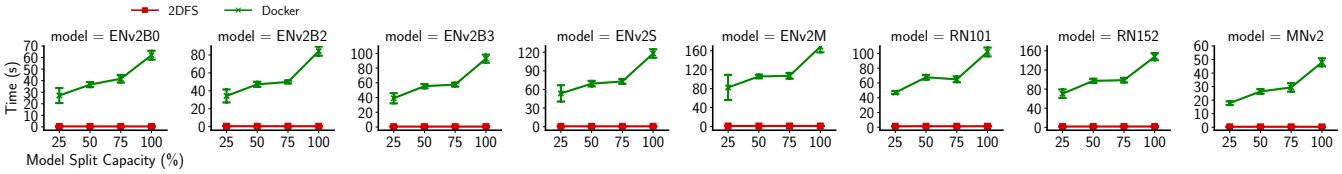

Figure 20: Images Build Time for different Split Partitions - 1 Image per Partition with Uniform Partitions.

images are generated. `2DFS` shows almost constant build time because it always generates the same `OCI+2DFS` image.

In §B compare the size of the exported `OCI+2DFS` image and the traditional `OCI` images to measure the space overhead of the new additional `2dfs.field` layer. We build the images for the `ENv2L`and `RN50` models with different split capacities, the same as previously done in fig. 7. For each split capacity, we build and export in `tar.gz` format one OCI image using Docker and one `OCI+2DFS`. The images show comparable sizes, with no additional space overhead for the `2dfs.field` layer. This happens because the two-dimensional data structure introduced is serialized as an array of hash-pointers + metadata, efficiently replacing the traditional OCI layers.

PathWeaver: A High-Throughput Multi-GPU System for Graph-Based Approximate Nearest Neighbor Search

Sukjin Kim Seongyeon Park Si Ung Noh
Junguk Hong Taehee Kwon Hunseong Lim Jinho Lee

Seoul National University

Abstract

Graph-based Approximate Nearest Neighbor Search (ANNS) is widely adopted in numerous applications, such as recommendation systems, natural language processing, and computer vision. While recent works on GPU-based acceleration have significantly advanced ANNS performance, the ever-growing scale of datasets now demands efficient multi-GPU solutions. However, the design of existing works overlooks multi-GPU scalability, resulting in naïve approaches that treat additional GPUs as a means to extend memory capacity for large datasets. This inefficiency arises from partitioning the dataset and independently searching for data points similar to the queries in each GPU. We therefore propose PathWeaver, a novel multi-GPU framework designed to scale and accelerate ANNS for large datasets. First, we propose pipelining-based path extension, a GPU-aware pipelining mechanism that reduces prior work's redundant search iterations by leveraging GPU-to-GPU communication. Second, we design ghost staging that leverages a representative dataset to identify optimal query starting points, reducing the search space for challenging queries. Finally, we introduce direction-guided selection, a data selection technique that filters irrelevant points early in the search process, minimizing unnecessary memory accesses and distance computations. Comprehensive evaluations across diverse datasets demonstrate that PathWeaver achieves 3.24× geomean speedup and up to 5.30× speedup on 95% recall rate over state-of-the-art multi-GPU-based ANNS frameworks.

1 Introduction

Various fields, such as computer vision [11, 34, 39], recommendation systems [13], natural language processing [35, 58], and information retrieval [17], utilize datasets consisting of multi-dimensional vectors representing larger data entities (e.g., image, text). These representations are used to efficiently retrieve data relevant to the input queries in various applications. One solution to finding k-closest data points (vectors) is k-Nearest Neighbor Search, where the k-closest data points are selected from the entire dataset based on the user-defined similarity metric, commonly the L2 distance. However, as the dataset grows, finding the exact solution becomes increasingly difficult due to the curse of dimensionality [15, 28, 38]. To address this challenge, Approximate Nearest Neighbor Search (ANNS) has been widely adopted, especially by products such as vector databases [2, 3, 5, 6, 18, 55]. ANNS performs nearest neighbor search on large datasets with reasonable execution times while maintaining high accuracy.

Among various ANNS solutions [23, 27, 32, 48], graph-based methods [20, 21, 40, 41, 54] have gained significant attention due to their ability to effectively represent neighbor relationships between data points. This representation allows for evaluating fewer data points while achieving higher accuracy compared to alternative methods [56]. Consequently, there has been a growing body of work on optimizing graph-based ANNS performance across diverse hardware platforms. While CPU-based optimizations [9, 12, 16, 22, 42, 43, 61, 64] offer algorithms that maintain accuracy, they are limited by the number of available cores, hindering their scalability when processing large, high-dimensional datasets that demand extensive computation and memory access.

To address such a computational burden, recent works [25, 31, 41, 44, 50, 53, 65] propose GPU-optimized search techniques to leverage the high-performance capabilities of GPUs. A prominent example is CAGRA [44], which accelerates single-GPU search by efficiently computing the L2 distance between queries and data points. It further leverages hash tables to eliminate redundant computations while optimizing for the GPU's thread and memory hierarchy. Another example is GGNN [25], which partitions large datasets into smaller, independent graphs that fit within a single GPU. This enables data-parallel searches across multiple GPUs.

While these approaches demonstrate significant performance improvements over CPU-based solutions, we identify key bottlenecks that hinder their ability to fully exploit the potential of GPUs:

- **Existing multi-GPU solutions suffer from low scale efficiency.** Prior works [25, 31] divide the dataset across GPUs to support ANNS on large datasets with GPUs, with each GPU independently processing queries (i.e., graph sharding). While this approach enables handling large datasets on GPUs, it requires each query to be processed multiple times across different GPUs, resulting in a low scale efficiency.
- **Majority of random initial nodes turn out to be unnecessary later.** To quickly search for near-optimal data points, existing approaches [41, 44, 50] rely on starting searches from numerous random initial points. However, due to the underlying beam search method, most of the neighbors explored from those random initial points are quickly discarded within a few iterations, leaving only descendants of the few best points. This incurs too much computational and memory overhead for the search, which is unnecessary for the final result.
- **Each iteration mandates too much overhead.** Visiting a vertex in a proximity graph yields distance computation with all its neighbors. Given that the typical degree of proximity graphs is around a few tens, this is a huge burden to the search. However, many of these neighboring data points are not selected as part of the top-k results, leading to unnecessary memory access and computation that hinders overall efficiency.

Based on these observations, we introduce **PathWeaver**, a multi-GPU framework designed to support graph-based ANNS on large datasets with scalable performance with minimal accuracy loss. PathWeaver is carefully designed to address the limitations above while exploiting the parallelism of GPU resources.

To address the scalability limitations of sharding-based multi-GPU search, we leverage our finding that each shard's seemingly independent search operations can be optimized by sharing intermediate search results with the following shard. We propose **pipelining-based path extension**, a mechanism that passes the search results of each shard to the next GPU in a pipelined manner. This enables subsequent GPUs to start their search from data points closer to the query within their shard, effectively reducing the number of search iterations only with negligible inter-GPU communication cost. One limitation of pipelining-based path extension lies in the first stage, whose search still has to be done from scratch. Our second scheme **ghost staging** addresses this issue by selecting more optimal starting points for each shard by prioritizing data points closer to the query, thereby improving the efficiency of the first stage. Finally, we propose **direction-guided selection**, which skips distance calculations for neighbors whose direction from the parent node significantly deviates from the direction toward the query. This approach further minimizes unnecessary distance computations, reducing both computational and memory overhead.

We implement the proposed techniques in **PathWeaver** and conduct extensive experiments on large datasets. PathWeaver improves the performance by 3.24× geomean speedup compared to the state-of-the-art GPU-based ANNS baselines at 95% recall rate, demonstrating its scalability and effectiveness.

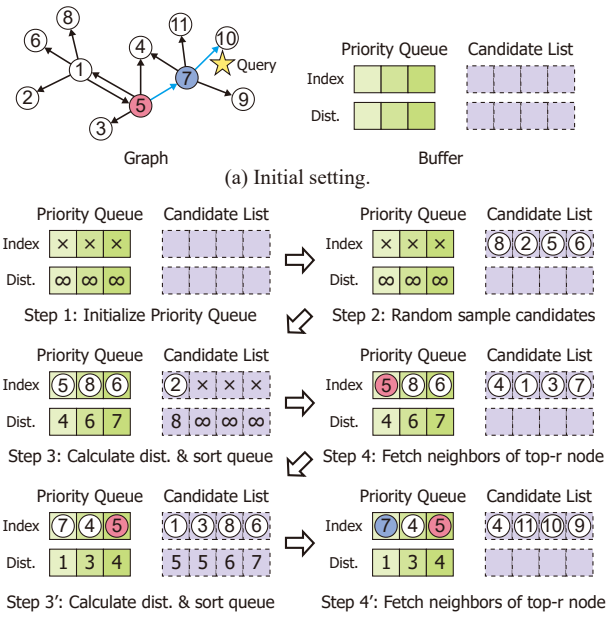
2 Background

2.1 Approximate Nearest Neighbor Search

Given a dataset $\mathcal{D} = \{x_0, x_1, \cdots, x_{n-1} \mid x_i \in \mathbb{R}^d\}$ with n data points represented as d-dimensional vectors, and a query $q \in \mathbb{R}^d$, k-Nearest Neighbor Search (k-NNS) identifies k data points $N_k(q)$ that satisfies the following:

$$N_k(q) = \underset{\mathcal{S}\subset\mathcal{D},|\mathcal{S}|=k}{\operatorname{argmin}} \sum_{x_i\in\mathcal{S}} dist(q, x_i), \tag{1}$$

where $dist(q, x_i)$ is the similarity measure between the query and data point, typically the L2 distance. As the size of $\mathcal{D}$ grows, performing exact k-NNS becomes computationally expensive due to the substantial memory access and computation overhead. To address this, many applications adopt approximate nearest neighbor search (ANNS), which employs efficient algorithms to approximate k-NNS results with significant reductions in execution time [37].



Among the various ANNS algorithms, graph-based ANNS [20, 21, 40, 41, 54] has been widely used due to its ability to effectively capture the relationships (distances) between data points [56]. Graph-based methods construct a proximity graph $\mathcal{G}$ where nodes represent data points and edges encode distances between them, allowing for compact representations of relationships and facilitating efficient graph traversal to approximate k-NNS results. Assuming that $\mathcal{G}$ is pre-constructed, the proposed PathWeaver targets accelerating the graph search process itself, addressing key inefficiencies and scaling challenges associated with large-scale datasets.

2.2 Approximate Nearest Neighbor Search Method on GPUs

Graph-based Approximate Nearest Neighbor Search (ANNS) algorithms have gained significant traction due to their ability to efficiently navigate complex datasets by leveraging graph structures. We briefly explain the overall search algorithm [44] on a constructed graph $\mathcal{G}$, as illustrated in Fig. 1a, to provide context for our optimizations. Note that many graph-based search algorithms [25, 53, 65] follow a similar workflow.

The graph-based search operates on two key data structures as shown in Fig. 1a:

- A *priority queue* $p = \{p_0, p_1, \ldots, p_{l-1}\}$ of size l, which stores the top-l ($k \le l$) intermediate nodes sorted by their distances to the query q.

(a) Initial setting.

(b) Stepwise execution of GPU-based ANNS.

Figure 1: Overview of approximate nearest neighbor search on GPUs.

- A *candidate list* $c = \{c_0, c_1, \ldots, c_{m-1}\}$ of size m, which acts as a buffer to hold the neighbors of the nodes being processed.

Given these structures, the algorithm iteratively refines the search process as depicted in Fig. 1b:

Step 1 The algorithm begins by initializing the priority queue p with dummy indices with ∞ distances.

Step 2 The candidate list c is populated with m randomly selected nodes from the graph.

Step 3 The distance $dist(q, c_i)$ is computed for each candidate node $c_i \in c$ using:

$$dist(q, c_i) = \|q - c_i\|_2, \tag{2}$$

where elements of the priority queue p and the candidate list c are sorted together based on the distances, ensuring that the closest nodes appear at the top of p.

Step 4 The neighbors of the top-r ($r \leq l$) nodes in the priority queue are fetched from $\mathcal{G}$ and the candidate list c is populated with these nodes.

Steps 3 and 4 are repeated until the priority queue receives no new entries or the pre-defined maximum number of iterations is reached. Then, the top-k nodes in p are returned as the approximate nearest neighbors.

This algorithm is based on carefully built proximity graphs, which encourage reachability (all vertices are reachable starting from any vertex) and convexity (avoids falling into local minima) [25, 44]. Based on such characteristics, the search algorithm aims for faster convergence towards the global minima by maintaining the priority queue that stores data points with small L2 distances and quickly dropping long-distance points.

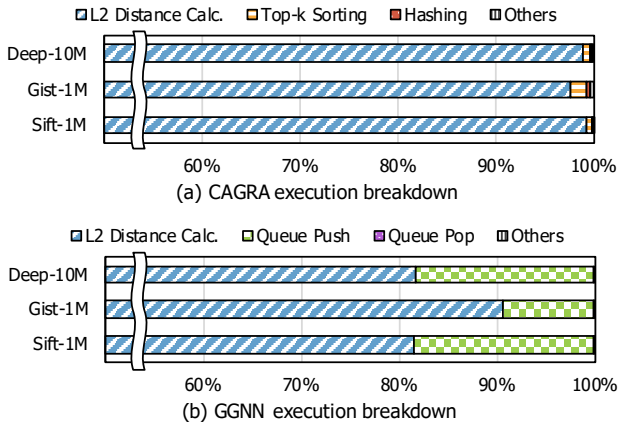


Figure 2: Execution time breakdown analysis of baseline ANNS.

Because the vector dimension typically ranges from a few tens to several hundreds, L2 distance calculation dominates the search time due to the overhead of loading and processing high-dimensional vectors. According to our measurements depicted in Fig. 2a, when using the current state-of-the-art method CAGRA [44], L2 distance calculation accounts for over 95% of the total search time, regardless of the dataset. To further analyze this trend across different methods, we also performed a breakdown of GGNN [25] and depicted in Fig. 2b found that over 80% of the time was still spent on distance calculations. Therefore, the key to high-throughput ANNS is to reduce the number of L2 distance calculations. For a search that converged in i iterations on a j-proximity graph (i.e., each vertex has j neighbors), the rough count of L2 distance calculation is $i \times j \times r$ (including duplicates). To achieve high throughput, PathWeaver mainly aims to reduce the number of search iterations i and number of examined neighbors out of j, while not sacrificing the search accuracy.

3 PathWeaver Design

3.1 Pipelining-based Path Extension

3.1.1 Scalability of Performance on Multiple GPUs

To diagnose the existing multi-GPU search method based on sharding [25], we compare the total number of search iterations between single- and multi-GPU setups using a multi-GPU extension of CAGRA and GGNN, as shown in Fig. 3a. The results indicate that the sharding-based approach scales inefficiently across multiple GPUs in both methods. For the

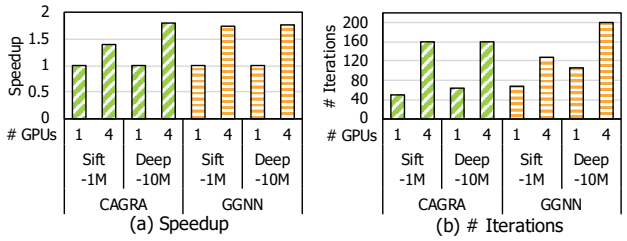

Figure 3: Performance scalability of prior work on Sift-1M and Deep-10M datasets with 4 GPUs.

Sift-1M dataset, using 4 GPUs yields only a 1.39× speedup in CAGRA, resulting in a scaling efficiency of approximately 35%. GGNN shows similar trends, achieving about a 1.7× speedup on both datasets, which corresponds to a scaling efficiency of around 43%. This inefficiency arises from the fact that the multi-GPU baseline performs a separate local search in each GPU's shard for every query. While this simple query-parallel design provides an easy parallelized solution for large datasets, the number of iterations needed does not reduce linearly with the size of a shard. As a result, the number of total iterations to complete a search increases with more number of shards, as depicted in Fig. 3b. In the case of the Sift-1M dataset in CAGRA method, the total iteration over all the shard scales with the number of shards results in 4× total iteration. In GGNN, increase of total iterations is slightly better at around 2×, but not enough to compensate for the overall scalability loss. This highlights the need for an alternative solution to achieve efficient performance.

3.1.2 Pipelining-based Path Extension Design

To amend the issue identified above, we propose *pipelining-based path extension*, a multi-GPU solution that enhances scalability by leveraging intermediate search results from other GPUs in a pipelined manner. As illustrated in Fig. 4a, the key idea is to create inter-shard edges from each node to the closest node in the adjacent shard.

The baseline sharding [25] (Fig. 4b) begins by randomly partitioning the input dataset into independent shards, with the number of shards matching the number of GPUs (4 shards in this example). After allocating these shards to each GPU, independent graphs are built for each shard/GPU. Note that in this baseline approach, there is no edge between the nodes in different graphs. Once the graphs are built, the baseline performs independent ANNS for all queries by starting from randomly selected nodes within each graph. Upon completing the search for all queries, each GPU stores the top-k data points for each query specific to its graph. For instance, after the searches are finished, $N \times k$ candidate data points are outputted across N GPUs. These results are then offloaded to the CPU for reduction to get the final top-k data points for each query. While this method provides an easily parallelizable solution with almost no communication, it requires more search iterations as revealed in Section 3.1.1 and thus scales inefficiently.

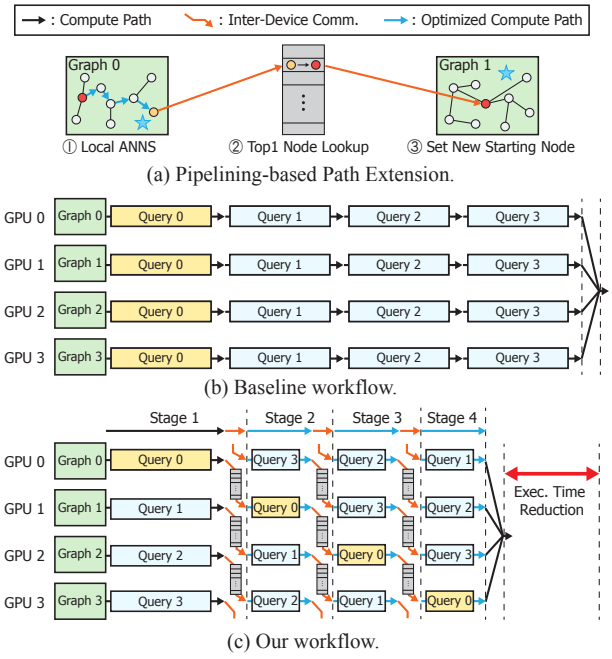

Figure 4: Illustration of the Pipelining-based path extension design.

In the proposed pipelining-based path extension design illustrated in Fig. 4c, the dataset is randomly partitioned in the same way as the baseline sharding approach to build independent graphs G_i for the shard on GPU i. However, after the graph construction, pipelining-based path extension takes a step further by creating uni-directional node-to-node connections between the shards of adjacent GPUs as shown in Fig. 4a. We define G_i to be adjacent to shards graph $G_{(i+1)\%N}$ for N GPUs, which form a ring topology. From each vertex in a shard, the nearest neighbor vertex is found in the adjacent shard, and an inter-shard edge is added between them. For example, the 0th GPU's graph connects all of its nodes to the closest node in the 1st GPU's graph, and nodes in the 3rd GPU to the 0th GPU, forming a ring-like uni-directional connection among graphs/shards. These inter-shard edges can be expressed as a mapping I:

$$I(u) = \underset{w \in G_{(i+1)\%N}}{\operatorname{argmin}} \; dist(u,w) \qquad \forall u \in G_i. \tag{3}$$

These connections are constructed once during the graph build phase and can be reused across searches. As detailed in Section 5.7, the additional overhead for creating these inter-shard edges is minimal.

To perform a search with the interconnected graph, each GPU is assigned a $|Q|/N$ chunk from the set of queries Q and starts the search as in the baseline sharding. After each query

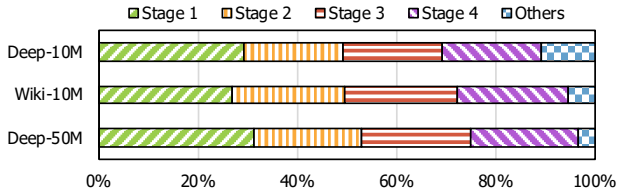

Figure 5: Execution time breakdown analysis with 4 GPUs after applying the pipelining-based path extension design according to the pipeline stages.

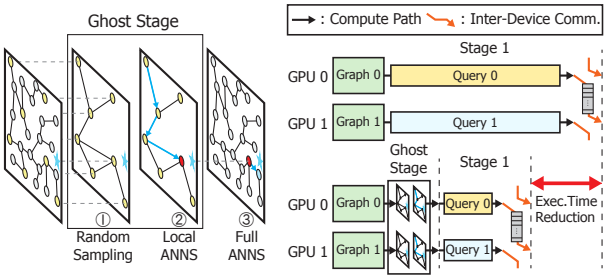
has converged in all GPUs, a part of the final local result Z is taken. From each of its vertices $z \in Z$, it continues searching from $I(z)$, which naturally takes place in the adjacent shard as if the search path has been extended. Because $I(z)$ has been designed to be close to the query, the search converges significantly faster than the baseline in fewer iterations. For example, in Fig. 4c, when searching with query batch 0 (yellow box), the search process begins on GPU 0 with graph 0. After the search completes on GPU 0, the result is passed to GPU 1, which continues the search on graph 1. As shown in the figure, the search time in stage 2 (blue arrow) is reduced compared to that of stage 1 (black arrow). This process is executed simultaneously on all GPUs and is repeated in a pipelined manner until every GPU has processed the queries originating from all other GPUs. Then the results are reduced in the CPU, similarly to the baseline.



As discussed in Section 6.4, because the only data transfer involved is the local result between the adjacent GPUs, the communication overhead is almost negligible compared to the substantial reduction in search time.

3.2 Ghost Staging

3.2.1 Execution Time Breakdown after Pipelining-based Path Extension

Fig. 5 illustrates the execution time breakdown of searching with pipelining-based path extension. As expected, the first search stage of pipelining-based path extension is the primary bottleneck. For example, the first search stage in the Deep-50M dataset takes up to 31%, while the other stages consume only up to 22%.

This bottleneck arises as the first search stage does not benefit from pipelining-based path extension and starts from random, potentially distant data points. As a result, more iterations are required to converge on the appropriate top-k candidates. As all GPUs are performing the initial stage of their own query, reducing this overhead could bring additional speedup.

(a) Ghost Staging. (b) Pipeline with Ghost Stage.

Figure 6: Illustration of the ghost staging design.

3.2.2 Ghost Staging Design

Motivated by pipelining-based path extension's ability to identify better starting points for subsequent GPU search stages, we propose *ghost staging*, a kind of hierarchical search [40] solution for improving the initial search stage on each GPU. Ghost staging adds a small auxiliary shard before the first stage, such that a high-quality data point close to the query can be located only in a few iterations. This approach significantly reduces the number of iterations needed during the initial search stage.

Fig. 6 illustrates how ghost staging reduces the number of search iterations during the first stage while maintaining accuracy. To create an auxiliary shard, ① ghost staging randomly samples a fixed number of random data points within a shard, referred to as ghost nodes. These ghost nodes are connected based on distances, creating a lightweight network. In addition, the inter-shard edges are added between the ghost nodes and the original nodes. Due to the relatively small number of ghost nodes, the preparation for ghost staging only adds negligible overhead to the graph build process (see Section 5.7). During ghost staging, ② a fixed number of starting points are chosen among the ghost nodes and the search algorithm from Section 2.2 is applied to locate ghost nodes near the query within a few iterations. ③ Once the relevant ghost nodes are identified, the search transitions to the original graph similar to pipelining-based path extension.

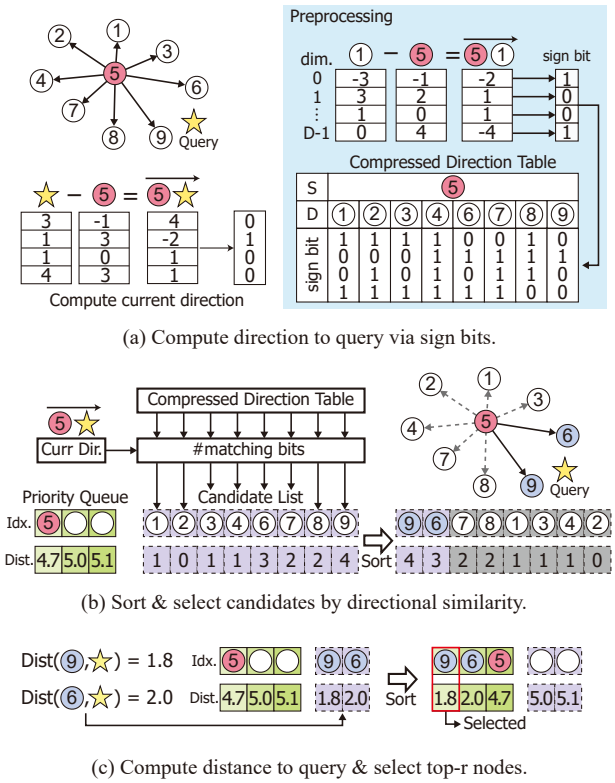
The high performance of ghost staging stems from ghost nodes acting as central hubs and their interconnections as highways within the expansive original graph. Moreover, ghost staging maintains high accuracy by locally searching the original graph for the remaining iterations. This is highlighted by comparing the search process of the baseline method and ghost staging in Fig. 6b. To reach the same data point close to the query, the baseline has to traverse many vertices due to the original graph's size. On the other hand, during ghost staging, taking a single step forward among ghost nodes has a similar effect of passing through multiple original graph data points. Even if ghost staging overshoots and bypasses the query, it can backtrack by the remaining search on the original graph.

Table 1: Unused Distance Calculation

Dataset	#Total Visits	#Discarded Visits	Ratio
Sift-1M [8, 32]	2.32E+7	2.00E+7	86.2%
Gist-1M [8, 32]	3.17E+6	2.81E+6	88.9%
Deep-10M [10]	2.68E+7	2.28E+7	85.0%

3.3 Direction-Guided Selection

3.3.1 Analysis on Unused Distance Calculation



Despite reducing the search iterations with pipelining-based path extension and ghost staging, the search procedure remains heavily dominated by the numerous L2 distance calculations. This partially stems from having to add all neighbors of each top-r node in the priority queue (Section 2.2), where the number of neighbors is usually in the order of a few tens [44]. While such a large number of neighbors is necessary to ensure reachability and convexity, it often introduces unnecessary computational overhead. During the search, we found that the majority of the data points added to the priority queue never reached the top-k region of the priority queue and were eventually discarded (unused) without being considered again because they were too far from the query compared to the other candidates.

In Table 1, we quantitatively measured the portion of the considered nodes, where **Total Visits** denotes the total number of nodes in the proximity graph that are accessed during the search, and **Discarded Visits** represents the nodes that are visited but never remain in the candidate buffer until the end of the search process to be included in the final top-k results. As depicted in the table, we find that the ratio of discarded node visits, which lead to unnecessary distance calculations, can exceed 80%. This indicates an interesting opportunity for additional optimization, where we could remove a substantial portion of the unused calculations if we can identify them in advance.

3.3.2 Direction-Guided Selection Design

We propose *direction-guided selection*, an optimization technique designed to accelerate the search process within each iteration. Direction-guided selection allows the search algorithm to bypass data points that are significantly unaligned with the query's direction relative to the current target node, as shown in the top graph in Fig. 7. By leveraging a set of lightweight operations including direction table reads and local sorting, direction-guided selection significantly reduces expensive vector reads and distance calculations.

The direction-guided selection process operates as follows: (a) During the off-line preprocessing phase, a compressed direction table is generated, storing the sign bits of the differences between the source node and its neighbors in the proximity graph. Each sign bit vector encodes the rough direction of an edge [46] and serves as a fast proxy to guide traversal during run-time search on the GPU. (b) On each iteration of the search, the sign bits of the direction between the query and the visiting node (node 5 in the example) are calculated. Then the number of matching bits is counted for each neighbor using the compressed direction table. The neighbors are sorted by their number of matching bits in descending order, and the top-n candidates are selected. In the example, with $n = 2$, nodes 9 and 6 are selected. (c) The distance is calculated between the query and the selected neighbors (node 9 and 6 in the example), and the priority queue elements are sorted by the order of their distances (e.g., nodes 9, 6, 5). Finally, top-r nodes from the priority queue are selected (e.g., node 9 with $r = 1$) and they become the next visiting nodes. To maintain accuracy, the last few iterations are regarded as cool-down phase, and the search is conducted without the selection. We use 30% of the max iteration as the default value.

(a) Compute direction to query via sign bits.

(b) Sort & select candidates by directional similarity.

(c) Compute distance to query & select top-r nodes.

Figure 7: Illustration of the direction-guided selection design.

Direction-guided selection effectively reduces the number of distance calculations while maintaining high accuracy. This is achieved by prioritizing candidates most aligned with the query's direction, significantly narrowing the search space. There is a small chance that direction-guided selection can drop meaningful candidates, because of the compression error in the direction table. However, due to the reachability and

convexity of the proximity graphs, this would typically result in an increased number of iterations until convergence instead of accuracy. We empirically found that the accuracy drop is almost negligible while the gain from the reduction in candidates dwarfs the increase in the number of iterations.

4 Implementation Details

PathWeaver's search kernel has been implemented based on the CAGRA search kernel, adopting its query-per-threadblock approach along with GPU-friendly bitonic sorting and hash tables. To maximize the benefits of fast register communication within a warp, we set the threadblock size to be equal to that of a warp (i.e., 32 threads).

To minimize the communication overhead in pipelining-based path extension, the total set of queries is sent to all devices, which has a negligible size compared to the dataset. Each device processes independent graphs generated from its respective shard and maintains a unique inter-shard edge table for its linked shard. At runtime, only a partial chunk of the query batch is processed, and the result is forwarded to the next GPU device.

While the number of results sent per query is a tunable parameter, we empirically choose to send only one to minimize communication overhead. Additionally, for pipelining-based path extension, a shard-to-shard lookup table needs to be precomputed. Every node within a single shard acts as a query to perform a search in the adjacent shard. The top-1 result from the search is stored in the lookup table for pipelining-based path extension.

Ghost staging can be implemented similarly to pipelining-based path extension, except that instead of connecting neighboring shards, it connects the extracted smaller auxiliary shard with the original shard.

In direction-guided selection, during processing of the sign bit table, all 1-bit signs are packed into one uint32. To efficiently compress the vector between the current node and the query, each thread subtracts the vector's elements and converts them into 1-bit values. During the runtime search process, the `__shfl_xor_sync()` intrinsic is used within a warp to enable efficient processing by performing fast intra-warp shuffle operations. Next, the precomputed sign bit table is looked up to retrieve the approximate sign bits of neighboring vectors. The similarity with the query vector is then computed by performing bit-wise XOR operations on uint32 units, followed by a `__popcll()` intrinsic call to count the total number of different bits. Finally, a min-sort is performed to find the node with the highest similarity. As mentioned above, direction-guided selection requires a precomputed compressed sign bit table generated on the CPU using multi-threading, where each thread handles the edges of a single parent node. For each neighbor, element-wise comparisons are performed, and the results are compressed into a uint32 using bit-wise shift and OR operations.

Table 2: Datasets used in evaluation

Target	Dataset	Dim. (d)	Size (n)	Type
Single GPU	Sift-1M [8, 32]	128	1M	float
	Gist-1M [8, 32]	960	1M	float
	Deep-10M [10]	96	10M	float
Multi-GPU	Wiki-10M [7]	768	10M	float
	Deep-10M [10]	96	10M	float
	Deep-50M [10]	96	50M	float

5 Evaluation

5.1 Experiment Setup

Environment. We have implemented and evaluated PathWeaver on a server with four NVIDIA RTX A6000 GPUs and an AMD EPYC 9124 16-Core CPU, where two GPUs are connected via NVLink Bridge [4], and each GPU pair is linked through a host PCIe switch. All environments run on Ubuntu 22.04 with CUDA version 12.1 and PyTorch 2.4.1.

Baselines. The following CPU and GPU baselines were chosen for evaluation.

- **CAGRA** [44] is the state-of-the-art GPU framework for graph-based ANNS. CAGRA proposes a heuristically optimized proximity graph for parallel search operations and incorporates techniques such as warp splitting and forgettable hashing to enhance search performance. We used the official implementation of the authors, where we extended it for multi-GPU settings (denoted as 'CAGRA w/ Sharding').

- **HNSW** [40] is a popular graph-based ANNS implemented for CPUs. HNSW introduces a hierarchical proximity graph, with each layer structured as an NSW [41] graph representing a subset of points. The search operation begins at the top layer and traverses through the hierarchy, achieving improved performance and accuracy. Because HNSW only supports execution on CPUs, we evaluated HNSW only in the single-GPU environment for fair comparison. We utilized 64 threads on CPUs for evaluation.

- **GGNN** [25] is another GPU implementation for graph-based ANNS. GGNN builds on the HNSW-inspired proximity graph, specifically optimizing it to leverage massive parallelism during the graph construction phase. Additionally, GGNN enhances search performance by efficiently utilizing shared memory and enabling parallel operations on data structures. To the best of our knowledge, GGNN is the only graph-based ANNS framework that supports multiple GPUs out of the box, where it uses the sharding method.

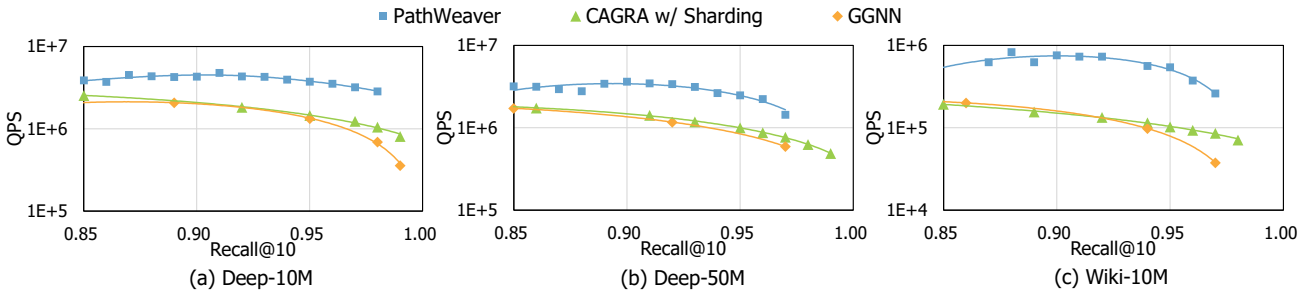


Figure 8: Performance comparison on multi-GPU environment.

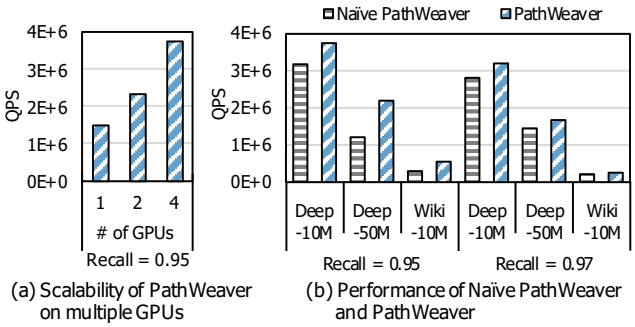

Figure 9: Performance comparison of Recall@10 between the naïve and pipeline method on multiple GPUs.

Datasets. We evaluate our method on a total of six datasets in which the vector dimension ranged from 96 to 960 as reported in Table 2. We analyzed single-GPU performance using datasets of varying sizes (1M, 10M) and dimensions (96, 128, 960) to demonstrate our method's effectiveness. For multi-GPU experiments, we selected larger datasets, scaling up to 50M in size and 768 in dimension. We took the first 10 million and the first 50 million part to create the Deep-10M and Deep-50M datasets from the Deep-1B dataset [1]. For graph building of PathWeaver, we used CAGRA's graph build algorithm, which offers the fastest build speed on GPUs. To ensure fairness, the out-degree of graphs was fixed to 64 for all datasets for PathWeaver's search and the CAGRA baseline evaluation.

Query Batch Size. We evaluated the performance and accuracy of PathWeaver and baselines using a query batch size of 10,000 for single-GPU tests. The exception was Gist-1M, where we used a batch size of 1,000. For multi-GPU evaluations, we employed a batch size of 60,000 to achieve high throughput and fully utilize multiple devices.

Performance Metrics. We tested two key metrics for the evaluation, following the typical performance metrics in the previous ANNS frameworks. The two key metrics and the details are as follows:

1. **Recall**: This metric quantifies the accuracy of the ANNS results by comparing them to the ground truth k-NNS results. For a query q, recall is defined as:

$$Recall@k = \frac{|\mathcal{N}_k^{KNNS}(q) \cap \mathcal{N}_k^{ANNS}(q)|}{|\mathcal{N}_k^{KNNS}(q)|}, \quad (4)$$

where $\mathcal{N}_k^{KNNS}(q)$ represents the k-NNS result, and $\mathcal{N}_k^{ANNS}(q)$ is the result obtained from the ANNS framework. Similar to prior work [25, 44, 53, 65], we target 95% recall@10 for most of the analyses unless otherwise noted.

2. **Queries Per Second (QPS)**: This metric captures the throughput of the framework by measuring the number of queries processed per second.

The primary objective of ANNS frameworks is to balance these two metrics—achieving high recall to ensure accuracy while maximizing QPS to deliver fast query processing.

5.2 Evaluation on Multiple GPUs

5.2.1 Performance Comparison on Multiple GPUs

Fig. 8 presents the performance comparison of PathWeaver with other multi-GPU baselines in a QPS-recall plot. Because CAGRA [44] does not support a multi-GPU environment out-of-box, we extended it with the sharding method as discussed by the authors. As shown in the results, PathWeaver outperforms all baselines. At a high recall of 95%, PathWeaver achieves 3.24× geomean speedup over CAGRA, the best-performing baseline. Moreover, PathWeaver achieves at most 5.30× speedup at the same recall rate in the Wiki-10M dataset. A similar advantage is maintained at a moderate recall 88%–92%, where PathWeaver achieves 3.36× speedup over CAGRA.

Among datasets, Deep-10M and Deep-50M both show similar QPS of around 3×10^6 for PathWeaver and 1.1×10^6 for both CAGRA and GGNN. However, for Wiki-10M, the throughput is an order of magnitude lower in all frameworks because Wiki-10M is composed of very wide vector indices of 768. This aligns with our finding that the ANNS throughput is less impacted by the size of the graphs. Even though

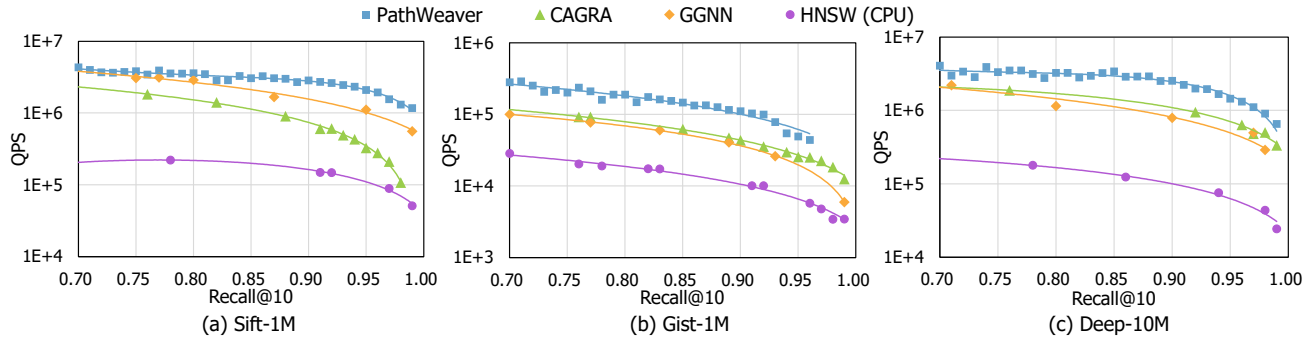

Figure 10: Performance comparison on a single GPU.

Deep-50M has five times more vertices than that of Deep-10M, the number of iterations until convergence is similar, which supports the motivation for pipelining-based path extension. However, having a wider vector per vertex in Wiki-10M dataset directly affects the performance. In this case, PathWeaver achieves more speedup than the other two datasets mainly due to direction-guided selection.

To demonstrate the efficiency and scalability of PathWeaver, we evaluated its performance while increasing the number of GPUs from 1 to 4, at a recall of 95%. The results are shown in Fig. 9a. Compared to that of using a single GPU, using four GPUs achieves 2.47× more speedup when comparing the fastest cases of each GPU setting, which represents 62% scale efficiency. Compared to that of the baselines shown in Fig. 3 for the same dataset Deep-10M, the scale efficiency is improved by 17%.

Fig. 9b further evaluates the impact of pipelining-based path extension on multiple GPUs. Compared to PathWeaver using the sharding method of baseline (denoted as 'Naïve PathWeaver'), the advantage of pipelining-based path extension is maintained across various datasets and target recall values. This indicates that PathWeaver scales stably on various settings.

5.3 Performance Comparison on a Single GPU

While PathWeaver provides a significant speedup with multiple GPUs, its benefit remains in single-GPU settings. Except for pipelining-based path extension, PathWeaver can still benefit from ghost staging and direction-guided selection on a single-GPU setting. We plotted the performance of PathWeaver and other baselines in Fig. 10. In addition to the GPU-based methods, we additionally study HNSW [40], a baseline method implemented on a CPU.

Overall, PathWeaver achieves a speedup of 3.43× over CAGRA. This speedup is primarily attributed to reduced distance computations due to direction-guided selection and fewer iterations resulting from the application of ghost staging. Similar to the observations from multi-GPU experiments, Gist-1M results in the slowest throughput due to its larger vector dimension of 960. In all cases under evaluation, PathWeaver exhibited better QPS-recall trade-off compared to the baselines.

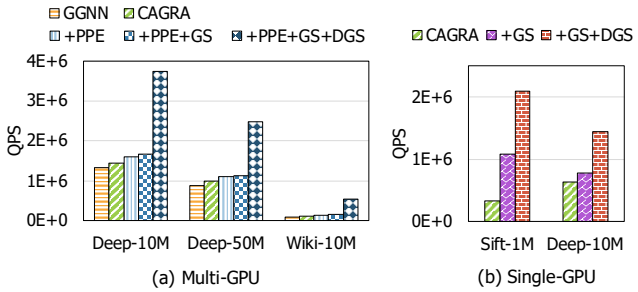

Figure 11: Ablation study of PathWeaver on (a) multi-GPU and (b) single-GPU settings. '+PPE', '+GS', and '+DGS' represent PathWeaver with pipelining-based path extension, ghost staging, and direction-guided selection, respectively.

5.4 Ablation Study

To demonstrate the impact of each scheme in PathWeaver, we conducted an ablation study using the Deep-10M, Deep-50M, and Sift-1M datasets on four GPUs, as well as Deep-10M and Sift-1M on a single GPU. In the results shown in Fig. 11, PPE, GS, and DGS represent pipelining-based path extension, ghost staging, and direction-guided selection, respectively.

For the ablation study on multiple GPUs, we used GGNN and CAGRA as baselines, and gradually applied PPE, GS, and DGS to analyze the effect of each, as shown in Fig. 11a. On top of the baselines, each component of PathWeaver adds consistent speedup across datasets with similar trends. In addition, Fig. 11b shows the ablation study on the single-GPU setting. Although pipelining-based path extension cannot be applied in this case, ghost staging provides higher speedup. This is because in the single-GPU setting, the entire search can be regarded as the first stage, which benefits from the ghost stage.

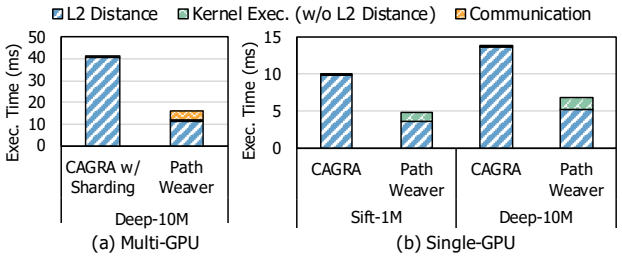

Figure 12: Search execution time breakdown on (a) multi-GPU and (b) single-GPU setting.

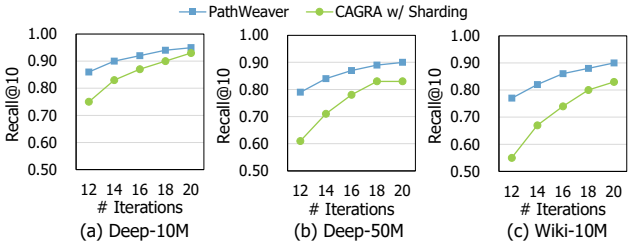

Figure 13: Accuracy comparison on different number of iterations.

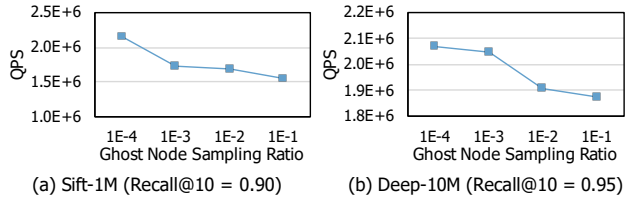

Figure 14: Sensitivity study on the relationship between the ghost node sampling ratio and QPS.

5.5 Execution Time Breakdown

To investigate how the execution time is spent in PathWeaver, we further broke down the execution time into three components: L2 distance calculation, rest of the kernel execution time, and inter-GPU communication time. The rest of the kernel includes random number generation, neighbor fetching, distance sorting, and hash table management for avoiding duplicate node visits. They are evaluated at 95% recall, with Deep-10M dataset for multi-GPU setting and an additional Sift-1M dataset for the single-GPU setting. To obtain the breakdown, we used `clock64()` function to separate the portion of L2 distance calculation within a kernel. For breakdowns of multi-GPU execution time, we measured the execution time with a certain portion of the code disabled, similar to the CPI stack [19] method.

The multi-GPU results are shown in Fig. 12a. We compare PathWeaver with extended CAGRA implementation for multi-GPUs (CAGRA w/ Sharding). As shown in the result, the L2 distance calculation is the dominating factor in both the CAGRA w/ Sharding and the fully optimized PathWeaver. In CAGRA w/ Sharding, no execution time is attributed to inter-GPU communication, since all searches are performed independently without any data exchange across GPUs. In PathWeaver, the communication time is incurred because of inter-stage data transfer of pipelining-based path extension. However, this results in fewer iterations required until convergence in subsequent stages, leading to a smaller L2 distance calculation. The rest of the kernel's portion slightly increases with optimizations in PathWeaver, due to the additional direction flag lookup process introduced by direction-guided selection. However, its portion is almost negligible in both CAGRA w/ Sharding and PathWeaver, making its impact minimal.

Fig. 12b depicts the breakdown on a single GPU. Because there is no communication, most of the time is spent on the L2 distance calculation. Thus, the speedups come from ghost staging and direction-guided selection. Instead of communication, the miscellaneous kernel execution time slightly increases in PathWeaver, which accounts for the ghost stages and the reduction of the dominant L2 distance calculation.

5.6 Detailed Analysis

In this subsection, we further investigate the effect of PathWeaver in terms of pipelining-based path extension, ghost staging, and direction-guided selection.

5.6.1 Pipelining-based Path Extension

To demonstrate the effect of pipelining-based path extension, we analyzed how the recall rate evolves by increasing the max number of search iterations in Fig. 13 on three datasets (Deep-10M, Deep-50M, and Wiki-10M). PathWeaver achieves high recall values with significantly fewer iterations. This is due to pipelining-based path extension, which enables each GPU to initiate the search process from a data point closer to the query using the search results from other GPUs. In contrast, the baseline requires substantially more iterations to reach comparable recall rates. For example, in the Deep-10M dataset, the baseline reaches a recall rate 0.90 with 18 iterations, while PathWeaver achieves this with only 14 iterations.

5.6.2 Ghost Staging

To evaluate the impact of the sampling ratio of ghost nodes on search performance, we conducted search operations on the Sift-1M and Deep-10M datasets using a single GPU, while varying the sampling ratio for building the ghost shard. As shown in Fig. 14, higher QPS was observed at lower sampling ratios of ghost nodes. For example, the QPS is 1.39× higher for sampling ratio 0.0001 compared to 0.1 in the Sift-1M dataset. We attribute this to the connections among the smaller set of ghost nodes, which facilitate larger iteration jumps

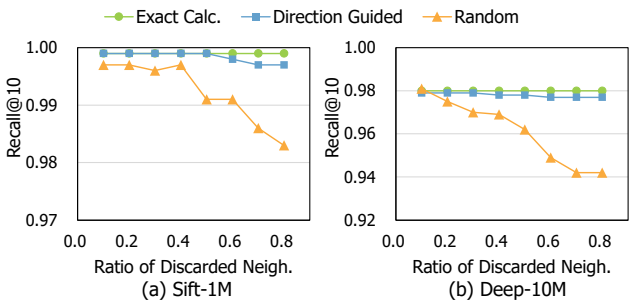

Figure 15: Comparison of neighbor selection strategies by varying the ratio of discarded neighbors.

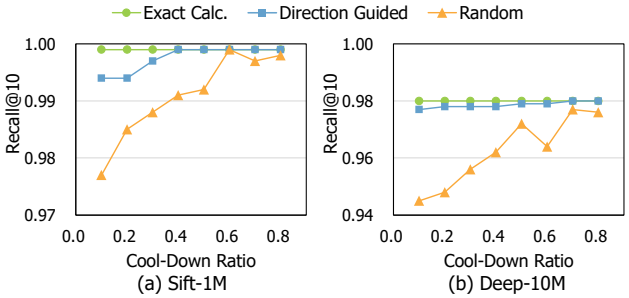

Figure 16: Comparison of neighbor selection strategies by varying the cool-down ratio of search iterations against the total iteration. A small cool-down ratio indicates that direction-guided selection or random selection is applied during the majority of the iterations.

within the original graph. The result indicates that a small-sized ghost shard is often sufficient, which provides another explanation for why ghost staging can bring speedup.

5.6.3 Direction-Guided Selection

To demonstrate the effectiveness of using direction bits as the neighbor discarding metric in direction-guided selection, we compared the performance of direction-guided selection against exact calculation (no discarding) and random neighbor discarding (randomly selecting neighbors).

Initially, the recall rate was evaluated for various discarded neighbor ratios while using a cool-down ratio of 0.5, as shown in Fig. 15. Compared to exact calculations, which achieve ideal recall, neighbor discarding in direction-guided selection results in a slight recall drop of at most 0.003, whereas random neighbor discarding causes a significant recall degradation of at most 0.038 for the Deep-10M dataset. Notably, PathWeaver maintains robust recall even with a discarding ratio of 0.7, in contrast to the significant recall decline observed with the random method.

Next, we analyze the recall rate by adjusting cool-down ratios with a fixed neighbor discarding ratio at 0.5, as shown

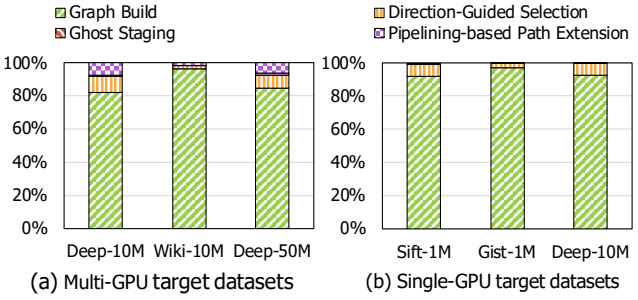

Figure 17: Graph build time overhead analysis.

in Fig. 16. Similar to the prior analysis, PathWeaver shows robust recall even when the cool-down ratio decreases, while the random method fails to maintain high recall.

For example, at a cool-down ratio of 0.3, neighbor discarding in direction-guided selection demonstrates only a minor recall drop of 0.002, compared to a significant degradation of 0.032 with the random discarding approach on the Deep-10M dataset. Both analyses demonstrate the effectiveness of using the direction of vectors when filtering out neighbors.

5.7 Graph Build Time Analysis

The preprocessing steps of PathWeaver, such as generating inter-shard connection edges for pipelining-based path extension, ghost nodes connections for ghost staging, and direction bit vectors for direction-guided selection, necessitate an overhead analysis to evaluate their impact. Therefore, we perform a breakdown analysis of the proximity graph build time, as shown in Fig. 17. Note that PathWeaver uses the graph build algorithm of CAGRA [44], represented as 'graph build'.

The results indicate that the overall overhead is less than 10% for datasets targeting a single GPU. The overhead of constructing ghost node connections was lower than generating direction bit vectors. This is because the latter requires creating direction bit vectors for all edges in the graph, while the former requires connecting a relatively smaller number of data points. For multi-GPU target datasets, the overhead was less than 4% for Wiki-10M, while it reached 15% for Deep-50M. This is because building the graph also involves many L2 distance calculations, whose overhead is proportional to the vector dimension, similar to the search kernel. Additionally, the overhead of constructing ghost shards remains negligible, with the overheads of generating inter-shard connections and direction bit vectors being comparable. The minimal overhead of creating inter-shard connections arises from leveraging the existing connections in the proximity graph. These connections provide information about which node in the next shard is closest to the target node in the current shard. Overall, for both cases of single- and multi-GPU settings, the additional graph build overhead from PathWeaver's designs is small.

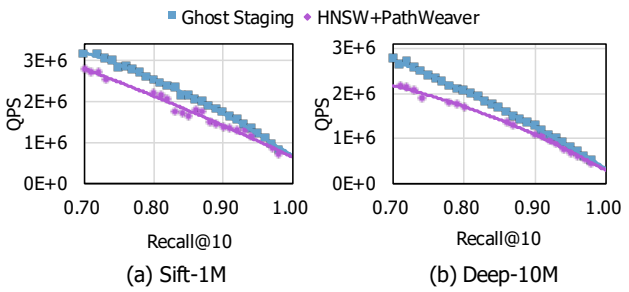

Figure 18: Comparing ghost staging and GPU-based HNSW.

6 Discussion

6.1 Comparing Ghost Staging and Existing Hierarchical Graph Approaches

Although ghost staging is a kind of hierarchical method, it differs from existing methods such as HNSW [40] and GGNN [25] in its objective and implementation. HNSW sequentially inserts each node into level n with exponentially decreasing probability as n increases, constructing a proximity graph at each layer. On the other hand, GGNN partitions the nodes, builds a graph within each partition, and finally merges them by selecting nodes for the next layer.

In contrast, ghost staging starts from an already-built proximity graph, and the extra layer is constructed by sampling vertices and connecting them. While existing hierarchical solutions aim to improve overall reachability and convexity by introducing hierarchy during graph construction, our approach uses the additional ghost stage solely to efficiently identify an entry node on the base proximity graph.

To investigate the difference, we conduct searching on the HNSW graph with our GPU-based search kernel and compare the results with those of ghost staging (direction-guided selection and pipelining-based path extension are disabled for fair comparison). As depicted in Fig. 18, ghost staging consistently achieves faster search speed compared to the HNSW graph even when it's searched with GPUs.

6.2 Managing Dynamic Updates

While PathWeaver currently targets static graphs, it is worthwhile to discuss dynamic updates to the proximity graphs [60]. Because PathWeaver is based on shards, any update would only involve modifying the affected shard. When rebuilding is needed, the cost mostly comes from the affected local graph, because the auxiliary data introduced by PathWeaver only accounts for a small portion as reported in Fig. 17.

For a small number of insertions, nodes can be added to one of the existing shards, followed by a rebuilding for the associated graph and the auxiliary data. If the number of insertions is small enough, the growth of the shard will not cause load imbalance. In such a scenario, the inter-shard edges can be incrementally updated because the small change in the local graph does not affect the similarity between existing vertices. For a large number of insertions, an additional shard can be created without modifying existing ones. For a small number of deletions, a deleted node may still act as a bridge between its neighbors. To preserve connectivity, a deletion flag can be used to logically remove the node. However, when a substantial portion of a shard is deleted, rebuilding the shard and its associated structures becomes beneficial.

6.3 Comparing Direction-Guided Selection with Static Graph Pruning Strategy

In ANNS, several approaches perform graph pruning [44, 50] in a static manner to reduce memory usage and improve query efficiency. This strategy reduces graph density by eliminating less important edges during index construction. While static pruning offers a consistent structure across all queries, it may not be optimal for query-specific behaviors.

On the contrary, direction-guided selection can be considered a dynamic pruning strategy. Instead of permanently discarding edges, it dynamically chooses a subset of neighbors during the search process, based on the direction to the query. One potential issue of its fixed top-n selection is that it might discard important candidates. Even though we did not observe a significant drop in recall in our experiments, one could instead prune based on the similarity criteria, as done in [66] for neural ranking. Such a method could preserve good candidates, at the potential cost of warp imbalances due to non-uniform pruning.

6.4 Overhead Analysis of Pipelining-based Path Extension

In this subsection, we quantify the communication overhead of pipelining-based path extension. First, the volume of inter-GPU communication is only $Q \times b_{idx}$, where Q is the number of queries and b_{idx} is the number of bytes per transmitted index. In contrast, the amount of GPU memory accesses scales with $I \times J \times Q \times v \times b_{elem}$, where I is the number of search iterations, J is the out-degree of each node, v is the vector dimension, and b_{elem} is the number of bytes per vector element.

Although inter-GPU channels (e.g., NVLink) are typically over 10× slower than GPU's memory bandwidth, the dominant cost still lies in the GPU's memory term, as the product $J \times v$ often exceeds 10^4. As a result, the reduction in I achieved by pipelining-based path extension has a much greater impact on total latency than the relatively small inter-GPU communication cost.

7 Related Works

7.1 Graph-based ANNS Solutions

CPU-based solutions. A range of CPU-based solutions has been proposed to enhance the construction and traversal of proximity graphs for approximate nearest neighbor (ANN) search. Key studies, such as [20, 21, 40, 41, 54], focus on designing efficient graph structures that are leveraged by the beam search algorithm to achieve scalable and effective ANN retrieval. To improve search efficiency, several methods incorporate further optimizations [9, 12, 16, 22, 42, 43, 61, 64]. For example, subgraph sampling and edge pruning techniques are utilized in [64] to reduce traversal overhead, while [16] explores reordering graph structures to enhance cache efficiency. Additionally, [12] introduces a novel distance function approximation that accelerates the search process, demonstrating significant performance gains in graph-based ANNS.

GPU-based solutions. SONG [65] represents the first graph-based ANN search solution for GPUs, leveraging GPU parallelism to address the bottleneck of computationally expensive distance calculations while optimizing data structures through various approaches. GANNS [62] and GGNN [25] build upon this by focusing on GPU-friendly implementations that efficiently utilize shared memory for maintaining data structures and parallelizing their operations. CAGRA [44] enhances graph construction and search processes on GPUs, employing techniques such as warp splitting and forgettable hash to achieve high throughput. On the other hand, PathWeaver moves beyond the sole reliance on proximity graphs during the search process. By integrating information from adjacent shards and considering query directionality, it achieves enhancements in both speed and accuracy.

Other platforms. Graph-based ANNS solutions have also been explored on alternative platforms to enhance performance [30, 36, 51, 57, 59, 63, 67]. Pyramid [67] introduces a hierarchical near-memory-computing (NMC) architecture specifically designed for efficient graph-based ANNS. Computational storage devices (CSD) are leveraged in works such as [36, 51], where software-hardware co-design accelerates search algorithms by integrating computation closer to data storage. DF-GAS [63] proposes a distributed FPGA-as-a-Service architecture, enabling parallel search operations across both full graphs and subgraphs. CXL-ANNS [30] employs memory disaggregation from the host via CXL to optimize graph-based ANNS performance.

7.2 Scaling ANNS to Large Datasets

For ANNS on large datasets, various approaches focus on compressing data vectors. Quantization-based methods [23, 26, 32, 33] achieve this by clustering nodes within a graph and replacing them with centroid-based representations. Similarly, SONG [65] utilizes 1-bit random projection to enable large datasets to fit within GPU memory.

Another prominent approach to handling large datasets involves hierarchical or hybrid architectures. Methods such as [24, 29, 45, 47, 49, 50] utilize storage devices to store large datasets, whereas BANG [53] combines CPU and GPU resources by maintaining the large graph index in CPU memory and leveraging GPU acceleration. FusionANNS [52] employs a combination of CPU-GPU collaboration and SSDs to optimize performance. These approaches enable cost-efficient processing of large datasets, though the achievable speedup remains inherently limited by the constraints of single-machine architectures.

Sharding datasets to fit into device memory and utilizing multiple devices has been widely investigated. Methods such as [14, 25, 31, 36] employ a multi-device strategy by partitioning datasets across devices, processing queries independently on each, and aggregating the results on the host. While these approaches enable distributed processing, achieving substantial and consistent speed-up as the number of devices increases often remains challenging. In contrast, our pipelining-based path extension achieves a proportional speedup with the number of machines used, effectively addressing the scalability limitations observed in previous methods.

8 Conclusion

We propose PathWeaver, a multi-GPU framework for graph-based ANNS that provides scalable and efficient performance on large datasets. PathWeaver addresses the main bottlenecks of graph-based ANNS through three key innovations: GPU-to-GPU communication to reduce unnecessary search iterations, a representative dataset search to refine starting data points, and data point filtering to minimize unnecessary memory access and distance calculation. Our evaluation results demonstrate that PathWeaver outperforms both CPU- and GPU-based solutions, achieving higher performance while maintaining accuracy.

Availability

We have open-sourced the code of PathWeaver and made it publicly available. The GitHub repository for PathWeaver can be found at `https://github.com/AIS-SNU/PathWeaver`.

Abstract

Deep neural network (DNN) training continues to scale rapidly in terms of model size, data volume, and sequence length, to the point where multiple machines are required to fit large models for training. Different distributed and parallel training strategies have been developed to support large-scale DNN training by partitioning the training state across GPUs. However, existing DNN training systems provide very limited support for reconfiguring parallelism strategies in the middle of the training via checkpointing. This limitation arises because distributed checkpoints are tightly coupled to specific model parallelism and hardware configurations, preventing large-scale training jobs from efficiently adapting to hardware failures or resource elasticity.

This paper presents *Universal Checkpointing* (UCP), a novel checkpointing system that enables flexible and efficient DNN training with reconfigurable parallelism. UCP overcomes challenges in existing systems by decoupling checkpoint structure from parallel training strategies and hardware configurations. In addition, we present a pattern-based reconfiguration pipeline that enables automatic, flexible, and efficient mapping of checkpoint state to various parallelism strategies. Evaluation on a range of DNN models, including state-of-the-art dense and sparse LLMs, shows that UCP enables reconfiguration for a broader set of widely used parallelism strategies than existing solutions while adding negligible reconfiguration cost. UCP has been successfully employed in real LLM training workloads, greatly enhancing their flexibility and resilience to dynamic hardware environments.

1 Introduction

The emergence of Large Language Models (LLMs) [6] has opened up new opportunities across various fields. In comparison to traditional methods, LLMs such as ChatGPT [42] and GPT-4 [1] have exhibited unique capabilities such as instruction following, commonsense reasoning, and few-shot generalization [26]. These abilities have been achieved primarily through unsupervised learning on massive model sizes, ranging from billions to even trillion-scale parameters [3, 9, 22, 54, 62]). However, as DNN continues to scale in model size, data size, and sequence length, multiple machines are required to fit the model for training. This has been made possible primarily through advanced distributed systems and parallelism technologies, where a model is partitioned across multiple devices and leverage the aggregated memory and compute capability from many GPU devices to train large-scale models [18, 21, 28, 37, 38, 46, 48, 51].

While demonstrating excellent training efficiency and scalability improvement, training modern DNNs/LLMs can still span several days or even months on highly optimized GPU clusters [2, 53]. For example, GPT-4 is reportedly trained on ~25,000 NVidia A100 GPUs over 90-100 days [19]. Given that training happens across many GPUs over an extended period, there is a high likelihood that of interruptions because of hardware failures, software bugs, or capacity management issues. For instance, the 54-day training of LLaMA 3.1 [54] on 16,000 GPUs encountered 419 failures, with training failing on average every three hours. In such cases, the model either faces prolonged and unpredictable failure recovery time or must adapt to a new training environment, such as continuing training with a different number of GPUs or migrating from one training cluster to another. However, existing parallelism strategies are hard to adapt, which calls for innovations that enable *reconfigurable parallelism*, which allows a training job to flexibly reconfigure its parallelism strategies while maintaining the same training convergence and accuracy.

One promising solution to enable reconfigurable parallelism is through the checkpointing system. Intuitively, a model checkpoint contains a snapshot of the model state, including weights, optimizer states, and additional metadata that captures the training progress (e.g., training iterations). If a checkpoint can be saved from one type of parallelism strategy (e.g., ZeRO-style data parallelism [46]) and reloaded to resume training with a different strategy (e.g., 3D parallelism [38]), it becomes possible to reconfigure parallelism across different hardware configurations. This results in more resilient DNN training in the face of hardware failures and allows for more flexible parallelism choices to adapt to resource

elasticity. Popular DL frameworks, such as PyTorch [20], Megatron [41], and DeepSpeed [47], already have their checkpointing systems and some research work has also proposed efficient methods for checkpointing [14, 36, 60]. However, are they sufficient to provide such reconfigurable parallelism?

Challenges of reconfigurable parallelism. Unfortunately, existing checkpointing systems are limited in supporting reconfigurable parallelism for three main reasons. First, existing checkpointing mechanisms are highly coupled to specific parallelism strategies [20, 33, 36, 60]. As a result, different parallelism strategies create distributed checkpoint files in different structures, and a checkpoint for a specific parallelism strategy cannot be loaded for another strategy. For instance, PyTorch Distributed Elastic [11] only allows adjustment of data parallel degrees (i.e., the number of data parallel workers), and there is currently no system that supports reconfiguring a checkpoint from ZeRO-style data parallelism [46] to 3D parallelism [38] or reconfiguring hybrid parallelism for sparse Mixture-of-Experts models [23].

Second, there lacks an automatic reconfiguration pipeline for a wide range of commonly used parallelism strategies. Because existing checkpointing systems are tightly coupled with specific parallelism strategies, only a small subset of these strategies can be reconfigured through checkpoints. This is typically achieved by implementing dedicated converters [20, 33] or ad-hoc conversion scripts [34]. However, this approach requires significant engineering effort and system expertise while still being error-prone, because it requires navigating a large and complex set of parallelism strategies and carefully examining how each strategy maps to model checkpoints. This includes determining whether each tensor operator in a model has its data replicated or partitioned, identifying the axis along which an operator is partitioned, and understanding how these replicated parameters and partitioned parameters map to distributed checkpoint files.

Third, as model sizes continue to increase, the overhead associated with reconfiguring from one parallelism to another becomes non-negligible. Larger models often require more time for reconfiguration, which can lead to sub-optimal training performance if not optimized. Therefore, it is important to ensure that the reconfiguration process is efficient and scalable. While there has been work optimizing the checkpoint saving and loading overhead [14, 36, 59, 60], few studies have focused on optimizing the reconfiguration overhead of distributed checkpoints.

Our approach. To address the aforementioned challenges, we take a different approach by introducing *Universal Checkpointing* (UCP), a novel checkpointing system that enables large-scale DL training with reconfigurable parallelism. UCP allows users to flexibly reconfigure a significantly larger and more complicated set of parallelism strategies compared to prior checkpointing mechanisms, including widely used parallelism strategies such as DP [29], TP [48], PP [18], SP [21, 30], ZeRO [46], and their combinations such as 3D-Parallelism [38, 51] with variable GPU counts. UCP achieves this through several techniques. First, we introduce *atom checkpoint*, which is a new checkpoint structure that decouples the checkpoint file from any specific parallelism strategy and hardware configurations, while being flexible to adapt to a wide range of parallelism strategies. Second, we introduce a *pattern-based reconfiguration pipeline* that enables reconfigurable parallelism on top of atomic checkpoints via a well designed *pattern set* and *pattern-based reconfiguration operations*. We show that this pipeline allows automatically and flexibly reconfiguring complex parallelism strategies such as 3D parallelism and ZeRO-style data parallelism over state-of-the-art LLM architectures, including dense LLMs, and architectures that require hybrid parallelisms, such as sparse Mixture-of-Experts (MoE) [22], and models with irregular attention such as Grouped-Query Attention (GQA) [4]. Finally, we introduce efficient system optimizations to reduce the reconfiguration cost via *nested parallel reconfiguration*, *redundancy-bypassing loading*, and *lazy reconfiguration invocation*, which makes impact of UCP on the training negligible.

We conduct extensive evaluation on large-scale LLM models, including both dense GPT [48] models and sparse MoEs [22]. Our evaluation results show that UCP enables reconfiguration of a significantly larger and more complex set of parallelism strategies from arbitrary distributed checkpoint files, outperforming prior checkpointing mechanisms. Additionally, we show that UCP is efficient and scalable, which adds minimal reconfiguration overhead. To summarize, we make the following contributions:

- We formulate the problem of reconfigurable parallelism for large-scale distributed training and develop Universal Checkpointing (UCP), a novel checkpointing system that enables reconfigurable parallelism for a broad set of commonly used parallelism strategies.
- We introduce atomic checkpoint, a new checkpoint structure that decouples checkpoints from specific parallelism strategies and serves as a common representation for flexible reconfigurable parallelism.
- We design a pattern-based reconfiguration pipeline, which provides systematic and automated parallelism reconfiguration through a carefully designed pattern set and pattern-based reconfiguration operations.
- We introduce nested parallel reconfiguration and lazy reconfiguration invocation, which significantly reduce the reconfiguration cost. Compared to the sequential approach used in ad-hoc conversion scripts, our nested-parallel method achieves a 14-257x reduction in time cost for models ranging from 7B to 1T parameters. The reconfiguration cost for 1T model is within 3 minutes, which is less than 0.001% of the total training time.

- We conduct extensive evaluation on models with multi-billion parameters and demonstrate the effectiveness of UCP in terms of accuracy, coverage, and efficiency.

UCP has been verified through the end-to-end training of several real-world large-scale models, including BigScience BLOOM (176B) [52], Microsoft Phi-3.5-MoE (42B) [3], UCB SmileyLlama (8B) [8] and RUC YuLan-Mini (4.2B) [17]. This has greatly improved these models' resilience to hardware failures during training, reducing their failure waiting time. It also provides these models flexibility to choose a better-suited parallelism strategy when the training environment changes via reconfigurable parallelism. We have implemented and open-sourced UCP in DeepSpeed[1]. UCP also becomes readily usable through popular DL frameworks that integrate the library as a backend, such as HuggingFace [61] and PyTorch lightning [45].

2 Background

We provide a brief introduction to the background of parallelism strategies for distributed training. In particular, training DNNs efficiently at scale typically involves the following parallelism strategies.

Data Parallelism (DP). DP is one of the most commonly used parallelism strategies for scaling DNN training on multi-GPUs. It divides a mini-batch into micro-batches across data parallel workers but the model state is replicated. Each worker independently computes a micro-batch and calculates gradients, which are subsequently synchronized through all-reduce to get consistent model parameters throughout training. To eliminate the redundancy of replicated model states in DP, zero redundancy optimizer (ZeRO) was introduced to progressively eliminate model redundancy in optimizer states (ZeRO-1), gradients (ZeRO-2), and weights (ZeRO-3) [46].

Tensor Parallelism (TP). To train models that exceed device memory, TP partitions compute and memory-intensive tensor operations (e.g., *matmul*) along non-batch axes across multiple devices. It then lets each GPU compute the partitioned operation in parallel and uses communication collectives (e.g., *all-reduce*, *all-gather*) at the split and merge point of these partitioned operators to ensure consistent states [48].

Pipeline Parallelism (PP). Different from TP, PP divides model states into multiple stages on different GPUs [18, 37]. Meanwhile, a pipeline scheduler splits a mini-batch into micro-batches and streams the micro-batches through different pipeline stages. Two consecutive pipeline stages exchange intermediate data via point-to-point communication. Such data dependencies lead to pipeline bubbles, i.e, computation stalls. Multiple pipeline schedules such as 1F1B [37] and interleaved 1F1B [38] have been introduced to reduce pipeline bubbles to improve overall pipeline efficiency.

[1] https://github.com/deepspeedai/DeepSpeed

Sequence Parallelism (SP). Motivated by training long-context LLMs, researchers have also developed SP, which divides the model activations along the sequence input dimension and leverages techniques such as distributed attention mechanism to hold the large activation memory from training long sequence inputs [21, 30, 31].

These parallelism strategies are often combined to scale out modern DNN training, and a training system needs to orchestrate different parallelism strategies with the goal to achieve high training efficiency. For example, the state-of-the-art training systems such as Megatron-LM and DeepSpeed, combine these parallelism strategies for scaling Transformer-based LLMs, known as 3D/4D parallelism [24, 38, 51].

3 Problem Formulation

In this section, we formulate the problem of reconfigurable parallelism for distributed DL training. In particular, as input, we are given (1) a training task that has a DNN model Φ with a model state of $\Phi(t)$ (weights and optimizer states) at training iteration t, (2) a *Source* parallelism strategy P_{src} that decides how $\Phi(t)$ is partitioned and executed in parallel on N_{src} parallel workers (e.g., 64 NVidia A100 GPUs), (3) a *Target* parallelism strategy, on a target hardware configuration with N_{tgt} workers (e.g., 48 NVidia A100 GPUs), to which the model training needs to be reconfigured. In both cases, a parallelism strategy can be DP [29], TP [48], PP [18, 37], SP [30], ZeRO [46], or a composition of those strategies such as 3D/4D parallelism [38, 51]. The objective is to design a reconfiguration mechanism that transforms $\Phi(t)$ from the *Source* parallelism strategy P_{src} to the target strategy P_{tgt}.

4 Challenges and Opportunities

In this section, we introduce the challenges prior work faces to offer reconfigurable parallelism and opportunities for improvement, which guides the design in the subsequent section.

Model parallelism implementation-coupled checkpoint saving/loading. The distributed checkpoints are highly coupled to specific model parallelism strategy. For example, data parallelism (e.g., PyTorch DistributedDataParallel [29]), one of the most commonly used parallelism strategies, replicates model weights and optimizer states across GPUs, and therefore only one rank (e.g., rank 0) saves the entire model states in a checkpoint file. When resuming training, each data parallel worker loads the same checkpoint file before launching the training iterations. Other parallelism techniques, such as ZeRO [46] and 3D parallelism [38], shard model parameters and optimizer states across GPUs. Since the model states are partitioned across GPUs, each GPU separately saves and loads checkpoint files that contain only a fraction of model state it owns. Fig. 1 shows the structure of checkpoint files from ZeRO-3, which is very different from others.

Model parallelism-coupled distributed checkpoints lead to a relatively simple checkpointing saving/loading pipeline, because the checkpointing loading is simply the reverse of

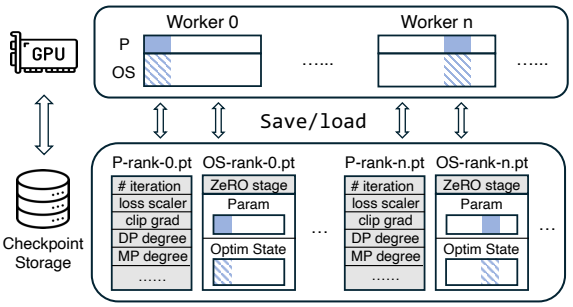

Figure 1: Existing distributed checkpoints are highly coupled to specific model parallelism strategy. Each worker in ZeRO-3 saves its own unique sharded model parameters (P) and optimizer states (OS). Reconfiguring ZeRO-3 requires altering each sharded parameter and optimizer states.

checkpoint saving process for each worker. This design also carries a performance advantage because distributed checkpoint saving requires to block all parallel workers, and having each parallel worker saves the model states it owns incurs no additional synchronization overhead and does not negatively impact the overall training speed. However, this coupled design makes it painful and error-prone to reconfigure the checkpoints to a different parallelism strategy, because developers need to hand-write conversion scripts to convert the checkpoint files from one parallelism to another. As a result, existing frameworks support reconfiguration of only a very limited set of parallelism strategies, e.g., changing the data parallel degree in distributed data parallel [10], or supports weight-only conversion of distributed checkpoints for inference-only evaluation (e.g., the conversion of optimizer states is not supported) [41]. As such, any node failure or resource reallocation in the training process will hobble the entire training process if there lacks support for a training job to reconfigure its parallelism on a new hardware environment.

Limited coverage of automatic reconfiguration pipeline for a large set of widely used parallelism strategies. Table 1 summarizes the state-of-the-art checkpointing systems for DL training. CheckFreq [36] is an efficient checkpointing system that overlaps the computation of training with checkpoint saving and adaptively tunes the checkpointing frequency at runtime based on I/O profiling. Gemini [60] introduces an in-memory checkpointing technique that checkpoints GPU state to local and remote CPUs and interleaves checkpointing IO with training computation to reduce the overhead, which impressively enables checkpointing on every training iteration. Both CheckFreq and Gemini accelerate checkpointing efficiency but do not provide support for reconfiguration of advanced model parallelism such as TP, PP, and ZeRO. Some concurrent work have proposed changing parallelism through checkpointing. For example, PyTorch Distributed Checkpointing (DCP) supports changing the parallelism degrees via loading-time resharding, e.g., after

	DP [29]	TP [38]	PP [37]	SP [30]	ZeRO [46]
CheckFreq [36]	✗	✗	✗	✗	✗
Gemini [60]	✓	✗	✗	✗	✗
DCP[2]	✓	✗	✗	✗	✓
MCP[3]	✓	▲	✓	✗	✗
UCP	✓	✓	✓	✓	✓

Table 1: Comparison of support for reconfiguring distributed checkpoints across various parallelism strategies. Triangle(▲) represents partial support with limitations.

all distributed checkpoint files are loaded to the CPU, each sharded parameter with a shape of $[X/n, Y]$ is concatenated to obtain the complete $[X, Y]$ parameter. The tensor is then resharded based on the current DP degree. Similarly, Megatron Dist Checkpointing (MCP) saves checkpoints with a local shape of $[PP*TP, X/PP, Y/TP]$. During loading, these checkpoints are concatenated to a global shape of $[1, X, Y]$ and then sharded based on the current PP and TP degrees. Both of these approaches are limited in that they only support a subset of parallelism strategies. Given that different parallelism strategies have different performance implications on various hardware, it is desirable to have reconfigurable parallelism that covers widely used parallelism strategies that are also easily extensible to different model architectures.

High reconfiguration overhead. Modern DNN sizes are often massive due to their large number of parameters, e.g., Transformers [26, 57] have increased by over 1000× in the past few years. Notable examples include PaLM [9] with 540 billion parameters and MT-NLG [51] with 530 billion parameters. The checkpoint size is approximately 12× the parameter count (4× for model parameters and 8× for optimizer states), thus checkpoint for these models reaches tens of TB in size. Given the huge checkpoint sizes, the reconfiguration time can be constrained by the bandwidth of the persistent storage [14, 60]. For example, it takes 42 minutes to checkpoint the model states of MT-NLG [51] to the remote persistent storage when the bandwidth is 20Gbps. Given the large and ever increasing model sizes, reconfiguration needs to have relatively low overhead in order to avoid becoming a major performance bottleneck.

5 Universal Checkpointing

5.1 UCP Design Overview

UCP is a distributed checkpointing system, specifically designed for handling large-scale DL training with reconfigurable parallelism. It allows flexible and efficient reconfiguration from any *Source* parallelism strategy to any *Target* parallelism strategy. Since training accuracy is the main re-

[2] https://pytorch.org/tutorials/recipes/distributed_checkpoint_recipe.html
[3] https://docs.nvidia.com/megatron-core/developer-guide/latest/api-guide/dist_checkpointing.html

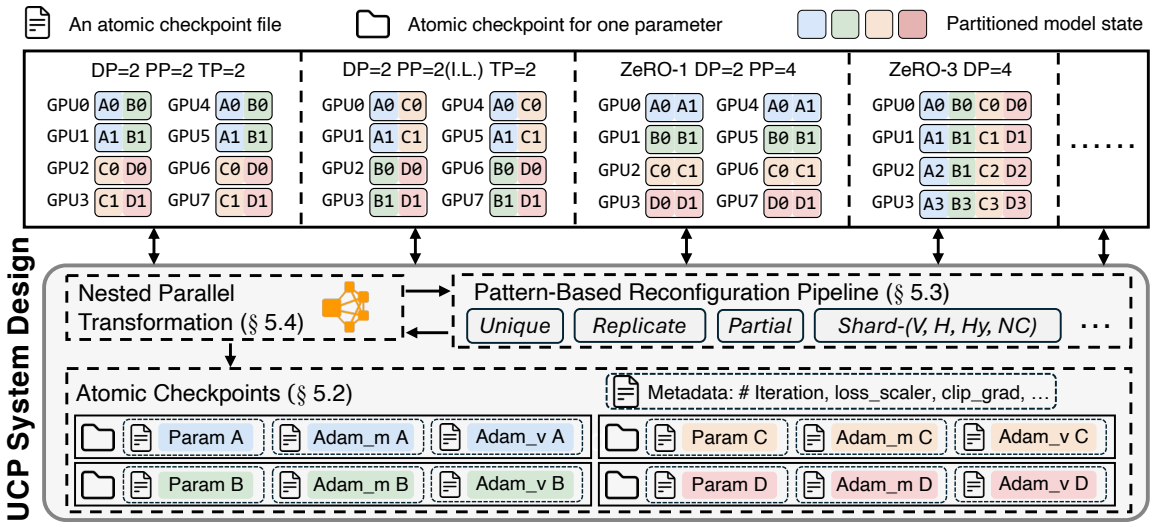

Figure 2: Overview of UCP system design. UCP enables flexible and efficient reconfiguration from any *Source* parallelism strategy, e.g., P_{src} (ZeRO-1 + PP) = (DP=2, PP=4) to any *Target* parallelism strategy, e.g., P_{tgt} (3D-Parallel) = (DP=2, TP=2, PP=2), via atomic checkpoints, pattern-based reconfiguration pipeline, and efficient optimizations such as nested parallel reconfiguration.

quirement, we focus on design choices that do not lead to training accuracy loss or related metric degradation. We first provide an overview of UCP and discuss each component in more details in subsequent sections.

Fig. 2 provides an overview of UCP. At a high level, UCP consists of three major components: atomic checkpoints, pattern-based reconfiguration pipeline, and nested parallel transformation. In § 4, we describe the challenge of parallelism-coupled checkpoints, which are cumbersome to reconfigure. We address this challenge by raising the level of abstraction, and decoupling the checkpoint file format from its parallelism strategy and hardware configurations through *atomic checkpoints* (§ 5.2). Atomic checkpoints enable radically simpler mechanism to achieve flexible reconfiguration, spanning the space of parallelism choices. UCP also provides a pattern-based reconfiguration pipeline to systematically and automatically reconfigure distributed checkpoints from a *Source* parallelism to a *Target* parallelism through atomic checkpoints (§ 5.3). UCP achieves this by carefully designing a parallelism pattern set and developing pattern-aware reconfiguration operations to automatically convert *Source* distributed checkpoints into atomic checkpoints and map atomic checkpoints to any *Target* parallelism strategy. UCP leverages *nested parallel reconfiguration*, *redundancy-bypassing loading* and *lazy reconfiguration invocation* to reduce the reconfiguration overhead such that reconfiguration only adds minimal overhead to the training process (§ 5.4).

5.2 Atomic Checkpoint

In existing DL distributed training systems, different parallelism strategy handles model states differently. For example, DP replicates and maintains a consistent view of model states during training across data parallel workers, so it is enough to have a single GPU for checkpointing. Other parallelism strategies, such as tensor-slicing parallelism or pipeline parallelism, partition model states along different axes and layers across GPUs. Therefore, each GPU creates a checkpoint file based on a snapshot of the partitioned model states that are in its local memory. Because of this highly parallelism-coupled checkpointing mechanism, practitioners need to hand-write conversion scripts to convert distributed checkpoints for different parallelism strategies, which incurs significant engineering cost and hard to maintain.

In UCP, we use *atomic checkpoints* to represent model states. An *atomic checkpoint* contains a consolidated view of the model states corresponding to a tensor operation, e.g., a merged state of fragmented states, if the tensor operation is partitioned over multiple parallel workers. Different model states (e.g., weights and optimizer states) have separate atomic checkpoint files, and all atomic checkpoint files corresponding to one parameter is considered as a conjunction of atomic checkpoints (e.g., a directory) to that parameter. In line with standard practices in mixed-precision training, UCP stores optimizer states in FP32 to maintain numerical stability and avoid loss of precision. While this increases checkpoint size, it ensures correctness during training. Without loss of generality, assuming the training uses the Adam optimizer [27], for each tensor operation, a conjunction of atomic checkpoints to its parameter has three atomic checkpoint files:

model.pt: A fp32 tensor represents parameter's weight.

adam_m.pt: A fp32 tensor represents first order moment.

adam_v.pt: A fp32 tensor represents second order moment.

The atomic checkpoint is much more fine-grained than most existing distributed checkpoints that have the entire local snapshot of individual parallel worker. An atomic checkpoint is also no longer coupled with any parallelism strategy or hardware configurations, e.g., it does not include any rank id, partitioning information, or additional data from specific sharding strategies such as padding for alignment. It simply maps each parameter in the model to a consolidated view of its weights and corresponding optimizer states.

The atomic checkpoint is sufficient to map to a wide range of parallelism algorithms, and it also enables flexible reconfiguration of parallelism through checkpoints. Critically, this representation is naturally data parallel when each data parallel worker needs to load a replica of the model states in a parameter-by-parameter basis. Also, as we identify partitioning patterns in many parallelism (§ 5.3.1), it becomes possible to define a set of primitives to automatically transform atomic checkpoints into specific parallelism strategies (§ 5.3.2). As such, UCP acts as a common interchange format between different distributed training techniques, and one does not need to implement individual converters from each *Source* to *Target* parallel config, significantly increasing the flexibility and coverage of reconfigurable parallelism.

Special consideration for data types. In practice, developers often adopt hardware-friendly training techniques such as mixed-precision training (MPT) [35], where both IEEE float16 weights and float32 weights and optimizer states are maintained to leverage the high computation throughput of hardware features such as TensorCore [32]. MPT affects the design of reconfigurable parallelism, as different states may have different data formats. Furthermore, dynamic mixed precision training saves checkpoints in one data format (e.g., float16) and switches to another one (e.g., bfloat16 or float32) at different training stages, which have different bit allocation policies between the mantissa and exponent [25]. Therefore, it is crucial to consider the data formats for checkpoints to accommodate these training techniques. In UCP, we keep all atomic checkpoints (weight/optimizer values) in float32, and add support to resume training in other data types, including float32, float16, and bfloat16, making it flexible to reconfigure parallelism with different data types.

5.3 Pattern-Based Reconfiguration Pipeline

Atomic checkpoints are decoupled from specific parallelism strategies. However, another important design choice remains unspecified: How to automatically convert distributed checkpoints *from* various P_{src} to atomic checkpoints and map atomic checkpoints to different P_{tgt} parallelism strategies? Most importantly, how to make sure that this automatic conversion process covers a wide range of widely used parallelism strategies as well as new parallelism strategies from state-of-the-art model architectures? The design choice here does not change the meaning of atomic checkpoints, but they are essential to ensure the utility of the resulting reconfiguration system. To provide answers, in this section, we develop a *pattern-based reconfiguration pipeline*.

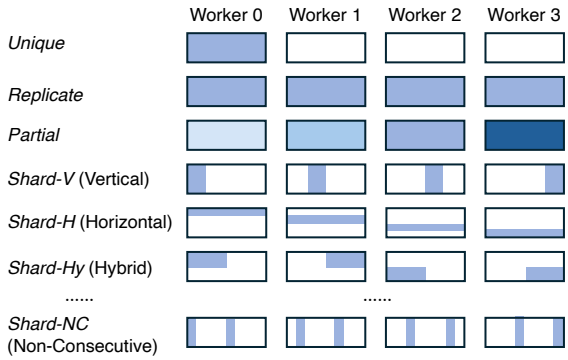

Figure 3: Illustration of patterns defined in UCP.

5.3.1 Designing the Pattern Set

To support flexible reconfiguration of parallelism based on atomic checkpoints, we seek an approach that can automatically map distributed checkpoints into atomic checkpoints. To achieve that, we look into patterns inside distributed checkpoint files so we can perform pattern-based transformation. The key consideration here is how to design and select the patterns. Good patterns should be able to have two key properties: coverage and flexibility. The coverage is desirable because it enables mapping between distributed checkpoints from a wide range of parallelism strategies and model architectures to atomic checkpoints. The flexibility facilitates subsequent parallelism reconfiguration operations. Given these two key properties, we propose the following pattern set.

Fig. 3 illustrates the pre-defined patterns in UCP. *Unique* means that a tensor is uniquely associated with a distributed checkpoint, which is commonly seen from checkpoints generated through inter-op parallelism such as pipeline parallelism. *Replicate* means one parameter will be replicated across multiple distributed checkpoints. For example, even though *matmuls* are sharded across GPUs in TP, other parameters such as LayerNorm and the Bias terms are replicated across GPUs because they are not compute and memory intensive. As a result, those replicated parameters will cause redundancy if we converted all those replicated parameters to atomic checkpoints. *Partial* indicates a parameter that is updated independently across GPUs, which corresponds to models with asynchronous training. More complicated patterns exist in intra-op parallelism strategies, which partition parameters along certain dimensions, e.g., *Shard-V* for column-wise sharding and *Shard-H* for row-wise sharding in tensor parallelism, *Shard-Hy*, which shards along multiple dimensions of the model states, and *Shard-NC*, which shards model states non-consecutively. We show later that the set of patterns we choose enables conversion of complicated parallelism strate-

gies such as ZeRO-3 [46] and 3D parallelism [38] while being flexible enough to also support new model architectures such as MoE [23] and GQA [5]. Note that although the set of patterns covers many existing parallelism strategies, this approach is general and extensible to support new parallelism patterns, not just the ones considered in the paper.

5.3.2 Pattern-Aware Reconfiguration Operations

Given the pattern set, UCP extracts the pattern information from distributed checkpoints and launches pattern-aware reconfiguration operations. In particular, Table 2 lists the main reconfiguration operations in UCP, including *Extract*, *Union*, *StripPad*, *UcpInfo*, and *Load*. For different patterns, each operation performs pattern-aware transformation, and Algorithm 1 demonstrates how the *Extract* and *Union* consolidate different parameter fragments based on their patterns. We use several concrete examples to illustrate how pattern-aware reconfiguration operations in UCP support complex parallelism strategies and different model architectures.

Table 2: Pattern-aware reconfiguration operations in UCP.

Operator	Definition
Extract	Takes distributed checkpoint files from P_{src} as input and returns a set of parameter fragments contained in that checkpoint file.
Union	A pattern-specific union is called on parameter fragments to obtain consolidated parameters.
StripPad	Strips pattern-specific padding from a consolidated parameter.
UcpInfo	Generates the metadata (e.g., shape and location information to a given rank) associated with P_{tgt} for each atomic checkpoint.
Save	Saves the consolidated model states for each parameter as atomic checkpoint files.
Load	Loads atomic checkpoints to each rank based on the *UcpInfo* of P_{tgt}. UCP loads atomic checkpoints in a layer-by-layer fashion to prevent model states from exceeding memory limits.

ZeRO Stage 3. The process of applying UCP's reconfiguration pipeline to ZeRO-3 checkpoints is illustrated in Fig. 4. If ZeRO-3 is the P_{src}, each DP rank persists the sharded parameters and optimizer states it owns to a checkpoint file, leading to N distributed checkpoint files in total when the DP degree is N. UCP then identifies parallelism patterns of ZeRO-3: ZeRO-3 flattens each tensor into a 1D tensor and shards the 1D tensor equally across different data parallel ranks. UCP identifies those tensors in ZeRO-3 distributed checkpoint files as the *Shard-V* pattern. Based on the pattern, UCP runs *Extract* and *Union* on fragmented parameters to create atomic checkpoints, which contain a consolidated view of parameters and optimizer states. One complexity of ZeRO-3 is that it adds padding to make sure the 1D tensor can be evenly divided across N DP workers for alignments. For example, for a parameter with a shape [1024], if the original DP degree is 3, then ZeRO-3 pads the parameter to [1026], such that each worker owns a fragment of [342]. UCP uses *StripPad* to remove the padding and uses *Save* to save the resulting atomic checkpoints to persistent stage.

Algorithm 1 Pattern-Aware Reconfiguration

```
▷ Extract
1:  for distributed checkpoint ckpt in storage do in parallel
2:    for param_name p, tensor t in ckpt do
3:      ToShuffler(p, t)
▷ Union
4:  param_list = FromShuffler()
5:  for param p in param_list do in parallel
6:    {T_1, T_2, ..., T_n} ← all tensors name matches p
7:    Switch p
8:      case PatternMatch(Replicate, p) then
9:        ucp_p = T_1
10:     case PatternMatch (Partial, p) then
11:       ucp_p = Sum(T_1, T_2, ..., T_n) / n
12:     case PatternMatch(Shard, p) then
13:       ucp_p = Concat(T_1, T_2, ..., T_n)
14:     case PatternMatch(Unique, p) then
15:       ucp_p = T
16:   if hasPadding(p) then
17:     ucp_p = StripPad(ucp_p)
18:   Save(ucp_p)
```

On the other hand, if ZeRO-3 is the P_{tgt}, each DP worker calculates its new partition metadata via *UcpInfo* and then loads atomic checkpoints to each rank sequentially, following the layer order and with alignment padding added for high performance. Using the previous example, assuming $N_{tgt} = 2$, UCP will resume training with each rank having the correct parameter shape [512] instead of [513]. Once all the partitioned states are loaded into a GPU, e.g., in the flatten memory attribute *fp32_partitioned_groups_flat* of ZeRO-3, the updated attribute is then broadcast to other necessary attributes, such as *fp16_partitioned_groups_flat* for MPT. Through this process, UCP flexibly reconfigures parallelism with ZeRO-3 either as P_{src} or P_{tgt} under various DP degrees.

3D parallelism. The reconfiguration process with 3D parallelism either as P_{src} or P_{tgt} is similar to ZeRO-3. However, since 3D parallelism consists of various parallelism strategies, it has its own set of complexities. Similar to ZeRO-3, when saving distributed checkpoints for 3D parallelism, each GPU only saves a slice of the model state it owns. However, the parameter pattern of 3D parallelism is much more complicated: parameters can have *Replicate* (e.g., *LayerNorm*), *Shard-V* and *Shard-H* (e.g., *matmul*), *Partial* (e.g., Alibi Embedding [44]) with TP degree > 1, and *Replicate* (e.g., Tied-Embedding) pattern and *Unique* (majority) with PP degree > 1. UCP significantly lifts the burden of manually converting distributed checkpoints from 3D parallelism through pattern

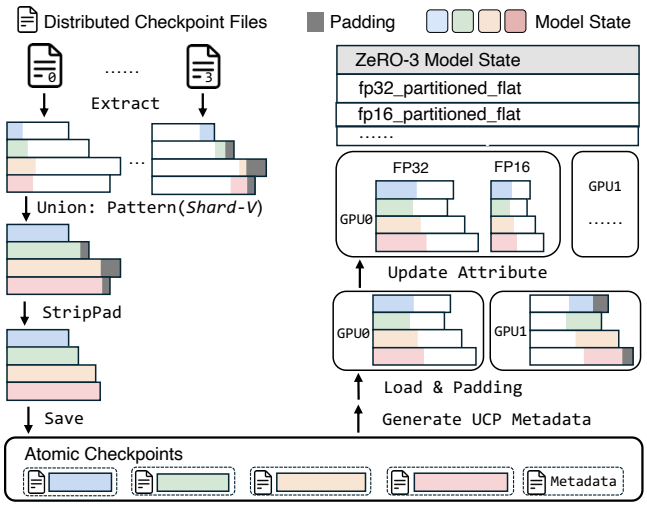

Figure 4: Workflow of UCP to flexibly reconfigure parallelism with ZeRO-3 either as P_{src} or P_{tgt}. The left side shows the process of converting checkpoints from P_{src} (ZeRO-3, DP=4) to atomic checkpoints. The right side shows how atomic checkpoints are converted to P_{tgt} (ZeRO-3, DP=2).

matching and using *Extract*, *Union*, *StripPad* to create consolidated atomic checkpoints without any padding. For example, depending on *Shard-V* or *Shard-H*, UCP would concatenate fragmented parameters from TP into a single consolidated tensor either with the row dimension or column dimension. Similar to ZeRO-3, if 3D parallelism is chosen as the P_{tgt}, a new mapping between atomic checkpoints and GPU ranks is generated first through *UcpInfo*, and each rank loads from atomic checkpoints based on the new mapping policy.

Additional complexities from 3D parallelism also come from the pipeline schedules. For instance, Interleaved 1F1B [38] is a pipeline schedule that reduces the pipeline bubbles by assigning non-contiguous layers of a model to the same rank, resulting in distributed checkpoints highly coupled with the specific order of layer assignment. UCP's atomic checkpoints are decoupled from such scheduling, as the parameters and optimizer states are only associated with their respective parameter names, allowing to reconfigure the mapping between each rank and the parameters.

Sparse Mixture-of-Experts and Irregular Attention GQA. The patterns described in Fig. 3 not only covers model sharding strategies for dense LLMs, as illustrated in the ZeRO-3 and 3D parallelism example, it also covers model architectures such as sparse MoE models [23] and irregular attention mechanisms such as GQA [5], both of which have received intensive interests in LLM training but also require more complex parallelism strategies. Fig. 5 illustrates the complexity. The MoE model in this example defines the weight tensor of an MoE's FFN layer as *[n_experts × hidden_out, hidden_in]*, which is a *fused* weight matrix different from standard MoEs that use separate matrices to represent different experts. With the fused matrix, one can apply TP to this layer. However, different from standard TP, the partition happens along the *hidden_out* dimension, which does not fall under the common *Shard-V* and *Shard-H* pattern. In UCP, this is handled through the *Shard-NC* pattern, which allows UCP to identify it as a 3-dim tensor and apply pattern-aware reconfiguration operations such as *Extract* and *Union* to still obtain a consolidated view of the *fused* matrix from distributed checkpoints.

In the GQA [5] example, the QKV matrices in the multi-head attention (MHA) are also fused together as one tensor. However, different from traditional MHA, the QKV in GQA have different sizes, causing the fused matrix to have an irregular shape of *[q_size + k_size + v_size, hidden]*, where *q_size != k_size == v_size*. If Tensor Parallelism (TP) is applied to this tensor, it needs to partition the tensor along the first dimension for each Q, K, and V but with different sizes. The *Shard-NC* together with shape info allows UCP to identify these variable-size fragments and apply pattern-aware reconfiguration operations accordingly.

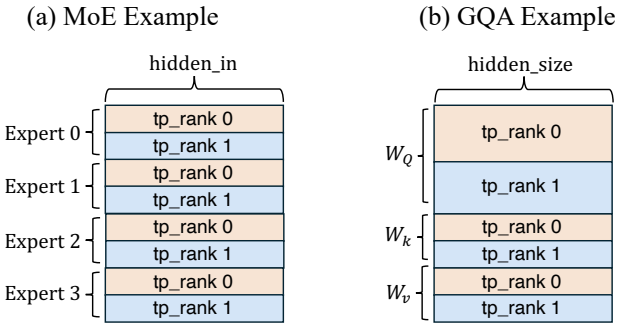

Figure 5: Illustration of the reconfiguration complexities from sparse Mixture-of-Expert models and models with irregular attention mechanisms, such as Grouped Query Attention (GQA). This figure shows examples of MoE with 4 experts and GQA, both with TP=2. The *Shard-NC* pattern allows UCP to identify partitions along different dimensions and variable-size fragments, and UCP supports reconfiguration operations based on these identified patterns.

These examples show that the pattern-based reconfiguration pipeline in UCP is quite flexible, supporting various parallelism strategies as either P_{src} or P_{tgt}. Meanwhile, its carefully designed pattern set allows it to support not only a wide range of complex parallelism strategies but also very extensible to both sparse Mixture-of-Expert models and models with irregular attention in addition to dense models. Introducing a new parallelism strategy involving patterns beyond UCP's current scope would require a similar amount of implementation effort as the examples presented above. We actively work with the community to identify these new patterns to extend UCP to have a wider coverage.

5.4 Efficient Reconfiguration

UCP is intended for high-performance training, therefore the operators described in § 5.3 need to scale well with larger models and more nodes. To achieve low reconfiguration cost, UCP leverages three optimizations: (1) Nested parallel reconfiguration, (2) Redundancy-bypassing loading, and (3) Lazy reconfiguration invocation.

Nested Parallel Reconfiguration. Motivated by leveraging additional nodes to increase the reconfiguration efficiency, we introduce a nested parallel reconfiguration scheme by formulating the reconfiguration as a MapReduce problem [12]. MapReduce was originally introduced as a programming model for processing large datasets in a distributed environment, and has been widely used in big data processing frameworks such as Hadoop [50]. MapReduce decomposes a problem into three phases: Mapper, Shuffler, and Reducer. In our case, as shown in Fig. 6, each parallel mapper reads a distributed checkpoint and parses it according to the parameter fragments of the tensors it contains. The shufflers send the output from mappers, i.e., the tensors each representing a fragment of parameter to the corresponding reducers assigned to process those parameters. The reducers process these parameter fragments based on specific pattern, such as *Shard* and *Partial*, which we discussed in detail in § 5.3.

It is important to note that parameters vary significantly in size. For example, in a 176B model, the embedding parameter has a size of [50257, 12288], while the bias of LayerNorm has a size of [12288]. Randomly assigning these parameters to workers would lead to imbalance, as both computation time and the loading/saving time are proportional to parameter size. This imbalance results in most workers idly waiting for the one handling the heaviest task, which dominates the overall conversion time. To address this issue, we introduce a pre-calculation based balancing method. The master worker divides parameters into N groups based on *numels*. For instance, with 4 workers, the master might assign the embedding parameter to worker 1, while distributing multiple smaller parameters like LayerNorm biases and weights across workers 2, 3, and 4 to achieve a similar total numel count per worker.

Building upon the balanced distribution of parameters across workers, we have implemented a second level of parallelism utilizing multi-core processing within each worker. This approach leverages the full computational capacity within a worker node by engaging all available CPU cores to process parameters concurrently. The nested parallelism strategy – balancing across workers and then across cores within each worker – maximizes resource utilization and minimizes idle time at both the node and core levels, leading to affordable conversion times for large language models.

Redundancy-bypassing loading. Each worker within the same DP group shares or partially shares (except ZeRO3-DP) the same model states, thus needs to load the same atomic checkpoint files. UCP eliminates redundant checkpointing loading by evenly distributing loading workloads among workers in the same DP group. Each rank reads its assigned atomic checkpoint files into CPU memory, transfers them to GPU memory, and then uses all-gather operations to distribute the data to other workers. This optimization significantly alleviates the IO bandwidth pressure by eliminating redundant data transfers from storage to CPU memory and leverages the high-bandwidth GPU-to-GPU interconnects (such as NVLINK at 900 GB/s) to redistribute data once it is loaded into GPUs. Moreover, UCP employs a memory-efficient loading design. UCP loads atomic checkpoints layer by layer and assigns tensors to GPUs based on the selected parallelism strategy. Once a layer is transferred to GPU memory, its tensors are released from CPU memory, reducing peak CPU memory usage from the size of full model checkpoints to that of a single layer.

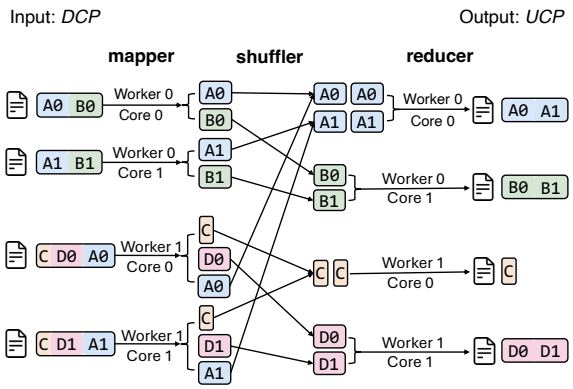

Figure 6: Illustration of the nested parallel reconfiguration process of UCP. UCP leverages a MapReduce-based approach to utilize the aggregated compute and bandwidth of multi-node multi-processors to convert distributed checkpoints into atomic checkpoints in parallel. Meanwhile, it performs careful load balancing to avoid the straggle problem.

Lazy reconfiguration invocation. The careful reader may think "when should the reconfiguration of parallelism be triggered?" or "Is it possible to directly consolidate distributed model states into a single checkpoint file when saving checkpoints?" Such a method has two drawbacks: Consolidating distributed model state into a single checkpoint unacceptably slows down training, and is impractical at extreme scales because there may not be sufficient memory to host the consolidated model states. To avoid slowing down normal training, we adopt a lazy invocation design for UCP. UCP reconfiguration is invoked *only* when a P_{src} and P_{tgt} are different or the hardware changes. This way, the distributed checkpoint saving logic does not need any change, and UCP only incurs $<0.001\%$ of the training time overhead when there is a need for reconfiguration of parallelism since reconfiguration does not add cost to the critical path length, i.e., the normal distributed training process.

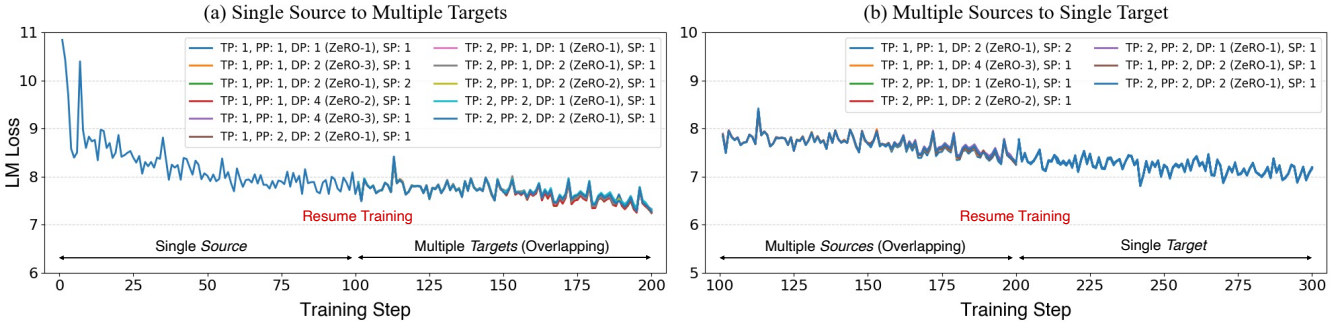

Figure 7: (a) Training curves of reconfiguring training from one *Source* of parallelism into different *Target* parallelisms. (b) Training curves of reconfiguring training from multiple *Source* parallelism strategies to the same *Target*.

6 Evaluation

We implemented UCP in DeepSpeed and evaluate UCP through a series of experiments on training LLMs. Overall, our evaluation aims to answer the following questions:

- Can UCP enable reconfigurable parallelism without compromising model training accuracy?
- How is UCP compared to existing checkpointing systems in terms of supporting flexible parallelism reconfiguration?
- Can UCP generalize to different model architectures?
- How does UCP affect the checkpointing saving and reconfiguration overhead?

6.1 Evaluation Methodology

Workloads. For the accuracy evaluation, we focus on evaluating GPT-style Transformer based models. We select several architectures from prior work: GPT-3 medium [7] ($L = 24, H = 1024, A = 16, 350M$ params), GPT-3 7B ($L = 32, H = 4096, A = 32, 7B$ params), a 176B GPT-3 style model ($L = 70, H = 14336, A = 112, 176B$ params), and a Mixtral-7x8B [23] style MoE model ($L = 32, H = 3072, A = 32, E = 16, 42B$ params), to cover different model configurations and model sizes. We use a subset of the Pile dataset [15] for training to evaluate the impact to the training loss with and without reconfigured parallelism from UCP.

Hardware. We conducted our experiments on: 64xA100 40GB GPUs (256GB DRAM, 10TB storage, 200Gbps interconnect). The evaluation of the 176B GPT style model was conducted on 384xA100 80GB GPUs. The efficiency evaluation of the 1TB model was conducted on 1024xMI250X 64GB GPUs. We measured the I/O bandwidth of the clusters: the NVIDIA GPU clusters achieved 5 GB/s, while the AMD GPU cluster achieved 3 GB/s. These bandwidth levels are comparable to those of consumer-grade SSDs or typical cloud provider offerings.

6.2 Evaluation of Reconfigurable Parallelism

UCP provides flexible reconfiguration from a *Source* parallelism strategy to a different *Target* varying hardware configurations. Since reconfigurable parallelism should not alter the training accuracy (model states preserved after the reconfiguration), we focus first to determine the accuracy impact of UCP with reconfigurable parallelism. After all, regardless how much reconfigurable parallelism a system offers, if it does not preserve training accuracy, it severely limits its applicability in practice. We conduct the evaluation through two categories of reconfiguration:

Single *Source* to multiple *Target*. To test if UCP allows resuming training with different *Target* parallelism strategies and hardware configurations, we first train the GPT-3 model using a configuration of TP=2, PP=2, DP=2 (ZeRO-1), and SP=1. Due to constraints in time and resources, we limited the experiment to the first 200 iterations. We enable UCP on the checkpoints saved at the 100th iteration and resume training using different parallelism strategies and GPUs. We record the LM loss for each iteration. Fig. 7(a) illustrates that the training can be seamlessly resumed using different *Target* parallelism strategies, while achieving consistent convergence if the training were to continue with the *Source* strategy. These results confirm that UCP enables resuming training to different hardware and parallelism configurations.

Multiple *Source* to single *Target*. Fig. 7(b) shows the training curves from multiple *Source* configurations to a single *Target*. We fix all random seeds in the system so that all training job starts with the same model initialization states. We train the GPT-3 model using different *Source* configurations. We then reconfigure their distributed checkpoints saved at the 100th iteration and resume training with a configuration of TP=2, PP=2, DP=1, and SP=1. The results show that regardless different *Source* configurations, all training jobs can resume their training with the same *Target* configuration. Most importantly, the resumed training curves match the curves from the *Source* at iterations 101–200. These results validate the effectiveness of UCP of reconfiguring parallelism while maintaining the training accuracy.

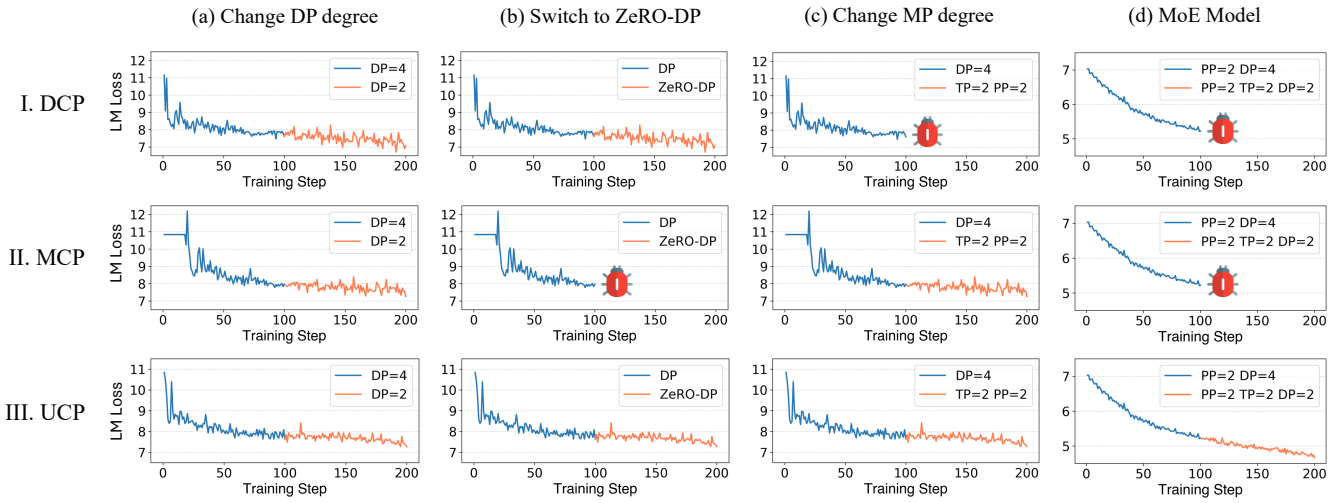

Figure 8: Training curves of (a) changing DP degree, (b) switching to ZeRO-DP, (c) changing MP degree for GPT-3 medium, and (d) for a MoE model when resuming the training from I.DCP [20], II. MCP [33], III.UCP in the middle. "Bug" indicates errors encountered when changing parallelism strategy with a given checkpointing system.

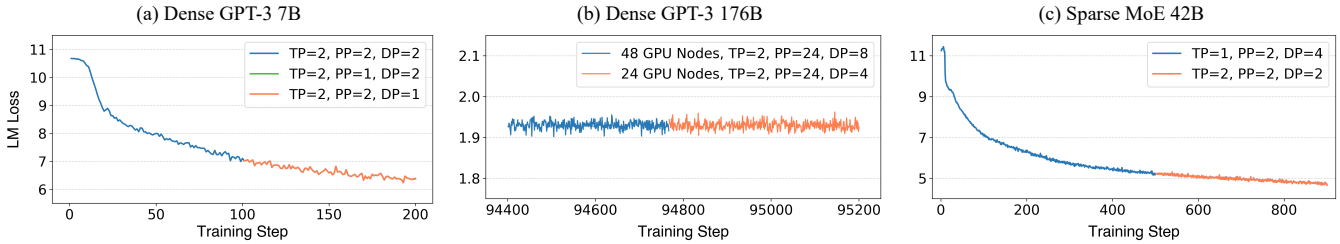

Figure 9: Training curves of (a) dense GPT-3 7B (b) dense GPT-3 176B (c) sparse MoE 42B when resuming the training from UCP in the middle.

Overall, UCP is able to flexibly reconfigure parallelism strategies from any *Source* and any *Target* because its introduced atomic checkpoints decouple distributed checkpoints from specific parallelism and hardware configurations, which serves as a common representation for reconfigurable parallelism. Furthermore, the reconfiguration pipeline provides unified and automatic parallelism reconfiguration through tensor pattern matching and pattern-based transformation primitives for a wide range of parallelism strategies.

6.3 Comparison with Alternative Methods

As shown in Table 1, some checkpointing systems have expanded their capabilities to accommodate reconfigurable parallelism, such as DCP and MCP. To demonstrate the flexibility of state-of-the-art checkpointing systems and validate the results presented in Table 1, we compare the flexibility of DCP, MCP, and UCP under four scenarios: (a) training with DP degree 4, then resume the training with DP degree 2; (b) switch to ZeRO-DP; (c) change the MP degree (including both PP and TP degree); (d) assessing flexibility when applied to a MoE model. For each scenario, we conduct training for 100 iterations, save checkpoints, then resume training with modified parallelism strategies for an additional 100 iterations.

As shown in Fig. 8, DCP supports changes in DP degree and switch to ZeRO-DP but fails to accommodate MP degree change. MCP, while supporting changing both DP and MP degree, shows limitations with MoE models and ZeRO-DP switch. It's important to note that "fail" and "limitation" in this context do not refer to an increase in training loss, but rather to system-level errors. In such cases, developers are required to either restart training from scratch or invest effort in crafting custom conversion scripts. UCP, on the other hand, successfully resumes training under all four scenarios. These results demonstrate UCP's ability to reconfigure a larger and more complicated set of parallelism strategies for DL model training than baseline methods.

6.4 Generalizability to Different Model Architectures

UCP is model architecture agnostic. As such, it is compatible with GPT models varying sizes and both dense and sparse model architectures. Fig. 9 show the training convergence for GPT-3 7B [56], GPT-3 176B [52], and a Mixtral-7x8B

style MoE [23], when resuming from UCP in the middle of training with new parallelism strategies. These figures show that training is seamlessly resumed with UCP, achieving consistent convergence that aligns with the initial training phase across these diverse models. UCP is able to achieve this because it considers a comprehensive set of parallelism strategies and model architectures when designing its tensor pattern matching and pattern-based transformation primitives, as demonstrated through the examples in § 5.3.2. Notably, the GPT-3 176B curve corresponds to a real-world case during the BLOOM 176B [52] training. On July 4, 2022 at 9:00 PM, after nearly three month training, the allocation of 48 nodes expired, and the replacement cluster offered only 24 nodes. Using UCP, the training job was seamlessly resumed on the smaller cluster without interruption. Without UCP, training would have either halted prematurely—leaving tokens incompletely consumed and potentially degrading model quality—or required restarting the entire three-month training process from scratch.

6.5 Reconfiguration Efficiency

Saving cost. As described in § 5.4, UCP incurs no additional saving costs compared to existing distributed checkpointing mechanism and uses *lazy reconfiguration invocation* to reconfigure parallelisms. The input of UCP is the basic distributed checkpoint that is saved periodically. Therefore, the saving cost of UCP is equivalent to that of the standard training process and does not impede the training speed.

Reconfiguration cost. The reconfiguration cost of UCP involves both (1) the transformation overhead from distributed checkpoints to atomic checkpoints and (2) the loading of atomic checkpoints to all parallel workers. Fig. 10 shows that the conversion time remains consistently bounded by approximately 3 minutes, even as model sizes scale up to 1T parameters. This efficiency is achieved through a combination of hardware scaling and the nested parallel conversion method (§ 5.4). The conversion can be executed directly within the training environment, which eliminates the need to transfer exceptionally large checkpoint files (up to TB in size) to different hardware infrastructure. Compared to the sequential(S.Q.) conversion, UCP nested parallelism(N.P.) approach achieves up to a 257x reduction in conversion time. Notably, when the model size increases, the number of GPU nodes also increases to partition the model to limited GPU memory, even for larger models such as LLaMA 3.1 405B that is trained on up to 2000 GPU nodes [54], the conversion time will expected to be bounded to several minutes and does not increase linearly.

To measure the loading cost, we compare UCP with directly loading from the saved distributed checkpoints. As standard distributed checkpoints cannot be loaded when there are changes in GPU counts or parallelism strategies, we keep the same GPU counts and parallelism strategies for the experiments. As shown in Fig. 11, loading from atomic checkpoints incurs approximately 10s overhead compared to standard

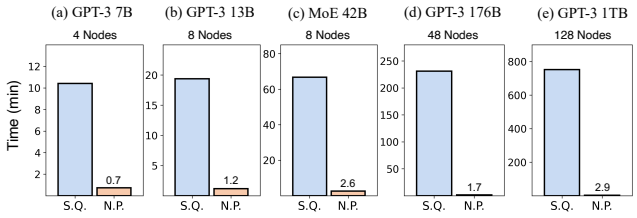

Figure 10: Time cost for converting distributed checkpoints to UCP atomic checkpoints with sequential (S.Q.) and nested parallel (N.P) approach across different model sizes.

distributed checkpoints, consistently across different model size, because the loading time is primarily dominated by the checkpoint data volume, whereas UCP does not change the checkpoint volume significantly. *Redundancy-bypassing loading* further eliminates redundancy when loading the atomic checkpoints within the same DP group. Moreover, the conversion and loading of atomic checkpoints is only triggered lazily (§ 5.4). Therefore, UCP's reconfiguration only accounts for a very small portion of the end-to-end training time.

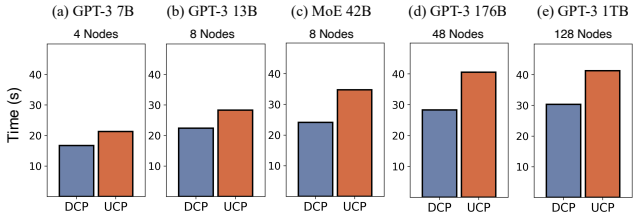

Figure 11: Time cost for loading standard distributed checkpoints (DCP) and loading the UCP checkpoints across models in different sizes.

Table 3 summarizes the end-to-end reconfiguration cost, including checkpoint save, transformation, and load times. In summary, UCP incorporates several system-level optimizations to minimize overhead. The Nested Parallel Reconfiguration is designed to minimize transformation costs, achieving up to a 257× reduction in conversion time. The Redundancy-bypassing loading optimizes loading time by avoiding redundant operations, resulting in a 3× to 20× speedup depending on the degree of data parallelism. The Lazy reconfiguration invocation reduces the frequency of invoking UCP, ensuring that it does not interfere with normal training. UCP is only triggered when a change in parallelism strategy is required. Therefoer, even for models with 1T parameters, total reconfiguration remains under 5 minutes, which is negligible compared to training durations. Although these results are obtained using bandwidth levels comparable to consumer-grade SSDs, UCP maintains functionality even under slower network and storage conditions. However, its performance in such scenarios will be limited by the available bandwidth and I/O throughput.

Model	Hardware Config	Save (min)	Transform (min)	Load (min)	End-to-end (min)
GPT-3 7B	4 nodes A100	0.29	0.73	0.36	**1.38**
GPT-3 13B	8 nodes A100	0.38	1.17	0.47	**2.02**
MoE 42B	8 nodes A100	0.42	2.64	0.58	**3.64**
GPT-3 176B	48 nodes A100	0.48	1.67	0.68	**2.83**
GPT-3 1TB	128 nodes MI250X	0.50	2.93	0.69	**4.12**

Table 3: End-to-end reconfiguration overhead for various models and hardware configurations.

7 Related Work

Checkpointing systems. Checkpointing is widely used as the basic mechanism for fault recovery. While naive checkpointing stalls training, asynchronous checkpointing approaches enable the overlap of disk I/O and model operations [36, 39, 40]. Just-In-Time (JIT) [16] checkpointing employs the state redundancy from DP, creating checkpoints only after failures. To waive the bottleneck from the low bandwidth of remote persistent storage, FastPersist [59] achieves higher bandwidth by extending local NVMe SSDs, and in-memory checkpointing methods [60] utilize remote CPU memories, allowing checkpointing over high-speed training networks. These techniques primarily focus on optimizing checkpoint saving efficiency, which lies on the critical path of the overall training process. UCP does not change the saving logic and is orthogonal to these optimization techniques, allowing for seamless integration.

Spot-instance training. There has been research on using spot instances for DNN training as they are much more cost effective. However, such dynamic environments make overhead of reconfiguration becomes a crucial factor. UCP already introduces several optimizations such as *Nested Parallel Reconfiguration*, *Redundancy-bypassing loading*, *Lazy reconfiguration invocation*, that bring the reconfiguration cost down from hours to a few minutes, making it a potentially viable solution for more elastic training with spot instances. However, prior work, such as Bamboo [55] and Parcae [13], suggest that the dynamism in many cloud spot instances can be extremely high. Therefore, it may require more efficient parallelism reconfigurability to adapt to those environments. We believe that is a very interesting future research study.

Reconfigurable ML systems. VirtualFlow [43] and Singularity [49] decouple DL jobs from physical devices, which enable flexible GPU mapping at runtime but require complex driver-level virtualization and does not support multi-dimensional parallelism changes. Tenplex [58] is a state management library by describing the state as a parallelizable tensor collection (PTC), and generates reconfiguration plans for job change at runtime. While Tenplex supports changing subsets of the parallelism, it is limited to intra-cluster reconfigurations, and storing partitioned parameters in host memory creates memory pressure and impacts training accuracy due to non-optimized state recovery. UCP supports cross-cluster migration while fully preserving training accuracy.

8 Conclusion

This paper presents Universal Checkpointing (UCP), a checkpointing system for training large-scale DNNs with reconfigurable parallelism. The primary goal of UCP is to enable flexible reconfiguration of parallelism strategies through distributed checkpoints. Therefore, UCP provides a new checkpoint structure called atomic checkpoints and builds a pattern-based reconfiguration pipeline that enables automatic and systematic reconfiguration of a broad set of commonly used parallelism strategies while preserving model accuracy. To reduce the reconfiguration cost, UCP introduces nested-parallel reconfiguration and lazy invocation to make the reconfiguration overhead negligible to the end-to-end training cost. Our evaluations on large-scale LLM training show that UCP enables reconfiguration of a larger and more complex set of parallelism strategies with low cost. UCP has been implemented and open-sourced via a PyTorch library for accelerating large-scale DNN training, and its effectiveness has been verified through real-world large-scale LLM pre-training tasks.

Abstract

Function-as-a-Service (FaaS) is the most prevalent serverless computing paradigm, offering significant flexibility to develop, deploy, and operate cloud applications. However, traditional FaaS frameworks face significant challenges in operating transactional stateful workflows, which often involve multiple functions with shared state. Previous solutions rely on external datastores to manage shared state, suffering from high communication overhead to guarantee transactional consistency for stateful workflows.

In this paper, we present RTSFaaS, an RDMA-capable transactional stateful FaaS framework that achieves high performance while guaranteeing transactional consistency. RTSFaaS exploits a lease-based concurrency control protocol to dynamically assign and transfer leases among workers to achieve concurrency control. Specifically, RTSFaaS incorporates two key designs: (1) an affinity-aware lease assignment mechanism that improves the benefit of caching by dynamically assigning data leases to selected workers according to the data function affinity, and (2) an RDMA-capable dynamic lease transferring mechanism to reduce the cost of locking by serializing concurrent data accesses with one-sided RDMA primitives. Experimental results show that RTSFaaS achieves up to 5× and 20× performance speedup compared with state-of-the-art transactional stateful FaaS platforms–Boki and Beldi, and up to 1.7× and 2.1× performance improvement when their concurrency control protocols implemented for RDMA networks are applied to RTSFaaS.

1 Introduction

Serverless computing [12, 22, 27] has gained increasing popularity since it promises to simplify the programming, deploying, and operating scalable cloud applications, particularly through the *function-as-a-service* (FaaS) paradigm [11, 17, 37, 45]. This paradigm is widely adopted by mainstream vendors, including AWS Step Functions [45], AWS Lambda [46], Azure Durable Functions [37], Alibaba Function Compute [11], and Huawei Cloud Functions [17]. FaaS simplifies cloud deployment by reducing the operational complexity of managing servers while providing scalability and elasticity [33]. Developers only need to program cloud applications with *functions* that can be executed elastically by FaaS platforms. To support complex applications, FaaS platforms allow developers to compose functions into workflows [32, 66], typically abstracted as *directed acyclic graphs* [33] (DAGs).

Although the mainstream FaaS paradigm is stateless, we argue that FaaS platforms should support state management for the stateful applications built with functions [25, 60]. For example, in a banking service scenario [23], a transfer business can be implemented with multiple functions and executed in a workflow (i.e., withdraw ⇒ deposit). Because the application state is shared, these functions should be processed within a single transaction to guarantee serializable consistency when concurrent transactions access the shared state. Current stateful FaaS platforms [24, 36, 48] rely on external datastores like Amazon DynamoDB [20, 43] and S3 [44] to manage the application state. While the disaggregation of compute and storage enables shared state management, it often introduces substantial performance overhead from frequent remote state accesses [30, 48], which challenges stateful FaaS platforms in achieving strong consistency without sacrificing performance.

First, the concurrency control usually leads to high communication overhead due to frequent remote accesses to the lock status. To guarantee transactional consistency for stateful workflows, state-of-the-art stateful FaaS platforms like Boki [25], Beldi [60], and T-Statefun [15] rely on a remote datastore to implement concurrency control protocols such as *two-phase locking* (2PL) [21, 49] and *optimistic concurrency control* (OCC) [1, 25]. However, these protocols require frequent remote communications for acquiring and releasing locks, as well as validating conflicts between concurrent function executions. This results in high latency, particularly in high-contention environments, since the communication overhead associated with *remote memory access* (RMA), lock

*Corresponding author: Haikun Liu (hkliu@hust.edu.cn)

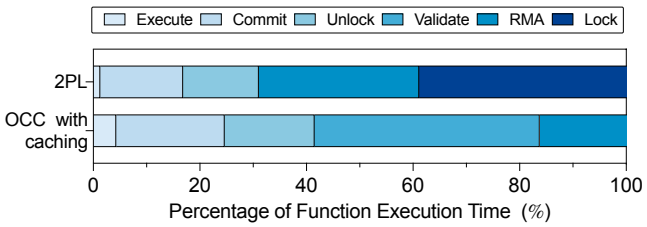

Figure 1: Breakdown of function execution time for the banking service workload. Both 2PL [60] and OCC with caching [25] are optimized using one-sided RDMA verbs.

management, and conflict validation becomes a significant bottleneck. As illustrated in Figure 1, these overheads remain the major performance bottleneck of stateful FaaS workflows even using RDMA networks.

Second, concurrency control protocols often undermine the efficiency of caching in stateful FaaS platforms. To reduce the performance overhead of remote state accesses, many stateful FaaS platforms adopt caching mechanisms that store frequently-accessed data locally [34, 48, 57, 61]. However, the benefit of caching is often limited when applications require strong consistency guarantees. In 2PL, the necessity of acquiring locks from a remote datastore diminishes the effectiveness of local caches since functions must acquire remote locks even when the cache is valid. Moreover, frequent state updates may invalidate the local cache, further reducing its efficiency. In OCC, while functions can read and modify the local cache optimistically, they must validate whether the original data has been modified by other transactions before committing a transaction. If conflicts are detected, the transaction is aborted and retried, offsetting the benefit of caching.

In this paper, we present RTSFaaS, an **R**DMA-capable **t**ransactional **s**tateful **FaaS** framework that achieves high performance while guaranteeing strong consistency. RTSFaaS exploits a lease-based concurrency control protocol to dynamically assign and transfer leases[1] among workers. Unlike traditional leasing mechanisms, our approach allows a worker to cache and control access to specific objects in a distributed cache with exclusive rights. Thus, there is only one replica of an object that is exclusively cached by a single worker from a global perspective. In this way, RTSFaaS allows a large majority of transactions to be executed with a strong affinity for cached objects, and thus reduces remote communication overhead and improves the benefit of caching. Specifically, RTSFaaS incorporates two key designs to address the aforementioned challenges of handling transactional stateful serverless workflows in current FaaS platforms.

First, we propose an **affinity-aware lease assignment mechanism** to enhance the benefit of caching by assigning a group of interdependent objects to a single worker with an exclusive lease. RTSFaaS maintains a statistical table to count the total number of requests and data access frequency for each worker. Upon each request, RTSFaaS exploits a score-based scheduling policy to assign it to a worker who has the strongest data affinity for the request according to the statistical table. After assigning a batch of requests to different workers, RTSFaaS uses the latest statistics to designate workers as leaseholders for each object. If a worker has the highest access frequency to an object, it becomes the leaseholder of the object. In this way, RTSFaaS allows more functions to execute with the local cache, thereby significantly enhancing the benefit of caching and reducing remote memory accesses.

Second, we propose an **RDMA-capable dynamic lease transferring mechanism** to significantly reduce the network communication overhead of locking. For each batch of requests, RTSFaaS decouples the function execution and the consistency guarantee into two non-overlapping phases: planning and execution. During the planning phase, workers identify data dependencies among functions to collaboratively construct a global *task precedence graph* (TPG), which is used to serialize the function execution. During the execution phase, RTSFaaS allows leaseholders to cache and control the access to specific objects with exclusive rights. These leaseholders independently prefetch the corresponding objects into their local caches. Then, they execute functions and dynamically transfer the lease of objects to others according to the global TPG, which ensures sequential data accesses. When a worker has to access objects that are not cached locally, the worker checks the lease of remote objects and directly accesses other workers' caches using one-sided RDMA verbs.

We implement RTSFaaS [42] using a cluster connected with RDMA networks and evaluate it with commonly-used microservice benchmarks [23, 25, 60]. Experimental results show that RTSFaaS improves the throughput of applications by up to 5× and 20× compared with the state-of-the-art stateful FaaS platform–Boki [25] and Beldi [60]. To further evaluate the efficiency of our lease-based concurrency control protocol, we implement their concurrency control protocols in an RDMA-enabled environment for comparison. Experimental results show that RTSFaaS achieves up to 1.7× and 2.1× performance speedup over these RDMA-based implementations.

In summary, we make the following contributions:

- We design RTSFaaS, an RDMA-capable transactional stateful FaaS framework that significantly improves the performance while guaranteeing strong consistency for transactional stateful serverless workflows.
- We propose an affinity-aware lease assignment mechanism that improves the benefit of caching by dynamically assigning data leases to selected workers according to the data-function affinity.
- We propose RDMA-capable dynamic lease transferring to reduce the cost of locking by serializing concurrent data accesses with one-sided RDMA primitives.

[1]The lease mechanism grants temporary access or ownership rights to a resource (such as data or a lock) for a specific period.

- Experimental results show that RTSFaaS outperforms state-of-the-art stateful FaaS platforms, achieving up to 5× and 20× higher throughput than Boki [25] and Beldi [60], respectively. Even when their concurrency control protocols are adapted to RDMA networks and integrated into RTSFaaS, our design still yields up to 1.7× and 2.1× performance improvements.

2 Background and Motivation

In this section, we present the background of transactional stateful FaaS workflows, discuss the limitations of existing solutions, and explore the potential of using *remote direct memory access* (RDMA) in FaaS platforms.

2.1 Transactional Stateful FaaS Workflows

The FaaS paradigm [4, 25, 30, 36, 48, 57, 60] has become increasingly popular for developing, deploying, and operating cloud applications. However, because of the stateless nature of functions [25], existing FaaS platforms can not efficiently support stateful applications that require state sharing and transactional processing, such as payment processing [30], travel reservation [60], inventory management [25], and business services [23].

To support these complex applications, multiple functions can be composed into a workflow, represented as a *directed acyclic graph* (DAG) [33, 45]. Each node in this graph corresponds to an individual function, while edges denote the execution order and the transfer of intermediate results between functions. For instance, in the banking service scenario as shown in Figure 2, several services such as payment (pay), saving (save), and transfer (withdraw ⇒ deposit) are provided. Despite the distinctiveness of these functions, they share the same application state, such as the balance of users' accounts. Additionally, the transactional semantics are crucial to ensure that the transfer service is registered simultaneously on both the recipient and sender accounts. Consequently, these functions in the workflow (withdraw ⇒ deposit) must be executed with a transaction. This requirement mandates FaaS platforms to guarantee transactional consistency, i.e., the results of concurrent transactions are conflict-equivalent to some serial execution of these transactions [25, 60].

2.2 Limitations of Existing Solutions

Current stateful FaaS platforms [24, 36, 48] rely on external datastores like Amazon DynamoDB [20, 43] and S3 [44] to manage the application state. While the disaggregation of computing and storage facilitates the shared state management, it makes the stateful FaaS platform struggles to achieve strong consistency while maintaining high performance. Existing stateful FaaS platforms either support weak consistency [34, 48, 57] or cause high performance overhead

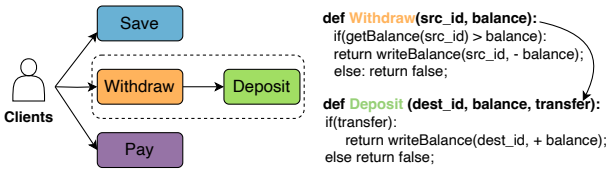

Figure 2: An example of the banking service workflow [23]

to ensure transactional consistency [15, 25, 30, 60]. None of them provides an efficient way to guarantee transactional consistency for transactional stateful serverless workflows.

Weak Consistency. A number of FaaS platforms have been designed on the basis of causal consistency principles, including Cloudbust [48], HydroCache [57], FaaSTCC [34], and CausalMesh [61]. These FaaS platforms exploit local caches on each computing node to achieve high performance. However, these platforms only guarantee weak consistency, such as *transactional causal consistency* (TCC) for workflows. To guarantee TCC, a workflow reads from a causal snapshot [34], and other workflows cannot observe its results until it is entirely completed. However, TCC allows anomalies such as stale reads and write-write conflicts, which do not satisfy the requirements of transactional stateful FaaS applications.

Transactional Consistency. To guarantee transactional consistency, stateful FaaS platforms like Beldi [60], Boki [25] and T-Statefun [15] rely on a remote datastore to implement concurrency control protocols, such as *two-phase locking* (2PL) and *optimistic concurrency control* (OCC). In 2PL, transactions ensure serializable execution by acquiring/releasing locks. In contrast, OCC allows transactions to read and modify the local cache optimistically, but conflicting operations must be checked before committing transactions. Unfortunately, these protocols lead to high communication overhead due to frequent remote accesses for lock management and conflict validation. Additionally, they often undermine caching benefits by invalidating cached data or causing frequent transaction retries.

2.3 Remote Direct Memory Access

RDMA is a networking technology that enables direct access to the main memory of a remote node over networks [6, 28, 67]. Unlike the TCP/IP protocol, RDMA can eliminate memory copying among buffers (zero-copy) via bypassing the OS kernel. Thus, it achieves high-bandwidth and low-latency network transmission with minimal CPU involvement. RDMA supports two types of verbs for remote memory accesses: one-sided and two-sided verbs [28]. Two-sided verbs (send, recv) use channel semantics in which the sender should interrupt the receiver's CPU to process network messages. In contrast, one-sided verbs (read, write, and atomic verbs) use memory semantics. The sender should first register a remote memory region on the receiver to perform RDMA operations. Then, the receiver's *RDMA network interface card* (RNIC) exploits

the *direct memory access* (DMA) mechanism to access data without involving its CPUs.

RDMA in the FaaS platforms. RDMA has been widely used in *high-performance computing* (HPC) and cloud computing scenarios, supporting distributed transactions [7, 19, 29, 53], disaggregated memory systems [31, 47, 52, 62, 63], and other data center environments [7, 13, 16, 54]. RDMA also offers new possibilities in the FaaS domain. Recent RDMA-based FaaS frameworks such as rFaaS [13], MITOSIS [54], and RMMAP [33] have exploited RDMA technologies for various application scenarios, including rapid remote forking [13], fast remote container initialization [54], and serialization-free state transfer [33]. Although these proposals have demonstrated the significant potential of using RDMA technologies for optimizing the performance of FaaS platforms, no effort has been made on transactional stateful serverless workflows using RDMA networks.

3 RTSFaaS Design

We first present the RTSFaaS architecture, and then describe the lease assignment and transfer mechanisms.

3.1 System Overview

Figure 3 illustrates the RTSFaaS architecture, designed for elastic autoscaling by disaggregating storage and compute resources [25, 48, 60]. RTSFaaS consists of three main components: the RTSFaaS driver, workers, and a *key-value* (KV) store using TiKV [39, 51], which supports geo-distributed replication mechanisms for high availability. The RTSFaaS driver and workers run in individual Docker containers [18]. Client requests, received by the API gateway, are routed by the RTSFaaS driver to appropriate workers. Each worker consists of a function scheduler, a set of executors, and a local data cache shared by all executors. The scheduler invokes a set of functions to execute the workflow within these executors according to the global *task precedence graph* (TPG). To eliminate the cost of data synchronization among multiple replicas and to save memory space, each KV object is exclusively cached by only one worker (i.e., a leaseholder), and can be accessed by another worker via RDMA operations when its lease is transferred to the remote executor. All workers' local data caches construct a global shared memory pool which serves as an intermediary between these executors and the KV store. In this architecture, RTSFaaS should address two key problems as follows.

(1) **How to exclusively cache objects in multiple workers to enhance the data-function affinity?** If objects are randomly or on-demand cached by different workers, executors usually have to frequently access objects from remote shared caches, causing significant network communication overhead. Thus, we propose an affinity-aware lease assignment mechanism to enhance the benefit of caching (Section 3.2).

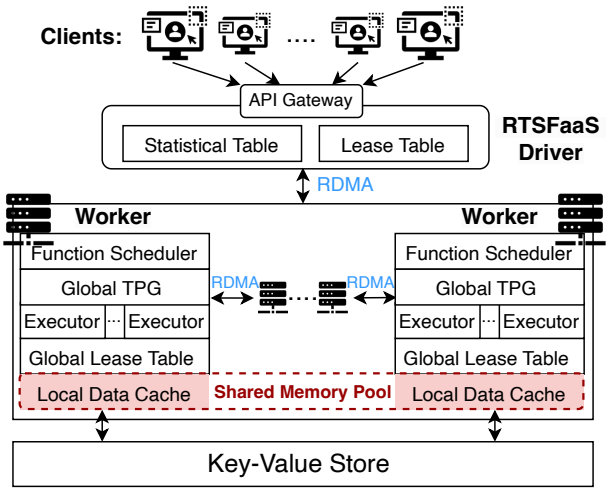

Figure 3: RTSFaaS architecture

(2) **How to access remote shared caches efficiently while maintaining data consistency when objects required by executors are missing in the local data cache?** In traditional concurrency control mechanisms, the data access is tightly coupled with the locking operation. They may suffer from high-latency data accesses when the contention for locks is intensive. Thus, we construct a TPG for functions with data dependencies to serialize the function execution, and dynamically transfer the lease of objects to other workers so that they can access these objects temporarily via one-sided RDMA operations (Section 3.3).

3.2 Affinity-aware Lease Assignment

To assign an incoming request to a worker so that they have the strongest data-function affinity, the RTSFaaS driver maintains a statistical table to record the following information for each worker: 1) the total number of functions N_i assigned to worker i; 2) for each KV object j, the total number of accesses $N_i(j)$ introduced by all functions in worker i.

When a request arrives, the driver identifies its read-write sets, denoted as $K = \{k_1, \ldots, k_n\}$, which includes all data items required by all functions in the current workflow. The affinity score A_i for worker i is calculated as the sum of access counts $N_i(k_j)$ for each key in K:

$$A_i = \sum_{k_j \in K} N_i(k_j)$$

The affinity score reflects how frequently the worker accesses all keys involved in the request. Thus, this request is preferentially assigned to a worker who has a strong data-function affinity. However, load balancing is also critical to prevent worker overloading. To achieve this goal, the total number of functions assigned to each worker (N_i), is used to compute a load balancing score S_i, which favors workers with fewer assigned functions. The load balancing score is

calculated using the following linear formula:

$$S_i = 1 - (N_i - min)/(max - min)$$

where *min* and *max* represent the minimum and maximum number of functions assigned to a worker. Thus, workers with lighter loads have higher scores.

To make a trade-off between data-function affinity and load balancing, the affinity score is also normalized using a linear mapping similar to the load balancing score. Let min' and max' be the minimum and maximum affinity scores among all workers. The normalized affinity score A'_i for worker i is calculated by:

$$A'_i = (A_i - min')/(max' - min')$$

The final score is calculated as the weighted sum of S_i and A'_i. By default, the RTSFaaS driver assigns equal weight to each score. Then, the driver forwards the request to the worker with the highest score and updates the statistical table. After a batch of requests is dispatched, a lease table is instantiated based on the statistics table, designating the worker with the highest affinity score as the leaseholder. If multiple workers get the same score, RTSFaaS assigns the lease to the one with the smallest worker ID.

3.3 RDMA-capable Dynamic Lease Transfer

RTSFaaS decouples the consistency guarantee and the function execution into two non-overlapping phases: planning and execution. In the planning phase, RTSFaaS constructs a *task precedence graph* (TPG) for functions with data dependencies to serialize the function execution. In the execution phase, RTSFaaS schedules the execution of functions based on the TPG, and dynamically transfers the lease of objects to other workers for concurrent state accesses.

3.3.1 Task Precedence Graph Construction

In the planning phase, workers identify fine-grained data dependencies within a batch of requests assigned to them and collaboratively construct a global TPG. Before delving into details, we first formally define the following terms:

Definition 1 (Workflow)**.** A workflow is defined as a set of functions $f_1, f_2, \ldots, f_n$ triggered by a client request. Each function f_i in the workflow accesses exactly one key. To satisfy this constraint, RTSFaaS decomposes any function that accesses multiple keys into a sequence of smaller functions, each operating on a single key, while preserving the original execution dependencies.

Definition 2 (Function Timestamp)**.** The function timestamp represents the time when a request invokes it. The driver is responsible for assigning a global timestamp to each request, ensuring a consistent ordering of requests across all workers.

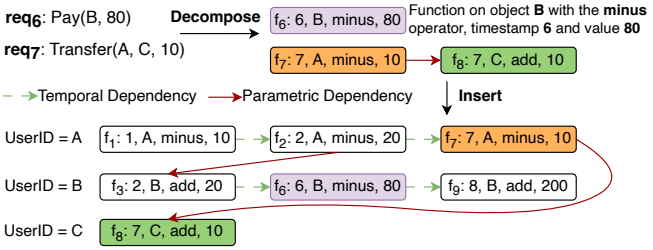

Figure 4: Dependencies and local TPG construction

For each workflow, all functions in the same workflow share the same timestamp. In this context, we define the timestamp of function f_i as $t(i)$.

Definition 3 (Temporal Dependency)**.** f_i temporally depends on f_j if they access the same state but are not invoked by the same workflow request, and f_i has a larger timestamp.

Definition 4 (Parametric Dependency)**.** f_i parametrically depends on f_j if they belong to the same workflow, and f_i needs the output of f_j.

For example, in Figure 4, $(f_6 : 6, B, minus, 80)$ is a function that operates on object B using the *minus* operator and a value 80 when the function timestamp is 6. f_6 temporally depends on f_3 as they access the same object B with different timestamps. Taking f_7 and f_8 as another example, they are triggered by a workflow request req_7 and f_8 needs the outputs of f_7. Thus, f_8 parametrically depends on f_7.

Definition 5 (Task Precedence Graph)**.** Given a batch of requests, the *task precedence graph* (TPG) abstracts functions as vertexes, and edges as temporal and parametric dependencies. Without losing generality, we represent the edge from f_i to f_j as $< f_i \rightarrow f_j >$, which means f_j depends on f_i.

Lemma 1 (Transactional Consistency)**.** If all functions invoked by a batch of requests Q are processed according to temporal and parametric dependencies, the transactional consistency is guaranteed.

Proof Sketch: The task precedence graph is a schedule of functions and we now prove it is conflict-serializable. According to the conflict serializability theorem [5, 38, 56], the schedule is conflict-serializable if and only if its conflict graph is acyclic. For temporal dependencies, if there is a direct edge from f_i to f_j, $t(j)$ is larger than $t(i)$. We assume that there is a cycle in the dependency graph, i.e., there is a set of edges: $< f_1 \rightarrow f_2 >, < f_3 \rightarrow f_4 >, \ldots < f_{n-1} \rightarrow f_n >, < f_n \rightarrow f_1 >$. This implies that the timestamps increase sequentially from $t(1)$ to $t(n)$, and $t(n)$ is less than $t(1)$. Such an assumption leads to contradictions. Thus, there must be no cycles in the dependency graph if we only consider temporal dependencies. Since parametric dependencies among functions only exist within the same workflow, they inherently avoid the cyclic pattern. Therefore, the conflict serializability is guaranteed, if all

functions are scheduled according to temporal and parametric dependencies.

Local TPG Construction. Each worker identifies fine-grained temporal and parametric dependencies within a batch of requests assigned to them and constructs a local TPG. Figure 4 illustrates how a worker constructs a local TPG for the banking service. At first, requests req_6 and req_7 are decomposed into individual functions f_6, f_7, and f_8, which represent vertexes in the local TPG. During this decomposition, parametric dependencies among functions in the same workflow can be identified. For instance, f_8 parametrically depends on f_7. To identify temporal dependencies among functions that may arrive out-of-order, workers insert newly arrived functions into key-partitioned sorted lists. In these lists, functions related to the same KV object are ordered by their timestamps. For example, even though f_9 arrives before f_6, the worker inserts f_6 before f_9 because f_6 has an earlier timestamp. Consequently, for a batch of requests, the worker sorts the functions related to the same object according to their timestamps. Then, temporal dependencies are identified by iterating through all functions in these sorted lists.

Global TPG Construction. When each worker has constructed its local TPG individually, all workers collaboratively build a global TPG based on the lease table provided by the RTSFaaS driver. As illustrated in Figure 5, node 1 has the lease of objects A and B, while node 2 owns objects C and D. RTSFaaS distinguishes *local functions* which access only locally cached data, and *remote functions* which have to access remote data. Using the lease table, each worker dispatches metadata associated with remote functions to the workers who are the leaseholders of the required data. For example, node 1 sends metadata of f_8 to node 2, and node 2 sends metadata of f_{12} to node 1. Workers collect these metadata from other nodes as virtual vertexes and integrate them with their initial local TPG to detect temporal dependencies. For instance, the virtual vertex $(N_1, 7, C)$ contains the metadata of f_8 from node 1 with timestamp 7 and accessing data item C. Thus, node 2 inserts $(N_1, 7, C)$ before f_{10} because f_8 has an earlier timestamp. In this way, each worker constructs a global TPG for a batch of functions that interact with objects stored in its local data cache.

3.3.2 Dynamic Lease Transferring

In the execution phase, each worker maintains a *global lease table* to facilitate dynamic lease transferring, and a *local data cache* accessible to other workers. The *global lease table* is used to determine which worker is the leaseholder of specific objects and the storage order of these objects on each worker. RTSFaaS restricts data prefetching and access control management to leaseholders. These leaseholders fetch the required objects from the KV store in advance to construct the local data cache, ensuring that the data is readily available for subsequent processing.

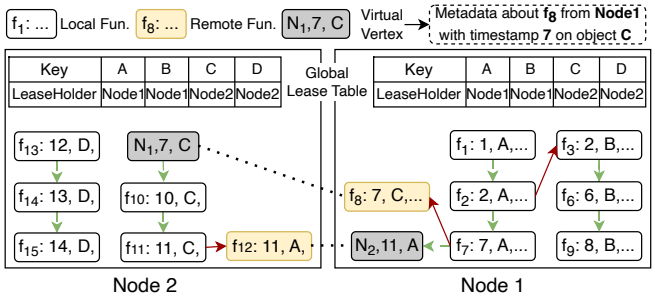

Figure 5: Global TPG construction

Local Cache. Workers share the local data cache by maintaining KV objects in the order of their keys. Each worker sorts KV objects based on the numerical values represented by their keys. When a worker is the leaseholder of a key, it proactively fetches the corresponding values from remote storage and writes them sequentially into pre-allocated memory regions. Additionally, each value is augmented with a 16-bit *lease flag* at the beginning to reflect its lease status. Initially, the lease of each value is assigned according to the lease specified in the global lease table. After processing a batch of requests, each worker writes back updates from its local cache to the remote KV store, ensuring a consistent view for the next batch and enabling fault tolerance (see Section 4.2).

Function Execution. RTSFaaS exploits a dynamic lease transferring mechanism to guarantee data consistency across local data caches. Functions are executed sequentially according to the global TPG generated during the planning phase. When a worker encounters a normal vertex (local or remote function), it first checks the global lease table to determine the data's location. For a local function, the worker accesses data directly using the starting address of its local memory region and calculates the value's offset based on the key index and value size. For a remote function, the worker calculates the memory address based on the starting address of the remote memory region and the key's index, retrieving data using one-sided RDMA verbs without involvement in remote CPUs.

Regardless of whether the data is cached locally or remotely, the worker must verify whether it has the current lease of the object by comparing its worker ID with the lease flag. The worker can continue to access data and execute functions only when the lease of the object has been transferred to it. This ensures that the worker can safely access or update the object only if it holds the data lease. After completing the data access, the remote worker then transfers the lease to the original leaseholder based on the *global lease table*. The leaseholder then continues to transfer data leases according to the global TPG. The leaseholder transfers the lease to other workers based on the virtual vertex, which contains metadata about the source worker and the object required. When a virtual vertex is scheduled, the leaseholder transfers the data lease to the corresponding worker by updating lease flags in its *local data cache*.

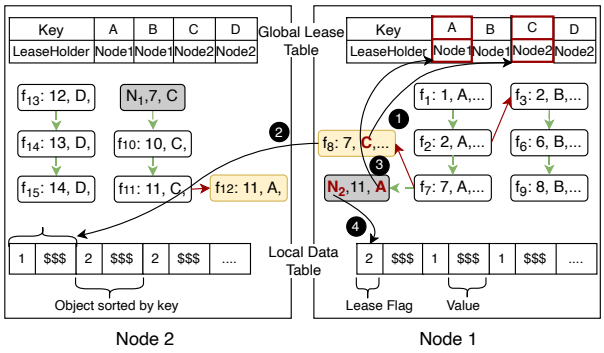

Figure 6: Dynamic lease transferring

As shown in Figure 6, workers adopt a breadth-first exploration mechanism to schedule functions based on the global TPG. Node 1 first picks an executor for f_1, as it has no unresolved dependencies. Once f_1 completes, f_2 becomes eligible for execution. After f_2 has been processed, f_7 and f_3 can be scheduled on different executors in parallel, as their data dependencies are resolved. f_8 presents a more complex case, as it is a remote function that requires access objects cached on other workers. To execute f_8, the executor first checks the global lease table to locate the object in Node 2 and get its index (0) in Node 2's local data cache (❶). It then uses one-sided RDMA verbs to fetch the remote object and checks the lease flag to ensure that Node 1 is the current leaseholder before performing any updates (❷). When scheduling the virtual vertex (N_2, 11, A), Node 1 checks the global lease table to get the index of the object (key = A) (❸). Then, it transfers the lease to Node 2 by updating the lease flag from 1 to 2 (❹). This indicates that once all dependencies of f_{12} are resolved, Node 2 can execute f_{12} by directly accessing object A from Node 1's cache.

Handling Transaction Aborts. To address transaction aborts, we adopt an approach inspired by Yao et al. [58], which effectively eliminates cascading aborts during transaction execution. While RTSFaaS resolves transactional conflicts before execution to ensure that no abort occurs due to such conflicts. However, transaction aborts may still result from constraints of database fields, such as non-negative balance. To handle this, RTSFaaS introduces a condition-variable check as the initial function within each transactional workflow. All subsequent functions in the transaction are parametrically dependent on this initial check. If the condition-variable check fails, it propagates disabled signals to the interdependent functions in the workflow, thereby avoiding cascading aborts and reducing their associated overhead during execution.

4 Implementation

In this section, we describe the RDMA-based data transfer protocol and fault tolerance mechanisms.

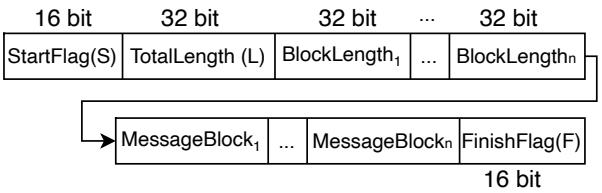

Figure 7: Data layout of RDMA messages

4.1 RDMA-based Data Transfer

4.1.1 RDMA Channel

The RDMA channel in RTSFaaS enables efficient communication between the driver and workers, as well as two workers. RTSFaaS employs a push-based data transfer model with RDMA write and a structured message layout to ensure reliability and parallel processing.

RDMA Verbs. RTSFaaS adopts RDMA write instead of RDMA read to achieve the push-based transfer model due to the following reasons: 1) First, since workers are usually computing intensive, the push-based transfer model empowered by RDMA write is preferable. This approach allows the driver to write the workers' memory directly, enabling workers to poll local memory efficiently. In contrast, using RDMA reads, the driver would continuously read the remote memory till the requested data is available, leading to additional network traffic and higher latency. 2) Second, the RDMA read entails a round-trip message, and results in higher latency and CPU utilization [16]. In contrast, one-sided RDMA write requires only a single trip per message.

Data Layout of RDMA Messages. We carefully design the data layout of RDMA messages to ensure data integrity and to support parallel processing. As illustrated in Figure 7, the message comprises several elements: a short start-flag S indicating the beginning of the message, the total message length L, and the length of each message block. The number of message blocks n corresponds to the number of parallel instances in the receiver, i.e., n is the number of its function executors for each worker. Subsequently, a set of message blocks follows, with each block containing a portion of the messages slated for processing. At last, a short finish-flag F denotes the end of the message.

4.1.2 RDMA Communication Protocol

Connection Establishment. In RTSFaaS, each worker establishes connections with the RTSFaaS driver and other workers, facilitated by a configuration file that specifies the network addresses of all nodes. During the initialization, each worker configures its RDMA resources, including memory regions for data transfer, completion queues, and queue pairs. Simultaneously, the driver sets up a listening endpoint to await connection requests from workers.

When a worker sends a connection request, the RTSFaaS driver responds by performing a handshake to exchange in-

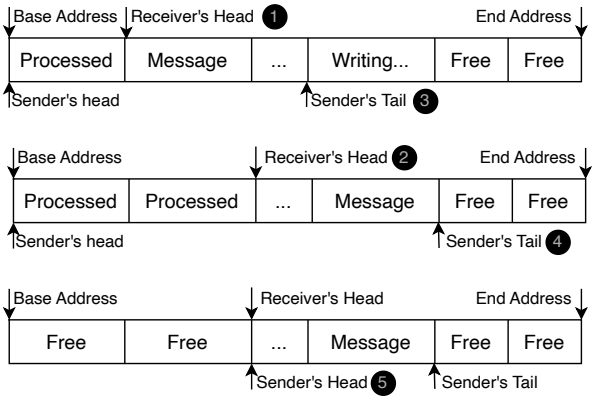

Figure 8: Circular buffer for data transfer

formation about memory regions. Simultaneously, workers exchange connection requests to establish direct connections with one another. During this process, the driver and workers exchange RegionTokens, which encapsulate details of shared memory regions, such as base addresses and sizes. These tokens enable direct memory access during RDMA operations.

Data Transfer. RTSFaaS achieves the RDMA-based data transfer using circular buffer [16, 19], as shown in Figure 8. As RTSFaaS adopts a push-based transfer model, the circular buffer is initialized in the receiver, and there is one buffer for each sender/receiver pair. The receiver periodically polls the buffer at the "Head" position to detect new messages (❶). As shown in the message layout, any start-flag value S in the head indicates a new message. Then, the receiver polls the message trailer based on the total message length L. When it becomes the finish-flag F, the entire message has been received because RDMA writes are performed in a FIFO order. Finally, the receiver advances the head pointer (❷).

The sender utilizes RDMA write to transfer messages to the buffer tail (❸), incrementing the tail pointer with each transmission (❹). It maintains a local copy of the receiver's head pointer and ensures that messages are only written up to that point. The receiver, on the other hand, lazily updates the sender's copy of the head pointer by writing the current head value via RDMA (❺). To minimize overhead, the receiver updates the sender's copy only after processing at least half of the buffer [19]. Consequently, the sender's head pointer always lags behind the receiver's, guaranteeing that unprocessed messages are never overwritten.

RTSFaaS employs a mechanism similar to the Chandy-Lamport algorithm [9] to ensure a consistent transition between the planning and execution phases for workers. In RTSFaaS, the driver maintains the global lease table, which records the current leaseholder for each data item. For each batch of requests, the driver assigns new leases for each data item and updates the lease table accordingly. After the driver has finished sending the requests for a batch, it broadcasts the updated global lease table along with a unique transition-flag message. Each worker then maintains a local copy of the lease table, synchronized with the driver's decisions, ensuring consistent lease ownership across all workers during the execution of the batch.

When workers receive requests, they first build a local TPG during the planning phase. Upon receiving the transition-flag and global lease table, workers collaboratively construct the global TPG. Once the global TPG is completed, workers move to the execution phase. The driver periodically injects the transition-flag to process requests in batches. The interval between injections is determined by the local cache capacity, as workers need to prefetch data items for each batch.

4.2 Fault Tolerance

For the storage layer, we rely on TiKV [39, 51]'s replication scheme for k-fault tolerance. In the computing tier, we adopt the standard fault tolerance approach commonly used in many FaaS platforms: if a machine fails, all machines reload the necessary data and re-execute the batch of requests to ensure that no task is lost. Once compute nodes have completed the transactions, their data caches are written back to the storage layer in batches, as discussed in Section 3.3. To ensure consistency and reliability during this write-back phase, we adopt a snapshot-based recovery mechanism combined with log-assisted tracking for efficient failure recovery.

After a batch of requests is completed, each compute node creates a snapshot of its local cache, which captures the latest state and is used for recovery in case of failures. Once all compute nodes successfully generate snapshots, they proceed to write back their local cache to TiKV [39, 51]. To assist the recovery, RTSFaaS maintains a lightweight log that tracks the progress of snapshot creation and write-back operations, recording the current operation and its status (e.g., "snapshot created," "write-back successfully"). If a failure occurs during snapshot creation, RTSFaaS reloads the original data for the failed nodes from TiKV [39, 51], re-executes the batch of requests, and regenerates the snapshot. For failures during the write-back process, RTSFaaS restores the failed node's local cache from its snapshot and reattempts the write-back.

This recovery mechanism ensures reliable failure handling in the compute layer. For example, when a write-back is completed before failure, RTSFaaS continues processing with zero downtime. If a failure occurs after snapshot creation but before write-back, the snapshot enables a retry within 233 ms. In cases of complete data loss, RTSFaaS can reload the original data, re-execute the batch, and regenerate the snapshot in 729 ms under a snapshot interval of 500 ms with a workload of 5,000 queries per second. In addition, the Docker startup and reconnection times for a cluster of one driver and four workers are 20.31s and 15.66s, which remains the dominant recovery overhead. Further improvements, such as RDMA-based optimizations used in MITOSIS [54], can be applied to reduce cold start latency.

4.3 Limitations

Handling Dependent Reads. Our lease assignment mechanism depends on knowing the full read/write set of each transaction, which becomes challenging in the presence of dependent reads. RTSFaaS follows a strategy similar to deterministic databases [35,50,65], where the driver performs early reads to resolve dependencies and determine the complete access set before assigning leases. While this approach ensures correctness, it introduces additional communication overhead due to the extra round-trip required for these early reads. Moreover, during the construction of the TPG, unresolved dependent reads are conservatively assumed to potentially interact with any prior or future operation. As a result, their metadata must be broadcast to all workers to capture possible global dependencies. This pessimistic strategy ensures correctness but incurs a non-negligible communication cost. Given the inherent difficulty of resolving dependencies for non-deterministic functions [41], developing more efficient solutions remains an important direction for future research.

Hotspot Contention on Remote Keys. Our affinity-aware lease assignment mechanism aims to reduce contention on remote keys by co-locating related functions and data. In large-scale deployments, it is still possible for tons of concurrent functions to acquire the lease on the same remote key. Our current design adopts a single logical leaseholder model per data item in the local data cache, which may become a bottleneck under high contention. Inspired by industrial systems such as PolarDB [8], one promising extension is to adopt a replicated-state model, where multiple read-only replicas are colocated with compute nodes to absorb read traffic, while a single primary replica coordinates updates. Such an approach could further improve scalability by mitigating lease contention hotspots.

5 Evaluation

In this section, we conduct a comprehensive evaluation of the design of RTSFaaS using a set of end-to-end experiments across several representative benchmarks. The source code is available on GitHub at `https://github.com/CGCL-codes/RTSFaaS` [42]. Our experimental studies aim to answer the following questions:

Q1: How well is the performance of RTSFaaS compared with the state-of-the-art transactional FaaS system using representative workloads? (Section 5.2)

Q2: Does the concurrency control protocol in RTSFaaS outperform those used in Boki [25] and Beldi [60] when all protocols are implemented in an RDMA-enabled environment, and how do varying workload characteristics influence their performance? (Section 5.3)

Q3: What is the performance overhead of RTSFaaS, and how different system configurations affect the performance of RTSFaaS? (Section 5.4)

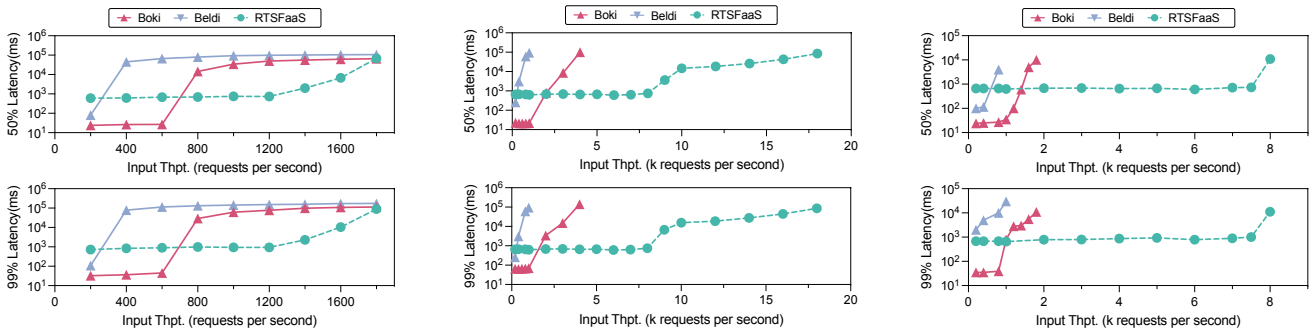
5.1 Experimental Setup

We deploy RTSFaaS [42] in a cluster with five physical machines, each equipped with Intel Xeon Gold 6230 processors and 128 GB DDR-4 memory. These machines are interconnected via Mellanox ConnectX-3 40/56 GbE network controllers, delivering a round-trip time of 7 µs for an RDMA operation. Within the cluster, one machine is designated as the RTSFaaS driver, while the remaining four serve as compute nodes that execute serverless functions. The driver and each worker operate in individual Docker [18] containers, each configured with 8 CPUs and 32 GB of memory. Each worker reserves 2 GB memory used for the local data cache.

RTSFaaS use TiKV [39,51], a highly scalable, low-latency, and easy-to-use key-value database for database management. The TiKV cluster configuration consists of three placement drivers to manage the metadata and maintain consistent partitions across the database, along with three TiKV nodes to store and manage KV objects.

This setup reflects the two-tier data organization in RTSFaaS. The first tier consists of the local data cache maintained by compute nodes within the same data center to enable low-latency RDMA access, with each data item having a single in-memory replica. The second tier is the TiKV-backed storage, which supports geo-distributed replication mechanisms for high availability.

5.2 Comparing to Transactional FaaS Systems



5.2.1 Baselines

In this evaluation, we compare RTSFaaS with the following stateful FaaS systems that guarantee transactional consistency.

Beldi [60] is a recent transactional FaaS system that leverages Nightcore [26] as its function runtime and uses a *two-phase locking* (2PL) protocol to ensure serializable consistency. In this experiment, Beldi [60] uses DynamoDB as its storage backend and operates on 8 function nodes.

Boki [25] adopts the *optimistic concurrency control* (OCC) protocol, leveraging a log-based conflict window for conflict validation. Boki [25] also uses a local cache on compute nodes to enhance read locality. We follow the experimental setup described in the Boki paper [25] to deploy 3 storage nodes, 3 sequence nodes, and 8 worker nodes.

For both Beldi [60] and Boki [25], each node runs on a c5d.2xlarge instance with 8 vCPUs, 16GB of DRAM, and hyper-threading enabled. The round-trip time between VMs ranges from 100 to 120 microseconds. To match these baseline conditions, we configure RTSFaaS with four workers, each of them provisioned with 8 cores and 32 GB of DRAM. In this experiment, we fix the batch interval at 500 ms to assess RTSFaaS's performance under stable conditions. We further explore the effects of varying batch sizes in Section 5.4.

(a) Movie Review (b) Travel Reservation (c) Bank Service

Figure 9: Latency vs. throughput for RTSFaaS, Boki, and Beldi on movie review, travel reservation, and banking service

5.2.2 Workloads

To make a comprehensive evaluation, we adapt and extend the following workloads from prior works [23, 25, 60].
1) The *Movie Review* workload simulates a movie review service where users write reviews for movies.
2) The *Travel Reservation* workload simulates a travel reservation service and consists of two main workflows that we implement: the search workflow, where users read and sort hotel and flight options by criteria such as rating and price, and the reservation workflow, which involves writing reservation details to secure hotel rooms and flights. These workflows are executed independently, maintaining a balanced 1:1 ratio between search and reservation requests.
3) The *Banking Service* workload simulates transfer operations between users. The withdraw function first reads the balance of the source account to verify sufficient funds, then writes the new balance by deducting the specified amount. Upon successful completion of the withdrawal, the deposit function is invoked to read the balance of the target account and update it by adding the specified amount.

5.2.3 Latency vs. Input Throughput

This section evaluates how the input throughput impacts latency for Boki [25], Beldi [60], and RTSFaaS across multiple workloads. Specifically, input throughput is defined as the rate of incoming requests per second to each system under test, while latency represents the total time taken from a user's request submission to the final receipt of execution results. As shown in Figure 9, RTSFaaS demonstrates superior performance compared to Boki [25] and Beldi [60] by maintaining consistently lower latency across increasing input throughput. When the median latency is 700 ms, RTSFaaS improves throughput by 2.0× (6.0×) in movie review workload, 4.0× (20×) in travel reservation workload, and 5.0× (17×) in banking service workload compared to Boki [25] (Beldi [60]).

Beldi [60] experiences higher latency even at lower input throughputs compared to Boki [25] and RTSFaaS because transactions may need to wait for locks. Since Beldi [60] uses remote locks, the overhead of acquiring and releasing locks is inherently higher due to network communication. Benefiting from the local cache and OCC, Boki [25] starts with lower latency at low input throughput because conflicts are infrequent. However, as the input throughput increases, more conflicts are detected during the commit phase, leading to more transaction rollbacks and retries, which could explain the steeper rise in both median and tail latency.

In comparison, RTSFaaS proposes a lease-based concurrency control mechanism that optimizes data locality and executes transactions without any concurrency-related aborts. Thus, RTSFaaS outperforms the other two systems as input throughput increases. Notably, RTSFaaS also exhibits constant latency even when the input throughput is low. This is because RTSFaaS commits a batch every 500ms, which introduces a fixed waiting time regardless of the input throughput.

5.3 RDMA-enable CC Mechanisms

In this section, we evaluate the effectiveness of RTSFaaS by comparing it to concurrency control protocols that rely on remote storage, as used in Boki [25] and Beldi [60]. To ensure a fair comparison and isolate the impact of network performance, we reimplement the concurrency control protocols from these platforms in an RDMA-enabled environment.
Approaches for Comparison. We compare RTSFaaS with
1) **Remote Lock:** Belid [60] ensures transactional consistency based on a variant of 2PL with wait-die lock. We enhance it by using RDMA atomic operations [59], such as *compare-and-swap* (CAS) and *fetch-and-add* (FAA) to implement lock management, including exclusive lock and share lock [10].
2) **Remote OCC + Local Cache**: As mentioned before, Boki [25] supports transactional consistency based on *optimistic concurrency control* (OCC). In addition to enhancing lock management with RDMA [53], we also implement local data caching. Thus, transactions can read and modify the local cache optimistically but must check whether any conflicting operations occur before committing transactions.

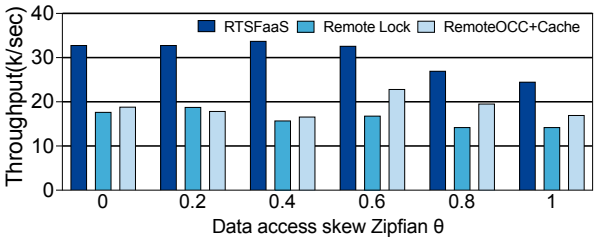


Figure 10: Impact of state access skewness

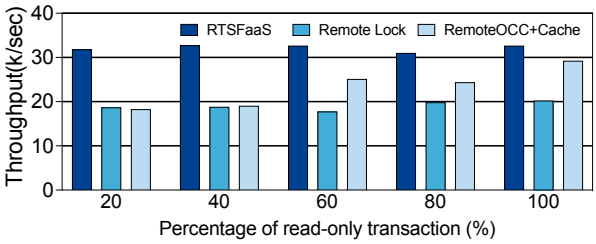

Figure 11: Impact of read-only transactions

Microbenchmark and Testbed Setup. We use a microbenchmark that reads or updates the values associated with a set of keys. The dataset contains 20,000 items, and we vary the data access skew, percentage of read-only transactions, and transactional workflow length to conduct a comprehensive evaluation. This section uses a simple RDMA-based key-value store to implement traditional concurrency control protocols. We evaluate RTSFaaS and other approaches using four workers, each equipped with twenty cores and 64 GB DRAM.

5.3.1 Impact of Data Access Skew

In this evaluation, we compare the throughput performance of RTSFaaS, remote lock, and the remote optimistic concurrency control under varying data access skew (Zipfian θ). To isolate the impact of data access skew, we configure the microbenchmark to consist entirely of write transactions, each with a transaction length of two. As shown in Figure 10, RTSFaaS consistently achieves the highest throughput across all skew levels. This robust performance is due to RTSFaaS's separation of consistency guarantees from execution, which reduces the overhead of remote locking during execution. Additionally, the affinity-aware lease assignment mechanism optimizes data locality, further enhancing throughput.

In contrast, the remote lock protocol consistently delivers the lowest throughput, primarily due to the high overhead associated with lock management. The throughput of using optimistic concurrency control exhibits a two-phase performance trend: initially, as the skew increases, its performance improves due to the effectiveness of caching, reaching around 23k/sec at θ=0.6. However, as the skew continues to increase, the performance declines sharply to about 16k/sec at θ=1. This decline is caused by higher contention, which leads to increased aborts and retries. As a result, the cache becomes less effective, further reducing performance.

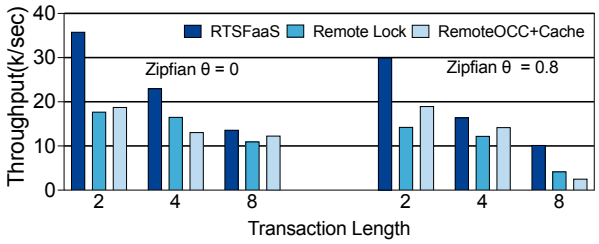

Figure 12: Impact of transactional workflow length

5.3.2 Impact of Read-Only Transactions

Figure 11 illustrates the throughput of RTSFaaS, remote lock, and the remote optimistic concurrency control as the percentage of read-only transactions changes. The remote optimistic concurrency control shows better performance at higher read-only transaction percentages due to effective caching. However, as the read-only percentage decreases, its performance drops because frequent non-local reads are needed to update the cache in the presence of writes, increasing contention and reducing cache effectiveness.

In contrast, RTSFaaS consistently outperforms other mechanisms, especially when the percentage of read-only transactions is low. This is because RTSFaaS improves data locality by assigning groups of interdependent data items to a single worker under the exclusive lease. Additionally, RTSFaaS allows workers to access each other's local caches directly using one-sided RDMA verbs, thereby avoiding the overhead of contacting the storage multiple times to obtain a fresh version. Since RTSFaaS processes read and write operations in the order of their dependencies, its performance advantage remains stable as the percentage of read-only transactions increases.

5.3.3 Impact of Transactional Workflow Length

As shown in Figure 12, we compare throughput across various transactional workflow lengths, which is defined as the number of atomic functions within a single workflow. As the transactional workflow length increases, the performance of all mechanisms declines. This performance decrease is attributed to the increased number of operations each request needs to process, which naturally leads to lower throughput.

For the remote optimistic concurrency control, throughput declines sharply with longer transactional workflows, especially at Zipfian $\theta = 0.8$. The decline is caused by the increased probability of conflicts as the length of each transactional workflow grows, which raises the likelihood of aborts and re-executions during the validation phase. The aborts and re-executions lead to wasted computational resources and a significant reduction in the effectiveness of caching. Similarly, remote lock consistently shows lower performance due to the increased lock contention in longer transactional workflows, which leads to more frequent remote lock acquisitions and increased communication overhead.

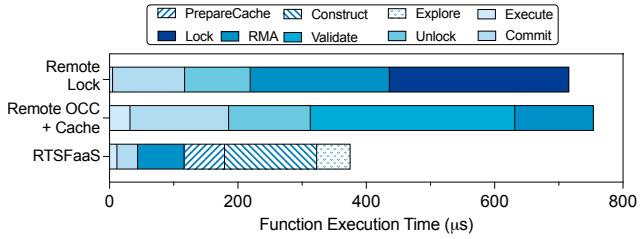

Figure 13: Function execution time breakdown

In contrast, RTSFaaS achieves superior throughput compared to others by serializing function execution through a global TPG, which significantly reduces the network communication overhead associated with lock operations.

5.4 Performance Influencing Factors

5.4.1 Factor Analysis

To further investigate the performance differences between RTSFaaS and directly implement the concurrency control protocols used by Boki [25] and Beldi [60] in the RDMA-enabled environment, this section decomposes the execution time of the function to perform a factor analysis. As depicted in Figure 13, both the remote lock and optimistic concurrency control protocols incur substantial overhead due to frequent interactions with remote storage, including operations such as locking, unlocking, and validation. This result highlights that merely adding RDMA on top of existing protocols designed for transactional consistency does not effectively alleviate the overhead of remote communication. RTSFaaS spends a substantial portion of time on the construction and exploration phases, where it constructs the global TPG and explores this graph to select functions for execution. Despite this additional task, RTSFaaS significantly reduces the communication overhead associated with frequent interactions with remote storage. Thus, RTSFaaS presents an overall improvement in performance compared to the other two protocols.

5.4.2 Impact of Batch Size

In this section, we evaluate the impact of batch size on the performance of RTSFaaS. The batch size, defined as the number of workflows handled between two consecutive punctuations, plays a critical role in RTSFaaS's performance. Figure 14 shows the throughput and latency of RTSFaaS under increasing batch size. The results indicate that throughput initially increases with the batch size, reaching a plateau at $n = 25600$ when the computational resources on each machine are fully utilized. However, this improvement comes at the cost of higher latency, particularly at the 99th percentile. This is because, in RTSFaaS, the function executor must wait for all requests in a batch to arrive before constructing the global TPG, which is done sequentially based on dependencies. As a result, earlier requests in the batch have to wait for later ones

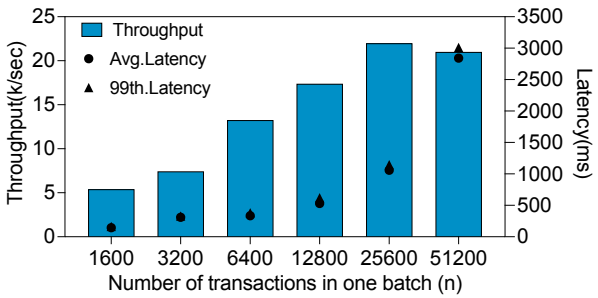

Figure 14: Effects of batch size on performance of RTSFaaS

to arrive, delaying the execution of earlier requests. Additionally, as the batch size increases, the time required to construct the global TPG also increases, further contributing to higher waiting times and higher latency at the 99th percentile.

Stateful Serverless Computing. As growing data-centric applications are apt to deploy in cloud data centers, both industry and academia have made significant efforts to enhance the performance and functionality of FaaS platforms. Various stateful FaaS platforms have been developed, some offering weak consistency [34, 48, 57], while others incur high-performance overhead [25,30,60] to ensure transactional consistency. Apiary [30] co-locates function logic and data management by wrapping a distributed transactional database management system like VoltDB [14], while Styx [40] co-locates the function execution with application states using a streaming dataflow execution model. Although Apiary [30] and Styx [40] support transactional consistency, they tightly couple storage and computation, making their system architectures fundamentally different from RTSFaaS. Other works, such as Shredder [64], propose cloud datastores that allow functions to execute directly on storage nodes. LambdaObjects [36] co-locates storage and computing by encapsulating data as objects tied to specific functions, inspired by object-oriented principles. However, none of these solutions supports serializable transactions with multiple functions. In contrast, RTSFaaS supports transactional stateful serverless workflows, and further exploits a lease-based concurrency control protocol to achieve high performance.

RDMA-capable Serverless Computing. RDMA technologies offer vast opportunities in the realm of serverless computing. Recent RDMA-based FaaS frameworks have different motivations, including remote fork [54], function scheduling [13], and state transfer [33]. MITOSIS [54] introduces an operating system primitive that aims to facilitate rapid remote fork by integrating the RDMA driver into the OS kernel. Similarly, rFaaS [13] introduces new RDMA abstractions that simplify the network stack for serverless computing, along with a decentralized resource allocation mechanism, which

allows function invocations at the microsecond level. In addition, RMMAP [33] proposes a new OS primitive that maps a remote memory region into a local process using RDMA, and thus can streamline the process of transferring states between any pair of functions, thereby eliminating the need for serialization and deserialization. Unlike these proposes that incorporate RDMA into serverless computing, our work attempts to address a different challenge. RTSFaaS focuses on improving transactional stateful serverless workflows to achieve high performance and strong consistency.

RDMA-enabled KV Stores and Transactional Storage. Existing RDMA-enabled KV stores, such as ROLEX [31] and LOLKV [2], provide strong consistency for individual operations, particularly through RDMA-friendly replication protocols. Thus, these RDMA-based key-value stores cannot be directly applied to FaaS platforms because FaaS requires transactional consistency for workflows, often involving multiple interdependent functions.

RDMA-enabled transactional storage systems exhibit a significant performance improvement for transaction processing [19, 29, 53, 62, 63]. FaRM [19], FaSST [29], DrTM [55], and DrTM-H [53] can support strong consistency for distributed transactions via 2PC/OCC RDMA-based approach. They are effective in monolithic architectures, whereas RTSFaaS is designed for the disaggregated architecture widely adopted in FaaS platforms. More importantly, RTSFaaS reduces remote communication overhead by employing a lease-based concurrency control protocol at the computation layer.

In addition, FORD [63] and Motor [62] further optimize distributed transactions through advanced techniques in disaggregated memory environments. FORD [63] accelerates distributed transactions by utilizing fast one-sided RDMA operations and consolidating operations such as reads and locks into a single RTT. On the other hand, Motor [62] leverages the *consecutive version tuple* (CVT) and one-sided RDMA operations to efficiently support multi-version distributed transactions, and thus reduces network round trips and improves concurrency. While FORD [63] and Motor [62] optimize the performance of individual transactions, they primarily focus on enhancing single RDMA operations. In contrast, transactional workflows involve a sequence of interdependent operations, where the outcome of one function may affect others. These transactional workflows should guarantee strong consistency and coordinate all functions. RTSFaaS addresses this problem by resolving the dependencies among chained functions, and guaranteeing transactional consistency via dynamic lease assignment and transfer, rather than just optimizing individual transactions.

To address communication overhead in RDMA environments, recent efforts such as ALock [3] enable local memory access without relying on RPCs or loopback, significantly improving synchronization efficiency. While ALock [3] targets fine-grained synchronization for low-level memory access, our lease mechanism emphasizes enhancing caching efficiency and managing dependencies among concurrent transactional workflows. Nevertheless, integrating ALock [3] into our dynamic lease transfer protocol could further improve coordination efficiency between local and remote memory accesses in disaggregated FaaS systems.

Deterministic Transactional System. Deterministic systems such as Calvin [50] avoid coordination overhead by predefining a global transaction execution order, thereby eliminating the need for distributed locks or optimistic validation. However, these approaches face limitations when applied to the disaggregated, dynamic nature of FaaS platforms. Specifically, Calvin [50] focuses on read-write conflicts over the same key, whereas transactional workflows in FaaS often involve complex data dependencies, such as parametric dependencies between functions, which may span multiple keys and require fine-grained coordination. Moreover, deterministic systems typically rely on static data partitioning, which constrains their ability to adapt to runtime function placement and workload variations. In contrast, our system introduces an affinity-aware lease assignment mechanism that dynamically adapts data ownership and placement according to function-data affinity, improving both load balancing and execution locality in distributed FaaS environments.

7 Conclusion

In this paper, we present RTSFaaS, an RDMA-capable transactional stateful FaaS framework that achieves high performance while guaranteeing transactional consistency. RTSFaaS exploits a lease-based concurrency control protocol to dynamically assign and transfer leases among workers to achieve concurrency control. Specifically, RTSFaaS incorporates two key designs to address the aforementioned limitations of current systems: an affinity-aware lease assignment mechanism and an RDMA-capable dynamic lease transferring mechanism. Experimental results show that RTSFaaS outperforms the state-of-the-art stateful FaaS platforms, achieving up to 5× and 20× higher throughput than Boki [25] and Beldi [60], respectively. Even when their concurrency control protocols are adapted to RDMA networks and integrated into RTSFaaS, our design still yields up to 1.7× and 2.1× performance improvements.

Abstract

This paper proposes *Swift*, a novel Bayesian Optimization (BO) based parameter configuration tuning approach for big data systems. The key idea is to leverage a generative AI approach, generative adversarial network (GAN) , to generate high quality configurations based on the evaluated configuration with the highest performance. Mixing these configurations with randomly generated ones has the effect of skewing search space toward the optimal configuration, leading to faster convergence and less optimization time. Our substantial experimental results on Apache Flink, Spark programs, and an industrial setting show that *Swift* significantly improves the performance of data analytics over state-of-the-art approaches in dramatically shorter time.

1 Introduction

To support a wide range of data analytics applications, frameworks such as Apache Spark [48] and Flink [45] typically provide more than one hundred configuration parameters. It is critical to set these parameters properly to achieve high performance. For instance, the Spark parameter `memory.fraction` [49] specifies the heap memory fraction for task execution and data storage. Its value significantly affects the performance of a program. A recent study [64] showed that tuning *multiple* parameters simultaneously can further improve program performance by up to 89×.

Unfortunately, tuning the configuration parameters to optimize performance is extremely challenging for two reasons. First, *the tuning space is vast* due to the large number of parameters and even larger range of values each parameter can take. For example, prior studies [4, 64] showed that there are 34 and 41 performance-critical parameters for Hadoop and Spark, respectively. Second, these parameters may *interact* with each other in a complex (e.g., non-linear) manner [1, 4, 8, 14, 31, 35, 64].

Due to the two challenges, traditional approaches for parameter tuning are not effective. The search approaches based on rules [60, 61] and analytical models [20] do not work well due to the over-simplified assumptions on parameter interactions. On the other side, approaches based on simulation [33, 38, 55, 56] require many time-consuming simulations to find the optimized configuration, even for a single program. These limitations gave raise to the machine learning based (ML-based) approaches [1, 2, 35, 64] with significantly higher speedups over rule-based alternatives [60, 61].

ML-based approaches directly learn from *a large number of experiments*. However, it is *time-consuming to collect samples by executing a program with a configuration on a real cluster*. Indeed, the state-of-the-art ML-based approaches such as OPPerTune [42], SelfTune [26], PARIS [62, 63] and Quasar [10] do suffer from this drawback, e.g., SelfTune and OPPerTune collect 756 and 252 training samples for a single workload [26, 42].

Bayesian Optimization (BO) has been demonstrated to require the fewest number of iterations to converge [6]. For this reason, BO is adopted in highly efficient ML-based approaches such as CherryPick [2] as the search algorithm. Even though BO requires fewer iterations, evaluating the configuration in each iteration by executing the program on a real cluster would typically take at least minutes [64].

To make BO converge faster and more smoothly, we utilize a **novel approach**: generating the *likely high quality configurations that lead to high performance* for BO algorithm in each iteration, which leads to the **key contribution** of the paper: we propose a method named *Swift* to use Generative Adversarial Network (GAN) [16] to generate configurations from the target configuration, so that they share similar distribution.

To generate a high quality configuration, the goal is to ensure that the configuration itself and its corresponding performance are *"similar but not too similar"* to the target one. The generated configuration and the target configuration can be regarded as two equal-length vectors. Intuitively, the performance of a program should be similar if the distance between the two vectors is short. However, we show that this intuition is not true by the following experiments.

We first explore an intuitive and simple approach which is named *One-Neighbor (ON)*. Essentially, ON uses the Manhattan distance to capture the similarity between configurations (vectors). However, we observed that configurations with similar vector distances to the target one can exhibit either similar or significantly different performance, rendering the approach ineffective for configuration generation. This led to our **key insight**: producing the *"similar but not too similar"* performance requires NOT ONLY a short distance between the two vectors BUT ALSO similar distributions of their element values. To this end, we identified Jensen-Shannon (JS) divergence [13] as the ideal metric, as it is a widely used method for quantifying the similarity between two probability distributions. By mathematic definition, JS divergence ranges from 0.0 to 1.0, and if a distribution is more similar to another one, the smaller JS divergence is. Notably, GANs inherently use JS divergence as a loss function to ensure generated images resemble input images. Although our work focuses on one-dimensional configuration vectors rather than images, we adapted this principle to our domain where training GANs is simple as well as fast.

Although leveraging GAN appears intuitive, its integration into BO optimization is not trivial and needs to be carefully designed. Overall, *Swift* works as follows. First, the GAN needs to be continuously trained by the "current best" evaluated and real sample with a noise that obeys a Gaussian distribution for each parameter. In each iteration, *Swift* uses GAN to generate 150 configurations in addition to 100,000 ones generated randomly. Thus, the pool that BO's acquisition function selects the configurations to evaluate in an iteration is a *mixture* of GAN-generated and randomly generated configurations. After a configuration is chosen, it is evaluated through real execution, and if its performance is better than the "current best", it is stored in the evaluated set (ES). The samples in ES will influence the selection in the future iterations. The details and rationales of the design will be explained in Section 3.2.

We comprehensively evaluate *Swift* using four Flink programs, twenty four Spark programs with three inputs each, and twenty three configuration-sensitive Spark SQL queries from TPC-DS [53]. We compare *Swift* against four state-of-the-art approaches: CherryPick [2], Selecta [27], DAC [64], and GML [18]. Since the last three achieve comparative speedups but require significantly more time to achieve the speedups compared to CherryPick, we take CherryPick as our baseline. It is worth mentioning that OPPerTune [42] and SelfTune [26] require over 10× as many samples as *Swift* and thus we did not compare them with *Swift* in the experimental section.

The experimental results show that *Swift* improves the throughput of Flink programs tuned by CherryPick by up to 1.59× (1.28× on average), and reduces their latency by up to 1.68× (1.31× on average). Most importantly, *Swift* completes the optimization in only 5.8 hours while CherryPick takes at least 12.5 hours. For Spark programs, *Swift* reduces their execution time tuned by CherryPick by up to 2.2× (1.2× on average). Similar to Flink, *Swift* takes up to 156% less time (61% on average) than CherryPick to optimize the performance of the experimented Spark applications.

We also evaluate *Swift* with a Flink program in a production cluster of an internet giant. The program was optimized by manual tuning and the optimization took a performance engineer *four days* to complete. The results show that *Swift* improves the throughput of this manually optimized program by 2.3× and reduces its latency by 2.8× in *only* 6.8 *hours*.

The rest of this paper is organized as follows. Section 2 discusses the background and motivation. Section 3 describes ON and *Swift* in detail. Section 4 discusses the experimental setup. Section 5 analyzes the results. Section 6 describes the related work and Section 7 concludes the paper.

2 Background and Motivation

2.1 Configurations of Big Data Systems

MapReduce is the first programming model designed for big data analytics applications [9] with various implementations such as Apache Hadoop [46] and Spark [65]. Later, many other frameworks have been deployed in industry, such as big table [7], GraphLab [34] for machine learning, Storm [52] for stream analytics, Pregel [36] for graph analytics, and Flink [45] for fused batch and stream analytics.

Although these frameworks serve for different domains, they all need to set a number of configuration parameters. Some parameters specify resource-related factors including CPU, memory, and network resources. For example, `spark.executor.memory` of Spark specifies the memory capacity allocated for an executor. This block of memory is further divided into execution memory, user memory, and reserved memory (e.g., 300 MB). Their sizes are controlled by `spark.memory.fraction` [43]. Other frameworks such as Apache Flink have similar parameters. For instance, parameter `taskmanager.memory.fraction` in Flink specifies the relative amount of memory that the task manager reserves for sorting, hash tables, and caching of intermediate results. The performance of big data systems is significantly influenced by such configuration parameters.

2.2 Limitations of Prior Work

Recent ML-based configuration tuning approaches [4, 15, 20, 21, 64] for Hadoop and Spark have demonstrated significant speedups. But as a general challenge, ML-based approaches need to evaluate a large number of samples in the real cluster, which takes at least several minutes per sample. As a result, it takes a long time (e.g., days or weeks) for the training/optimization to obtain the optimal configurations.

Figure 1 shows the time used by Bayesian Optimization (BO) to tune the configuration parameters of six typical Spark SQL queries ($q14a$,$q14b$,$q23a$, $q23b$, $q64$, and $q72$)

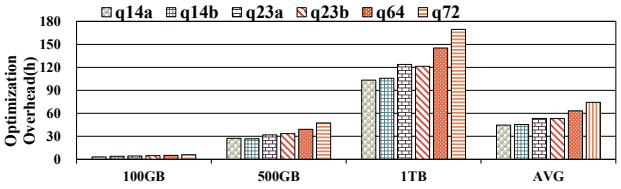

Figure 1: The time taken by using BO to tune the configurations of queries (e.g., $q72$) from TPC-DS [53] for optimal performance.

from TPC-DS [53] for optimal performance with three different input data sizes. It shows that, when the data size is 500 GB, it takes more than 30 hours to optimize each single query's performance. As the input data size increases, the time used to optimize its performance also increases rapidly. For example, it takes at least 100 hours when the input data size is 1 TB. In fact, the common size of data processed in industry ranges from several hundreds of GBs to TBs. As mentioned earlier, other ML algorithms require even longer time than BO to generate training samples to achieve same performance. The long training time significantly hinders the applicability of ML-based approaches in practice.

2.3 Bayesian Optimization

BO incorporates prior belief about objective function f and updates the prior with samples drawn from f to get a posterior that better approximates f. In this paper, f is program's performance ($perf$) which is a function of configuration parameters (c_i). Note that $perf$ can be execution time, latency, or other performance metrics. The goal is to find a vector $\{c_1, c_2, ...c_i, ...c_n\}$ named *optimal configuration* that leads to the highest performance for a program with the minimal number of evaluations[1]. To efficiently search the optimal configuration, surrogate model and acquisition function play the key roles [28]. Different models lead to different efficiency and complexity. We need a model which achieves a good trade-off between the two. Mockus et al. [37] show that the Gaussian Process (GP) is well-suited to serve as a surrogate model. We therefore choose GP in this study.

Acquisition function is used to select the next sample in each BO iteration. The selected sample is expected to achieve the largest improvement. An effective acquisition function is Expected Improvement (EI)—picking the point which can maximize the expected (performance) improvement over the current best [40]. The detailed calculation of EI can be found in [40]. Here, we introduce its typical implementation [12] which is adopted and substantially modified in our system. In the implementation, a function called *acq_max* is used to find the maximum of the acquisition function. It consists of two steps. First, it generates *n_warmup* (e.g., 10^5) random samples and finds the sample ($S1$) with the maximum potential improvement. Second, it runs the L-BFGS-B algorithm [66] from *n_iter* (e.g., 250) random starting points to find another sample ($S2$) with the maximum potential improvement. Finally, *acq_max* chooses the sample with higher improvement from $S1$ and $S2$ as the next sample for evaluation (iteration). Both steps generate samples randomly.

[1] We define sample evaluation as the execution of a program with a configuration.

2.4 Generative Adversarial Networks (GAN)

GANs belong to a new class of machine learning algorithms where generative (G) and discriminative (D) models are simultaneously generated in a competitive setting [17]. The objective of D models is to correctly label samples from either the G models or real data. In contrast, the objective of G models is to deceive the D models. In other words, the G models try to produce samples that are categorized as real data by the D models. As such, G models can be considered as a team of counterfeiters while D models are the law enforcement agents trying to detect the "counterfeit currency". Both teams try to improve their methods until the counterfeits are indistinguishable from the genuine ones [16].

Advantages: GANs can generate data that have the *distribution* similar to the input data [16, 17]. As a result, GANs are widely used to generate similar versions of the image, text, video, and audio object. By using GANs and machine learning, one can easily recognize objects such as trees, streets, bicyclists, persons, and parked cars, and can also calculate the distance between different objects. It is worth mentioning that although diffusion models [41] have been widely used, they are notorious for their large data requirements and long-training process [24, 39]. GAN, however, works significantly faster and it can even outperform diffusion models for various datasets [25].

Disadvantages: GANs may be hard to train. The reason is two-fold: first, there are too many factors (e.g., features to represent a speech) to learn by the standard GAN algorithm; second, the criterion of being highly similar is too strict. For example, the generated speech is required to be exactly the same as the input one. This may make the training process of a GAN very lengthy. To address this issue, more than 1,000 GAN variants are developed to deal with a special use case [23]. For example, WGAN (Wasserstein GAN) proposes a better way to measure the distance between the generated data distribution and that of the input one, which can generate more similar image to the input image than the standard GAN does [3]. Since we consider at least 27 parameters, it is also challenging to train a standard GAN model. We address this challenge in Section 3.2.2.

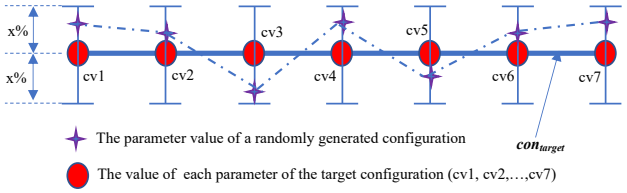

Figure 2: An illustration of how ON generates configurations.

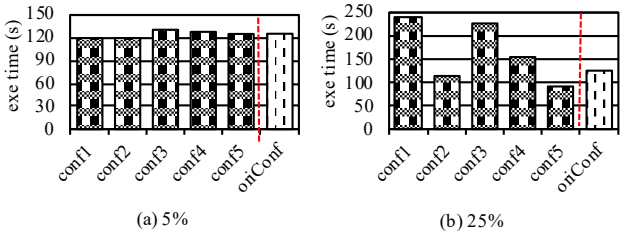

Figure 3: The performance made by ON generated configurations where the element values are within 5% (a) and 25% (a) of those of the original one.

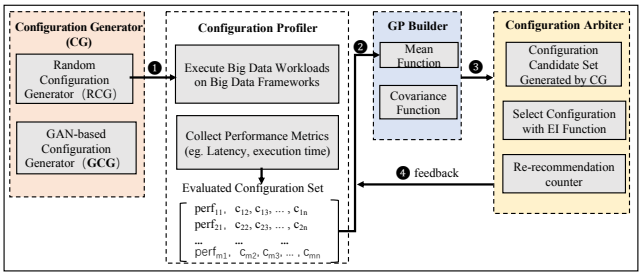

Figure 4: The block diagram of Swift Methodology.

3 Configuration Generation

We propose two approaches to generate configurations: One-Neighbor (ON) and the Swift. ON is a simple approach that generates configurations according to a target configuration based on small random perturbations, whereas Swift leverages GAN to generate configurations that share similar distribution with the target sample.

We define a configuration as a vector *conv* where its elements are the parameter values, as shown in Equation (1).

$$conv = \{c_0, c_1, ..., c_i, ..., c_{n-1}\} \quad (1)$$

where *conv* is a configuration, c_i is the i^{th} parameter value of *conv*. Example configuration parameters (c_i) for Flink and Spark programs are shown in Table 1. n is the number of configuration parameters in *conv*. In this study, n is 27 for Flink and 34 for Spark, as shown in [44].

A *sample* is defined as equation (2) shows.

$$spv = \{pf, conv\} \quad (2)$$

where *spv* is a sample, pf is the performance (e.g., execution time or latency) of a program produced by configuration *conv*.

3.1 One-Neighbor

One-Neighbor (ON) generates a configuration by producing its each parameter value randomly around the corresponding value of the target with a noise threshold. ON assumes that similar configurations produce similar performance for a given big data program. The similarity between two configurations $conv_1$ and $conv_2$ can be measured as their in-between Manhattan Distance, as shown below in equation (7).

$$MD(conv_1, conv_2) = |c_{11} - c_{21}| + ... + |c_{1n} - c_{2n}| \quad (3)$$

where c_{11} and c_{1n} are the first and n^{th} parameter value of $conv_1$, c_{21} and c_{2n} are the first and n^{th} parameter value of $conv_2$. To generate similar configurations according to a target configuration, we make the distance between two corresponding parameter values such as $|c_{11} - c_{21}|$ of two configurations be between 0 and $x\%$ (x is the threshold) randomly. The parameters are all normalized to $[0.0, 1.0]$.

Figure 2 visualizes how ON generates configurations according to a target configuration $conv_{target}$ which is represented by the bold line. The red circles (e.g., $cv1$ and $cv2$) on the bold line denote the parameters values of the $conv_{target}$. To generate a configuration *conv* similar to $conv_{target}$, we need to generate each parameter value around the corresponding value (e.g., $cv1$) of $conv_{target}$. To this end, as shown in Figure 2, we randomly generate a value between $(cvi - x\% \times cvi)$ and $(cvi + x\% \times cvi)$ $(i = 1, 2, ..., 7)$. The star marks show the generated parameter values, and the dashed line in Figure 2 shows a randomly generated *conv*.

The hope is that, based on ON, the performance of a program configured by *conv* is similar to that of the program configured by $conv_{target}$ when the threshold $x\%$ is small (e.g., 5% or 25%). However, Figure 3 shows that it is not the case. First, when $x = 5$, the performance by the ON generated configurations is almost the same. This does not add valuable samples. Second, when $x\%$ is around 25%, the performance corresponding to *conv* (e.g., $conf1$) can be as much as 2× slower than that of *conv_target* ($oriConf$ shown in Figure 3(b)).

3.2 Swift

3.2.1 Overview

Swift is a BO-based fast configuration tuning mechanism for optimizing the performance of big data systems. The key idea is to generate some configurations by GAN in each iteration for BO's acquisition function to choose from. These configurations highly likely produce high performance. *Swift* consists of four components shown in Figure 4.

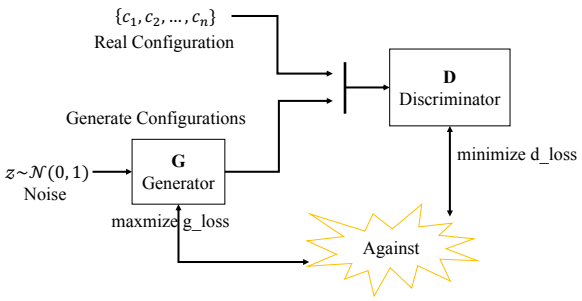

Figure 5: How GAN generates configurations.

- **Configuration generator** generates a number of configurations, either randomly or using GAN.
- **Configuration profiler** executes a program with a configuration and records its performance (e.g., execution time). If a configuration's performance is better than that of all samples in the evaluated set (ES), the configuration and its performance is inserted into ES as a new element.
- **GP (Gaussian process) builder** builds a model based on the samples in ES. The model is updated whenever a new sample is inserted in ES. It is used by BO.
- **Configuration arbiter** implements the new procedure in *Swift* that allow each BO iteration to select from a mixed pool of GAN-generated and random configurations.

3.2.2 Configuration Generator

Swift requires two configuration generators: a Random Configuration Generator (RCG) and a GAN-based Configuration Generator (GCG). The RCG sets each configuration parameter to a uniformly random value within the parameter's value range. In contrast, GCG leverages GAN's nature to generate the configuration that mimics the data distribution of the element values of target configuration.

Figure 5 shows how the GCG generates configurations. As explained before, a GAN consists of a discriminative model (*D*) and a generative model (*G*), which are both implemented by fully connected layers, as shown in `Listing 1`. GCG has two inputs: (1) the current target configuration that achieves high performance so far; and (2) a set of *noise* data which obey Gaussian distribution. The target sample is one of the samples in ES. A noise configuration is generated in two steps. First, we create a random value generator for each parameter. Second, we use a function (e.g., `nextGaussian()`) provided by a statistic software package (e.g., `java.util`) to generate values that obey Gaussian distribution for each parameter. In this way, we obtain a set of noise configurations where the values of each parameter obey Gaussian distribution.

The noise configuration is given to the Generator (G) and the target one (`real_conf0`) is given to the Discriminator (D) of our GAN model, as shown in `Listing 1`. G consists of three fully connected layers. The first layer performs a non-linear transformation by using the active function *ReLu* on the given noise configuration, generating `G_L1` as the output. The second layer performs another *ReLu* transformation on `G_L1`, producing `G_L2`. It is then given to the third layer to change its dimension to a specific number (e.g., the number of configuration parameters) and output `G_out`.

D first uses *ReLu* to perform a non-linear transformation on the target configuration, producing `D_L0`, as shown in lines 12 and 13. Subsequently, `D_L0` is given to the next layer, performing another non-linear transformation by using the active function *sigmoid*, as well as generating a probability `prob_conf0` ranging from 0.0% to 100.0%. Next, D performs a *ReLu* transformation on `G_out` and produces `D_L1` which is given to the next layer of D to perform a *sigmoid* transformation, generating another probability `prob_conf1`. It is used to calculate the *G_loss* to improve G to generate configurations more similar to the target. At the same time, the probabilities `prob_conf0` and `prob_conf1` are used to compute the *D_loss* to improve D to distinguish the target configuration from the generated ones more accurately.

```
1  Listing 1 An implementation of GAN.
2
3  dim=27 # the number of configuration parameters
4
5  with tf.variable_scope('Generator'):
6     G_in=tf.placeholder(tf.float32,[None,dim])
7     G_L1=tf.layers.dense(G_in,128,tf.nn.relu)
8     G_L2=tf.layers.dense(G_L1,64,tf.nn.relu)
9     G_out=tf.layers.dense(G_L2,dim)
10
11 with tf.variable_scope('Discriminator'):
12    D_L0=tf.layers.dense(real_conf0,128,
13                         tf.nn.relu)
14    prob_conf0=tf.layers.dense(D_L0,1,
15                         tf.nn.sigmoid)
16    D_L1=tf.layers.dense(G_out,128,
17                         tf.nn.relu, reuse=True)
18    prob_conf1=tf.layers.dense(D_L1,1,
19                         tf.nn.sigmoid, reuse=True)
20
21 D_loss= -tf.reduce_mean(tf.log(prob_conf0)
22                         +tf.log(1-prob_conf1))
23 G_loss=tf.reduce_mean(tf.log(1-prob_conf1))
```

Note that the goal of the non-linear transformations performed by the active functions *ReLu* and *sigmoid* is to capture the complex features such as data distribution hidden in the values of the target configuration. This makes it possible to use GAN to generate configurations according to only one target configuration, i.e., the one with top-1 performance. A similar approach has been used in computer vision where the authors use GAN to repair a tiger face paint [58]. The inputs of their GAN are one damaged paint and some noise data.

Solution for the hard-training issue. The ultimate goal of GAN in general applications such as image generation is to make `prob_conf0 = prob_conf1`. To achieve this goal, the training of GAN may suffer from the "hard-training" issue—the training process may lead to an infinite loop to satisfy the above condition. However, usage of GAN in *Swift* does not suffer from this problem for two reasons. First, the data type

in *Swift* is one dimension (vector), instead of two (image) or higher dimension in other applications. As a result, the training process is easier.

Second, *Swift* does not and *should not* need the above condition, because the generated configuration is *not* expected to have the same performance. It is not only unnecessary but also *harmful* to the search, i.e., if we always achieve the same performance, BO cannot find the better configuration. Thus, it is in fact *required* to let the performance be within a range (e.g., $\pm 25\%$) of the performance of target sample, which provides the opportunity to generate better configurations.

Guided by these rationales, we train the GAN for a *fixed* number of iterations(i.e., 20 in our experiments). We observe that it typically ensures the performance of generated configurations remains within ±25% of the target sample's performance. Notably, even if 20 iterations fail to bring the performance within ±25%, this does not hinder the optimization process—we can still utilize the generated configurations to complete the search for optimal configurations and achieve the best possible result.

3.2.3 Configuration Profiler

The configuration profiler executes a program with a configuration and records its performance, generating a sample $spv = \{pf, conv\}$ defined in equation (2). After profiling a program a number of times, all the vectors form a matrix that represents ES as shown in Figure 4. A configuration is considered to be evaluated if we know its performance, but it is only inserted into ES if its performance is better than the performance of all rows in ES.

3.2.4 Gaussian Process Builder

To build a GP that outputs the performance pf of a program with a given configuration, we first leverage the *configuration profiler* to generate kk vectors (spv). Then, we use these samples to calculate the initial performance mean and covariance cov between the performance and a configuration as follows.

$$\widetilde{pf} = (\sum_{i=1}^{kk} pf_i)/kk; \widetilde{cf_j} = (\sum_{i=1}^{kk} cf_{ji})/kk \tag{4}$$

$$cov(pf, cf_j) = (\sum_{i}^{kk} (pf_i - \widetilde{pf})(cf_{ji} - \widetilde{cf_j}))/kk \tag{5}$$

with $\widetilde{pf}$ the mean performance of the kk executions, pf_i the performance in the i^{th} sample, cf_j the j^{th} value of a sample, and cf_{ji} the value of the j^{th} parameter of the i^{th} sample.

Thus far, we already have the two essential elements, mean and covariance functions, to define a GP. The last element we need to build a GP is the smooth kernel function which represents how similar two configuration parameters are in terms of performance. If two configuration parameters perform similarly, they have high covariance, and vice versa. There are numerous smooth kernel functions that satisfy this need. We choose $Matern5/2$ [59] as it does not require strong smoothness and is preferred to model practical functions [40]. During BO, the GP model is updated when ES is updated.

3.2.5 Configuration Arbiter

This component is responsible for guiding the steps for each BO iteration. To clarify the mechanisms of *Swift*, let us first explain the iterative process in the conventional BO as shown in Figure 6 (a). All the components in *Swift* can be repurposed for conventional BO as the needed functionality is the same or simpler. In each iteration, a number of configurations (e.g., 100,000 in the example) are randomly generated by the configuration generator. Then, the internal BO algorithm selects a configuration using the acquisition function (EI) for this iteration. If the configuration is not already contained in ES, the configuration profiler executes the program on the real cluster. The execution takes the majority of time of an iteration and the BO optimization. Ideally, the BO algorithm will select the configuration with less and less execution time, so the time spent in each iteration will decrease. A sample is inserted into ES if its performance is higher than the one with the highest performance in the current ES, i.e., "current best"; otherwise (or the selected configuration is already in ES), it is discarded and the BO moves to the next iteration. It means that the effort in this iteration is wasted.

The number of iterations (and the total BO optimization time) is determined by the quality of configurations selected in each iteration: good selections lead to faster execution time decrease and less number of iterations. However, with random configuration generation, the BO algorithm, which needs to consider both exploitation and exploration, may occasionally select a configuration that leads to longer execution time. It will directly increase the BO optimization time.

In our experiments, we observe that the execution time based on a configuration can be $2\times$ slower than the execution in the previous iteration. The iterative BO optimization terminates when the performance does not improve for a number (e.g., five in the example) of consecutive iterations. At this point, the configuration of the sample with the highest performance is given as the outcome. With random configuration generation, the execution time decrease can be slow with fluctuation. We conceptually provide how the execution time is changed over iterations on the left of Figure 6 (c).

Swift reduces the BO optimization time by mixing the randomly generated configurations for each iteration with GAN-generated configurations that have similar *distribution* with the "current best". This design emphasizes both *exploitation*, which takes advantage of the previously obtained information—the target sample—to acquire rewards, and *exploration*, which tries to reach the global optimal with random samples. The workflow of configuration arbiter is shown in Figure 7, and Figure 6 (b) shows a concrete example.

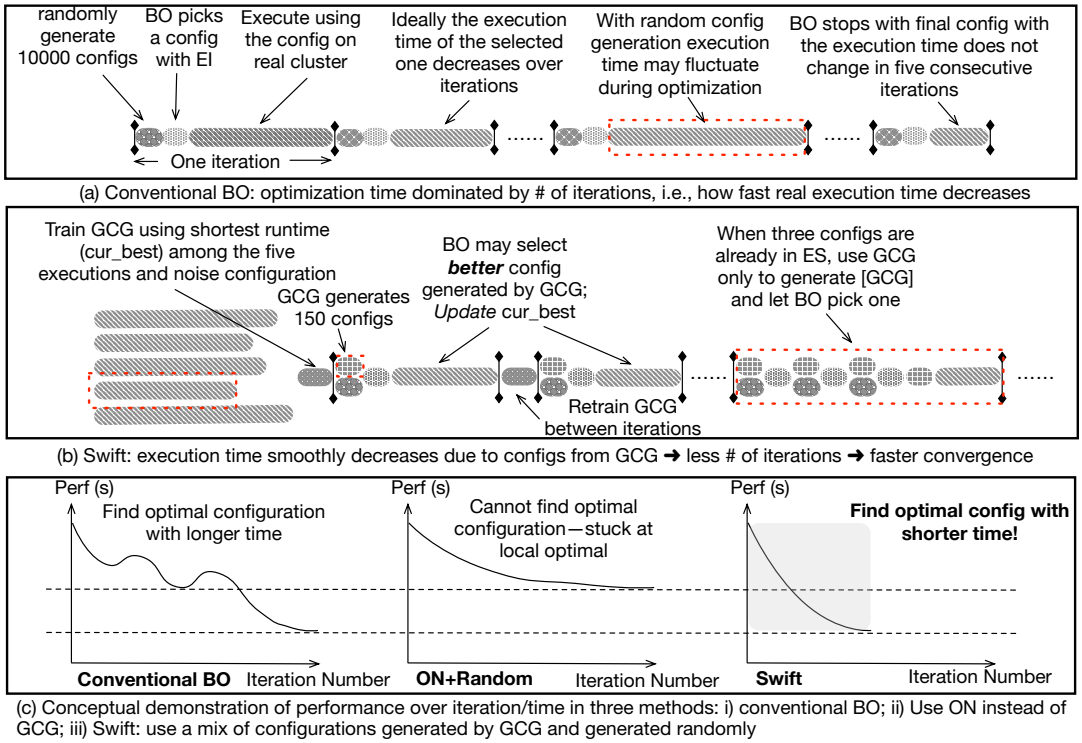

Figure 6: Comparing Conventional BO and *Swift*

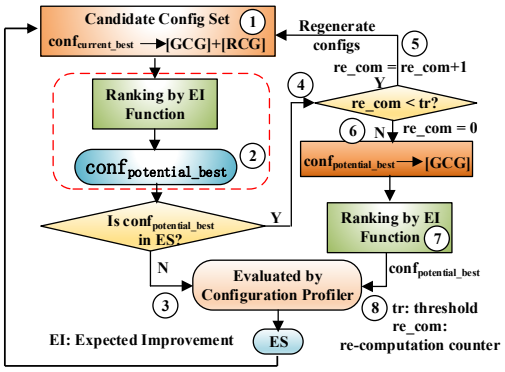

Figure 7: Workflow of the configuration arbiter.

For GAN to generate configurations, it needs to be trained first. To do that, *Swift* first randomly generate five configurations and evaluate them on the real cluster; the configuration with highest performance among the five is used as the target sample to train the GAN with a noise configuration that obey Gaussian distribution for each parameter. The training procedure is described in `Listing 1` and can be done very fast, e.g., several seconds. The training of GAN is triggered whenever the "current best" is updated.

After the first training, BO iterations can start. Different from the conventional BO, the candidate configuration pool is composed of [RCG], a large set (e.g., 100,000) of configurations generated, and [GCG], a small set (e.g., 150) of configurations generated with GAN (step ①). Then, the same to the conventional BO, the algorithm selects the configuration with the highest potential performance (step ②). The high quality configurations in [GCG] can help the BO algorithm to overcome the "bad luck" and make it more likely to select good configurations. As a result, compared to BO, the selected configuration in each iteration in *Swift* tends to be better with *faster and more consistent* execution time decrease, which is shown conceptually on the right of Figure 6 (c). This benefit is clearly observed in our experiments, see Figure 19.

If the selected configuration is not already in ES, it is evaluated by the configuration profiler (step ③). Otherwise, *Swift* gives a small number of chances to re-generate [GCG]+[RCG] and repeat the selection (step ④ and ⑤). The threshold is controlled by *tr* and is set to three in our experiments. The counter *re_com* keeps the number of re-generation attempted. After *re_com* reaches *tr*, if the selection is still contained in ES, *Swift* will generate a new pool of candidates just by [GCG] without the random configurations (step ⑥). BO selects a configuration from the set as the last attempt (step ⑦) before moving to the next iteration. If the selected configuration is not in ES, it is evaluated by the configuration profiler (step ⑧).

For simplicity, we do not show the case when the selected configuration is already in ES in Figure 7. In this case, *Swift* moves to the next iteration. The rationale for this design is to capture the following scenario. BO may try to select a con-

figuration in [RCG] with the highest performance potential, but it is already in ES. However, the second or third best is a configuration in [GCG]. Instead of wasting the iteration, after *tr* attempts to select from [GCG]+[RCG], BO can just focus on [GCG] and still select a high quality configuration.

In principle, we can replace the [GCG] generated by GAN with configurations generated by ON with small perturbation so that the performance is within ±25%. However, as discussed before, such configurations are too similar to the target one and will negatively affect the search. The issue is that, such very similar configurations with good performance tend to make the BO algorithm more likely to stuck at the local optima when terminated. It is conceptually illustrated in the middle of Figure 6 (c). Although the performance increases consistently, but the mix of ON generated and random configurations make search stop with a sub-optimal performance.

3.2.6 Termination Condition

To design the termination condition for Swift, we first define the performance improvement as follows.

$$imp = \frac{|pf_{i+1} - pf_i|}{pf_i} \times 100\% \tag{6}$$

with imp the performance improvement in percentage, and pf_i and pf_{i+1} the performance of the i^{th} and $(i+1)^{th}$ iterations, respectively. During the iterations of Swift, if we observe imp is less than a threshold (e.g., 5%) and N (e.g., 6) iterations have been performed, we terminate Swift searching and take the configuration found in the last iteration as the optimal configuration. This ensures that *Swift* does not terminate the search too soon and only finds the sub-optimal configurations. Moreover, this also prevents *Swift* from struggling to make marginal improvements.

4 Experimental Setup

4.1 Apache Flink Experimental Setup

Our experimental cluster consists of four Linux servers. One server serves as the master node which runs the Job Manager and the other three serve as slave nodes which execute the Task Managers. Each server is equipped with an Intel(R) Xeon(R) CPU E5-2407 2.20GHz 4-core processor and 32GB DRAM. The OS of each node is SUSE Linux Enterprise Server 11. We use Flink 1.4.2 in this study.

We evaluate four programs from the Flink version of HiBench: *FixWindow* (FW) is a window-based aggregation which evaluates window operations in the stream frameworks. *WordCount* (WC) tests the performance of the stateful operators and the cost of checkpoints/Ackers. *Repartition* (RP) evaluates the shuffle efficiency. *Identity* (ID) tests the read-/write efficiency of an external input source represented by a Kafka cluster. Data streams for all the benchmarks are from a Kafka cluster [47], and the input data speed is 1000MB/s.

We also evaluate Swift on a real production cluster of an internet giant. In this experiment, we use two docker containers as Job Managers and ten docker containers as Task Managers. The docker containers are managed by a customized version of Kubernetes [50]. Each container is equipped with 4 CPU cores (Intel(R) Xeon(R) CPU E5-2698 v3 @ 2.30GHz), 8GB memory, and 10GB/s Ethernet network. All the containers share a 100GB network disk. The OS is CentOS 7 with Linux kernel 3.10.0-327.28.3.el7.x86_64 and the Apache Flink version is 1.4. We use a real-time log analysis program written in Flink, which has been manually optimized by the engineers of the company. This optimization took the engineers four days and we use the optimized performance as our baseline.

We choose a wide range of Flink configuration parameters that significantly influence performance, including *memory management*, *execution behavior*, *networking*, *parallelism*, etc. Table 1 shows 5 example parameters and all the 27 parameters experimented in this study are shown in [44]. The last column of Table 1 provides the default values of the parameters and can be found at Apache's website [11]. The third column shows the value range of each parameter.

4.2 Spark Experimental Setup

Our Spark cluster consists of eight servers. One server serves as the master and the others serve as slaves. Each server is equipped with Intel (R) Xeon (R) CPU E5-2630 v3 @2.40GHz and 64GB of memory. The OS of each server is Ubuntu 16.04 LTS and Spark version is 2.2. The resource manager is Yarn v1.22.19.

We employ 24 Spark benchmarks from HiBench [51], each with 3 input data sets. These benchmarks cover a wide range of Spark applications including machine learning, web searching, graph processing, SQL, and micro-benchmarks.

As discussed earlier, we choose a wide range of Spark configuration parameters that significantly influence performance, including *shuffle behavior*, *data serialization*, *memory management*, *execution behavior*, *networking*, etc. Table 1 shows five example configuration parameters and [44] lists all the 34 experimented parameters in detail. The last column of Table 1 provides the default values of parameters which are recommended by the Spark team [43]. The third column shows the value range of each parameter.

It is worth mentioning that *Swift* does not distinguish hardware specific configurations, i.e., configurations generated by *Swift* for a Spark or Flink program on one hardware platform are optimal on this specific platform and are essentially not portable to a different platform.

Table 1: Description of five example Flink and five example Spark configuration parameters.

Framework	Configuration Parameters-Description	Range	Default
Flink	**parallelism.default** - The default parallelism for programs that have no parallelism specified.	1-24	1
	taskmanager.numberOfTaskSlots - # of parallel operator or function instances a TaskManager runs.	1-8	1
	jobmanager.heap.mb - JVM heap size (in megabytes) for the JobManager.	1024-4096	1024
	taskmanager.heap.mb - JVM heap size (in megabytes) for the TaskManager.	1024-10240	1024
	taskmanager.memory.fraction - The relative amount of memory that the task manager reserves.	0.5-0.8	0.7
Spark	**spark.shuffle.file.buffer** - Size of the in-memory buffer for each shuffle file output stream, in KB.	2-128	32
	spark.executor.cores-The number of cores to use on each executor.	4-30	core #
	spark.driver.memory-Amount of memory to use for the driver process, in MB.	1024-36864	1024
	spark.executor.memory-Amount of memory to use per executor process, in MB.	7168-36864	1024

5 Results and Analysis

5.1 Study of GAN Related Issues

Impact of Random Seed In *Swift*, the randomness in the 5 initial executions may lead to great uncertainty. To study this, we employ 5 random seeds to generate 5 configurations for the Flink version of *wordcount*. We run it with the generated configurations and observe the mean, standard deviation and minimum of the 99^{th} percentile latency. Figure 8 shows the results with random seeds (5, 11, 66, 250, and 1024). We see that the means and standard deviations of the 99^{th} percentile tail latency of *wordcount* are significantly different among each other. However, the standard deviation of the minimum 99^{th} percentile tail latency with different random seeds is 8.7 and the corresponding coefficient of variation (CoV) is only 0.06, which indicates that the latency is highly similar. Thus, the different random seeds do not affect *Swift* very much.

Thus we run one experiment using the default seed and do not use different seeds with multiple runs. We argue that on the one hand, if different seeds are utilized, the optimal performance and configuration may vary, the search processes exhibit similar experimental results, as proved by small CoV values. On the other hand, many benchmarks are evaluated (4 Flink and 24 Spark programs), which eliminate the randomness of one program with a particular seed.

Quality of GAN Generated Configurations In this section, we experimentally show the similarity and high quality of the GAN-generated configurations. For similarity, we first randomly generate a real configuration for Flink programs with 27 parameters. Then we use GCG to generate three artificial configurations using the real one as the target. Figure 9 (left) compares the four configurations in a Kiviat plot. We can clearly see the similarity among the four. Quantitatively, the Manhattan distances between the generated configurations and the real one are 1.56, 0.7, and 1.47, which are small.

For configuration quality, we run the Flink program *Fixwindow* with a real configuration with high performance, ten GAN-generated configurations, and the default configuration. Figure 10 (a) shows the performance comparison. The red and orange dashed lines represent performance with the real and default configurations. All GAN-generated configurations have performance close to that of the real configuration with maximum relative variation 25.7%.

Comparing to One-Neighbor This section quantitatively compare the configurations generated with ON and GAN. We generate 110 configurations by each of the two methods ($\pm$25% noise for ON) based on a real configuration for the Spark version of *PageRank*. We calculate the Manhattan

distance (MD) and Jensen-Shannon (JS) divergence [13] of configuration in the two sets to the real configuration. That is, we calculate 110 Manhattan distances (MD) and 110 JS divergences for the ON generated configurations; we also compute 110 MDs and 110 JS divergences for the GAN generated configurations. Then we compute $ratio_{md}$ and $ratio_{js}$ as equations (7) and (8) show, respectively.

$$ratio_{md} = MD_{on}/MD_{gan} \tag{7}$$

with MD_{on} the MD of an ON generated configuration to the real configuration, and MD_{gan} the MD of a GAN generated configuration to the real one.

$$ratio_{js} = JS_{on}/JS_{gan} \tag{8}$$

with JS_{on} the JS divergence of an ON generated configuration to the real configuration, and JS_{gan} the JS divergence of a GAN generated configuration to the real one.

If $ratio_{md}$ is close to 1.0, it indicates that the ON and GAN generated configurations have similar MDs to the real configuration. If $ratio_{js}$ is significantly larger than 1.0, it implies that the GAN generated configurations' value distributions are much more similar to the real configuration's value distribution than the those of the ON generated configurations.

We then compute (min,max,avg) of $ratio_{md}$ and $ratio_{js}$. For Manhattan distance, the (min,max,avg) of $ratio_{md}$ is (0.46,2.81,1.05). For $ratio_{js}$, the (min,max,avg) is (5.15,30.46,5.58) as shown in Figure 10 (b). Clearly, we see that while the configurations in both sets can be considered "similar" to the real configuration, but the distribution (captured by JS) of GAN-generated configurations is much closer to the real configuration than ON-generated ones. As such, the GAN generated "similar but not too similar" configurations to a real one also guarantee the "the similar but not too similar" performance, whereas ON generated ones do not.

We plot the performance distribution of 110 GAN- and ON-generated configurations as blue solid and red dashed lines in Figure 11. We see that the GAN-generated configurations follow a Gaussian distribution with mean execution time (86.8s) very close to the real configuration (87.4s); while the ON-generated configurations follows an irregular long-tail distribution. Moreover, ON can generate configurations of which performance spreads in a large range. This means that it may generate low quality configurations despite small Manhattan distance. Overall, the performance of GAN-generated configurations is *"similar but not too similar"* while the performance of ON-generated configurations varies significantly.

GAN with Multiple Target Configurations It is interesting to understand whether it is beneficial to use multiple target configurations to train our GAN model. To answer the questions, we choose three configurations for *PageRank* with execution times 87.4s, 87.6s, and 88.5s, respectively. We use the three configurations to train the GAN model and generate 110 configurations. The green solid line with rectangles in

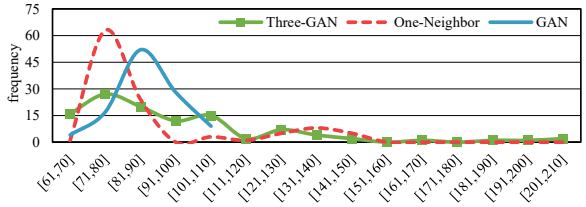

Figure 11: The performance distribution of *PageRank* with GAN, ON, or 3-input-GAN generated configurations.

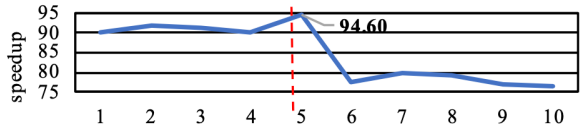

Figure 12: The speedup with different number of initial configurations for *repartition* over default configurations.

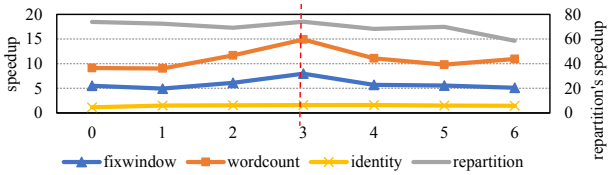

Figure 13: The performance variation with different values of tr. The X axis represents the tr values.

Figure 11 shows the performance distribution with a long tail, which can make the BO optimization even longer. The reason is that the GAN model tries to learn the data distribution of parameter values of all the three input configurations. The results suggest that the GAN model should be only trained with the configuration with the best performance so far.

5.2 Flink Programs on Lab Cluster

Number of initially evaluated configurations. Figure 12 shows the speedups of program *repartition* when using different number of initial evaluated configurations to provide the first target sample to train the GAN model. The performance reaches the highest when five configurations are evaluated and then drops. It is because more random configurations increase the chance of getting the "very bad" configurations. Based on this result, *Swift* initially evaluates five configurations

Tolerance threshold The tolerance threshold controls the times that we allow the acquisition function of BO to select the same sample to evaluate on the real cluster in the next iteration. A large threshold may waste time without much improvement, while a small threshold may make the optimization stuck at a local optima. Figure 13 shows how the threshold (x-axis) affects the performance for four Flink programs. For all of them, the best speedups are obtained when the threshold is three. Thus we use this number in *Swift*.

Figure 14: Latency improvements over CherryPick. FXW-Fixwindow, RPT-Repartition, WCT-Wordcount, IDY-Identity.

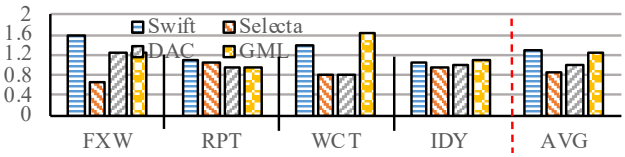

Figure 15: Throughput improvements over CherryPick.

Table 2: The number of evaluated configurations (trial executions) used to find the optimal performance.

Bench	Swift	CherryPick	Selecta	DAC	GML
Fixwindow	25	50+	100	750	500
Repartition	17	50+	100	550	440
Wordcount	23	50+	100	600	460
Identity	24	50+	100	600	420
In Total	89	200+	400	2,500	1820

Optimization time. We compare *Swift* with four parameter tuning approaches, including CherryPick [2], Selecta [27], DAC [64], GML [18]. For a fair comparison, we re-implement CherryPick, Selecta, DAC, and GML and carefully tune their hyper-parameters to achieve the highest performance.

Table 2 shows the number of trial executions used to find the optimal performance for the Flink programs with different approaches. It clearly indicate *Swift* requires much less number of trial executions. Note that the number of trial executions may not accurately represent the final time cost because a Flink program may take different time to execute with different approaches. We therefore also report the time used to find the optimal performance in Table 3. It shows that *Swift* takes only 6.3 hours at most and 5.8 hours on average to find the optimal performance for the 4 Flink programs. In contrast, the average times taken by CherryPick, Selecta, DAC, and GML are 2.2×, 4.3×, 9×, and 7.2× of that of *Swift*.

Speedup. Figure 15 shows the throughput improvements of the four Flink programs tuned by Swift, Selecta, DAC, and GML over by CherryPick. Swift improves the throughput of the four programs by 1.28× on average and up to 1.59× over CherryPick. Figure 14 and Figure 15 show the throughput improvement and latency reduction comparison. In both aspects, *Swift* clearly outperforms other approaches. It is worth noting that the main goal of *Swift* is making the optimization faster. The results are particular encouraging because *Swift* actually *achieves better performance with shorter time*.

Production Cluster. We evaluate a Flink program used to analyze the logs of servers in a real time. The results show that Swift improves the throughput by 2.3× and reduces the latency by 2.8× in only 6.8 hours compared to the four-day manual optimization. Table 4 compares the values of the six important parameters from the manual tuning and *Swift*. We see that *Swift* indeed significantly adjusted the values to achieve better performance.

Table 3: Time (in hours) used to achieve the improvements.

Bench	Swift	CherryPick	Selecta	DAC	GML
Fixwindow	6.3	12.5+	25	62.5	40.1
Repartition	4.3	12.5+	25	45.8	38.9
Wordcount	5.7	12.5+	25	50	38.5
Identity	6	12.5+	25	50	42.3

akka.framesize	10MB	16MB

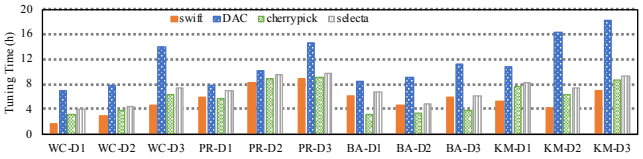

Figure 16: Optimization time comparison.

5.3 Spark Programs Evaluation

Optimization time. Figure 16 compares the optimization time of different approaches for Spark programs. The average time overheads of Swift, DAC, CherryPick, and Selecta are 5.1, 11.3, 5.9, and 7 hours, respectively. We see that *Swift* reduces optimization time more for Flink programs than for Spark programs. It is because of the different program characteristics: Spark programs are batch processing while Flink programs are streaming processing. We also evaluate *Swift* on a heterogeneous cluster consisting of eight x86 servers and four ARM servers with 24 Spark programs from HiBench, each with three input datasets. Figure 17 shows the average speedup and optimization time reduction for each program. *Swift* still significantly outperforms CherryPick. This indicates that *Swift* is robust in significantly different clusters and workloads, which is helpful for practice use.

Speedups. Figure 18 shows the speedups of the four approaches compared to the default configurations. We can see that *Swift* achieves slightly higher speedups but still with much shorter optimization time.

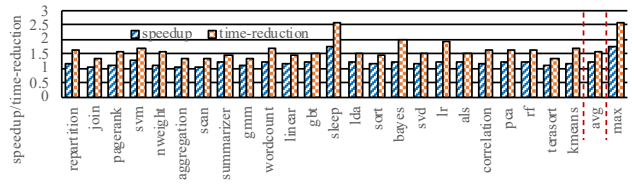

Figure 17: The optimization time reduction comparison with CherryPick for 24 Spark benchmarks.

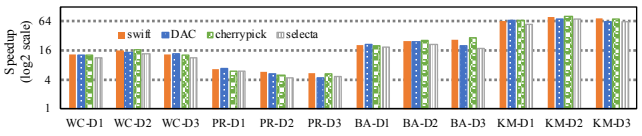

Figure 18: Speedup comparison. The baseline is the execution time of each program with default configuration.

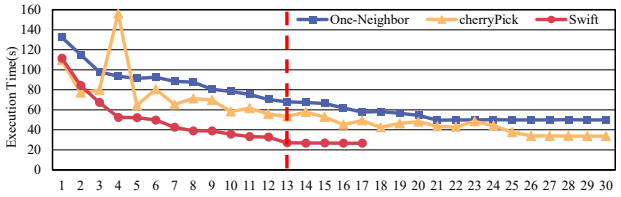

Figure 19: The performance of Spark WordCount tuned by the configurations selected by ON, CherreyPick (BO), and *Swift* during iterations. The X axis denotes the iteration number.

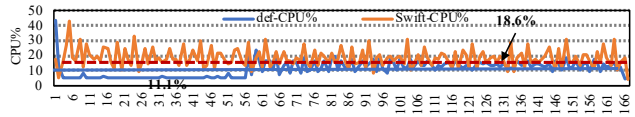

Figure 20: CPU utilization of *Fixwindow* tuned by Swift and with default configuration. The X axis represents samples.

5.4 Insight and Discussion

***Swift* skews the search space**. In *Swift*, mixing randomly and GAN-generated configurations has the effects of skewing the search space toward the optimal configuration, leading to faster convergence. In contrast, with uniformly random configurations, CherryPick searches in a uniform space. Figure 19 shows the performance of configurations selected in each iteration in *Swift* and CherryPick. We can see that, *Swift* converges faster and more smoothly without fluctuation.

Case study. Finally, we deeply analyze on *Fixwindow*. *Swift* accelerates it by 10.7× compared to the default configuration. Figure 20 and Figure 21 show the comparison of CPU and memory utilization comparison. We see that CPU utilization is increased by around 7.5% but the memory utilization is drastically reduced from 46.8% to 20.1%. From such results, we understand that the performance improvement is due to the busier CPU with reduced memory accesses.

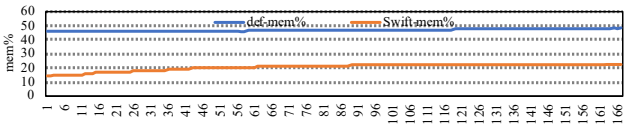

Figure 21: Memory utilization of *Fixwindow* tuned by Swift and with default configuration. The X axis represents samples.

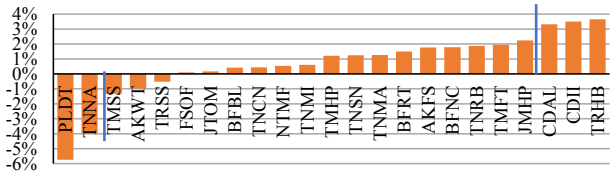

Figure 22: The importance quantification of configuration parameters for *Fixwindow* with respect to performance. The descriptions of the abbreviations along X axis are in [44].

We further investigate how the parameters affect performance, taking *Fixwindow* as an example. Figure 22 shows the 5 parameters affecting the performance most significantly. The increases of *TRHB*, *CDII*, and *CDAL* improve *Fixwindow*'s performance while those of *PLDT* and *TNNA* decrease the performance. The three parameters that positively correlate with performance are all related to memory. *TRHB* specifies whether we should enable bloom filter for the hybrid hash join operations in *Fixwindow*. Bloom filter is a bit vector which is a probabilistic data structure telling us that the element is either definitely not in the set or may be in the set. The default configuration sets it to *false* while Swift set it to *true* because *Swift* is able to detect if a lot of operations' values are in a set. The usage of bloom filter therefore reduces the memory consumption, which increases the CPU utilization.

Limitations. Although *Swift* demonstrates excellent performance, it still has several shortcomings. First, *Swift* was tested exclusively in single workload scenarios and may not fully generalize to complex data processing environments with concurrent workloads (i.e., workloads co-running to maximize hardware resource utilization). Future work is needed to address this limitation. Second, *Swift* requires the setting of several thresholds that are inherently tied to specific cluster environments. For instance, if there is a change in cluster hardware—such as replacing x86-based server CPUs with ARM-based ones—these thresholds may need to be reconfigured accordingly, posing challenges for system adaptability. Third, when dealing with extremely large input data sizes, such as 10 PB, the process of generating even a single trial configuration becomes prohibitively expensive. In such cases, *Swift* may struggle to operate efficiently.

6 Related Work

CherryPick [2] employs BO to optimize cloud configurations. It suffers the drawback of the polarized and unstable quality of configurations. Selecta [27] takes latent factor collaborative filtering and singular value decomposition to recommend near-optimal storage configurations with few samples. Ernest [54] builds a performance model via the job behavior and then predicts its performance on larger dataset sizes.

Another line of efforts use machine learning to build performance models, including DAC [64], RFHOC [4], OtterTune [1],QTune [29], Rafiki [35], Startfish [22], and gray-box based approaches [5], etc. However, the cost of collecting samples is expensive. In contrast, *Swift* reduces the cost significantly. Other search-based approaches take parameter tuning as a black-box optimization issue and uses variant search algorithms to find the optimal configurations [6], including BestConfig [67], Mronline [30], SelfTune [26], OPPerTune [42] and Gunther [32]. They can be applied to general scenarios. However, the key limitation is that they take a long time to find the optimal configuration since they evaluate each randomly generated configuration on a real cluster, e.g., OPPerTune requires 252 samples to tune parameters [42], which is time-consuming. In contrast, *Swift* reduces this time significantly.

Simulation-Based Approaches. Simulation models can capture both the internal metrics of systems and the externally observed workload relationships including [33, 55, 56] and [38]. These approaches need to probe system internals and is hard to cover all factors that can affect performance. In contrast, *Swift* works well on real big data systems.

Rule- and Analytical Model-based Approaches. Rule-[57, 60, 61] and analytical model-based [19, 20] approaches leverage the experiences of human experts (e.g., tuning instructions) to tune parameters for computing systems. They can quickly improve performance. However, deep understanding of the target system is required, which is not easy for emerging systems. In contrast, *Swift* does not need that.

7 Conclusion

This paper proposes *Swift*, a novel Bayesian Optimization (BO) based parameter configuration tuning approach for big data systems. The key idea is to leverage a generative adversarial network (GAN) to generate high quality configurations based on the evaluated configuration with the highest performance. Mixing these configurations with the randomly generated configurations has the effects of skewing the search space toward the optimal configurations, leading to faster convergence and less optimization time. In particular, our results show that *Swift* is able to achieve *better* performance than all existing approaches.

Abstract

Mobile applications exhibit increasingly high memory demands, making efficient memory management critical for enabling fast and responsive user experiences. However, our analysis of Android systems reveals inefficiencies in the current kernel-level memory reclaim design, which struggles to meet the performance demands of modern apps and fails to exploit upgraded storage devices. To address this challenge, we propose PMR, a parallel memory reclaim scheme. PMR introduces two key techniques: proactive page shrinking (PPS) and storage-friendly page writeback (SPW). PPS enhances the memory reclaim process by decoupling the time-consuming steps of page shrinking and page writeback for parallel execution, while SPW optimizes write I/O operations through batched unmapping of victim pages for bulk, efficient writeback. Experimental results on real-world mobile devices demonstrate that PMR can improve application response times by up to 43.6% compared to the original Android memory reclaim approach.

1 Introduction

The memory requirements of mobile applications are growing significantly, imposing high pressure on modern mobile devices [19, 28, 34]. Many applications now require gigabytes of memory, including popular social networking apps, video streaming apps, and web browsers. By contrast, the physical memory capacity of mobile devices has seen only modest increases, with flagship models such as the latest iPhone 16 series offering just 8 GB of DRAM [15], and the upcoming Samsung Galaxy S25 Ultra series equipped with 16 GB [16]. Running just a few such apps can quickly create significant memory pressure on mobile devices. If this pressure is not properly managed, the applications may experience slowdowns, restarts, or crashes, severely affecting the user experience [10, 20, 32].

To effectively alleviate memory pressure, Android-based mobile systems employ various memory reclaim mechanisms, the most notable being kernel-level memory reclaim (including memory swapping and direct reclaim) and user-space Low Memory Killer Daemon (LMKD) [13]. Specifically, first, when the amount of free memory falls below a pre-defined low watermark, the kernel wakes up a memory swapping thread (i.e., *kswapd*) for asynchronous memory reclaim in background [12]. Second, if *kswapd* fails to provide sufficient free memory for incoming requests, the kernel performs a direct reclaim for synchronous, blocking memory reclaim until the pending memory requests are satisfied [35]. Finally, if neither of these can recover the system from critically low memory, the system resorts to an LMKD process to release memory through selective process killing. However, once an app process is killed, the next time when the app is relaunched, users may notice a long restart latency and loss of all user context [25, 34]. In summary, LMKD termination can quickly relieve memory pressure but has serious side effects. In contrast, kernel-level memory reclaim is transparent to users and more cost-effective for mobile systems that emphasize interactive experience [19, 28, 34].

While LMKD should be avoided whenever possible, applying kernel-level memory reclaim in current systems is challenging. Our experiment reveals that current kernel-level memory reclaim is surprisingly sluggish in practice, failing to keep up with the growing memory demands of applications and being unable to fully utilize advanced mobile device hardware. Specifically, we observe that dozens of LMKD events can occur within just a few minutes (see Figure 2), suggesting the heavy reliance of current systems on frequent LMKD to alleviate memory pressure. As mentioned earlier, one of the primary reasons for this aggressive killing is the inefficiency of kernel-level memory reclaim. Also, while application memory footprints can easily reach several gigabytes, the memory

†The corresponding author is Liang Shi (shi.liang.hk@gmail.com).

reclaim throughput remains unexpectedly low, less than 150 MB/s at most (see Figure 3). The consistent upgrades for mobile devices have failed to reverse this trend, further confirming the existence of bottlenecks in kernel-level memory reclaim.

To this end, we are motivated to conduct in-depth analysis to illustrate the reason for the inefficient kernel-level memory reclaim. Experiments show that the current reclaim scheme is limited by the rigid reclaim path, and therefore cannot exert the performance of evolving storage devices. Specifically, the memory reclaim procedure follows a sequential execution flow in which two key steps slow down the overall process: (1) *Page Shrinking*, which extracts victim pages from the kernel page list for subsequent reclamation, and (2) *Page Writeback*, which checks whether the victim page is reclaimable and then writes them back to the flash-based storage device. Intuitively, the selection of the victim page should be very fast, and the bottleneck of memory reclaim is more on the I/O operation of page writeback. However, the time breakdowns of memory reclaim suggest that page shrinking and page writeback account for 55% and 45% of the total reclaim latency, respectively. Each round of memory reclaim spends more than one-half of the time waiting for the result of the page shrinking. The current page shrinking step uses multiple conditions to classify reclaimable pages, leading to pessimistic victim selection and repeated iterations to meet memory requirements. For page writeback, the unmapping operations are slow and create fragmented pages, limiting the use of the high write throughput of modern flash-based storage devices. This design can neither meet the demand for fast memory reclaim nor maximize the performance of storage devices.

Motivated by these observations, we propose PMR, a parallel memory reclaim method for fast application response on mobile devices. The core idea of our method is to redesign the kernel's existing memory reclaim path to improve page reclaim efficiency. Specifically, we decouple selected key steps in the reclaim process and parallelize them, thereby accelerating memory reclaim. PMR consists of two parts: proactive page shrinking (PPS) and storage-friendly page writeback (SPW). PPS enables asynchronous execution of page shrinking, preparing an adequate amount of victim pages ahead of memory reclaim bursts. SPW performs unified page unmap on an application-by-application basis and batches I/O operations to exploit the internal parallelism of flash storage devices. Our evaluation results show that PMR prevents LMKD from terminating processes and guarantees quick response time for the running applications compared with the original kernel.

The major contributions of this paper are as follows.

- We firstly benchmark the memory reclaim on mobile devices and reveal the sluggish kernel-level memory reclaim. And then we identify the root cause: (1) sequential execution of page shrinking and page writeback introduces unnecessary delays; (2) page shrinking does not prepare sufficient victim pages, incurring frequent memory reclaim calls; (3) the page unmap mechanism generates fragmented page write I/Os, which under-utilizes the internal parallelism of flash storage.
- We introduce PMR to enhance the original memory reclaim process, involving proactive page shrinking and storage-friendly page writeback. The former decouples page shrinking and page writeback, and the latter performs storage-friendly I/Os to accelerate page writeback.
- We deploy PMR on real mobile devices. The experimental results show that when enabled PMR, the application response time is reduced by 43.6% compared to the original system memory reclaim approach.

2 Background and Motivation

2.1 Memory Reclaim on Mobile Device

Linux-based Android mobile devices have three memory reclaim schemes to manage memory pressure: memory swapping, direct reclaim and LMKD. First, when the system detects that the free memory watermark is lower than a predefined threshold ($watermark_{low}$), memory swapping is triggered to perform asynchronous memory reclaim with a kernel thread *kswapd*. Second, if the free memory level is still critically low, direct reclaim is activated to perform synchronous memory reclaim. Third, if the kernel-level memory reclaim (memory swapping and direct reclaim) fail to relieve the memory pressure, Android provides LMKD to release memory by killing processes selectively.

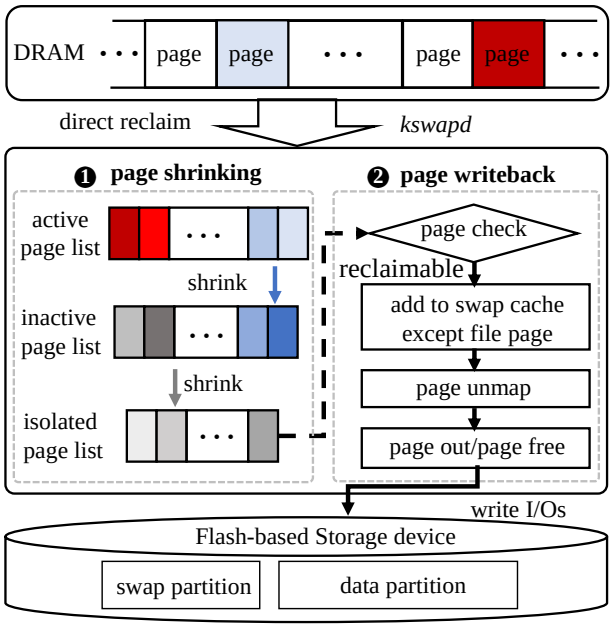

Figure 1: Traditional kernel-level memory reclaim path on mobile device

Although LMKD effectively alleviates memory pressure, killing processes cause loss of the application context and long restart of applications. By contrast, kernel-level memory swapping and direct reclaim are preferred [29, 31, 34]. Recently, mobile device manufacturers, such as Samsung [43], Huawei [21], have included flash-based memory swapping for memory expansion [1,21,43,54]. Figure 1 shows that both memory swapping and direct reclaim follow the two steps for page reclaim: (1) Page Shrinking and (2) Page Writeback.

Page Shrinking. The kernel organizes memory pages into four LRU page lists per memory zone for each NUMA node: inactive anonymous page list, active anonymous page list, inactive file page list, and active file page list. When memory reclaim is triggered, the kernel demotes infrequently used pages from the active page list to the inactive page list, as well as takes out infrequently used pages from the inactive page list for page writeback. Whenever memory reclaim occurs, the kernel calculates the scan ratio for each page list. The `nr` array logs the scanned page count for each page list. Specifically, the kernel executes page shrinking in two steps: First, memory swapping or direct reclaim determines the total number of pages to be reclaimed (`nr_to_reclaim`) and the number of pages to be scanned for each round `nr_to_scan`. Second, the kernel scans all four LRU lists for `nr_to_scan` pages. The scan continues until the array `nr` is empty or the reclaimed pages (`nr_reclaimed`) reach the reclaim target. The victim pages found during the scan are added to the temporary `page_list` to be written back later.

Page Writeback. Once the pages are collected, the kernel performs page-by-page writeback, involving the following steps: First, the kernel performs a page check to confirm whether it can enter the subsequent reclaim process, including page references, page locks, etc. Second, when the page passes the check, the anonymous page is added to the swap cache and allocated a page table entry of swap space. Third, the system performs page unmap and page out for both anonymous and dirty file pages. Specifically, page unmap sets the page table entry mapping the anonymous page to the previously allocated swap type table entry or clears the process page table entry mapping the file page. Page out calls `page->mapping->a_ops->writepage` in the page descriptor to write back the page asynchronously. Finally, the page reclaim is complete, and the memory space occupied by the page is free.

2.2 Preliminary Study of Memory Reclaim

To understand the performance characteristics of the memory reclaim process, we performed extensive experiments on multiple mobile devices equipped with different sizes of memory and storage, including Google Pixel 5, Redmi Note 11 and Google Pixel 6 pro, as shown in Table 1. The experiments involve popular applications to reflect realistic user scenarios. Detailed experimental settings can be found in Section 5. We enabled flash-based swapping with a 2 GB swap partition on all these mobile devices. Our evaluation consists of two parts: First, we measure the frequency of the LMKD process and its impact on application response time. The time refers to the system's duration on transitioning from one application running in the foreground to another, showing the need for efficient memory reclaim. Second, we demonstrate the limitations of the current memory reclaim performance by showing that it fails to keep pace with the growth of app memory footprints.

2.2.1 Frequent, Expensive Process Killing

To quantify the execution behaviors of LMKD, we composed a workload that switches back and forth among 36 applications with various app-use durations and employed the `logcat` command [11] to collect LMKD killing events. To avoid bias, we present the average of ten rounds of application response time.

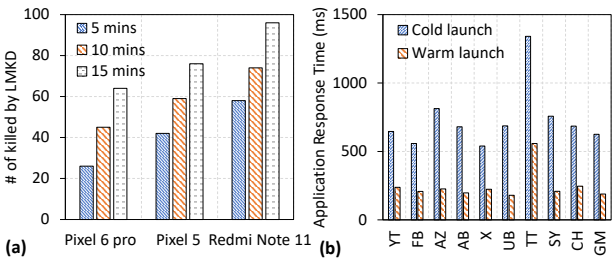

Figure 2: Frequent occurrences of LMKD have a large negative impact on application responsiveness. (a) Many processes are killed among different mobile devices; (b) Applications suffer from long restart latency when the processes are killed on Pixel 6 pro. (YT: YouTube, FB: Facebook, AZ: Amazon, AB: Angry Birds, X: Twitter, UB: Uber, TT: TikTok, SY: Spotify, CH: Chrome, GM: Gmap.)

As shown in Figure 2(a), even though the newest Pixel 6 pro has 12 GB of DRAM, it still experienced 26 process killings after five minutes of workload replay, with more processes being killed by LMKD as the workload ran longer. By contrast, because Pixel 5 and Redmi Note 11 feature small amounts of DRAM, they experienced more LMKD killings under the same workload. Here, switching to an application killed by

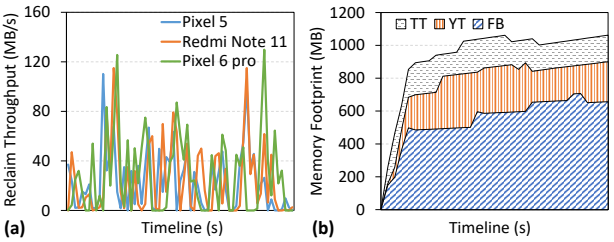

Figure 3: Low memory reclaim throughput accompanying growing memory requirements of applications. (a) Memory reclaim throughput barely improves on fast storage; (b) Extremely high memory demands of applications.

LMKD requires a restart (cold launch). Figure 2(b) shows that the application response time is 3.1 times longer on average than the latency of the warm start of the application, that is, switching to a live cached application. The frequent LMKD killing events degrade application responsiveness and severely impact user experience. Considering the triggering conditions of LMKD mentioned above, frequent LMKD comes from the ineffective kernel-level memory reclaim that fails to alleviate memory pressure in time.

2.2.2 Sluggish Memory Reclaim

To confirm that kernel-level memory reclaim does not match app memory demands, we measured kernel reclaim throughput and app runtime memory footprint. Once the system performs memory reclaim, the kernel writes dirty file pages and anonymous pages back to the storage device. Considering that other processes in the system will also perform write operations for file pages during the memory reclaim, we employ the write throughput of the swap partition as a reliable indicator of the memory reclaim throughput, And there is indeed a high percentage of reclaimed anonymous pages that need to be written back to the swap partition [50].

Figure 3 shows our two findings. First, as shown in Figure 3 (a), memory reclaim throughput fluctuates below 80 MB/s most of the time, and interestingly, reclaim performance remains consistently low across different generations of mobile devices. Specifically, while Pixel 6 pro features faster flash storage than Pixel 5 (UFS 3.1 versus UFS 2.1), the average reclaim throughput of Pixel 6 pro is only 10% higher than that of Pixel 5. On the other hand, Figure 3(b) shows that the memory footprint size of three popular applications expands quickly during the initial startup phase, reaching between 400 MB and 1 GB. It is evident that the memory reclaim process falls far behind the application memory demands.

In summary, **while app memory footprint is increasingly high, the hardware advance does not benefit the efficiency of kernel memory reclaim. This inefficiency results in frequent LMKD killings, which has a negative impact on the user experience. These findings direct our further investigation toward analyzing the memory reclaim procedure.**

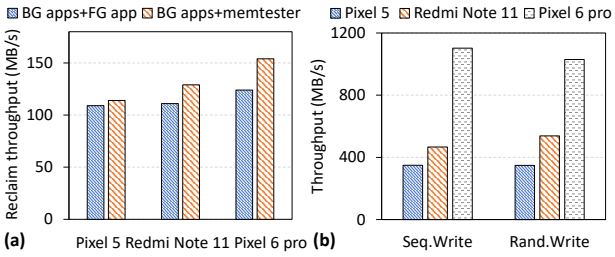

Figure 4: (a) I/O performance w/ or w/o I/O conflict. (b) Random and sequential write throughput with 4 KB I/Os.

3 Performance Bottleneck Analysis

As mentioned in Section 2.1, the kernel-level memory reclaim involves scanning kernel pages and accessing the flash storage. Based on these two key steps, we examine the root causes of memory reclaim stalls.

3.1 I/O Utilization

Intuitively, the stagnant memory reclaim may be first attributed to poor I/O performance, which includes two aspects: I/O conflicts and the storage device itself. According to previous studies, the write I/Os of memory reclaim may conflict with the read I/Os of other processes, and I/O conflicts are considered to be an important factor affecting application performance [18, 30, 39]. However, the storage bandwidth determines the upper limit of the memory reclaim.

3.1.1 Low Impact of I/O Conflicts

To quantify the impact of I/O conflicts on memory reclaim, we conducted two workload scenarios: (1) Saturating memory pressure by running multiple background applications and provoking memory reclaim by switching applications to foreground (`BG-apps+FG-app`); (2) Running background applications and use the `memtester` command [48] to allocate memory and provoke memory reclaim (`BG-apps+memtester`). `BG-apps+FG-app` represents a scenario in which memory reclaim suffers from intensive I/O conflicts because switching applications to the foreground involves reads from the storage. In contrast, memory reclaim requires writing pages to the flash storage. `BG-apps+memtester` represents another scenario in which memory reclaim is almost free from I/O conflicts because `memtester` requests for memory without generating additional read I/O operations.

Figure 4 (a) shows the peak memory reclaim throughput under both workloads on different mobile devices. Taking Pixel 6 pro as an example, the peak reclaim throughput with `memtester` (light conflict) is only 8.3% higher than the throughput with switching applications to the foreground (severe conflicts), and similar results are displayed by Pixel 5 and Redmi Note 11. In other words, I/O conflicts have a low impact on memory reclaim throughput. This is because reads

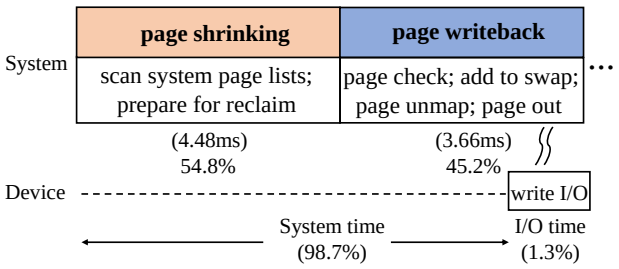

Figure 5: Average time breakdown of memory reclaim path.

are much faster than writes in flash storage, and under I/O conflicts, they only lightly affect the latency of swap writes [47].

3.1.2 Excessive Storage Bandwidth

Storage bandwidth is also a critical factor for overall I/O performance. We measure the write throughput of flash storage using the `fio` tool [2], with the results shown in Figure 4(b). The internal 128 GB UFS 2.1 flash storage in the lowest profile Pixel 5 achieves a random write throughput of 378 MB/s, three times higher than the memory reclaim throughput reported in the previous section. By contrast, the high-profile Pixel 6 pro with UFS 3.1 flash storage demonstrates an even greater capability, achieving throughput at around 1000 MB/s for random and sequential writes. In other words, the memory reclaim process significantly under-utilizes the storage bandwidth, suggesting the inefficiency lies within the system software rather than the hardware.

3.2 Sub-optimal Memory Reclaim Path

To identify bottlenecks in the memory reclaim path, we dissect the time overhead by measuring the delay of each major step using the kernel command *ktime* [3].

3.2.1 Sequential Execution of Key Steps

Figure 5 shows a breakdown of the total memory reclaim latency, contributed by page shrinking and page writeback: First, for each round of memory reclaim, the page shrinking step spends 4.48 ms on average, which accounts for 54.8% of the total memory reclaim time. The page writeback step contributed to the rest 45.2%, using 3.66 ms on average. Interestingly, although the page shrinking step does not involve any I/Os, it uses more than one-half of the total latency just to prepare victim pages for reclamation. Second, each round of page reclaim goes through a serial flow of page shrinking and page writeback, i.e., page writeback must wait until victims have been prepared by page shrinking. In other words, this sequential execution flow significantly limits the potential benefits of enhanced flash storage performance in improving memory reclaim efficiency.

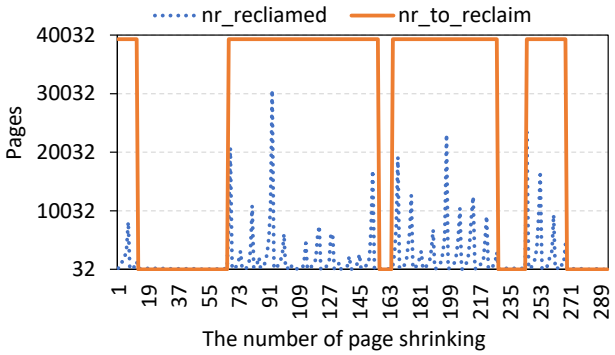

Figure 6: nr_to_reclaim vs nr_reclaimed when system performs memory reclaim.

3.2.2 Inefficient Page Shrinking

As mentioned earlier, the kernel-level memory reclaim consists of memory swapping and direct reclaim. For memory swapping, the expected number of pages reclaimed in each round of invocation is the maximum of `SWAP_CLUSTER_MAX` and `watermark_high` (whose default value is 39340 pages, approximately 154 MB). For direct reclaim, this value is `SWAP_CLUSTER_MAX`, 32 pages by default.

Figure 6 illustrates the expected number of pages to be reclaimed (`nr_to_reclaim`) versus the actual number of pages reclaimed (`nr_reclaimed`) during runtime. When memory swapping executes, although it is expected to reclaim 39,340 pages, the actual number it reclaims is far fewer than the expected value. This is because, during memory reclaim, the page shrinking step examines `nr_to_reclaim` LRU pages in the kernel page lists, but only a small portion of these pages can be reclaimed. Specifically, pages that have been recently referenced or are locked for page writeback cannot be reclaimed. Additionally, page shrinking terminates early if it experiences highly unbalanced scanning between anonymous pages and file pages [14]. As a result, page shrinking is repeatedly invoked to gather sufficient reclaimed pages, making the entire procedure inefficient.

3.2.3 Internally Blocked Page Writeback

Page writeback is responsible for performing the actual page reclaim based on the page type, including page checking, unmapping victim pages, and writing the pages to storage, etc. Intuitively, I/Os for page writing may be the performance bottleneck, but our analysis reveals a different result.

Figure 7 shows a breakdown of the page writeback step into unmapping pages and writing pages (page out). Unexpectedly, the time overhead of page unmap is relatively high and extremely unstable. This is because to unmap a page, page table entries of all processes that share the page must be modified through a reverse mapping mechanism, and this procedure is prone to interruption, so its completion time is extremely unstable [34]. Moreover, not only unmapping but

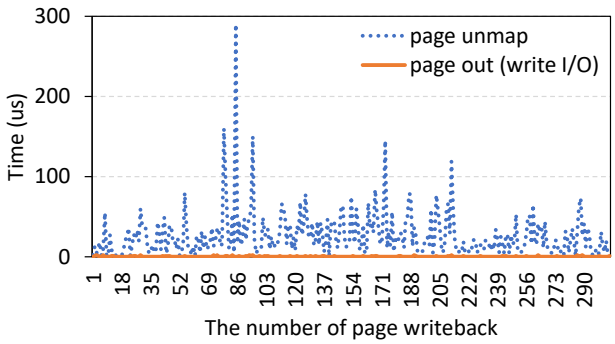

Figure 7: Time breakdown of page writeback (the time of page out is not zero but fluctuates under a few microseconds).

also writing of pages is performed page by page. Writing flash at the page granularity is inefficient and slows down the whole writeback step.

In summary, **sluggish memory reclaim is mainly due to the sub-optimal memory reclaim path, including three aspects: (1) page writeback waits on the results of page shrinking, introducing unnecessary delays; (2) page shrinking suffers from inefficient reclaim and repeated invocation; (3) page unmap latency is highly unstable and produces small writes that cannot unleash the potential of flash storage.**

4 PMR Design

4.1 Overview

The basic idea is of PMR to parallelize key steps of memory reclaim to fulfill application memory demand and thus improve application response. Intuitively, there are two typical ways to perform parallel memory reclaim. First, the kernel can create multiple memory reclaim threads, e.g., Mutiplek-swapd [36] wakes up multiple kswapd threads to perform memory swapping to relieve memory pressure. Second, it is possible to exploit the performance advantage of flash storage through bulk I/Os. For example, SEAL [29] performs memory swapping in units of applications, rather than page by page. However, for the former, multi-threaded memory reclaim is prone to conflict with each other and burden the CPU because they occur simultaneously. For the latter, simply increasing the I/O size still does not resolve the suboptimal execution flow of memory reclaim. Unlike previous work, PMR parallelizes key steps in the memory reclaim path based on observations in Section 3.2.

To realize the basic idea, PMR consists of two components: proactive page shrinking (PPS) and storage-friendly page writeback (SPW). Figure 8 shows an overview of PMR. PPS decouples page shrinking and page writeback to prepare sufficient victim pages in advance, and it includes a kernel thread *kshrinkd* and a victim page list to perform page shrinking independently. Specifically, its operation involves three steps: (❶) Based on pre-defined conditions, *kshrinkd* is activated. (❷) An independent page shrinking procedure moves pages from the system page LRU lists to the victim page list. (❸) The new victim page list is carefully maintained to ensure sufficient pages are provided for page writeback.

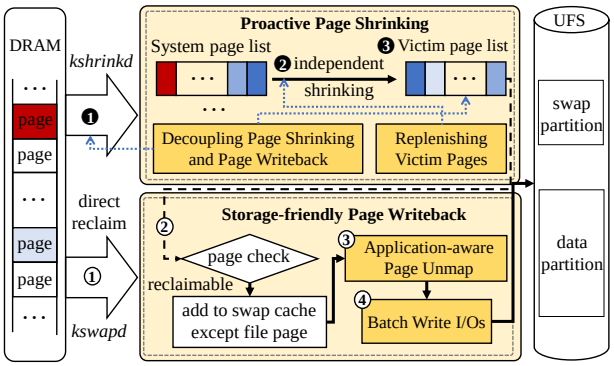

Figure 8: Overview of PMR.

SPW performs application-aware page unmap, and batches write I/Os for efficient page writeback. It redesigns the page unmap process to align with storage-friendly I/O sizes, enabling bulk writes that exploit the internal parallelism of flash storage. Specifically, it works in four steps: (①) When the system runs low on memory, *kswapd* or direct reclaim is triggered for memory reclaim. (②) Unlike the existing design, page writeback is triggered immediately since *kshrinkd* may already have prepared sufficient pages in the victim list. (③) Reclaimable pages undergo application-aware page unmap. (④) A batch of unmapping pages are written to flash storage through efficient bulk I/Os.

There are two key challenges in the implementation of PPS and SPW. First, *kshrinkd* is supposed to prepare sufficient victim pages, subject to the timing of the shrinkage and the granularity of each. The shrinking must be carefully timed to avoid conflicts between page shrinking and other processes accessing pages. The shrinking granularity should meet the need to reclaim memories without creating waste. And the victim page list needs careful maintenance to control overhead. Second, the batch size of the application-aware page unmap must be carefully controlled. The batch size should be sufficiently large to ensure efficient write I/Os, yet not so large as to introduce unnecessary delays in page writeback. The following sections detail the design of PPS and SPW.

4.2 Proactive Page Shrinking

To produce an adequate supply of victim pages for page writeback at a low cost, PPS decouples page shrinking and page writeback and carefully determines the timing and granularity of page shrinking.

4.2.1 Decoupling Page Shrinking and Page Writeback

Existing kernel-level memory reclaim follows the sequential flow of page shrinking first and then page writeback. When the system suffers memory pressure, page shrinking first isolates victim pages to the temporary `page_list`, and page writeback performs subsequent page reclaim.

Two challenges arise regarding the decoupling of page shrinking and page writeback. First, current page shrinking and page writeback are operated by the same thread. Concurrent execution of the two steps is required to achieve the decoupling. Second, the existing page shrinking design uses function `isolate_lru_pages` to temporarily remove eligible pages from the system LRU page lists for subsequent page writeback. With decoupled page shrinking and page writeback, access to the eligible pages between page shrinking and page writeback requires coordination. To address these two challenges, firstly, page shrinking is offloaded to a new kernel thread *kshrinkd*, and page writeback is left to memory swapping and direct reclaim. Secondly, the temporary `page_list` isolated by page shrinking have been redesigned as a new victim page list to coordinate the page production and consumption between *kshrinkd* and page writeback.

Independent *kshrinkd* Thread. *kshrinkd* is designed to perform page shrinking independently and prepare sufficient victim pages in advance. We standardize *kshrinkd* runtime rules to achieve this goal. First, the triggering of *kshrinkd*, no longer depends on memory pressure, but on whether enough victim pages are prepared. When the system faces memory pressure, kernel-level memory reclaim directly accesses the pages produced by *kshrinkd* to perform page writeback. Second, unlike existing page shrinking, which may terminate early without producing the expected number of victim pages, such as when `nr_anon` or `nr_file` are zero, our enhanced *kshrinkd* uses a continuous scanning loop to ensure the target is reached. Finally, to minimize changes to the kernel, *kshrinkd* inherits the page shrinking algorithm from the existing memory reclaim, e.g., calculating the number of pages that need to be scanned for each LRU page list.

Victim Page List Maintenance. When page shrinking and page writeback can be done in parallel with the help of *kshrinkd*, we need to consider how to preserve the victim pages that were produced by *kshrinkd*. The traditional LRU isolation mechanism is limited by factors such as lock contention, and the number of pages that can be isolated each time is limited. Based on this, we maintain a new victim page list and filter eligible pages from the system LRU list by *kshrinkd*, including those pages that are not locked and not frequently referenced. Specifically, we use a reserved bit in the page table entry to record these pages as isolated pages (`PG_ISOLATED`). And *kshrinkd* will move these pages from the system LRU list to the victim page list. Also, to avoid access conflict to the victim page list, lightweight spinlocks are used to ensure normal page accesses for *kshrinkd* and page writeback. In this way, we can reserve sufficient pages in the victim page list to perform efficient page isolation services for subsequent page writeback.

Algorithm 1: Always Ready Page Shrinking

```
Input: nr_victim_page: the actual number of pages in the victim
       page list (The initial value is 0);
nr_ideal_victim_page: the ideal number of pages in the victim page
list (The initial value is δ);
shrink_size: the number of page shrinking each time ;
if System Start then
    while nr_victim_page < nr_ideal_victim_page do
        kshrinkd starts;
        shrink_size = nr_ideal_victim_page ;
    kshrinkd sleep;
Once page writeback is required, provide victim pages;
if Memory Swapping or Direct Reclaim Start then
    while nr_victim_page < nr_ideal_victim_page do
        kshrinkd starts;
        shrink_size = nr_to_reclaim ;
```

4.2.2 Replenishing Victim Pages

The decoupling of page shrinking and page writeback introduces the challenge of ensuring that *kshrinkd* maintains an adequate supply of victim pages for page writeback. To address this challenge, a new control loop is introduced, as detailed in Algorithm 1, which describes our always-ready page shrinking procedure. At system startup, *kshrinkd* is activated, and it continues the collection process until *nr_ideal_victim_page* pages have been inserted into the victim page list. Once this target is met, *kshrinkd* transitions to a sleep state. On memory reclaim requests, the victim pages from the new page list are isolated for page writeback, while in the meantime, the page shrinking procedure is reactivated to replenish victim pages. This ensures a consistent supply of victim pages for writeback, maintaining system efficiency and readiness. Further details are discussed below.

Page Shrinking Watermark. To ensure sufficient victim pages, we set a page shrinking watermark. The parameter *nr_ideal_victim_page* (i.e., δ in Algorithm 1) specifies the target number of victim pages that should be maintained in the new victim page list. To prevent delays in page writeback due to insufficient victim pages, *nr_ideal_victim_page* must be large enough, and its value should be carefully determined through an analysis of application responsiveness. Our sensitivity study in Section 5.5 recommends an empirical setting of 462 MB, ensuring a sufficient supply of victim pages for efficient memory reclaim.

Timely Page Shrinking. The efficiency of our page shrinking design depends on both the timing of *kshrinkd* activation and the batch size of page shrinking. Unlike the on-demand approach of existing memory reclaims designs, which is triggered by low watermarks or allocation rates, our design ac-

tivates page shrinking ahead of memory bursts. At system startup, *kshrinkd* collects victim pages until *nr_victim_page* reaches *nr_ideal_victim_page*, then enters a sleep state. Later, when system memory reclaim is invoked, even if the victim page list is not yet empty, *kshrinkd* is reactivated for parallel execution. In this case, the shrinking batch size is set to `nr_to_reclaim`, one third of *nr_ideal_victim_page*, and iterations continue until *nr_ideal_victim_page* victim pages have been prepared in the list.

In the design of PPS, the system needs to maintain a victim page list as a communication bridge between page shrinkage and page writeback. To circumvent page thrashing (between the system LRU list and the victim page list), a novel page type, the isolated page, is introduced as the victim page selection criterion for page shrinking. This inevitably raises concerns about the performance overhead of maintaining these pages. However, PPS merely screens isolated pages in advance, which can enhance the efficiency of page isolation operations. Furthermore, the parameter *nr_ideal_victim_page* determines whether the system can provide sufficient victim pages for writeback. The default setting of 462 MB is equivalent to three times the fixed number of pages for each memory swapping. Although different applications appear to require different amounts of memory to be reclaimed, it is challenging to set different default settings according to the types of applications. The current fixed default values are derived from sensitivity experiments and are committed to ensuring the performance of most applications. A more detailed maintenance design of the victim page list will be the focus of future work.

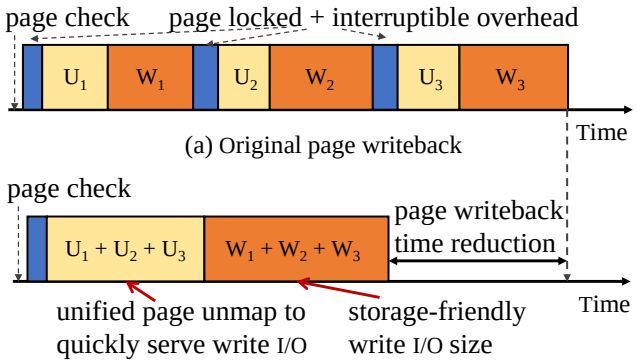

Figure 9: Page writeback scenarios with and without storage-friendly page writeback. U_i is the i^{th} page unmap, and W_i is the corresponding write I/O. SPW expedites paged writeback by exploiting the parallelism of flash storage devices.

4.3 Storage-friendly Page Writeback

A victim page must first be unmapped before being written back to the flash storage. Even though our page shrinking design collects batches of victim pages (i.e., `nr_to_reclaim`), with the existing page writeback procedure, pages are written back to flash storage in a page-by-page manner (4 KB each). In addition, as previously detailed in Section 3.2.3, the page unmap process suffers from highly unpredictable delays, affecting page writeback efficiency. To address these performance issues, SPW introduces application-aware page unmap followed by batched page-out (page writeback).

Figure 9 compares the original page writeback process and our SPW design. Unlike the original approach, SPW separately clusters page unmap operations and page write actions. The clustered page unmap, called an application-aware unmap, mitigates the cost of locking, avoids interference from other contending processes, and accumulates multiple pages for storage-friendly write I/Os. Subsequently, pages can be written back through bulk write I/Os, which better exploits the internal parallelism of flash storage.

4.3.1 Application-aware Page Unmap

There have been prior methods for resizing unmap job sizes to avoid interference from other processes and kernel activities [34]. In contrast, SPW takes a different approach by introducing an application-aware page unmap to enable storage-friendly write I/O operations. The core idea is to organize pages based on their associated processes and determine the unmap job size according to the performance characteristics of the underlying flash storage. Specifically, the application-aware unmap design must carefully handle interrupts to avoid long tail latency and exploit the performance gains of bulk write I/Os on flash storage, effectively balancing throughput and latency.

To minimize interference from other processes and kernel activities and improve the unmapping efficiency, SPW exploits the big-LITTLE processor architecture commonly found in modern mobile devices [46]. Specifically, in addition to increasing the job size for page unmap, SPW assigns a high priority to the page unmap thread and affiliates the thread with a big core, ensuring that the thread is not preempted during execution. With the privileged execution of the application-aware unmap procedure secured, the next focus is on determining the optimal job size for the unmap procedure based on the performance efficiency of flash storage.

4.3.2 Batch Write I/Os

Application-aware page unmap removes the obstacle for implementing bulk write I/Os, which can improve the efficiency of memory reclaim by utilizing the parallelism of storage devices. Next, we analyze the characteristics of flash-based storage devices to find the most cost-effective I/O size.

As shown in Figure 10, write throughput improves with larger I/O sizes, though the improvement is non-linear. The marginal gain saturates when I/Os are large enough to fully utilize parallelism, but increasing the I/O size further introduces high latency. On the Google Pixel 6 pro, a 10 MB I/O

size achieves 1261 MB/s, effectively balancing throughput and latency. Interestingly, cumulative write throughput does not benefit from additional threads due to lock contention. Based on these insights, our design collects unmapped pages from the new victim page list and composes them into bulk write I/Os based on the device-specific size. To address potential performance challenges with larger unmap sizes, a sensitivity analysis of this parameter will be presented in Section 5.5, to ensure an efficient balance between unmap and writeback performance.

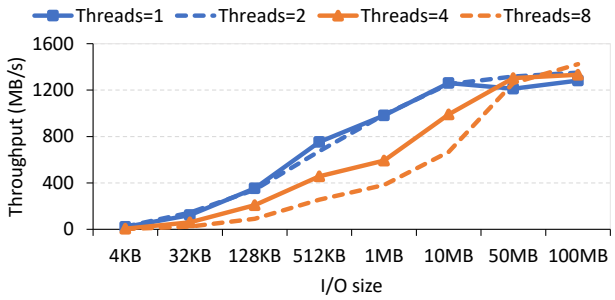

Figure 10: The throughput for random writes varies with the sequential block size and the number of threads in flash memory on Google Pixel 6 pro.

While the existing kernel handles pages individually, our SPW technique batches page unmapping and submits groups of pages to the block layer in bursts. As SPW simply increases the granularity of page unmapping, it inherits the page check and lock mechanisms from the existing kernel with minimal modifications. Our SPW is also orthogonal to the I/O plugging [24] mechanism, which operates at the block layer and is opaque to the page reclaiming process. By contrast, our SPW prepares batched I/O at the system software layer, allows more precise timing control, accelerating I/O submission and reducing merge latency.

4.4 Implementation and Discussions

Implementation Detail. Our implementation of PMR follows the principle of a minimally invasive approach, reusing existing kernel functions whenever possible. This section focuses on PMR's implementation aspects.

To implement *kshrinkd* for page shrinking, the `kshrinkd_init` function is executed as part of the kernel initialization process within `start_kernel`. Within `kshrinkd_init`, `kthread_run` is invoked to create a *kshrinkd* thread for each memory node, similar to *kswapd*. The page shrinking mechanism previously managed by *kswapd* is transferred to *kshrinkd*, with its activation now depending on the insufficiency of pages in the new victim page list, rather than the original *kswapd* activation conditions. Additionally, a new page list type, `LRU_VICTIM`, is introduced as an intermediary between page shrinking and page writeback. The *kshrinkd* thread scans the original LRU page lists and moves eligible victim pages to the new list, enabling page writeback to swap out these pages efficiently. To further optimize performance, the page unmap mechanism performs batch page writes based on the device-optimal I/O size. Using the `/proc` interface, our implementation allows for dynamic adjustment of the unmap unit size (`mem_unmap_unit`) on-the-fly.

Orthogonality. To keep our design simple and focused, several default memory reclaim settings are retained in this paper. First, although studies have shown that LRU-based page replacement strategies may not be optimal [32,34,51], our implementation inherits the default LRU-based victim page selection strategy. This decision is based on the fact that PMR is compatible with any page selection strategy and achieves performance improvements regardless of the strategy used. Second, as previous studies have extensively explored optimizing the trigger conditions for memory reclaim [19,27,30,58], we choose not to modify them. Instead, PMR focuses on accelerating the execution of memory reclaim and serves as a complementary approach to these efforts. Finally, despite research on optimizing memory reclaim by adjusting its size [32,50], we do not modify the original kernel setting, as PMR operates with its own job size for page shrinking and page writeback.

Future Use Cases of PMR. The deployment of large language models (LLMs) [6,37,55] on mobile devices imposes significant memory pressure on mobile systems, leading to severe performance degradation for such memory-demanding applications. On the other hand, the performance of mobile storage devices based on NAND flash has seen significant improvements, with the latest UFS 4.0 delivering a 1.8 times higher I/O bandwidth compared with UFS 3.1 [4,8,38,45]. With such a high flash storage bandwidth, there is great potential to reshape the memory reclaim process.

5 Evaluation

5.1 Experiment Setup

Evaluation Platforms and Workloads. We adopt different real mobile devices as our experiment platform, as mentioned in Table 1, and flash-based memory swapping is enabled for memory swapping on these mobile devices, and the swap partition is set to 2 GB.

Experiments are conducted by following the three steps: (1) We installed the pre-selected 36 applications (10 switching applications and 26 background running applications) on the device to begin each experiment. (2) We used *adb* [9] command to collect evaluation results while performing automated tests with UI Automator [53] that emulates UI touches of users. *adb* is a versatile command-line toolkit, and we can use the command "adb shell starts the app's package name (PKN)" to start apps and record the launch latency. UI Automator is adopted to generate pseudo-random streams of user events, such as clicks, touches, or gestures, as well as a

number of system-level events. The app's PKN and the total number of user events we want to generate are provided to run this tool. Specifically, we use UI Automator to run background applications and adopt *adb* to switch the selected ten applications and record the launch latency as response time. We performed the same automated tests in ten rounds and calculated the average to avoid basis. The order of application switching is changed randomly in each round.

Table 2: Applications and automated user interaction.

Category	Foreground Applications	Auto user inputs
Browser	Chrome	Browse/Read posts
Social Network	Facebook, Twitter	Browse/Read posts
Multimedia	YouTube, Tiktok	Watch videos
Business Utility	Amazon, Gmap, Uber, Spotify	Browse and search Listen music
Game	Angry Birds	Play a stage

∗Background applications: Browser (Firefox, Opera), Social Network (WhatsApp, Instagram, Skype, WeChat, LinkedIn), Multimedia (Spotify, MXPlayer, Netflix, Capcut), Online shopping (Taobao, eBay, AliPay, BOA, Paypal), Business Utility (Booking, Gmail, New York Times, BBC News, OfficeMobile, GoogleDrive), and Game (Hill Climb Racing, Boom Beach, ClashRoyale, Call of Duty).

Evaluated Schemes. Five schemes are implemented and measured to show the effectiveness of PMR. **1) Original Memory Reclaim (OriginalMR)** represents the baseline of evaluation, which is inherited from native Linux. Inefficient memory reclaim results in memory pressure and cannot be relieved in time, causing processes to be killed frequently. **2) Acclaim [32]** represents the state-of-the-art work that is closest to this study, which relocates free pages from background applications for foreground applications and adjusts the size of *kswapd* according to the predicted allocation workloads. **3) Fleet [19]** represents the latest memory reclaim optimization idea on mobile devices, which proposes a foreground-aware GC-swap to combine Android Runtime (ART) GC and kernel-based memory swapping. **4) PMR** represents our proposed framework, which combines PPS and SPW.

5.2 Application Response Evaluation

To understand the benefit of PMR on application performance, application response time is evaluated among existing memory reclaim schemes. Application switching may expose memory reclaim when the system is under memory pressure. Different memory reclaim schemes can lead to different application response times due to performance differences. It is a critical performance metric for smartphone users.

Figure 11 shows the application response time of the evaluated schemes. First, OriginalMR suffers the worst response time, several times higher than other schemes. This is because when the system is under memory pressure, original memory reclaim fails to relieve memory pressure in time, and the system tends to kill the application. In this case, the application response time is equivalent to a cold launch. Second, Acclaim and Fleet reduce the response time by an average of 32.4%, 35.7% compared to OriginalMR, respectively. This is because Acclaim reduces direct reclaim and page fault by a foreground-aware page eviction and a dynamical size of the *kswapd*. Fleet designs kernel-based memory swapping and ART GC together to avoid mutual interference between different levels of the system memory reclaim.

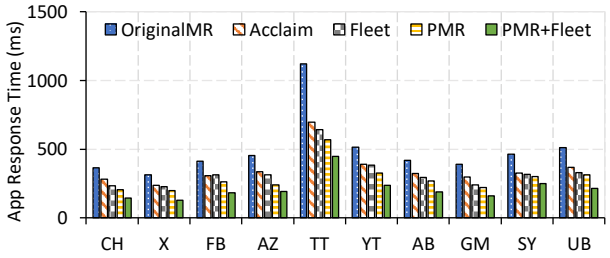

Figure 11: Application response time among different memory reclaim schemes on Google Pixel 6 pro.

Unlike previous works, PMR achieves fast memory reclaim to boost application response by proactive page shrinking and storage device-friendly write I/O. The application response time decreases significantly compared with OriginalMR, with the decreases reaching 43.6%. Also, PMR also has significant performance improvements over Acclaim and Fleet. More importantly, thanks to PMR's focus on improving the common memory reclaim path, it is perfectly complementary to both Acclaim and Fleet. For example, when PMR and Fleet are used together, application response time is reduced by 67.4% compared to OriginalMR and improved by 38.9% compared to Fleet alone. This is because Fleet effectively improves the accuracy of memory reclaim and avoids invalid memory reclaim, while PMR can speed up memory reclaim.

5.3 Memory Reclaim Evaluation

To further understand the performance improvement brought by PMR to application responsiveness, we separately evaluated the memory reclaim throughput and other performance indicators of the system during the following experiments, including the number of LMKD, direct reclaim, and page faults. On the one hand, memory reclaim throughput can intuitively see the benefits of memory reclaim in ensuring system memory availability. On the other hand, the number of LMKD indicates the efficiency with which the system memory pressure is alleviated. In contrast, direct reclaim and page fault indicate the impact of memory reclaim on the application [32]. Note that in this subsection, since Acclaim also focuses on kernel-level memory reclaim optimization, we choose it as the state-of-the-art work for comparison, rather than Fleet, which focuses on the joint design of ART GC and memory swapping.

5.3.1 Memory Reclaim Throughput

Figure 12 shows the memory reclaim throughput under different mechanisms. First, the memory reclaim throughput of OriginalMR and Acclaim shows the same trend. That is, it changes in a very low range. The reason why OriginalMR suffers this performance loss has been revealed previously. Acclaim is committed to reducing the number of direct reclaim and page faults and does not optimize the memory reclaim path, so it also fails to improve memory reclaim throughput. Secondly, compared with previous work, PMR benefits from a parallelized memory reclaim path, which not only avoids passive waiting for page writeback, but also accelerates the traditional page writeback. The results show that the peak memory reclaim throughput of PMR is increased by 82.8% and 75.5% respectively compared with OriginalMR and Acclaim. The huge improvement in memory reclaim throughput shows that PMR can perform memory reclaim at a faster speed, which explains the performance improvement of PMR in terms of application response time. Also, since Fleet focuses more on the accuracy of memory reclaim and does not essentially affect the reclaim throughput, it was not chosen as the comparison object in the following experiments.

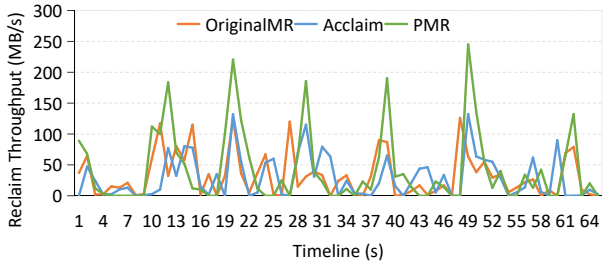

Figure 12: Memory reclaim throughput among different schemes.

5.3.2 Reduction of LMKD/Direct Reclaim/Page Fault

LMKD can cause applications to suffer long restart delays. Direct reclaim, which is a synchronous memory reclaim, has a direct impact on application allocation page requests. Page faults can cause long page reads. To understand the improvement of application response due to PMR, we further analyze the above three performance indicators.

Figure 13 shows the number of LMKD, direct reclaim and page fault under different memory reclaim schemes. First, OriginalMR suffers the most from LMKD, direct reclaim, and page faults. Acclaim benefits from foreground-aware memory reclaim, which can effectively reduce the number of direct reclaim and page faults. However, it essentially does not effectively alleviate memory pressure, and LMKD still occurs frequently. Secondly, unlike Acclaim, PMR can effectively alleviate memory pressure with the help of fast memory reclaim and avoid the frequent occurrence of LMK. Compared

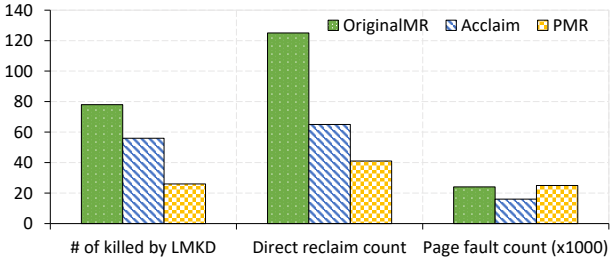

Figure 13: The number of killed applications, direct reclaim and page fault among different schemes.

with OriginalMR and Acclaim, PMR reduces LMKD by 82% and 54% respectively. Moreover, when memory swapping can effectively alleviate memory pressure, direct reclaim will naturally decrease, PMR reduces it by 45% compared to Acclaim. Since PMR does not change the victim selection page, the page fault rate remains the same as OriginalMR.

5.4 Storage Utilization Evaluation

In this subsection, we calculate the memory reclaim throughput on different mobile devices under the same application running condition to demonstrate the efficiency of PMR by taking advantage of evolving storage devices to improve the efficiency of memory reclaim. Specifically, Pixel 5 and Pixel 6 pro were selected as experimental platforms, with the former equipped with a 128 GB UFS 2.1 storage device and the latter equipped with a 256 GB UFS 3.1 storage device. Similar to the previous experiment, 26 applications were running in the background, and six applications were switched back and forth in the foreground, including YouTube, Facebook, Twitter, TikTok, Gmap and Camera. We collect the memory reclaim throughput during the switching of these six applications.

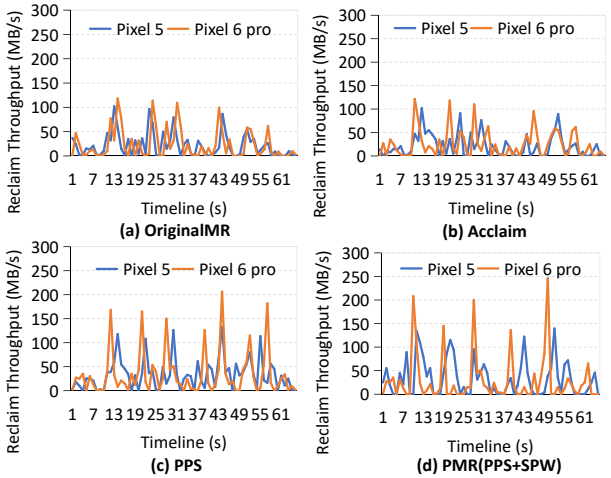

Figure 14: Memory reclaim throughput for different schemes under different mobile devices.

Figure 14 shows the memory reclaim throughput of different memory reclaim mechanisms on different mobile devices. First, OriginalMR and Acclaim pay little attention to the performance improvements of storage devices. This is because Acclaim only focuses on optimizing the victim page selection scheme and dynamically adjusting the size of *kswapd* to reduce direct reclaim and page faults, lacking any design for storage devices. Secondly, compared with the previous mechanisms, the newly proposed PPS significantly improves the memory reclaim throughput, especially the performance of storage devices. For example, for Pixel 6 pro, the maximum throughput of PPS reaches 205 MB/s, which is an 45% increase compared to Pixel 5. Finally, the integration of PPS and SPW can not only provide sufficient victim pages for page writeback in advance, but also enable storage-friendly page writeback to maximize the storage device's performance. The results show that the average throughput on the Pixel 6 pro is 65% of that on the Pixel 5.

5.5 Sensitivity Study

To further understand PMR, several sensitive studies are performed, including the ideal number of pages in the victim page list (*nr_ideal_victim_page*: δ) and the size of the application-aware page unmap.

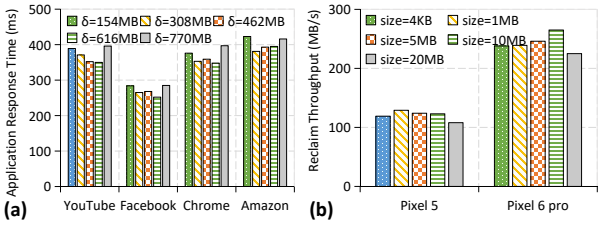

Figure 15: (a) Application responsiveness by varying δ (the ideal number of pages in the victim page list); (b) Memory reclaim throughput by varying the size of the application-aware page unmap.

The ideal pages in the victim page list: δ aims to control the capacity of the victim page list, which directly affects the performance of memory reclaim. Figure 15 (a) shows the effect of changing δ from 154 MB (equivalent to `nr_to_reclaim`) to 770 MB on the application response time. First, as δ increases, the application response time decreases and then increases again. δ is not as large as it should be. This is because a larger δ means that more pages are placed in the victim page list, and pages may face repeated transfers between the victim page list and the system LRU page list, which increases page access overhead. Second, the change in δ has a limited impact on the application's responsiveness because the victim page list is inherited from the system LRU page list, which does not introduce new data structures or memory overhead.

The size of the application-aware page unmap: The size of the application-aware page unmap affects both the performance of the unmap and the efficiency of write I/O. Figure 15 (b) shows the effect of different sizes of the application-aware page unmap on the memory reclaim throughput. First, the optimal value for this size varies from one mobile device to another, for example, the Pixel 5 is 1 MB while the Pixel 6 pro is 10 MB, depending on the underlying storage device.

5.6 Overhead Analysis

In this section, we evaluate PMR's overheads: (1) the performance overhead of PPS and SPW in the current design and (2) the flash write overhead induced by proactive disk writeback.

Performance Overhead. The performance overhead of PMR is broken down into three parts. First, PPS enables an independent *kshrinkd* thread to be responsible for page reduction. However, because shrink can only inherit some of the functions of the original *kswapd*, while the *kshrinkd* brings CPU overhead, the CPU overhead of *kswapd* will also be reduced. Second, PPS maintains a separate victim page list. Although these pages come from the system's original inactive page list, they will not cause new memory overhead. Also, to maintain a sufficient number of victim pages, some additional lock protection needs to be added, which also brings CPU overhead concerns. Finally, SPW adjusts the priority of application-aware page unmap to avoid interference by processes, which may also bring potential performance overhead. As shown in Table 3, PPS increases CPU overhead by 2.0% compared to OriginalMR, while PMR increases by 5.3%.

Table 3: Performance overhead.

	CPU Overhead		
	kswapd	***kshrinkd***	**Total**
OriginalMR	24.31	0	24.31
PPS	13.94	10.97	24.91
PMR (PPS+SPW)	14.51	11.1	25.61

Flash Write Overhead. PMR is more effective in evicting pages, which allows it to reduce application kills. This results in more aggressive flash writes. To evaluate the possibility that excessive flash writes may wear out the flash device, we ran the system with and without PMR for half an hour and collected the write volumes. The experimental results show that PMR increases flash writes by 12.1% compared to OriginMR. In fact, as the storage capacity of mobile devices increases, the lifespan anxiety of storage devices has been greatly alleviated. The impact of PMR on flash device lifespan is negligible and worthwhile compared to the benefits.

6 Related Work

Memory Reclaim Optimization. Many previous works enhance the memory reclaim schemes [7, 20, 41, 44, 49, 52]. First, Fastswap [7] and Hermit [41] optimize how and where

page reclaim is executed (e.g., offloading to a dedicated CPU or spawning threads), while our work improves what is executed, i.e., we redesign the reclaim path itself to make it inherently more efficient. This deeper improvement makes existing mechanisms like Fastswap and Hermit more effective. With our faster page reclaim, Fastswap no longer needs a dedicated CPU, and Hermit requires fewer threads for the same performance. Second, recent studies [27, 58] perform ahead-of-swap to optimize memory swapping. For example, SmartSwap [58] predicts the appropriate swap time based on the design model, and Marin [17] swaps out objects in advance by analyzing the objects working set. Unlike them, PMR does not modify the timing of memory reclaim, but only prepares the victim pages in advance.

Also, another method is to update the LRU-based victim page selection criteria [32, 34, 56] Since PMR is dedicated to accelerating the common memory reclaim path, it is compatible with any effective victim page selection algorithm. Multiplekswapd [36] enables multiple memory reclaim threads to perform proactive memory reclaim. However, blindly using multiple threads will induce mutual interference and will not achieve the expected reclaim effect, especially on mobile devices with limited resources. In contrast, PMR can achieve the purpose of parallel reclaim by enabling an additional page-shrinking thread. Finally, researchers also focus on coordination between ART garbage collection and kernel-level page swapping [19, 27] to boost memory reclaim performance. Unlike these studies, our work targets system-level kernel reclaim logic directly. Combining our kernel-level improvements with Fleet [19] yields even more significant gains, highlighting their orthogonality and the broader applicability of our solution.

Storage-friendly I/O Management. Although the performance of flash storage devices is improving rapidly, current system software is still deficient in leveraging the performance of storage devices. Many researches have been devoted to the design of storage-friendly I/O management [5, 23, 30, 34, 40, 42, 57]. Paralfetch [42] performed a pre-scheduling of launch-related disk read requests for fast I/O reads, and overlaps app execution with disk prefetching for hiding disk access time from the app execution. Its basic idea is close to our work, PMR also pre-schedules page shrinking and page writeback in advance and achieves fast page writeback. SWAM [34] dynamically modifies the size of page unmap to avoid interference with high-priority operations for fast swap-out. Differently, PMR performs bulk page unmap to server storage-friendly page out, which organizes pages by application and determines the size of the unmap based on the performance characteristics of the storage device.

Application Response Optimization. There are a number of strategies to optimize application responsiveness on mobile device [18, 22, 26, 28, 33, 39, 46]. ASAP [46] performed pre-paging by combining application switch footprint estimators and minimizing resource waste for CPU cycles and disk bandwidth during an application switch for fast application switch on mobile devices. Fasttrack [18] proposed a foreground app-aware I/O management scheme to accelerate foreground I/O requests by preempting background I/O requests in the entire I/O stacks, including the storage device, and preventing foreground app's data from being flushed from the page cache. CacheSifter [33] classified cache files into three categories online and greatly reduced the number of writebacks on Flash by dropping cache files that most likely will not be reused to boost application performance. Unlike them, PMR performs parallel memory reclaim path to boost application response.

7 Conclusion

In this paper, we propose PMR, a parallel memory reclaim scheme for fast application response on mobile devices. The basic idea of PMR is to parallelize the memory reclaim path to leverage ever-evolving storage devices and enhance memory reclaim. Specifically, PMR firstly decouples page shrinking and page writeback and prepares sufficient victim pages in advance to quickly serve subsequent page writeback. And then, PMR performs application-aware page unmap and page out in batches to achieve a storage-friendly page writeback. Experimental results demonstrate that PMR effectively improves memory reclaim throughput and boost application response.

SAVE: Software-Implemented Fault Tolerance for Model Inference against GPU Memory Bit Flips

Wenxin Zheng, Bin Xu, Jinyu Gu[✉]*, Haibo Chen*
Institute of Parallel and Distributed Systems, School of Computer Science, Shanghai Jiao Tong University

Abstract

Machine learning models are used in safety-critical edge applications such as autonomous driving, industrial robots, and satellites. However, GPU memory bit flips can significantly reduce the model accuracy. Existing mitigations either compromise accuracy or introduce substantial overhead.

Our insight is that *not all hardware bits are created equal* and *bit flips vary in their impact on model inference*. Specifically, for the GPU memory, modern AI accelerators provide bit-flip-free but small reliable memory. For the model inference, due to nonlinear activation functions in the model, some bits are naturally robust against flips, while other vulnerable bits can silently corrupt results. Thus, we prioritize the allocation of vulnerable bits' computations in the reliable memory to enhance the robustness of the model inference.

We propose SAVE, a software-implemented fault tolerance system that protects model inference without modifying the model and with minimal performance impact. SAVE operates in four stages: *S*election to identify vulnerable bits based on the intrinsic characteristics of model inference, *A*llocation to prioritize computations related to more vulnerable bits in reliable memory, *V*erification to efficiently detect errors through asynchronous CPU checks, and *E*dit to recover from detected faults. Evaluation across computer vision, robotics, and decision-making models shows that SAVE maintains model accuracy even under 4K bit flips while incurring less than 9% performance overhead.

1 Introduction

Machine learning models already play an important role in safety-critical edge scenarios including autonomous driving [2, 54, 71], financial systems [6, 43], combat operations [10, 82], and military satellites [32]. The models on local edge devices handle a large amount of data, e.g., 20TB per day for one satellite [89] and 30TB per day for one autonomous driving car [1]. These on-device edge GPUs are more likely to have memory bits unintentionally flip due to unstable voltage in Unmanned Aerial Vehicles (UAVs), changing temperatures in cars, or radiation in space. Protecting inference safety against memory bit flips on these edge devices is crucial while challenging. For example, one satellite may experience approximately 16 million bit flips daily [89], and traditional Error Correction Code (ECC) [35, 68] proves insufficient, as it provides only single bit errors correction [68] while even a single escaped bit flip can cause complete accuracy loss and false decisions [29].

Current approaches to protect model inference against bit flips on edge accelerators fall into two categories based on whether they modify the model structure. The first category modifies the model structure to enhance model robustness, including specialized activation functions [89], compression [37, 76], and quantization [40]. However, these methods often compromise accuracy and lack generality across different models. The second category preserves model structure while implementing protection through redundancy, such as Triple Modular Redundancy (TMR) [5, 13, 57, 60, 79] and ECC [35, 68]. Although these approaches preserve accuracy and generality, they either incur substantial overhead (2× for TMR) or provide limited error correction capabilities (ECC).

In this paper, we focus on the second category and propose an efficient software mitigation named SAVE against bit flips in GPU memory, which improves the reliability of model inference results without retraining the model or sacrificing accuracy.

Our first insight is that **not all hardware bits are created equal**. Modern edge-deployed AI accelerators like NVIDIA Orin provide bit-flip-free safety islands [67], while hardware manufacturers [25, 52] implement SRAM soft error detection in e.MMC [26] for L1 cache protection. SAVE leverages these reliable memory regions for reliable model inference.

However, these reliable memory regions are limited (only around 5-6MB in Orin [67]). Relying solely on them requires frequent CPU-GPU memory swapping, which inevitably increases performance overhead. Our evaluation shows it introduces more than 1,000× performance overhead for both computer vision and robotics decision-making models.

Our second insight is that **not all bit flips in software are fatal or silent**, which offers the chance to hybridly use

reliable memory and normal memory for model inference computation. During computation, the bits can be classified into three categories: *robust bits* that don't affect inference results, *ranging bits* that can be verified through simple range checks (e.g., the Sigmoid function's sign bit must be zero as outputs range from 0 to 1), and *vulnerable bits* that silently corrupt the model. SAVE strategically allocates computations involving vulnerable bits to reliable memory while computing robust bits in normal memory, efficiently minimizing memory swapping while maintaining result correctness.

Specifically, SAVE contains four stages to enhance the reliability of model inference against GPU memory bit flips, namely, *S*election stage, *A*llocation stage, *V*erification stage, and *E*dit stage.

Selection stage: robustness analysis and output range analysis. Machine learning models are programs that are easier to analyze data and control flow compared to general software. Thus, SAVE analyzes the model with data flow, control flow, and mathematical properties to identify robust bits in each value. For example, activation functions like ReLU [64] and GELU [38] yield outputs close to zero for negative inputs, meaning changes to the significand of its input will have little impact. Additionally, SAVE assesses each layer's output range to find ranging bits. For example, for image classification models, the image pixel value gives the range of the input value. The known input range, together with the model parameters, gives the output range of each layer. Some of the exponent bits or sign bits can be verified by these ranges without recomputation. SAVE sets all remaining bits as vulnerable bits. The findings are stored in a bit attribution cache to accelerate further verification.

Allocation stage: robustness-aware GPU memory management. Based on offline robustness analysis, SAVE prioritizes allocating reliable memory to computations with more vulnerable bits. To optimize the use of limited reliable memory, SAVE employs in-place computation techniques, including overwriting input tensors with output results during matrix multiplication. Model parameters are intentionally placed in normal memory because they have copies stored in CPU memory, allowing for bit flip detection through CPU-GPU consistency checks during verification.

Verification stage: lightweight runtime verification. SAVE implements distinct verification mechanisms to accelerate the runtime verification. Values in reliable memory are considered correct and do not require verification. For values in normal memory, SAVE verifies the correctness differently according to their roles. For model parameters, it uses DMA to copy them back to the CPU during runtime for double-checking without impacting model inference. For other values, SAVE verifies the correctness of ranging bits using the valid output range. To reduce the performance overhead, it verifies vulnerability bits with integer computation using the integer computation resources to avoid heavy floating-point recomputation.

Table 1: Model degradation due to bit flips. (1): The models with softmax. (2): ResNet, VGG. (3): 8-bit quantization models. (4): ASR: Attack Success Rate.

	Model	Flipped Bits	Accuracy Degradation
NaN [29]	EfficientNet	3	82.00% → 0%
FIASM [46]	Softmax(1)	1	97.4% → 62%
TBD [40]	CV(2)	1	Up to 99% drop
BFA [73]	ResNet18(3)	13	69.8% → 0.1%
DHB [37]	ResNet20(3)	28	81.39% drop
TBT [74]	ResNet18(3)	84	92% ASR(4)
TA-LBF [9]	ResNet18(3)	1507	100% ASR(4)
T-BFA [75]	ResNet18(3)	27	100% ASR(4)
Our Experiments	ResNet	1	Up to 99% Drop
	ViT		
	CogACT		

Edit stage: eliminating bit flips. When an error is detected, SAVE simply restarts the inference computation from the faulting model layer.

To demonstrate the efficiency and effectiveness of bit flip mitigation, we test SAVE across various computer vision, robotics, and decision-making models. The results show that SAVE incurs less than 9% performance overhead for end-to-end latency in model inference and maintains the model's accuracy even in the case of 4K bit. To compare existing approaches, we propose a new metric, *AccurateLatency*, which penalizes high latency and low accuracy in inference. SAVE is 90% lower than state-of-the-art methods under *AccurateLatency*.

In summary, our contributions are as follows:

- An idea of arranging computation related to vulnerable bits in reliable memory to improve the reliability of model inference.
- A prototype system, SAVE, to mitigate GPU memory bit flips by using robustness-aware GPU memory management and lightweight runtime verification and recomputation.
- An intensive evaluation that demonstrates the efficiency and effectiveness of SAVE.

2 Background

2.1 GPU Bit Flips on Edge Inference

Machine learning models greatly improve decision and recognition accuracy. So, many on-device edge scenarios like autonomous cars [2, 54, 71] and satellite image recognition [32] use these models for local inference. To support these applications, GPUs are widely used for model inference due to their high parallelism and efficiency. These GPUs are often deployed in edge devices, such as drones and satellites, where they can process data locally and make real-time decisions. However, the GPU memory reliability in the edge device can be easily compromised by physical factors such as unstable

cell voltage, radiation, and temperature fluctuations. Such decreased reliability will result in unintended bit changes in GPU memory, commonly referred to as bit flips. Bit flips are a common occurrence across various edge-deployed GPU devices [90]. For instance, the memory flip rate in UAVs operating under low voltage conditions can reach 3.5% [86]. In space devices, radiation exposure can cause flip rates as high as 10%, with multiple cells potentially flipping simultaneously [89]. On some lower-end devices, an average of 3,900 bit flips may occur per day [80]. One satellite can experience 16 million bit flips per day due to cosmic rays [89].

These bit flips can significantly degrade model accuracy. Research indicates that even a single bit flip can reduce model accuracy by more than 60%, as demonstrated in Table 1. Such accuracy degradation can have severe consequences for downstream applications. In financial systems, erroneous results can silently affect stock trading volumes or target prices. In aerospace applications, corrupted decisions or navigation calculations can result in mission failures.

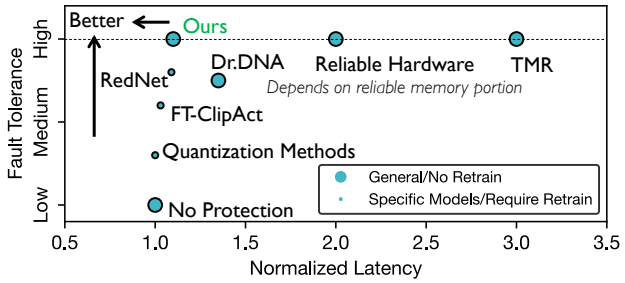

Figure 1: Comparison of different bit flip mitigation methods.

2.2 Existing Approaches

Existing approaches to safeguard inference safety on edge devices against bit flips can be categorized into two types based on whether they modify the AI model. A comparison of these approaches is shown in Figure 1.

The first category involves modifying the model structure or its outputs to enhance model robustness. Some methods [33, 47, 53, 89] employ hashing-based techniques to generate weight group signatures and verify parameters. Other approaches propose using quantization [37, 40, 76] and specialized activation functions, such as FT-ClipAct [39], RedNet [89], and Ranger [16], to mitigate the impact of bit flips. Additionally, Dr.DNA [61] leverages the distribution of activation results to detect and correct bit flips. However, these methods often require retraining the models or result in reduced accuracy.

The second category preserves the original model structure while implementing protection mechanisms through software or hardware redundancy. For instance, ECC can detect and correct limited bit errors. However, ECC is typically deployed only in high-end devices [4, 51] and is unavailable on many off-the-shelf GPUs. Moreover, it incurs additional costs, including a 10% to 20% increase in memory usage and a 2% to 3% reduction in performance [20, 24]. Furthermore, in extreme scenarios such as those involving cosmic ray impacts [89], a large number of bits may flip simultaneously, exceeding the error correction capacity of ECC and causing it to fail. Triple Modular Redundancy (TMR) [60, 79] is a general software solution to improve computational reliability. However, it requires threefold computation, rendering it prohibitively expensive for many scenarios [89].

2.3 Reliable Memory Exists on GPUs

We observe that "not all bits are created equal" on GPUs. Specifically, certain portions of GPU memory exhibit higher reliability, presenting opportunities for reliable computing. This observation is supported by the following two facts.

First, NVIDIA Orin, a widely-used edge AI accelerator, provides safety islands [67], which account for only 0.009% of the total memory and are guaranteed to be free of bit flips. Additionally, hardware manufacturers [25] offer soft error detection features for SRAM in e.MMC [26], enabling hardware-based protection for L1 cache. Second, similar to bit flips observed in DRAM on CPUs [8, 49, 50], a significant portion of GPU memory bits may be prone to flipping, while others remain stable and never flip (effectively functioning as safety islands). The properties of these bits are determined during manufacturing and are influenced by factors such as the chip fabrication process, memory cell voltage stability, and resistance to environmental stress. Defective bits prone to flipping can be identified through experiments using rowhammer-like tools [84, 96, 97] or through environmental testing [12, 19, 34, 87, 89]. Bits that are not prone to flipping can be treated as reliable memory and leveraged during inference.

2.4 Fault Model and Goal

Our work attempts to leverage the reliable memory on GPUs to improve the robustness of model inference against GPU memory bit flips under the following assumptions: 1) initial model parameters and inputs on the CPU side do not experience bit flips, as they are protected by orthogonal reliable methods on CPU-side memory; 2) registers, cache, and a small portion of memory on the GPU are free from bit flips; 3) the GPU reliable memory can be detected by environmental testing like Rowhammer-like tools [11, 14, 22, 51]; 4) the remaining GPU memory may experience random bit flips, including both single-bit and multi-bit flips; 5) the GPU kernel binary could fit within the reliable memory because of its small size after pruning [69].

It is important to note that the goal of SAVE is to *enhance* the robustness of model inference under GPU bit flip conditions, rather than strictly guarantee inference correctness under all possible flip scenarios.

3 Basic Idea and Insights

3.1 Basic Idea

A strawman solution is making all the computation conducted within the reliable GPU memory. However, the size of reliable memory is typically too small (e.g., less than 10MB) to accommodate GPU kernel computation with large matrices. Thus, we need to partition the kernel computation so that the input, model parameters, and output can fit into the small reliable memory. This involves continuously transferring data between the CPU and GPU reliable memory. According to our tests on both one visual model [23] and one decision model [15], this approach would result in a more than 1000× increase in model inference latency, which is unacceptable.

Our basic idea is also utilizing only the reliable GPU memory for improving the reliability of model inference. The key difference from the strawman solution lies in that our system (SAVE) hybridly uses reliable memory and unreliable memory on the GPU.

We first find that it is feasible to pre-load all the model parameters into unreliable memory, which can save more reliable memory for accommodating the kernel input and output. This is because 1) there exists an intact copy of model parameters on the CPU side; 2) the parameters in the unreliable memory can be copied back to the CPU side for verifying consistency, by using the free CPU-GPU PCIe path with the dedicated memory copy engine during kernel execution without hurting performance.

When executing the first layer's kernel computation of the model, SAVE copies the input matrix to reliable memory and launches the kernel for computation. After the first layer completes, it pulls the kernel's parameters back to the CPU and compares them with CPU-side parameters to verify that no bit flips occurred in the unreliable memory during kernel computation. This procedure is overlapped with the kernel execution of the next layer. While there exists an extreme edge case where a bit might flip before computation and revert before CPU verification, this time window is negligibly small, and we do not consider such extreme cases.

The output of the first layer's kernel computation is also placed in reliable memory, in-place overwriting the input to serve as input for the next layer's computation with another copied version to serve as the last reliable output. This process continues layer by layer until completion. During this process, if the total memory required for input/output in any layer's kernel computation exceeds the size of reliable memory, SAVE still partitions the kernel's input to ensure each computation fits within reliable memory capacity, and swaps intermediate results to CPU memory for temporary storage.

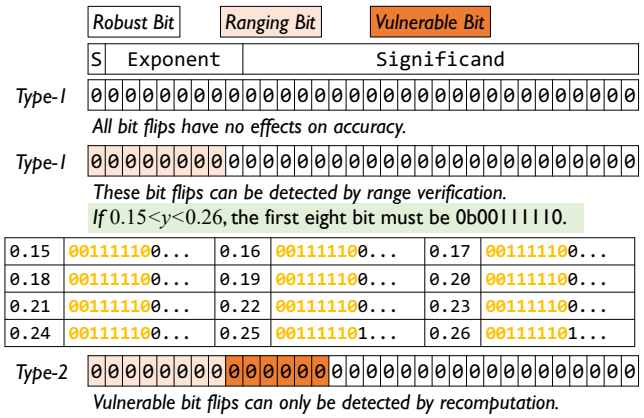
Besides model parameters, we also find that some parts of the kernel input can also be placed on the unreliable memory without sacrificing the model inference accuracy, which helps to minimize the needed partition of kernel computation. Next, we introduce our insights on how to select data for computation in unreliable memory and vice versa.

3.2 Insights on Bit Robustness

When placing computation data in unreliable memory, we need to detect the correctness of computation results, specifically to identify errors in computation results caused by bit flips. While detection can be simply achieved through recomputation and result comparison, this would incur significant performance overhead or require double the computing resources.

We discovered that not all bit flips have equal impact on model accuracy, which presents an opportunity to reduce the fault detection overhead. Different from general-purpose computing, the non-linearity of model computation makes some bit flips have little impact on model accuracy. We conduct an experiment with the ResNet-50 model, flipping each bit in every kernel's input values individually and measuring the impact on model accuracy. The experiment results show that there exist *robust bits* whose flips have no impact on model accuracy; the remaining non-robust bits affect the accuracy and can be further categorized into *ranging bits* and *vulnerable bits*. The former ones may cause `NaN` and reduce model accuracy to 0, while the latter causes gradual accuracy degradation. Additionally, we found that some values consist entirely of robust bits and ranging bits (**type-1 values**), while others contain vulnerable bits (**type-2 values**).

For computations involving type-1 values, we compare results against pre-computed result thresholds; if ranging bits flip, results will fall outside these thresholds, which eases the fault detection. For type-2 values, recomputation is necessary to verify result correctness. We designed an asynchronous CPU-based verification method that doesn't impact GPU model inference, which is detailed in §4.4. For reliable memory allocation, we prioritize matrices with more type-2 values to minimize recomputation needs.



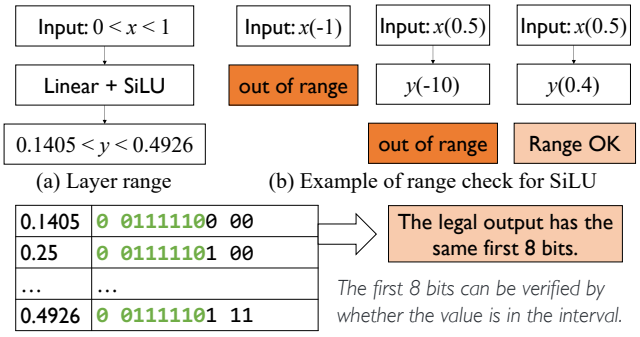


Figure 2: The classification of bits and its mapping.

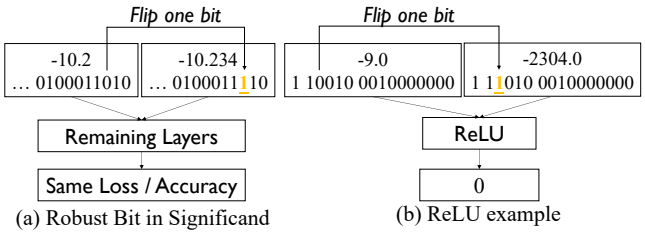
Finding all the robust bits and ranging bits by testing all the bits is impractical due to the large number of bits. At the same time, the robustness of a single bit cannot be directly

extended to multiple bits. Thus, we explore the mathematical properties of the model to quickly find the robust bits and ranging bits and find a method to extend the single bit robustness to multiple bits. We found that the impact of bit flips on results depends on how big perturbation a model calculation can tolerate. If the change from the bit flip stays within this range, accuracy is not affected. We choose 10^{-5} for perturbation as it is a conservative estimation, ensuring common models remain unaffected by perturbations [3, 44, 72]. Such bit robustness comes from the mathematical properties of the model computation, and thus, we design an offline analysis method of bit identification (§4.2).

Ranging Bits. Current machine learning models rely on nonlinear activation functions. These functions, in combination with the input data range, produce a small, valid output range. This reduces the cost of numerical validation, as values outside this range can be identified as errors without computation, as shown in Figure 3(a, b). It is important to note that the input data range is also predefined. For example, pixel values typically fall within the range of 0-255 or 0-1 (a model program often maps pixel values to this smaller range). These output range constraints can be mapped to the specific bits of the number, reducing the number of bits that need to be verified, as illustrated in Figure 3(c).



(a) Layer range (b) Example of range check for SiLU

(c) Ranging Bit Mapping

Figure 3: The ranging bits of the value and its fast verification.

Robust Bits. Robust bits can be identified based on the floating-point representation and the model structure. As shown in Figure 4(a), the last few bits of the significand have minimal impact on the results [27, 30, 63, 83], and can, therefore, be directly designated as robust bits. Additionally, the model structure contributes to robust bits. For instance, the negative input of a ReLU function does not affect the output as long as the input remains less than 0, as illustrated in Figure 4(b). These bits are marked as robust bits based on specific input conditions.

(a) Robust Bit in Significand (b) ReLU example

Figure 4: The flipped robust bits and their effects.

4 Design

4.1 Workflow Overview

SAVE is built on PyTorch, a widely used machine learning inference framework. Figure 5 illustrates its entire workflow, which consists of four key stages working together to achieve reliable inference:

Selection Stage performs a one-time offline static analysis to identify three types of bits: robust bits with minimal impact on accuracy, ranging bits that can be verified through range checks, and vulnerable bits identified conservatively as the remaining bits. The analysis results guide runtime memory allocation and verification.

Allocation Stage manages the placement of data between reliable and unreliable memory. Based on the analysis of the prior stage, it prioritizes placing computations with more vulnerable bits (more type-2 values) in reliable memory while assigning computations with more robust bits and ranging bits (more type-1 values) to unreliable memory. An eviction mechanism is also implemented to optimize the use of limited reliable memory resources.

Verification Stage detects faults caused by bit flips. It employs asynchronous CPU-GPU verification along with output range analysis results to minimize fault detection overhead.

Edit Stage addresses error recovery when faults are detected. It ensures that the latency of model inference remains unaffected in normal cases without bit flips. For cases where faults occur, SAVE restarts the inference process from the faulting model layer.

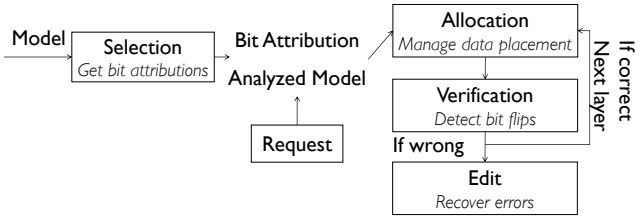


Figure 5: The overview of SAVE.

4.2 Selection Stage

This stage performs static analysis to classify three types of bits in each value: ranging bits that can be verified through

range checks, robust bits with minimal impact on accuracy, and vulnerable bits requiring strict protection. The analysis comprises two phases: range analysis and bit attribution analysis.

Phase 1: Range Analysis. SAVE determines the valid range for each value by propagating ranges through the model's computational graph layer by layer. Since the model structure is a directed acyclic graph (DAG) with deterministic operators (purely computational), this analysis can be performed statically. For simplicity, we assume each layer contains a single operator corresponding to one kernel.

Figure 6 illustrates this process with a concrete example: 1) SAVE initializes the input range as [0, 1] for the input layer. 2) This range is propagated to the next layer's operator (Op), which performs matrix multiplication. Since the weight matrix is fixed (model parameters), SAVE knows the relationship between input X and output Y of the Op. Based on the propagated input range, SAVE determines that the output range will be [-0.75, -0.1]. 3) The subsequent ReLU operator, which outputs zero for negative inputs, allows SAVE to determine that its output range is exactly 0. 4) For the final Add operator, one input is known to be 0 (from ReLU) and the other is the original input X ([0 to 1]), resulting in a final output range of [0 to 1]. The code snippet of this example is shown in Appendix B.

Phase 2: Bit Attribution Analysis. Using the ranges calculated in Phase 1, SAVE identifies ranging bits and robust bits.

Ranging Bits Identification. For each value, SAVE identifies ranging bits as those that must have the same value for all possible values within the computed range. These typically include the sign bit (e.g., must be 1 for range [-0.75 to -0.1]) and exponent bits constrained by the range bounds.

Robust Bits Identification. SAVE identifies two types of robust bits: 1) Value-based robust bits: For both upper and lower bounds of each range, if flipping a bit in the significand causes a numeric difference less than 10^{-5}, it is considered robust. The common robust bits between both bounds become the robust bits for that range. 2) Operator-induced robust bits: Some operators, particularly activation functions, create additional robust bits. For example, with ReLU and negative inputs, only the sign bit needs verification since all outputs will be zero regardless of the input's exact value.

Fine-Grained Analysis Results. Some operators, such as Op in the example above, exhibit points where the monotonicity of the input-output relationship changes. Some other operators may have extremely wide output ranges. In these situations, SAVE partitions the output range into multiple intervals and performs separate ranging and robust bit analyses for each interval. This approach enables more precise bit attribution during runtime based on actual values. To reuse the analyzed bit attribution results efficiently, SAVE stores the analyzed results in a bit attribution cache.

To manage cache pressure caused by storing bit properties across numerous intervals, SAVE optimizes memory usage by combining each linear operator with its subsequent nonlinear operator into a single composite operator. The cache then stores the ranging and robust bits for these combined operators instead of for individual ones.

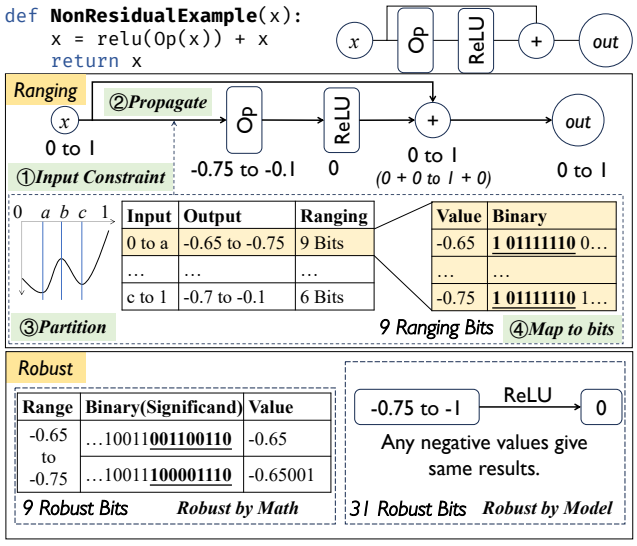

Figure 6: The process of range analysis in Selection stage.

4.3 Allocation Stage

While bit attributes can help reduce reliable memory usage in theory, existing computing and memory management interfaces do not support bit-level management. To address this limitation, SAVE employs matrix partitioning to manage memory allocation based on the proportion of vulnerable bits in each computation block after partitioning.

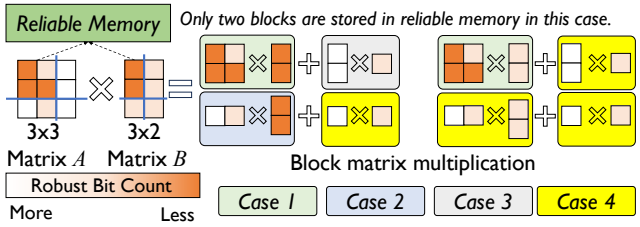

Figure 7: Blocking matrices multiplication examples and partitioning. Both matrix A and B in the figure are non-parameter matrices.

Specifically, when executing GPU kernels, SAVE partitions the input matrices into four sub-matrices, with the partitioning strategy designed to create significant differences in the proportion of vulnerable bits across blocks, as shown in Figure 7. During memory allocation, sub-matrices with higher

proportions of vulnerable bits are prioritized for placement in reliable memory, and sub-matrices with lower proportions of vulnerable bits are preferentially allocated to unreliable memory. The weight matrices of kernels (model parameters) are always allocated in the unreliable memory. To implement this, SAVE maintains two separate memory pools for reliable and unreliable (normal) memory, and hooks into the memory management interface in the framework.

The allocation strategy also carefully considers the output memory placement for each sub-matrix computation. For example, computation results containing more ranging bits and robust bits are preferentially allocated to unreliable memory, as they can be efficiently verified through range checks. This creates four distinct scenarios for each partitioned matrix, depending on the input and output memory placements, as illustrated in Figure 7:

- Case 1: Both input and output in reliable memory.
- Case 2: Input in reliable memory, output in unreliable memory.
- Case 3: Input in unreliable memory, output in reliable memory.
- Case 4: Both input and output in unreliable memory.

For the cases above, SAVE adheres to the rules of in-place modification after the CPU has stored the values. Specifically, SAVE transfers a copy of the output to the CPU.

For computations with output stored in reliable memory (Cases 1 and 3), in-place modification significantly reduces memory usage. However, since SAVE needs to maintain a reliable result on the CPU, immediately performing in-place modifications would erase the trace of reliable computations, impacting subsequent verification. To address this, SAVE retains a copy in reliable memory until the CPU has fully received the result. For computations with output stored in unreliable memory (Cases 2 and 4), SAVE transfers the output to the CPU for verification. Once the CPU verifies the output, it is deemed reliable, and the corresponding data in unreliable memory is in-place modified. For input values stored in unreliable memory (Cases 3 and 4), SAVE verifies their correctness by comparing the input with the recorded reliable input.

4.4 Verification Stage

SAVE requires fault detection for computations involving unreliable memory. A straightforward approach would be to recompute each kernel and verify result consistency, as shown in Figure 8(a). However, since both recomputation and verification would occur on the GPU, subsequent kernel computations would be blocked until verification is completed, significantly impacting model inference time.

Instead, SAVE introduces an efficient verification mechanism that offloads most verification work to the CPU through PCIe and unified memory, minimizing the overhead on model inference latency. This mechanism handles two distinct cases:

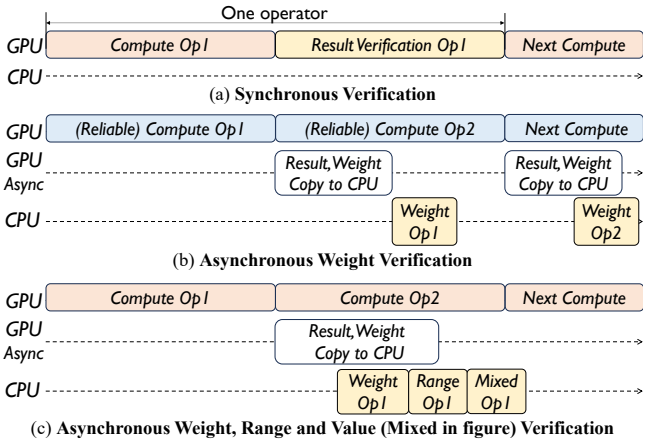

Figure 8: The overview of verification stage. The computation in red means the input is in unreliable memory. The computation in blue means the input is in reliable memory. The weight matrices are in unreliable memory.

Case 1: Kernel Input in Reliable Memory. When input matrices are placed in reliable memory (some partitioned matrices can fit in the reliable memory owing to the allocation stage), only the model parameters (weights) stored in unreliable memory need verification. SAVE asynchronously copies weights from GPU memory to CPU after each computation and uses parallel CPU threads to compare against the original CPU-side copy. As illustrated in Figure 8(b), weight transfers occur through the GPU's DMA engine without blocking kernel execution, allowing weight verification to run concurrently with the next kernel's computation.

Case 2: Kernel Input in Unreliable Memory. When input matrices reside in unreliable memory, SAVE performs three types of verification: weight verification as described above, range verification for ranging bits, and lightweight recomputation for vulnerable bits.

Range Verification. To verify numerical ranges efficiently, SAVE splits the work between GPU and CPU. Specifically, SAVE implements a range verification kernel as shown in Appendix C. It retrieves valid ranges for each value from the selection stage cache and launches the kernel. The kernel computes the differences between the value and its range bounds, uses the `signbit` function to get the sign bits of these differences, and performs OR on the sign bits to produce the output (where a zero indicates the value falls within range). After the kernel completes, the output matrix is transferred to CPU memory, where multiple CPU cores verify that all elements equal zero, confirming no ranging bit flips occurred.

This GPU-CPU split design is intentional because performing all verification on the CPU would introduce significant latency that would impact end-to-end model inference time. By dividing the work between GPU (numerical operations)

and CPU (final verification), SAVE achieves better overall performance. During the whole verification, the bandwidth of PCIe is not the bottleneck since not all values need to be verified on the CPU. To further minimize overhead, the range verification kernel is fused with its corresponding computation kernel.

Mixed Precision Recomputation Verification. Recomputation is required to verify the calculated results involving vulnerable bits. Directly recomputing multiplication or division kernels on the CPU would be highly time-consuming. To address this, SAVE aims to minimize the recomputation burden, enabling it to be conducted asynchronously on the CPU without introducing significant performance overhead.

Since ranging bits are verified by their ranges and robust bits are ignored, the number of bits requiring verification is reduced to less than half of the original count. This reduction allows the verification process to shift from high-precision computation (heavyweight) to low-precision computation (lightweight). Figure 9 illustrates the conversion process.

Specifically, for multiplication or division of x and y, the sign bit of the result can be obtained by XORing the sign bits of x and y. The exponent bits of the result can be obtained by adding or subtracting the exponent parts of x and y. Once the new exponent bits are determined, SAVE re-estimates the robust bits and removes the robust bits for further low-precision verification. The significand of the result can be computed by converting the significand of x and y (excluding robust bits) into 16-bit or 8-bit integers (low and mixed precision), then performing multiplication or division. CPU SIMD instructions are leveraged to accelerate these low-precision integer operations in parallel.

Appendix D presents the pseudocode for multiplication recomputation running on CPU. Lines 7 and 11 extract the significand of x and y. Since normalized floating-point numbers (1.significand) omit the leading 1 in their integer part, lines 24-25 restore this implicit 1. Then, robust bits are removed through shift operations before performing the final multiplication.

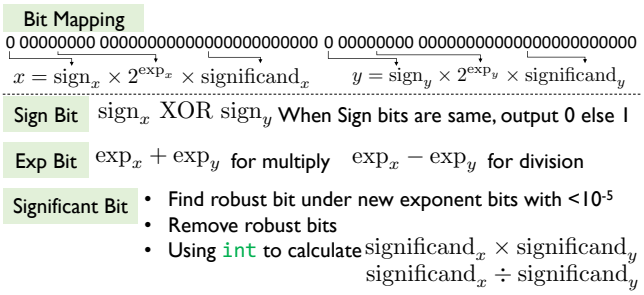

Figure 9: The verification process of multiplication and division.

The addition and subtraction kernels are very lightweight on GPU (and are hard to efficiently implement on CPU) thereby, their recomputation does not incur much overhead on the overall model inference latency. So, SAVE verifies the results by simply recomputing them.

5 Evaluation

To show the effectiveness of SAVE, we evaluate it by answering the following questions:

- What is the overhead of SAVE for normal execution?
- How effective is SAVE in protecting against bit flips?
- What is the overhead of each part of SAVE?

5.1 Evaluation Setup

We evaluate the effectiveness of our method through the approach of simulated flipping. We use GPUs for desktop PCs and embedded devices as the platform to evaluate the performance of SAVE. We follow our fault model, wherein the registers, cache, and a specific portion of memory (exactly 6MB) are assumed to be free from bit flips, and the CPU is considered free from bit flips. Our bit flip setting aligns with previous work [89], using real satellite flip characteristics from RedNet [89] to build a physical flip bit trace to test SAVE's effectiveness.

Baseline. To demonstrate the effectiveness of SAVE, we compare it against the unmodified original model (Original), Triple Modular Redundancy (TMR), and state-of-the-art protection methods (Dr.DNA [61] and RedNet [89]). Since RedNet cannot be directly applied to models, we retrain the model with RedNet, ensuring that the training configurations match those of the original model. For Dr.DNA, which includes several mitigation methods outlined in the original paper, we adopt the fastest mitigation strategy to evaluate end-to-end performance without errors. For TMR, we employ its mitigation strategy to measure recovery accuracy.

5.2 Metrics: *AccurateLatency*

In a fault-tolerant system, maintaining model correctness is crucial. To evaluate model performance, we propose a new metric, *AccurateLatency*, defined as: $\text{AccurateLatency} = \text{Latency} \times (1 + \text{ErrorRate})$.

This metric represents the average inference time under the assumption that a second inference is always correct when given an *ErrorRate*. If the error rate is 0%, the *AccurateLatency* is equal to the original latency. Instead, if the error rate is 100%, the *AccurateLatency* is equal to double the original latency, meaning the first inference does not produce any correct results. It shows the optimal average correct inference time. For a system with inference protection, an increase in the *ErrorRate* suggests that some errors have slipped through the system or that there has been an impact on the accuracy rate compared to the original model.

5.3 End-to-end Performance

We first evaluate the overall performance impact of adding SAVE and analyze the time overhead required for model in-

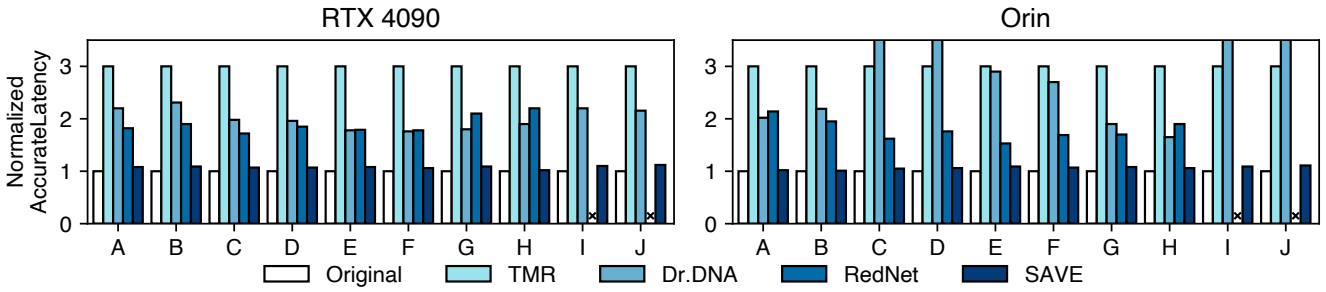

Figure 10: The accurate latency of several models with SAVE. ×: RedNet cannot apply to CogACT and RDT due to the activation function changes. The models used in this evaluation are shown in Table 2.

Table 2: The models used in our evaluation. *: We evaluate the validness of the model output by checking whether the output action is reachable.

	Model	Dataset
A	ViT [23]	ImageNet-1K [21]
B	ViT [23]	AID [93]
C	ResNet-50 [36]	ImageNet-1K [21]
D	ResNet-50 [36]	AID [93]
E	MobileNetV2 [42]	ImageNet-1K [21]
F	MobileNetV2 [42]	AID [93]
G	Decision Transformer [15]	ValidCheck*
H	Decision Transformer-M [15]	ValidCheck*
I	CogACT [55]	ValidCheck*
J	RDT [59]	ValidCheck*

ference. Normalized latency is used to present performance across different models and datasets.

As shown in Figure 10, SAVE introduces minimal overhead compared to the original model execution while maintaining high accuracy. On average, SAVE adds only 8% latency overhead across various models and datasets, which is significantly lower than that of TMR (3×). This low overhead is achieved through our efficient vulnerable bit identification and selective protection strategy. For vision models such as ViT, the overhead is slightly higher (8–10%) due to the increased number of matrix operations requiring protection. Compared to other state-of-the-art methods, SAVE achieves better accuracy. For Decision and Embodied AI models, RedNet's accuracy drops by more than half due to changes in activation functions, leading to substantial performance degradation.

5.4 Accuracy under Bit Flips

We evaluate the fault tolerance capability of SAVE under two bit flip patterns with varying bit flip probabilities. The flip patterns are virtual consecutive address flips and physically contiguous region flips. The first pattern is more likely to occur during memory access, while the second pattern is

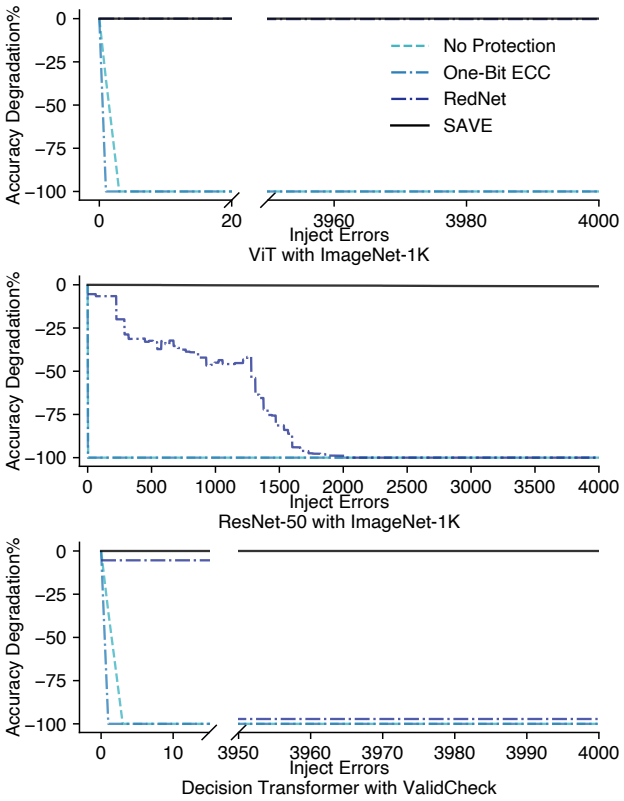

Figure 11: The accuracy degradation under virtual consecutive address flips.

typically caused by physical interference. We test the overall inference accuracy and inference time after attacks with different bit flip probabilities. The accuracy refers to the correctness rate after flipping bits across 100 consecutive inferences at the same position. Additionally, the correctness of Dr.DNA is comparable to SAVE in our tests under the fastest mitigation selecting strategy. We also examine single-bit error correction using ECC, noting that when two-bit errors occur, ECC fails to repair them. This results in program termination or infer-

ence failure. We mark this situation as 0% accuracy. If ECC's correction capability is extended to n-bit errors, the accuracy curve will shift to the right by n bits.

5.4.1 Virtual Consecutive Address Flips

We simulate virtual address consecutive memory flips by randomly modifying the bits on the addresses, and we test the accuracy after attacks involving selecting random flips among all bits. As shown in Figure 11, SAVE maintains high accuracy for up to 4096 consecutive bit flips for both ResNet-50 model and Decision Transformer. In contrast, the original model's accuracy drops significantly to below 5% with just 3 consecutive bit flips. Due to the activation function changes, RedNet's accuracy on Decision Transformer quickly drops below 10% after 32 bit flips, while on ResNet-50 with ImageNet-1K, RedNet's truncation effect causes the accuracy to continuously decline, dropping below 10% after 1600 bit flips. Due to error value detection and repair mechanisms, both Dr.DNA and SAVE maintain zero accuracy degradation. The results demonstrate that SAVE's selective protection strategy effectively preserves model accuracy under bit flip attacks while introducing minimal overhead.

5.4.2 Physically Contiguous Region Flips

When facing the physical interference, the bit flip impact is not continuous in a row but continuous in the physical space. This makes the impact of the model appear to be flipped at intervals. For this, SAVE tests the physical flip pattern given in RedNet with exactly the same proportion and simulation setup.

As shown in Figure 12, The physically contiguous bit flips cause changes in values at multiple-spaced positions, which differs from virtual consecutive address flips, where 32 consecutive bits need to be flipped to affect a single value. The results also show the same trend. RedNet, which employs modified activation functions, experiences significantly faster accuracy degradation under physically contiguous flips compared to virtual consecutive flips, with the model becoming almost completely ineffective after 1500 bit flips. For the Decision Transformer, due to the non-adjacency between flipped bits and spatial bits, errors rapidly propagate throughout the entire model, causing complete model failure with just 6 bit flips. Both Dr.DNA and SAVE maintain accuracy fluctuations within 1% across all models, which can be attributed to normal performance variations.

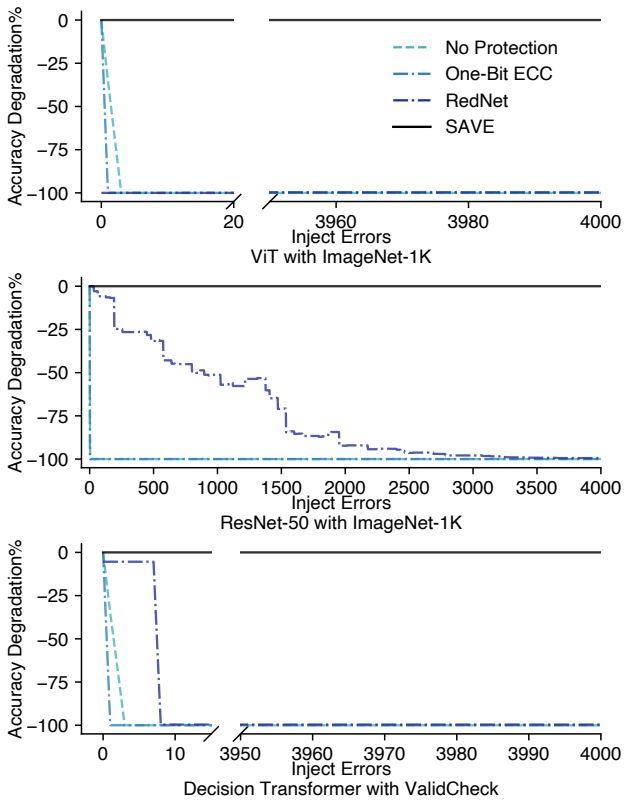

Figure 12: The accuracy degradation under physical contiguous region flips.

5.5 Sensitivity Analysis

5.5.1 Performance of different reliable memory sizes

One important part of SAVE is the size of reliable memory. To evaluate this, we test the performance overhead for different models with various working sets under different sizes of reliable memory. The results are shown in Figure 13. When the working set size is smaller than the reliable memory, reliability is guaranteed with nearly zero overhead, and SAVE shows almost no noticeable overhead. When the working set size exceeds the reliable memory, extra computation is required to ensure reliability in inference. By combining bit properties with ranging properties, the verification cost is reduced by 71%. The reduced calculations come mainly from skipping the validation of robust bits, and using the properties of the range to assess the results.

5.5.2 Performance of different GPUs

Different GPUs produce different performance due to their varying computing capability. We test the performance overhead of SAVE on different GPUs by measuring their overhead on latency. As shown in Figure 14, the additional overhead generated by the model on all platforms is less than 9%. The error rate of the model does not increase during our test.

5.6 Ablation Study

To show the detailed characteristics of each stage in SAVE, we analyze the effect of each stage.

5.6.1 Selection Stage: Analysis Time.

Model analysis in SAVE is a one-time task. Identical models do not require re-analysis. If a model is updated, re-analysis is necessary. A full analysis is required if the model's structure

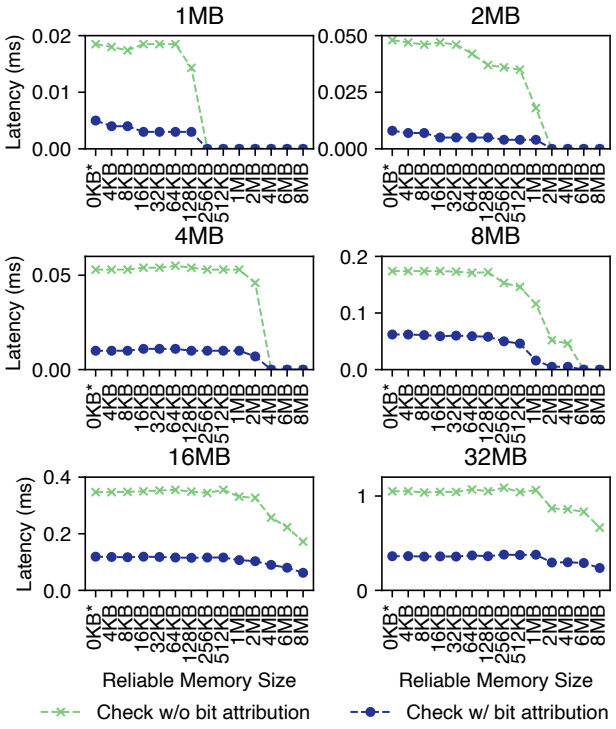

Figure 13: The performance overhead over different size working sets and reliable memory. 0KB means that the reliable memory is not used.

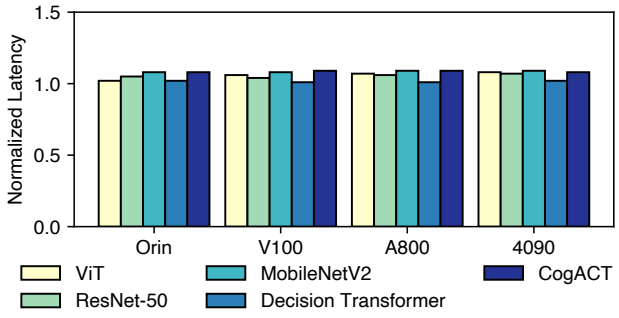

Figure 14: The performance overhead of different GPUs.

changes or all parameters are replaced. If only some parameters change, only the affected parts need analysis. To evaluate this, we test the time required for the same type of model to analyze different data sizes. As shown in Figure 15, the analysis time is under 10 seconds for all models when a full model change occurs. As the size of the modified parameters decreases, the analysis time in SAVE correspondingly decreases.

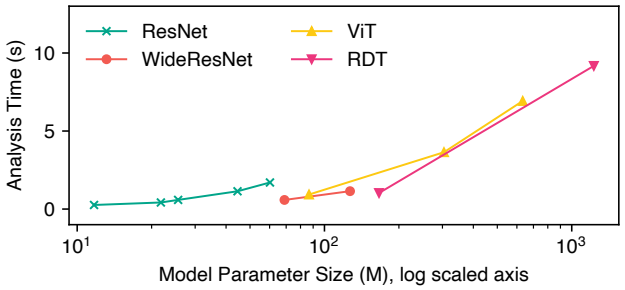

Figure 15: The analysis time of different models.

5.6.2 Selection Stage: Correctness Rate.

The key to the result reliability comes from the selection stage of SAVE. If there are too many false negatives, SAVE will fail to protect the model due to ignoring too many vulnerable bits. If there are too many false positives, SAVE will incur significant extra overhead due to protecting too many robust bits. To show the correctness, we scan all 374,372,224 weight bits in ResNet-18 model with ImageNet-1K dataset and count the number of bits that are correctly identified as robust or non-robust, as shown in Table 3. This robustness property refers to single bit flip effects. Although the proportion of robust bits exceeds 76.5%, they are widely distributed throughout the entire region, which means it is infeasible to drop the 76.5% robust bits.

Table 3: The correctness rate of bit analysis in the selection stage.

	True Robust	False Robust
Predicted Non-Robust	40,866,576 10.9%	47,061,573 12.5%
Predicted Robust	286,444,075 76.5%	0 0.0%

The distribution of different bits is highly related to the operator. For matrix multiplication of ViT, each number has at least one ranging bit, with a total of 90% robust bits. For the normalization operator, each number has at least three vulnerable bits, with a total of only 55% robust bits. We show the bit attribution distribution for some outputs after ResNet's activation function and for ViT's output after normalization, as shown in Figure 16.

5.6.3 Allocation Stage: Memory Movement Size.

SAVE reduces the number of bits to be protected by identifying robust bits in the previous step, thereby reducing the number of times data is transferred using reliable memory and thus reducing memory transfer overhead. We conducted an experiment with the ViT model and showed the amount of reliable memory used under different configurations of SAVE.

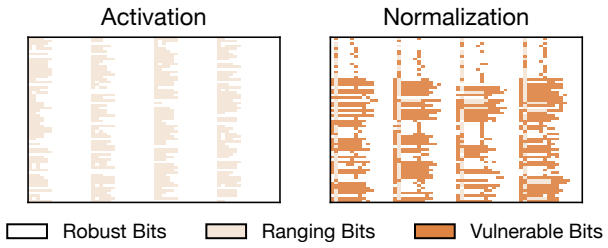

Figure 16: The distribution of different bits.

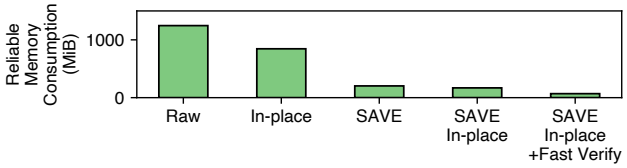

Figure 17: The reliable memory consumption of SAVE.

After completing the selection stage offline, SAVE places only 17% of the original inference memory into reliable memory, significantly reducing the memory footprint, as shown in Figure 17. Moreover, since many values only have the sign bit and the highest bit of the exponent being unreliable, SAVE uses range check to fast verify the correctness, thus replacing reliable memory calculation with judgment. This fast path can further reduce the memory footprint by 95% compared to the model's single inference, as shown in Figure 17.

5.6.4 Verification Stage: Verification Efficiency.

SAVE uses asynchronous verification on the CPU to reduce the overhead of verification. We first test the performance of using the CPU for mixed precision verification, as shown in Figure 18. Through fully utilizing the SIMD and dedicated copy engine on GPU, the matrix multiplication of 1024×1024 only takes 38ms, which is 98.2% less overhead compared to direct CPU floating-point multiplication. We also test the performance of asynchronous verification, as shown in Figure 19. We execute 100 times of verification and calculate the total time to reduce the fluctuation. The results show that the asynchronous verification incurs 0.05% overhead of frontend computation. Compared with synchronous verification, the overhead is reduced by 22%.

Resource Overhead. SAVE uses asynchronous verification, which requires additional CPU resources for verification. We test the CPU overhead of SAVE and found that it incurs 20% additional CPU resource overhead compared to the original model. For the host memory, SAVE only incurs an additional size exactly the same as the model parameter size.

5.6.5 Edit Stage: Recovery Time.

The recovery time is also important after an error occurs. We inject a single bit flip to trigger `NaN` value to test the recovery time of different methods.

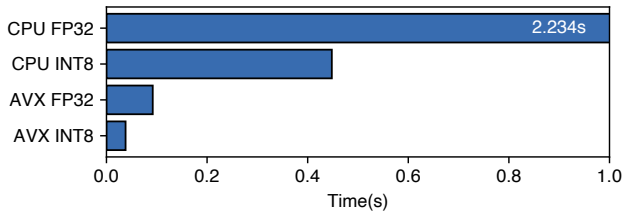

Figure 18: The mixed precision verification performance of SAVE.

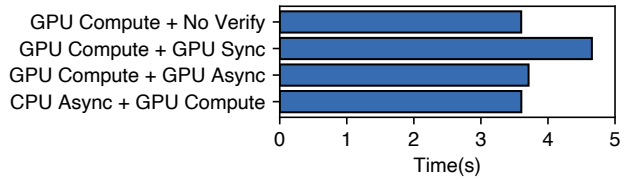

Figure 19: The asynchronous verification performance of SAVE.

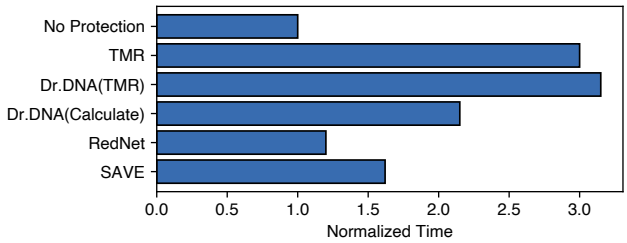

Figure 20: The recovery time of different methods.

As shown in Figure 20, the recovery time of SAVE is higher than that of RedNet since RedNet simply clips out-of-range values, whereas SAVE must synchronize valid values and perform partial recomputation in reliable memory. The major difference in recovery time between SAVE and RedNet is the overhead of recomputation. In the correct method system comparison, the recovery time of SAVE is 24% less than Dr.DNA and 46% less than TMR, which is due to SAVE's reduced computation, only recomputing the range where the error occurs.

5.6.6 Support for lower precision models

When performing inference on the edge, fp16 or even 8-bit integer quantization is often used. SAVE is not bound to the model precision, so it can be directly applied to other precision models. In other precision models, the total number of robust bits will decrease due to the reduction in the model's overall bit length, leading to increased overhead. To show the performance of SAVE in lower precision models, we test the ViT model with ImageNet-1K dataset. Since we cannot

remove the quantization effects on the accuracy and neither Dr.DNA nor RedNet can be applied to lower precision models, we only show the latency of SAVE. As shown in Figure 21, SAVE achieves 10% to 15% overhead compared to the original model.

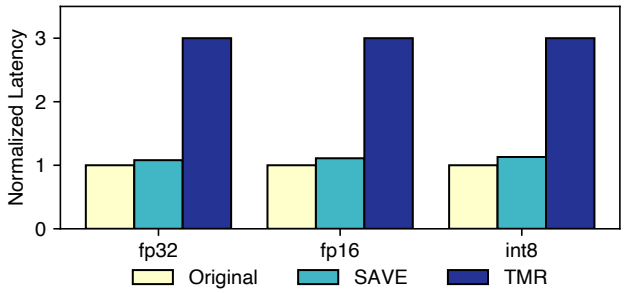

Figure 21: The performance of SAVE in lower precision models.

6 Discussion

We are currently focusing on small-scale edge models because they are more safety-critical in scenarios like decision-making on self-driving vehicles, drones, industrial robotic arms, or satellites. In contrast, large language models supporting chat systems or multi-modal generation systems may tolerate occasional inference errors, as users can easily detect irrelevant responses or generated images with minor imperfections (which may not even affect user experience). The design of SAVE is flexible across different models and can withstand multiple bit flips as long as the changes of these bits are smaller than the model's allowed perturbation. While SAVE could potentially be applied to large language models, additional work would be needed, such as protecting KV Cache, which we leave as future work.

SAVE relies on a portion of reliable memory to enhance model inference reliability, which can be much smaller than the average memory usage during model inference. We believe this research has important implications for hardware-software co-design supporting reliable model inference in space and other extreme environments. To our knowledge, there are currently no GPU computing cards that can fully resist cosmic radiation. Our design demonstrates that through the combination of hardware-implemented small reliable memory and software-implemented fault tolerance, we can effectively improve inference reliability against bit flips.

7 Related Work

Hardware based protection. Various hardware mechanisms have been proposed to mitigate bit flip attacks efficiently. Some work [49, 70, 78, 81, 95] increase DRAM refresh rate or limit row access times within one refresh interval to protect potential victim rows. ZebRAM [50], GuardION [85] and CATT [11] protect sensitive data from vulnerable rows. DEACT [31] prevents vulnerable rows from being accessed further. Some work [77, 91, 92, 100] leverage in-DRAM swapping to shuffle the DRAM rows. AEP [98] uses masks on hardware to protect the model. DNN-Defender [99] use gradients to detect critical bit and swap the rows in DRAM. HARDeNN [48] adds three-module redundancy for weights and activation layers. Compared to SAVE, these work requires complex hardware implementation, focusing on bit flips by RowHammer attack. They support for specific-structured models. SAVE provides a general solution to all models without hardware or model modification. Hardware-based ECC also serves as a hardware bit flip mitigation method. RowHammer [22, 49] states ECC is useful to defend RowHammer attack despite of the expensive cost. However, some work [14, 18] show that carefully-designed ECC-aware RowHammer could bypass these ECC mechanisms and the ECC can only correct one bit and detect two bits typically [66] and GPUs [65]. SAVE can tolerant multiple bit flips.

Software based protection. Some software-implemented solutions have been proposed to reduce the impact of bit flips on the entire model. Software Error Resilience [45] use TMR for protecting silent data corruption. TBD [40] proposes quantization to restrict the bound of DNN parameters. Parameter binarization [37, 76] construct binarized DNN to flatten the bit flip's impact to parameter's neighbors. Some work [17, 56, 62, 94] enhance the ability of models to resist adversarial attacks. Some work [7, 28, 41, 58, 88] use different encoding schemes to protect the model parameters. Modelshield [33], Hashtag [47] and RADAR [53] introduce hashing-based methods to generate weights group signature and make verification for parameter. RedNet [89] gives the first systematic study of bit flips in DNNs in space and proposes a software-based solution to mitigate bit flips in DNNs. Compared to these work, SAVE keeps the model accuracy and ensures the inference latency by introducing fast verification.

8 Conclusion

SAVE provides a software-based inference fault tolerance solution, which preserves model structure to provide the largest compatibility with existing models. It uses GPU memory management and lightweight runtime verification to mitigate bit flips with acceptable overhead. The results show that SAVE incurs less than 9% performance overhead for end-to-end latency in model inference while maintaining accuracy.

Appendix

A Artifact Appendix

This artifact provides the source code of SAVE, a detailed readme, and scripts to reproduce the main experimental results of the USENIX ATC 2025 paper—"SAVE: Software-Implemented Fault Tolerance for Model Inference against GPU Memory Bit Flips" by Wenxin Zheng, Bin Xu, Jinyu Gu, Haibo Chen. SAVE is a software-based solution that enhances the reliability of GPU-based model inference. We provide instructions to build the software package and run experiments. Our artifact obtained the "Artifacts Available", "Artifacts Functional" and "Results Reproduced" badges from the Artifact Evaluation process of USENIX ATC 2025.

Artifact repository. All project source code, along with comprehensive instructions for building and running the main experiments on SAVE, is available in the following git repository: https://github.com/peterzheng98/gpu-memory.

```

Identifying and Analyzing Pitfalls in GNN Systems

Yidong Gong, Arnab Kanti Tarafder, Saima Afrin, and Pradeep Kumar

William & Mary

Abstract

Papers on recent graph neural network (GNN) systems have established a clear trend of not showing training accuracy results, and directly or indirectly relying on smaller datasets for evaluations majorly. Our in-depth analysis shows that the omission of accuracy results leads to a chain of pitfalls in the system design, implementation, framework integration, and evaluation process, questioning the practicality of many of the proposed system optimizations, and affecting conclusions, lessons learned. We analyze many GNN systems and show the fundamental impact of these pitfalls. We further develop hypotheses, recommendations, and evaluation methodologies, and provide future directions. Finally, a new prototype, GRAPHPY, is developed to show the quantitative impact of the pitfall and establish baseline memory consumption and runtime information for GNN training. GRAPHPY also establishes a new line of optimizations rooted in solving the system-design pitfalls efficiently and practically that can be productively integrated into prior works.

1 Introduction

In today's data-driven applications, deep learning (DL) has gained prominence. Within this ecosystem, many real-world data can be stored as *sparse matrices* or *graphs*. To this end, graph neural network (GNN) models, e.g., GCN [33], GAT [49], GIN [58], GraphSage [20], and others [5, 67] are playing an increasingly important role. System optimizations play a critical role in improving the run-time, which has become exceedingly time-consuming even when using powerful accelerators, such as GPUs. There are several *semantic-preserving* GNN systems, which keep the same underlying GNN model, have proposed numerous system-level optimizations. These works can achieve up to a 15× speedup in training runtime on a single GPU [9, 14, 16, 26, 27, 44, 54, 56, 57, 64, 66].

In this work, we analyze such system-level optimizations from the prospect of the two most important aspects of GNN system design, implementation, and evaluation as listed next.

1) Unique need for GNN computation. *Forward computation* calls *kernels* (operations) from input layer to output layer, deriving prediction values. They are compared with ground truths to derive the loss. *Backward computation* uses the loss and invokes kernels from the output layer to the input layer to compute gradients and update model parameters. It accesses *state-tensors*, which hold results that are produced in forward computation (maybe *sparse*) and may require a *transpose* (Fig. 1a). Forward and backward computations have many design trade-offs (studied in this paper) that require careful navigation in system building, optimization, and evaluation.

2) Role of framework. The framework helps invoke and manage the forward and backward computation through *computation graph* that helps in invoking the right computation operation (kernel), and manages the memory. Hence, the framework code represents the overhead, while the kernel represents the actual usage of the computation device, e.g., GPU. So, a custom GNN system is likely to have a different overhead apart from different kernel performance.

We argue that the above aspects have not been understood well, leading to many *system design, implementation, and evaluation pitfalls* (Fig. 2). This paper, identifies these pitfalls, still unknown to the community, when building a GNN system in which individual kernel-level optimizations and the framework both play significant roles. The in-depth systematic analysis is backed by re-interpreting existing evaluation results, performing new experiments using additional methodologies, code-study, and a comprehensive prevalence study.

To this end, we make three main contributions:

a) Introducing Pitfalls. Majority of single-GPU GNN systems have established a clear trend of *not measuring training accuracy* [14, 24, 26, 27, 29, 32, 35, 52, 54, 56, 57, 60, 64–66], while a few [14, 27] do not even implement backward computation. Our measurements show *abnormal accuracy* in many GNN systems published in the top-tier systems conferences. Our investigation confirms *system design pitfalls* and numerous *significant implementation issues* in those systems.

Further, our *novel analysis on framework-runtime overhead* reveals that training speedup on smaller datasets is primarily due to low framework overhead and not by individual kernel and system optimizations (claimed). Unfortunately, many prior works concluded better training time largely or exclusively using smaller datasets as they report frequent out-of-memory (OOM) in popular baselines of PyTorch-Geometric [12] (PyG) and DGL [53] during peer comparison. Moreover, mini-batching and sampling-based GNNs [20] always produce smaller graphs for training.

Lastly, *memory consumption measurement by our methodology* shows that DGL, an almost universally and many times the only used baseline, suffers from *framework-memory overhead* pitfall. Its internal memory management leads to around

13 GB of additional GPU memory usage in a well-known open-source dataset, which is majorly responsible for its huge memory consumption and OOM. This has allowed memory-saving works to report highly inflated memory saving by using DGL as the only baseline; we question their analysis of the baseline and reported gain in memory saving.

We note that these pitfalls are not measurement oversight or software bugs as they create serious flaws in requirement understanding, system design, implementation, and evaluation, solving which reinforces the need to correctness tests alongside performance results, and for detailed analysis across the stack to identify changes in resources use in the evaluation process and critical system design thinking.

b) Impact Analysis and Hypothesis. We aim to increase awareness of the existence of these flaws by answering: *why* do such pitfalls occur despite the best intentions of the researchers and community (*Hypothesis*); and *what* are the major implications of these pitfalls in current GNN systems (*Impact*). They are important as these pitfalls have led to a compromised system design and implementation, misunderstanding of design trade-offs, inflated performance gain, and affecting other aspects of GNN workflow: wrong conclusions, improper lessons learned, and hindering the adoption of these research advances. Such pitfalls also *stifle innovations* as a correct system is unlikely to outperform such works.

c) Recommendation, Future Direction, and a Reference System. We address *how* to ensure future works do not suffer from similar pitfalls (*Recommendation*) and outline directions to further tackle these issues, specifically framework overhead establishes a new area of research and draws an analogy to Operating Systems research for future direction.

To help make these recommendations concrete, we introduce GRAPHPY, a prototype GNN system that: a) quantitatively shows the impact of these pitfalls, demonstrating the significance of identifying these issues and highlighting the extent of overstated results they cause; b) establishes baseline memory consumption and runtime to advance future research by protecting them from inflated gains; c) offers *practical* design choices to address a few pitfalls, which can be productively integrated into prior works.

The proposed system designs enable *data-locality* along with correct *exploitation of dataset symmetry* that can be used by almost all GNN systems, thereby GRAPHPY opens a new territory of system optimizations rooted in solving system design pitfalls. This simple design establishes many components of GRAPHPY as the state-of-the-art design.

Evaluations are done throughout the paper to show that pitfalls exist. They show that pitfalls in these systems lead to not fully representative performance results, and many are even slower than the same baseline on mid-size datasets (§7). GRAPHPY reduces memory consumption on average by 6.92×, 3.4×, and 1.96× and achieves on average 1.69×, 1.22×, 2.20× training runtime speedup, respectively, for GCN, GIN, and GAT-1 models over DGL. Further, GRAPHPY can train GCN on a billion-edge graph on a GPU due to its memory-efficient design and removal of framework-memory pitfall, while DGL cannot train even a 500 million-edge graph, highlighting inefficiencies in existing baselines.

Using GRAPHPY as a baseline against a recent work of dgNN [66], a kernel-fusion based system, shows that the latter is slower by 1.48× on training time while providing only 6.4% average memory saving for GAT. This brings critical discussion on trade-offs in kernel-fusion, so far not known to the community.

The remainder of the paper is organized as follows. §2 presents the prevalence analysis and scope, while §3 provides background and an overview. §4 and §5 discuss two categories of pitfalls, §6 outlines future directions and introduces our proposed prototype, GRAPHPY, while evaluations are done in §7. §8 reviews related works on similar papers that present pitfalls in other domains, and we finally conclude in §9.

2 Prevalence Analysis and Scope

The paper focuses on *single-GPU GNN systems* by analyzing over 20 systems [4, 9, 12, 14, 25–27, 29, 32, 35, 47, 50, 53, 54, 56, 57, 59, 60, 64, 66] in depth in the last 5 years. Most of these are GNN training systems and were published in top systems conferences, such as OSDI, ASPLOS, ATC, MLSys, EuroSys, SC, IPDPS, HPDC, PPoPP, etc., to avoid being termed as cherry-picking. We note the following important points:

- The paper is not related to reproduction issues. *We indeed can successfully reproduce similar results using their artifact description and evaluation (AE) documents. We sincerely appreciate the authors' efforts in providing such comprehensive documentation and their help through emails; it would have been impossible to build this work without them.*
- The paper is based on our interpretation of published results, which we reproduced, and additional evaluations that we performed on accuracy, framework overhead, and kernel run-time through newer methods. We confirm the observations through a code study. It may be possible that our extensive search may have missed a paper which do not suffer from pitfalls. However, that does not solve the case that the studied pitfalls are prevalent. It is essential to note that not all GNN papers succumb to every pitfall, and the paper does not seek to cast blame on all techniques proposed by prior works.
- We have discussed with the authors of GNN systems having pitfalls over email/teleconference/face-to-face to avoid misunderstandings or potential conflicts regarding the paper. Overall, we received positive and encouraging feedback. Supplementary material (appendix) shows code analysis and discussion, while we open-sourced GRAPHPY and other artifacts for healthy discussions[1].
- Single-GPU systems are *foundational* because their performance and memory consumption form the basis for

[1] https://github.com/the-data-lab would contain the open-source material

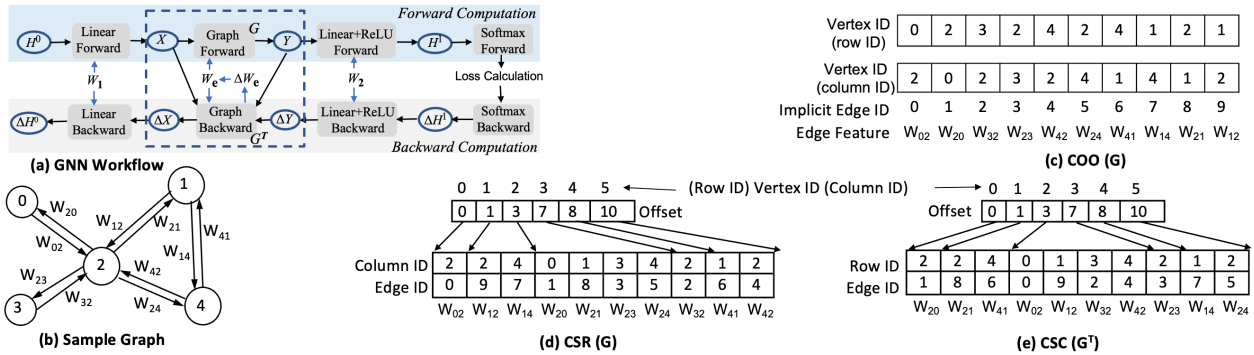

Fig. 1: (a) A GNN layer: X, Y, and W_e (edge-level tensor, e.g., attention score in GAT) are *state tensors*, which are generated in the forward pass and then retained for use in backward computation. G is a sparse matrix, and G^T its transpose. (b) Sample graph/sparse matrix (c, d, and e) CSR, CSC, and COO formats along with edge ID indirection used in DGL where consecutive edge ID is used in COO, so CSR and CSC store explicit edge ID arrays (discussed in §5.2).

other settings. Additionally, with the increase in memory size in modern GPUs and the advent of numerous memory-saving techniques, such as lower precision and quantization [8, 19, 23, 28], gradient check-pointing and/or re-computation [66], kernel fusion [57, 66], better mini-batching plus sampling [50] have allowed a GPU to train larger datasets. Hence, our analysis and corresponding evaluation methodologies emphasize single-GPU systems to establish the right foundation and methods first. We then briefly extend one pitfall of framework runtime overhead to multi-GPU systems [6, 7, 15, 30, 40, 46, 48, 52, 52, 55, 61, 62, 68, 69].

3 Background and Overview

Storage Formats. In a graph G = (V, E), V and E refer to the vertex/row set and the edges/non-zero elements (NZE), respectively. We continue to use both the graph and sparse linear algebra terminologies. Specifically, features and computation are referred to as vertex-level and edge-level, while rows, columns, and non-zero elements refer to datasets. Fig. 1 shows a sample graph and its storage formats.

The *coordinate list (COO) format* stores two arrays of rows and columns where a row and column pair indicates one NZE (or edge) of the graph. Kindly note its implicit edge ID array in the figure, which shows the format is not sorted by row ID. DGL uses COO in this way. The *compressed sparse row* (CSR) format stores NZE in a row sequentially and uses the offset array to point to the start of the row. For a directed graph, its transpose is also stored, called *compressed sparse column* (CSC) format, which stores the columns consecutively. The *degree* of a row is the row length. The CSR and CSC formats also show edge ID arrays that DGL introduces due to its specific COO format layout, and are discussed later.

3.1 Taxonomy on GNN Kernels and Models

Sparse Kernels: The sparse kernels used in GNN models can be broadly classified into two types [53]: **SpMM** (sparse matrix dense matrix multiplication) and **SDDMM** (sampled dense dense matrix multiplication) and their variants.

We first focus on two SpMM ($Y \leftarrow AX$) variants, namely, weighted (**SpMMve**) and unweighted (**SpMMv**) versions. In the former, edges contain a weight requiring an *edge-level tensor* (W_e) of size $|E|$, which can only be interpreted using the graph topology. The unweighted version assumes 1.0 as edge weight, so storing W_e is unnecessary. Kindly note that X and Y are *vertex-level tensors* as their size is $|V| \times |F|$, where $|F|$ is feature-length of each vertex.

Backward Computation and Transpose of Sparse Matrix. For SpMMve ($Y \leftarrow AX$), its backward computation needs to include both *transposed SpMMve* ($\delta X \leftarrow A^T \delta Y$) and SDDMM ($\delta W_e \leftarrow A \odot (X^T \triangle Y)$), where δ represents gradients of the tensors. We denote transposed SpMMve as $SpMMve^T$. The sparse matrix (A) itself can be viewed as two parts: the static part(the graph topology) and the dynamic part(the edge-level state tensor W_e). More details are in §4.1.2.

SDDMM kernel ($\delta W_e \leftarrow A \odot (X^T \triangle Y)$) generates an edge-level tensor (δW_e) from two vertex-level tensors read using graph topology to perform dot product and their reduction.

The *degree-norm* is a graph-based normalization kernel that divides vertex-level tensors by the corresponding vertex degrees to stabilize GNN training and mitigate the influence of high-degree nodes. GNN systems usually implement degree-norm along with SpMM and SDDMM.

Two Classes of GNN Models: In this work, we broadly divide the GNN models into two classes for their in-depth analysis.

- **Class A (Attention-Based GNNs): Vertex-Level + Edge-Level Tensors.** Example models include GAT and GaAN [49, 67], etc., that learn edge-level attention scores. The attention score represents the importance of neighboring nodes during training. The edge-level tensors encode trainable attention scores derived from graph vertices using trainable parameters. As a result, this class employs SpMM (weighted) and SDDMM kernels, involving both vertex-level and edge-level tensors, making the computation more complex.
- **Class B (Non-Attention-Based GNNs): Vertex-Level Tensors Only.** This GNN class does not employ dynamic

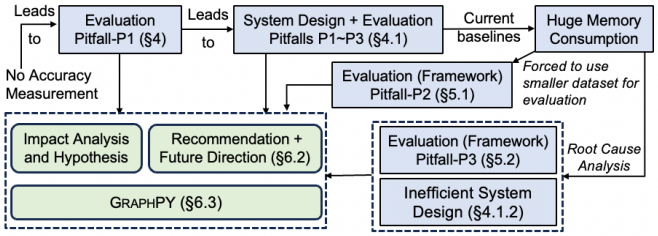

Fig. 2: The complex relationship between pitfalls and our recommendation. GRAPHPY prototype helps quantify the impact of the pitfalls while providing some practical and deployable solutions to a few pitfalls.

attention scores. Notable examples include GCN [33] and GIN [58]. These models use unweighted SpMM, relying solely on vertex-level tensors since no attention mechanism is involved. Hence, it does not employ SDDMM kernels. Further, it usually deploys degree-norm kernels. Thus, this GNN class significantly differs from class A GNNs.

3.2 Overview of Pitfalls

This paper unveils many GNN system related pitfalls. Fig. 2 shows a high-level overview of various pitfalls and their relations. It categorizes them into two main evaluation-related types, which leads to many system design and framework-level pitfalls. A brief overview is discussed next.

Accuracy Related Evaluation Pitfalls (EVAL-P1, §4). This category of pitfalls is due to not reporting the achieved training accuracy by prior works on the semantic preserved models. Our evaluations show abnormal accuracy. Prevalence studies and detailed code analyses unearth several underlying system design (SYS-*) pitfalls (§4.1.1, §4.1.2, §4.1.3, §4.1.4) that directly cause or exacerbate these evaluation inaccuracies, but end up providing runtime speedup.

Framework Related Evaluation Pitfalls (EVAL-P2 and EVAL-P3, §5). The framework refers to the *Python and C++ integration code that integrates individual computational kernels (written in CUDA) to deep learning platforms* such as PyTorch, TensorFlow, etc., where the latter manages the computation graph and memory.

When training runtime is evaluated using small datasets, the measured time primarily reflects framework-runtime overhead rather than actual time spent on the GPU. We show that different systems differ in framework overhead, while the usage of smaller datasets for evaluation is universal, such as in sampling-based GNNs that produce a smaller sampled graph to train the model on a GPU. We further observe excessive memory consumption by framework integration-related inefficiencies in DGL [53], a popular GNN baseline, which remain unknown to the community. This has caused inflated results on memory-saving techniques and often forces runtime evaluations to be conducted on small-sized datasets due to frequent out-of-memory (OOM) errors on mid-sized datasets.

After identifying these pitfalls, we present recommendations and future directions (§6.2), and propose a baseline system, called GRAPHPY (§6.3), that helps in quantitatively demonstrating the impact of these pitfalls (§7) and outlines design solutions that can be integrated in prior pitfall infested systems to overcome a few pitfalls.

4 EVAL-P1: Lack of Accuracy Measurement

Introduction and Prevalence Study. Several GNN systems have established a clear trend to not report training accuracy in their papers. [14, 24, 26, 27, 29, 32, 35, 51, 52, 54, 56, 57, 60, 64–66] Fig. 3 shows that many papers with which we experimented exhibit abnormal accuracy. DGL accuracy is for reference. All experiments are run on an Nvidia A100 GPU. Datasets and other details are presented in §7.

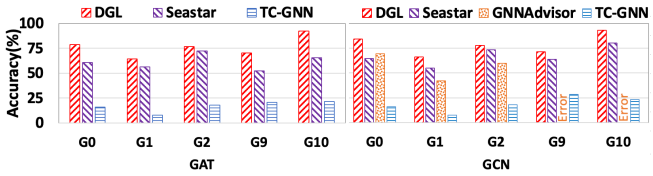

Fig. 3: Accuracy comparison: TC-GNN does not provide GAT, hence AGNN is substituted here as both are attention-based (Class A GNN). We also discuss other works in the text. DGL is for reference.

Class A GNN. Seastar [57] has 4.5% – 26.9% accuracy drop, while TC-GNN [56] has very low accuracy on all datasets for GAT. FuseGNN [9] GAT shows NaN during training on Reddit and could achieve only 58% accuracy, way below DGL's 92.4%. Huang et al. [27], and TLPGNN [14] are not measured as they do not implement backward computation. GNNAdvisor has not implemented GAT.

Class B GNN. GCN training accuracy in TC-GNN is abnormally low. Seastar accuracy drops by 4.5% - 19.8%. GNNAdvisor [54] drops by 14.8% – 24%. Also, GNNAdvisor throws a memory corruption error for Reddit and OGBN-products, which is also reported by others [14]. Huang et al and TLPGNN do not have backward computation implemented. Ge-SpMM [26], which does not report accuracy, could not be run due to major code reorganization in DGL to which it was integrated. Featgraph [25], which is integrated into DGL, we could not install it correctly despite help from its authors and trying several GitHub branches though it did report accuracy on Reddit. Except for DGL, only PyG and FuseGNN have normal accuracy on GCN.

Fundamental Problem or Evaluation Oversight? Significant accuracy drop is not an evaluation oversight, as these systems usually aim for the *semantic-preserving model*, the same model as the baseline (DGL in this case), with changes being tailored for their system optimizations. §4.1 analyzes these systems to show that the lack of accuracy evaluation has allowed many fundamental issues in design, implementation, and analysis to persist.

4.1 Misunderstood Backward Computation

Our analysis for drop in accuracy is attributed to *insufficient inclusion both of the backward computation and of its impact on the opportunities to optimize the forward pass.* Indeed, backward computations are complex as they often enforce the saving of state tensors during forward computation, introduce transpose requirements, and can be computed in an order determined by the computation order in forward computation. Thus one can find runtime performance-enhancing bugs in their wrongly designed system. We also note that correct baselines deploy inefficient designs despite the availability of efficient choices. The next few sub-sections present these system design and implementation pitfalls.

4.1.1 SYS-P1: Omitted State Tensor

Definition and Example. Many forward-computation-focused optimizations fuse kernels to optimize the performance of their forward computation, while neglecting state tensor requirements because the backward computation is not implemented. The backward computation of any operator needs to access the *state-tensor*– the input and/or output tensors of the corresponding forward operator. The requirement to materialize state tensors is not limited to sparse operations; other commonly used operations, e.g., ReLU, Dropout, etc., also require storing state tensors. Such tensors must be *saved during forward computation* for use during backward computation, or recomputed during the backward computation.

Huang et al. [27] and TLPGNN [14] prototyped one giant fused forward kernel that fused many sparse kernels along with other operations, such as ReLU, etc. TLPGNN omits the materialization of the attention scores in GAT, which are edge-level state tensors. Similarly, both skip materializing state tensors for ReLU, which are essential for correct gradient computation during backpropagation. It is important to emphasize that both works aim to optimize GNN training, not inference, and therefore are not evaluated in the context of inference performance.

Fundamental Issues. The performance gain claimed by aggressively fusing operations in a forward-only computation does not hold if one attempts to fix this pitfall by properly materializing or recomputing the state tensors. Doing so introduces additional steps that lead to performance degradation, invalidating the originally reported speedups. For example, *recomputation* of state-tensors [66] itself requires saving some other tensors as state-tensors during forward computation, which is used during backward computation to recompute the actual state-tensor(s). This saving and re-computation procedure leads to additional slowdown, meaning that the claimed speedup is not practical, even if the fused kernel optimizations are technically sound.

4.1.2 SYS-P2: Regarding Sparse Matrix Transpose

Definition and Examples. Backward SpMM computation ($\delta X \leftarrow A^T \delta Y$) requires the transpose of A. The sparse matrix (A) itself can be viewed as two parts: the static part (the graph topology) and the dynamic part (the trainable and generated edge-level state-tensor W_e). Though one can pre-process the graph to keep the transpose of the topology, the *generated* W_e requires a transpose at run-time. W_e is never symmetric, even if the sparse matrix (graph topology) is symmetric, due to the GNN model design. This sub-section discusses the absence and efficiency of transpose in prior works, as cuSPARSE already provides a high-performing native $SpMM^T$.

• *SYS-P2-1: No Transpose.* Many works [14, 27] don't implement backward computation by ignoring this problem, TC-GNN [56] substitutes forward SpMM in place of backward SpMM for its attention-based GNN. Kindly note that the popular GNN benchmarking datasets are square sparse matrices, so not performing a transpose doesn't lead to a dimension mismatch, hence it cannot be caught during compilation/runtime unless accuracy is measured. Thus, they also gain non-practical performance.

• *SYS-P2-2: Omitting comparison with a Key Baseline of cuSPARSE $SpMM^T$.* Many systems developed additional mechanisms for transpose even when relying on cuSPARSE. However, they completely ignore the fact that cuSPARSE natively offers $SpMM^T$ without performing the explicit transpose of A. Our measurements (Fig. 10) show that SpMM^T by cuSPARSE is still the fastest. Thus, this pitfall allowed many sub-optimal system designs to dominate the GNN solutions. Even worse, as we explain next, such additional mechanisms introduce additional memory consumption. We first analyze DGL for its memory-intensive SpMM^T approach, followed by alternate mechanisms. This also serves as an understudy for our reference system (§6.3).

DGL. To support SpMM^T, DGL relies on *edge ID abstraction* in graph storage. Each edge in the DGL graph is assigned a unique numerical identifier in the range of $[0, |E|)$. Its allocation is determined by its COO format (used for SDDMM implementation): the offset of each edge in COO is its implicit edge ID (see Fig. 1c). However, the order of edges in DGL's COO (i.e., storage layout) is determined by the dataset file or parsing module which is often performed by the user (external factor), and hence its COO is neither stored in CSR-style (rows are laid out consecutively) nor in CSC-style (columns are laid out consecutively). In such cases, both CSR and CSC contain an explicit array of edge IDs (Fig. 1(d) and 1(e)).

DGL introduces eShuffle, an internal GPU kernel, that rearranges the input edge-level tensors using the edge ID array of CSR and CSC to generate a new edge-level tensor for SpMMve and SpMMve^T respectively so that DGL can use the same SpMM API of cuSPARSE after eShuffle. The eShuffle kernel slows down performance by 64% of cuSPARSE SpMM on Reddit (§7) on both forward and backward, hence it is very costly. So any system integrated into DGL suffers from similar issues, but an independently developed system can get additional performance benefits if it does not perform transpose, while forward-focused systems automatically gain 64% speedup without any optimization.

Memory consumption in DGL for storage formats is $2|V|+6|E|$ due to CSR ($|V|+|E|+|E|$), CSC ($|V|+|E|+|E|$), and COO ($|2E|$) irrespective of GNN models. Due to eShuffle, DGL also consumes an additional $|E|$ memory.

PyG and MariusGNN. PyG implements SpMM and SpMM^T by materializing dot products of size $|E| \times |F|$ using GPU global memory before performing reduction in its original design of using the COO format. Hence, PyG exhibits OOM more frequently, as it cannot run on an A100 GPU with 40GB of memory, and this issue has been reported by prior works [9, 27]. However, cuSPARSE does offer an efficient SpMM and $SpMM^T$ on COO, which is not used. Lately, PyG uses CSR without materializing dot products on GCN, however, GAT (which uses SpMMve/SpMMve^T) still materializes them. MariusGNN uses a PyG-like solution using CSR format, i.e., it materializes the dot products in GPU global memory. This mechanism is slower than native cuSPARSE APIs (§7.1).

Other Mechanisms. Seastar and FeatGraph also rely on edge ID indirection for GAT in both the forward and backward computations. FuseGNN relies on *cusparseCsr2cscEx2*() API (which transposes the topology and edge-level tensor) plus their custom forward SpMM to implement SpMM^T. The cusparseCsr2cscEx2() API is slower by 130% of cuSPARSE SpMM on Reddit, thus, this mechanism is even more costly.

Fundamental Issues? Dropping the transpose requirement (A^T) in SpMM^T provides GNN systems with unfair performance gain; while introducing an inefficient solution by ignoring the key baseline of cuSPARSE leads to no progress to the state-of-the-art in basic kernel design of $SpMM^T$ (§7.1). Both of these issues are fundamental from a research perspective.

4.1.3 SYS-P3:Incorrect Order of Backward Operations

A few works that attempt kernel fusion in the forward computation do not order their backward operation correctly, which leads to better performance at the expense of wrong training.

Definition and Example. The backward operations, as the name suggests, invoke the kernels in the reverse order to the forward operations. For example, if operator A is called first followed by operator B, then the backward computation first needs to call the backward of operator B followed by the backward of operator A. However when the operators A and B are fused in forward, their backward requires a different custom fused kernel to take care of the ordering.

For example, GNNAdvisor [54] fuses the SpMM and degree-norm operators during the forward. However, its backward computation did not reverse the order. For Seastar [57] in GCN, the accuracy drop is similar to GNNAdvisor. This is because Seastar relies on a lambda function specification for fused forward SpMM and degree-norm in the forward() API of the GCN layer to generate CUDA code. The generated code always calls degree-norm after SpMM. We suspect that code-generation logic may not be intelligent enough to generate correct backward fusion.

Fundamental Issues? An independent *degree-norm* fetches the degree of every *row*, thus occurring $|V|$ data load. It can easily be fused with forward SpMM, as degree-norm usually happens on the output tensor of SpMM. However, during backward, it should be called on the input tensor of the SpMM. Hence, a correct fusion during backward computation needs to fetch the degree of column ID of every NZE, thereby performing $|E|$ data load fetch. Hence, a wrongly fused kernel gains performance due to less data load and computation.

4.1.4 SYS-Others: Additional Pitfalls

The following additional errors have been observed in GCN: no model bias parameter in GNNAdvisor, Huang, et al [27], and TLPGNN in their GCN; and absence of bias and *degree-norm* array in TC-GNN in its GCN. In DGL, the bias parameter is enabled by default, while performing degree-norm operation. In GAT, no dropout layer is there in the fused GAT model of Seastar, TLPGNN, and Huang et al., introducing which requires complex changes to their backend due to the fusion. Huang et al use the same allocated memory to keep the attention score for every model layer without recomputation. TC-GNN does not implement SpMM and SDDMM kernels with odd dimensions of feature-length needed in the last layer of GCN and AGNN models, yet its training script calls these kernels with those feature lengths. These errors indicate design and evaluation issues.

4.2 Discussion and Hypothesis

The accuracy evaluation is effort-intensive exercise due to various compilation, installation, and usage issues that are common with academic prototypes. Additional supporting software has since changed substantially, like deprecated APIs. Many systems rely on generated features and labels, while each system has its own way of loading the dataset, which takes time to understand and modify to read from the labeled dataset. Hence we limited accuracy evaluation to top-tier conferences only. Further, our goal is to be fully sure when we report abnormal accuracy. It is possible that other systems that did not show accuracy may be correct, but will not solve the pitfall as future works may continue to make erroneous decisions if accuracy is not measured.

Hypothesis: Automatic Backward Computation. We hypothesize that the complex differences between forward and backward computations in the DL frameworks' abstraction could be a reason: the model and layer definitions only explain the forward computation, while the backward code is invoked automatically for each forward operation and remains hidden from the usual code walk-through, but depends on the output of the forward pass. Hence, without correctness evaluation, it is hard to get the implementation right. Such pitfalls are independent of hardware settings, though we only analyzed the code of single-GPU GNN systems.

5 Framework Overhead + Evaluation Pitfalls

Introduction and Prevalence Study. Many prior works showed *frequent OOM on popular baselines* (DGL and PyG) thereby almost all single-GPU GNN training systems [4,9,14,24,26,32,47,47,53,54,56,57,59,63,64,66] have exclusively or majorly relied on *smaller datasets to conclude better training runtime*. E.g., GNNAdvisor, Ge-SpMM, TC-GNN, and others [4, 24] relied *exclusively* on smaller datasets for training runtime comparison. FuseGNN [9], dgNN [66], and Seastar used only one mid-size dataset(Reddit), while the remainder are smaller datasets. However, many have shown OOM on this mid-size dataset for some DGL models.

Though *sampling-based* GNN [29,31,36,37,43,50,62–64] evaluates large datasets, it should be noted that they sample only a *batch* of vertices of the dataset in each iteration to generate a smaller graph to run training/inference. Hence, *the resultant sampled graph is small on which training is run*.

Fundamental Problem or Evaluation Oversight? As discussed earlier (§3.2), framework implies Python and C++ code to glue the individual kernel to PyTorch (or TensorFlow, etc.) that runs CPU in a GPU-based system. We show (§5.1) that training runtime on smaller graphs is dominated by the framework runtime overhead in GPU-based systems. So, the training speedup in such cases is due to the lower framework overhead (unknowingly) instead of better kernel runtime (claimed). This invalidates the analysis done by prior system evaluations on this metric. Further, the framework design has become a major reason for OOM in DGL (§5.2), introducing framework memory overhead which is very large compared to memory consumption due to inefficient GNN design(§4.1.2). As DGL has been a universal baseline, it has affected almost every GNN system evaluation because prior works reported highly inflated memory saving, frequent OOM in DGL, and better training runtime on smaller datasets.

This section analyzes the role of the framework– the runtime and memory overhead– to show that we have not fully understood the fundamental role of the framework in GNN system building. To illustrate these facts, the next few subsections run new evaluations using a novel methodology and analyze the source of different frameworks in DGL versus other systems. We use an Nvidia A100 GPU. Datasets and other details are the same as in §7.

5.1 EVAL-P2: Framework Runtime Overhead

We define the *training time* as the total wall-clock time to finish the training. Kindly note that prior works do not include data transfer time, if any, as part of training time measurement in a GPU-only setting [14, 25–27, 54, 56, 57, 66].

The *framework-runtime overhead* is defined by Eq. (1): sum of the time consumed by the CPU in a GPU-only training system without counting the time spent on waiting for GPU, if any. Hence, the source of the overheads is roughly Python/C++ code execution in the CPU, including the cost of kernel launches, which is usually asynchronous to the CPU.

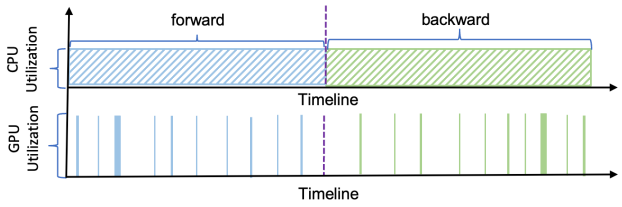

Fig. 4: Illustration of CPU and GPU activity timeline during a GCN training iteration on DGL on the Cora dataset, clearly showing the GPU idle time where framework overhead executes exclusively on CPU. This illustration is a simplified version of the profiler output.

$$Overhead = \sum_{k}(CPUTime - CPUWaitForGPUTime) \quad (1)$$

Challenges and Approach. The overhead is a problem only if it can not completely be overlapped by GPU execution, i.e., *significant* GPU idle time between kernel executions is a problem where only overhead is executing (in CPU).

A naive method to gather this information is to observe it from the timeline view of execution, e.g., using the Nsight tool, as shown in a simplified Fig. 4 for one training iteration. As shown, the CPU remains consistently active throughout the training iteration, whereas the GPU experiences frequent idle periods. This indicates that the GPU is underutilized, leading to CPU-side overheads (framework runtime overhead) dominating the overall training time. However, the process is manual and error-prone, takes a huge amount of human effort, and must be repeated for all combinations of GNN systems, models, and datasets– a gigantic task nonetheless.

In light of these observations, our approach is to collect the runtimes: training (TT), overhead (OT), and GPU execution (GT). OT(%) identifies the overhead percentage compared to training time, while 100 – GT(%) is the percentage time where overhead is executed *exclusively* and is the metric of interest.

5.1.1 Measurement and Analysis

Fig. 5 shows the overhead during DGL GCN training for different-sized graphs. **a)** Framework overhead is 100% for up to 4 million edges: reduction in framework overhead would automatically improve training runtime, while any GPU runtime improvement or slight slowdown would bear no consequence to training runtime. E.g., the GPU runtime is only

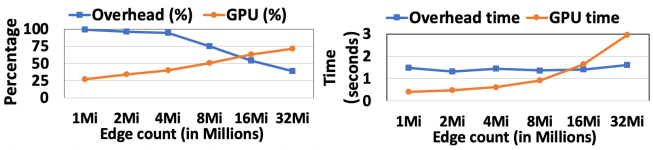

Fig. 5: DGL framework-runtime overhead when training GCN (200 iterations) on graphs ($|V|$=32,768). **Left:** framework overhead is 100% of training time when edge-count is $<$ 4 Million. **Right:** Overhead remains similar irrespective of the edge count.

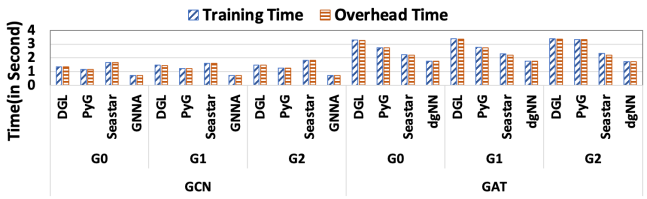

Fig. 6: Training and framework runtime overhead for DGL, PyG, GNNAdvisor (GNNA), and dgNN for GNN models training for 200 epochs. Seastar also has almost 100% overhead for these datasets.

around 25% at 1 Million edge, implying almost 75% overhead is not overlapped with GPU. The overhead (close to 100%) is almost the training time. **b)** Up to 32 million edges: idle GPU time (100 - GT(%)) remains *significant* where overhead is executed alone, thus playing a major role in training time. **c)** Only when the graph size becomes large, e.g., in Reddit (around 229 million edges, not plotted) DGL framework overhead is only 5.42% while the GPU runtime is close to 100%, resulting in almost no GPU idle time, implying no role of overhead in training time.

Fig. 6 shows that the overall training time is dominated by the framework overhead when evaluated for multiple GNN models across three widely used small datasets: Cora, Pubmed, and Citeseer; all have less than 100k edges.

Overhead varies in different systems due to Python/C++ code differences. In DGL, its generic Python-based message passing infrastructure, and conversion of PyTorch tensor to DLPack tensor to DGL-specific tensor are a few things that allow it to be extensible, supporting PyTorch, Tensorflow, MxNet, etc., but all of them are framework overheads. Systems that develop GNN from scratch hardly rely on the DGL front-end. E.g., GNNAdvisor has lowered its overhead mostly due to no implementation of message passing, removing bias parameters in its GCN layers, and using C++ to write GNN layers instead of Python to lower framework overhead.

Systems integrated into DGL, e.g., GE-SpMM [26] (not shown in Fig. 6), which replaced DGL with its sparse kernels, have not shown performance gain in their paper for GCN for smaller datasets on which it relied exclusively, despite showing better SpMM kernel time than cuSPARSE. However, it attributes this observation to the number of prediction classes not being a multiple of 32 without providing any evidence.

5.1.2 Measurement on Sampling-based GNN Systems

We now focus on a 3-layer GraphSage model with a batch size of 256 and fan-out as [10, 10, 10], which produces three sampled graphs, one for each GraphSage layer. In Reddit and OGBN-Products, our measurements show that the maximum edge count in the sampled graph is always less than 0.45 million in DGL, which is very small (see Fig. 5). Hence, further measurements indicate a close to 100% overhead for training on these two datasets. For example, the actual training procedure took around 48 seconds in the OGBN-Products dataset for 10 epochs (1 epoch has 768 iterations). The total overhead was almost 100%.

When doing the same measurement in MariusGNN [50], the training time improved to around 22 seconds but still had close to 100% overhead. Even for the paper100M dataset, one of the largest datasets used in sampled GNN training, the generated sampled graph has between 13k–2M edges [50], which is small enough as per Fig. 5.

GraphSage uses GCN for training on sampled graphs. So, we conclude that the framework overhead dominates training time in sample-based GNN systems. In other words, GPU kernels play no significant role in training time in this case.

5.1.3 Hypothesis and Discussion

GNNs are primarily impacted by framework runtime overhead because their computation cost is proportional to the batch size, as the trainable parameters are not large. E.g., in GCN and GraphSage, the trainable weights are of size $|F_{input}| \times |F_{output}|$ (plus bias), which are usually small. The computationally significant computations in these models are GeMM (matrix-matrix multiplication) and SpMM. GeMM depends on batch size and feature-length, while SpMM depends on graph size and feature-length. Both are lightweight in powerful GPUs for smaller graphs.

To this end, multi-GPU training time on sampling-based GNN is also impacted by the overhead, as we measured DGL on up to a 4-GPU single-node system using the data-parallel method. The data-parallel GNN training divides the mini-batches among GPUs while replicating the model. Partitioning mini-batches causes an even smaller mini-batch size per GPU, but replicating the model forces the replication of the same framework overhead to each GPU. This results in lesser computation per GPU, leading to large GPU idle time (100-GT(%)) where the framework overhead runs exclusively. Moreover, the network communication time is insignificant in GNN as it only communicates (in bulk) the gradients of trainable parameters, whose count is small as discussed above.

Indeed, any other model where a small batch size makes computation lightweight will likely suffer from the same framework runtime overhead. Exploring those models remains out of the scope of this paper due to the focus on GNN. A few additional examples are presented in the appendix.

More importantly, as GPU performance continues to improve, kernel execution will be faster, but the CPU overhead runtime would remain almost similar (single-threaded execution). Hence, it would lead to comparatively large framework overhead (100 - GT(%)) for the problems discussed in the paper. This trend suggests that the performance issues discussed in this paper would be even more critical in the future as increasingly powerful GPUs are adopted. Hence, we believe that relying on the specific GPU (Nvidia A100) did not significantly influence our observations.

5.2 EVAL-P3: Framework Memory Overhead

Many papers have shown frequent OOM on slightly older GPUs for mid-size datasets on PyG and DGL, which is aligned with our measurement. However, the excessive mem-

ory consumption has forced prior GNN systems to heavily or even exclusively rely on smaller datasets for comparing training runtime leading to EVAL-P1 (§5.1). We have described OOM for PyG in §4.1.2. This subsection explores the role of the framework for large memory consumption in DGL.

Observation. GCN training consumes 23.2GB of GPU memory (Fig. 16(a)) on the Reddit dataset. Our code-study in DGL GCN locates these inefficiencies: *a)* storage cost (§4.1.2); and *b)* to implement SpMMv in GCN, DGL uses a *dummy edge-level tensor* ($|E|$ additional memory) with each value as 1.0 to use cuSPARSE, which offers only SpMMve API.

However, these known memory inefficiencies aren't the primary reason, as an $|E|$ and $|V|$ memory implies only around 875 MB and 1 MB in Reddit, respectively. PyTorch memory profiler results attributed the largest memory to $torch :: empty()$, a memory allocator API, without providing any higher-level information.

Methodology. To develop insights, we evaluate memory consumption at storage format, kernel, and iteration levels. **1)** For DGL's SpMM kernel-level memory analysis, we printed the memory usage right before and after its call on Reddit ($|F|$=32) and found a massive 12,982 MB memory consumption. However, our direct evaluation of cuSPARSE SpMM shows only around 936 MB consumption. **2)** DGL SDDMM kernel consumed exactly 936 MB of memory.

A simple estimate also shows 936 MB as the actual memory consumption for both sparse kernels. SpMM includes the input tensors (vertex-level tensor and edge-level tensor: $|V| \times |F| + |E|$) and the output tensor (vertex-level tensor: $|V| \times |F|$). The scratchpad memory for cuSPARSE SpMM is tiny, while SDDMM does not need it. *Thus, we note that DGL introduces a framework memory overhead of around 12,046 MB (12,982 - 936) in SpMM, as known memory consumption cannot account for it.* Another DGL version also introduced a 6,340 MB of memory overhead in SpMM, thus confirming that it is not a version-specific problem.

DGL SpMM uses a PyTorch Python API to allocate memory for the input and output tensors of sparse kernels but SpMM scratchpad memory allocation is performed internally in the back-end that uses a different mechanism. Specifically, DGL's usage of DLPack tensor makes its back-end independent of PyTorch. So the back-end brings PyTorch through non-standard integration and uses its C/C++ API for this allocation. This non-standard integration of PyTorch is the reason for the memory overhead, as the PyTorch profiler pointed to allocation routine $torch :: empty()$ as the largest memory consumer while SDDMM has neither any internal allocation nor memory overhead.

The novelty of our method lies in the flexible granularity of measuring memory consumption to locate issues. A kernel-level granularity has shown issues with non-standard PyTorch integration. When we changed the granularity to an iteration level, we noticed a memory leak in dgNN (§7.2.3). PyTorch profiler alone is not sufficient in either case.

6 Future Direction and GraphPy

Pitfalls presented in §4 and §5 have renewed our understanding of system design and implementation for GNN models and the role of the framework respectively. Hence, the natural progression is awareness of the impact of these pitfalls on research progress and human resource development (§6.1), and overcoming them collaboratively through recommendations, future research direction (§6.2), and a prototype to quantitatively measure the impact (§6.3).

6.1 Additional Impacts

We presented the impact of the pitfalls when discussing them, including questionable or inflated speedup in runtime and memory saving. Here we present some high-level impacts.

Extensive and Wider Effect. A GNN system with lower training accuracy due to pitfalls impacts inference when deployed. Framework overhead impacts almost every sampling-based GNN system. Moreover, as DGL extends the same design to its multi-GPU setting, and is a widely used system as a baseline and even for system integration [15, 25, 26, 57], it has impacted almost every GNN system in their evaluation analysis due to the framework overheads.

Stifling Innovations. A new system with valid optimization may not outperform pitfall-infested works without committing similar or other pitfalls unless one characterizes the issues prevalent in prior works in their research paper, leaving them with less space to describe their contributions. Hence, if the community is unaware of them, genuine progress in system optimization may not happen.

Inadequate Training to Future Leaders. The discussed pitfalls indicate questionable research practices [41]; otherwise, they would not have open-sourced their code. These issues indicate that senior researchers are not dedicating enough time to review trainees' deliverables or teach them appropriate research methods [2].

6.2 Recommendation and Future Direction

Measuring training accuracy is the most important feedback for the correctness, and hence should be enforced or must be reasoned on why it is not needed (Recommendation #1).

Performance Runtime Related. Smaller datasets alone cannot be used to conclude a better runtime if the system is not specifically designed and rightly evaluated for such cases (Recommendation #2), such as by treating the framework runtime overhead as a primary metric. For non-sampled GNN, if available labeled datasets are not of mid-size or larger, we recommend relying on datasets through generation tools [17, 18] and other graph repositories [42, 45] for training runtime comparison (Recommendation #3).

Framework runtime overhead presents a new area of research, analogous to Operating Systems. E.g., when we zoom into one kernel operation, it is becoming faster due to powerful GPUs, better algorithms, and other innovations such as quantization, pruning, sampling, etc. At the same time, frame-

work overhead is like a system call overhead, which remains constant and understudied, and runs in a single CPU core. Thus, *the DL framework is more like an Operating System to allow hardware usage without introducing much overhead like the system calls*. Thus, the future lies in studying those overheads (Future Works #1).

Lastly, the systems with no backward implementation or accuracy issues risk being sidelined for evaluations by future works, as some pitfalls can only be addressed via invasive efforts. A systematic approach is a standardized system benchmarking tool. Such work remains a work in progress (Future-Work #2). Till then, *directly evaluating kernel runtime can be a stop-gap solution* (Recommendation #4) for non-sampled based GNN works, to not discard their advances in basic kernel design (SpMM and SDDMM). This is impossible if prior works have only fused kernels with pitfalls.

Memory Consumption Related. *Frequent OOM and memory consumption should be analyzed* (Recommendation #5) like runtime with the same zeal (as we do in §5.2) without any pre-assumption while attributing memory saving quantitatively. Otherwise, we will continue to have highly inflated results. For GNN systems with non-standard integration, additional verification of memory consumption is needed.

6.3 GRAPHPY Design

Quantitative demonstration of the impacts of the pitfalls remains an open challenge, specifically to claim that the progress of the state-of-the-art has been compromised as they have allowed inefficient design to be declared better. Such analysis requires a new prototype where various pitfall-infested design choices could be evaluated quantitatively using ablation studies and controlled experiments. This motivates GRAPHPY, the proposed prototype.

By design, GRAPHPY mostly imitates DGL and manually fixes pitfalls by removing DGL's: *a)* framework-memory overhead, *a)* message passing, *c)* inefficient design of using eShuffle in forward computation, and *d)* avoiding dummy edge-level tensor in SpMMv. The design choices let us evaluate framework-level and GNN system design pitfalls while establishing baseline memory consumption as discussed next.

6.3.1 Framework-Level Design

GRAPHPY removes *framework-memory overhead* by following PyTorch plugin documentation rather than using the DGL style of non-standard PyTorch integration (§5.2). Hence, all memories are allocated using Pytorch APIs imported using the standard integration.

Removal of message passing is achieved by directly relying on basic sparse kernels of SpMM and SDDMM, as both are equivalent. Message passing APIs are mapped to sparse kernels anyway by DGL. Hence, GRAPHPY does not lose anything from it but minimizes the framework overhead. Hence, when we keep the same kernel as the one used by DGL, it allows us to evaluate framework-level pitfalls.

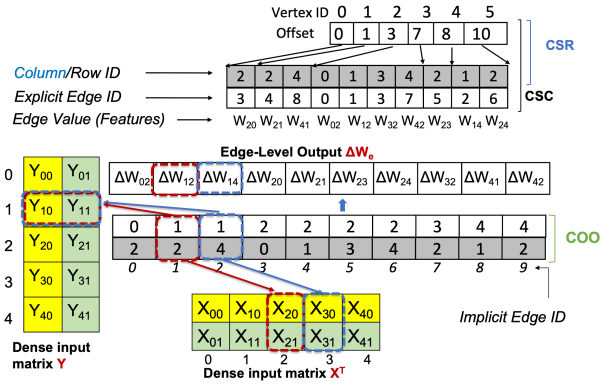

Fig. 7: GRAPHPY storage format for sample graph (Fig. 1b): The CSR format is assigned the implicit edge IDs. The COO is then generated from it, which enables caching of Y data in SDDMM. There is only one copy of the grayed array representing the Column ID array, which is shared among COO, CSR, and CSC. The Offset array is shared between CSR and CSC. The edge ID array is for CSC only.

6.3.2 GNN Kernel Design

In the forward computation, GRAPHPY substitutes DGL's eShuffle+SpMM with only SpMM. The removal of eShuffle is achieved by fine-tuning the storage format: GRAPHPY assigns an implicit edge ID to its CSR format by treating edge position as edge ID. In contrast, DGL assigns an implicit edge ID to its randomly ordered COO (§4.1.2). An implicit edge ID array in CSR, as shown in Fig. 7, makes the eShuffle in forward computation a no-op, hence, it is removed. Kindly note that CSC needs an explicit edge ID array, as shown in the figure. However, both share the storage structure due to dataset symmetry, which is achieved by storing the graph edges in both directions as an enrichment process, which almost all prior GNN systems do.

GRAPHPY then generates COO from the CSR (CSR-way): edges are stored in row-major as shown in Fig. 7. In comparison, DGL generated CSR from the randomly ordered COO. Our design choice allows the column ID array to be shared between the CSR and COO, while the COO also gets an implicit edge ID array.

In the backward computation, GRAPHPY implements $SpMM^T$ either as eShuffle+SpMM or using cuSPARSE-native SpMM^T. We implement both for comparison. However, we implement eShuffle+SpMM as one kernel because eShuffle is an intermediate kernel whose output is used by SpMM only. This saves the memory of eShuffle output ($|E|$). Thus, it becomes almost a drop-in replacement for cuSPARSE-native SpMM^T and is not a GNN kernel fusion technique.

Another advantage of eShuffle removal from forward is an automatic data-locality/caching enabled in SDDMM (on CSR-way COO), which is implemented as edge-parallel as in DGL. For example, when a warp processes two edges, such as (0,5) and (0,10), the features of source vertex 0, fetched during the first edge, can be reused when processing the latter,

Table 1: Dataset details. * indicates labeled dataset. Others use 150 generated features ($|F|$) and 7 prediction classes ($|C|$).

Graph Dataset Name	Vertex Count	Edge Count	$\|F\|$	$\|C\|$
Cora(G0)*	2,708	10,858	1,433	7
Citeseer(G1)*	3,327	9,104	3,703	6
Pubmed(G2)*	19,717	88,648	500	3
Amazon(G3)	400,727	6,400,880	150	7
As-Skitter(G4)	1,696,415	22,190,596	150	7
Cit-Patent(G5)	3,774,768	33,037,894	150	7
Stackoverflow(G6)	2,601,977	95,806,532	150	7
Hollywood(G7)	1,069,127	112,613,308	150	7
LiveJournal(G8)	4,847,571	137,987,546	150	7
OGBN-Products(G9)*	2,449,029	123,718,280	100	47
Reddit(G10)*	232,965	229,231,784	602	41
Orkut(G11)	3,072,627	234,370,166	150	7
UK-2002(G12)	18,520,486	596,227,524	150	7
Kron-25(G13)	33,554,432	1,073,741,824	150	7

as it would automatically be cached in the hardware cache. DGL's randomly ordered COO has no such advantage.

SpMMv is implemented using cuSPARSE SpMMve, which uses a dummy edge-level tensor like DGL, while we also provide a native SpMMv that does not use a dummy edge-level tensor. This enables benchmarking of the slowdown caused by the dummy edge-level tensor. Kindly note that backward SpMMv requires the transpose of the topology only due to the absence of edge weights. Hence, SpMMv^T is always SpMMv on CSC. We have an in-place degree-norm.

In total, the format costs in GRAPHPY is only $|V|+3|E|$ where CSR/CSC needs ($|V|+|E|$) + COO ($|E|$) + Edge ID array ($|E|$) in CSC for class A GNN. For GCN, GRAPHPY need only CSR ($|V|+|E|$).

GRAPHPY provides additional advantages. *a)* Its *practical* design choices are deployable to address a few pitfalls, thereby influencing a large number of existing systems. *b)* It protects future works from showing inflated gains, otherwise, they might continue to rely on current inefficient baselines or other pitfall-manifested systems for benchmarking, leading to compromised evaluations.

7 Experiments

The datasets are listed in Table 1. Only Cora, Pubmed, Citeseer, Reddit, and OGBN-Products datasets are labeled. The first three datasets are referred to as *small*. We use an Nvidia A100 GPU (40GB memory) and CUDA version 11.3. We focus on node classification using GCN, GIN, and GAT (with 1 and 3 heads implying edge feature length). In GCN and GAT, the intermediate feature length is 16, which implies that GAT-3 has 48 as the feature-length for each vertex. For GIN, the intermediate vertex feature length is 64. The feature lengths have been set based on the code of the original model paper, thus covering various feature lengths.

We used DGL version 1.1.0 throughout the paper. We also compare against Ge-Spmm [26], GNNAdvisor [54], Huang et al [27], FeatGraph [25], TC-GNN [56] and MariusGNN [50]. PyG runs out of memory on Reddit and OGBN-Products, so it is not benchmarked. We use dgNN [66] as a case study to understand the true impact of its kernel fusion and memory-saving techniques (§7.2.3) in the presence of no framework memory overhead and correctly designed SpMM^T.

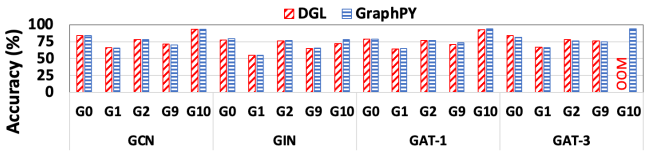

Fig. 8: Accuracy measure of GRAPHPY and DGL. Other systems have accuracy issues(§4, Fig. 3).

Accuracy Check Before Comparison. Fig. 8 shows the accuracy of GRAPHPY compared to DGL to show that GRAPHPY has normal accuracy. Thus, GRAPHPY can be used for other evaluations to show the impact of pitfalls in later sections.

7.1 GNN System Design Pitfalls Evaluations

Fig. 9 shows that the simple design changes have brought large speedup benefits to GRAPHPY over DGL. For the Reddit dataset, GRAPHPY achieves around 2.30× speedup for GCN, 1.36× for GIN, and 2.37× for GAT-1 over DGL. For GAT-3, DGL resulted in OOM. Smaller datasets are plotted later in Fig. 17 to discuss framework overhead. This subsection discusses the reason behind the speedup by focusing on kernel evaluations. We also discuss the impact of system design pitfalls on accuracy and runtime using the GRAPHPY prototype and other systems.

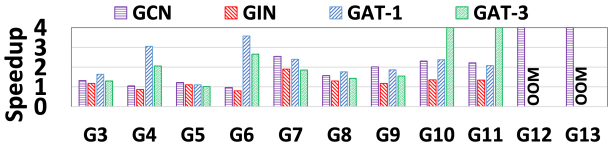

Fig. 9: GRAPHPY speedup over DGL for GNN training time (200 iterations). A speedup of 4 means that only DGL has OOM. OOM means that both DGL and GRAPHPY have OOM. (Higher is better.)

7.1.1 SpMMve^T and eShuffle: Quantitative Analysis

Fig. 10 plots the execution time of the SpMMve^T kernel. The SpMMve^T is natively implemented by cuSPARSE, but DGL used eShuffle+cuSPARSE SpMMve as a substitute (§4.1.2).

a) SYS-P2: DGL's eShuffle+SpMMve is 1.64× slower than the cuSPARSE-native *SpMMve^T* API. Worse, DGL also used eShuffle during forward computation, further contributing

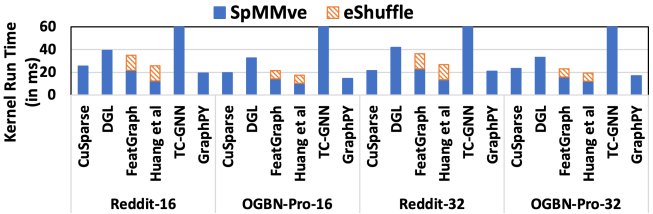

Fig. 10: SpMMve^T kernel time for 16 and 32 features. TC-GNN is very slow and has been clipped. (Lower is better.)

to the slowdown. FeatGraph also performs slower as it focuses only on forward SpMM, and not in $SpMM^T$. As it is integrated into DGL, it would suffer DGL's eShuffle issues.

b) EVAL-P2: TC-GNN uses SpMMve in its backward computation instead of SpMMve^T. Despite this advantage, its kernel is slower by over 3× and 54× on OGBN-Products and Reddit, respectively, for feature-length 32. Because it relies on fine-grained tiling to use tensor core, which does not suit the unstructured sparsity of mid-size graph datasets. *This result demonstrates that exclusively focusing on smaller datasets (EVAL-P2) by TC-GNN leads to misleading conclusions.*

c) SYS-P1: Huang et al. do not implement backward computation (SYS-P1), so we add our eShuffle time to their SpMMve time to simulate SpMMve^T. Other mechanisms, such as cusparseCsr2cscEx2() API, are not considered as it is almost 2× more costly than eShuffle. Its performance over cuSPARSE SpMMve^T is not noticeable and is slower in some cases.

d) GRAPHPY*'s Fused eShuffle+SpMMve is a state-of-the-art SpMMve^T solution* as it achieves 31.97×, 1.60×, 1.27×, and 1.24× speedup compared to TC-GNN, FeatGraph, cuSPARSE, and Huang et al., respectively. Kindly note that GRAPHPY is a vanilla vertex-parallel SpMMve, which is slower than the SpMMve of Huang et al due to the latter's custom format and workload-balanced design. Despite that, GRAPHPY SpMMve^T outperforms it and others.

e) GRAPHPY*'s SDDMM is state of the art*. Focusing on designing transposed SpMM has indirectly allowed GRAPHPY to gain huge performance in SDDMM due to the data-locality (§6.3). Fig. 11 shows that GRAPHPY achieves 2.99× speedup over DGL SDDMM. Both systems use edge-level parallelism on GPUs using the COO format, but GRAPHPY's COO is stored in a CSR-way (row-major) while DGL's COO is randomly laid out. Many other GNN systems do not have a separate SDDMM. FeatGraph does provide SDDMM, but its idea has been merged with DGL. cuSPARSE is very slow [64], which we have also observed, and hence has not been plotted. We compare against dgNN SDDMM in §7.2.3. However, the fact is that GRAPHPY achieved a huge performance with just a small change in DGL's COO to make it a CSR-way COO.

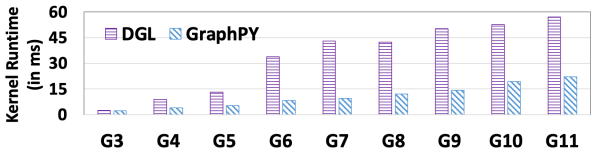

Fig. 11: SDDMM kernel runtime for DGL and GRAPHPY for feature-length 32. Both are edge-parallel. (Lower is better.)

f) SYS-P2-2: Fig. 12 shows that substituting SpMM^T with SpMMve leads to achieving an average of 1.34×, a notable training runtime speedup, for two widely used mid-size datasets, when GRAPHPY is used as an underlying system. Further, this pitfall also corrupts the training accuracy (Fig. 13) by 26.8%, 16.1%, 18%, 15.63%, and 11.96% in G0 – G2, G9, and G10 respectively.

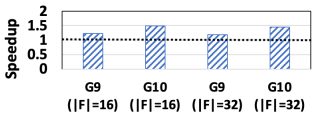

Fig. 12: Omitting the transpose operation (§4.1.2) from GAT backward computation wrongly leads to faster training.

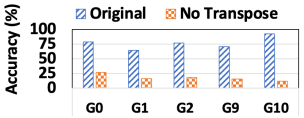

Fig. 13: Removing the transpose operation in GAT backward computation drops training accuracy.

In summary, DGL's performance slowdown is marred by bad design choices despite having easier options. Other systems suffer from various other pitfalls affecting their performance or accuracy, However, the takeaway is that a simple format change has allowed GRAPHPY to achieve state-of-the-art performance. This change is very practical to easily integrate into other systems to either gain performance or implement SpMMve^T to fix their system.

7.1.2 SpMMv and Dummy Edge-Level Tensor

A similar analysis for SpMMv is plotted in Fig. 14. We use cuSPARSE as the baseline.

a) EVAL-P2: TC-GNN and MariusGNN (both published in 2023) are the slowest systems. TC-GNN is slower by 3.07× and 38.67× on OGBN-Products and Reddit, respectively, over cuSPARSE. MariusGNN, a sampling-based GNN system, is 6.18× and 9.71× slower, respectively, due to the materialization of dot products in the GPU global memory (§4.1.2). GNNAdvisor is also slower (1.20×) than cuSPARSE despite using a workload-balanced technique, and is 1.98× slower than the workload-imbalanced solution of Ge-SpMM, even though it uses its caching design. Unfortunately, it materializes the dot products in GPU shared memory, leading to lower performance. As they have specifically mentioned their kernel design to be a reason for better performance, *they got impacted by EVAL-P2 (evaluation on smaller datasets only).*

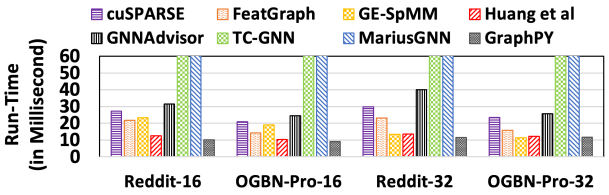

Fig. 14: SpMMv kernel time: TC-GNN and MariusGNN runtime have been clipped.(Lower is better.)

b) Dummy edge-level Tensor: cuSPARSE and Huang et al provide SpMMv using their SpMMve + dummy edge-level tensor with each value as 1.0, which incurs additional data-load. Hence, Huang et al (despite a workload-balanced solution) still perform similarly to SpMMv of the workload-imbalanced solution of Ge-SpMM. We believe it could have made a greater impact had it implemented a native SpMMv.

c) GRAPHPY's vanilla vertex-parallel SpMMv is better

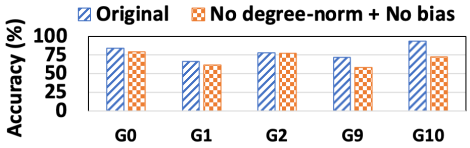

Fig. 15: Removing the degree-norm and bias operation in GCN leads to a large accuracy drop in mid-size datasets. (Higher is better.)

than all prior works, e.g., it outperforms workload-balanced GNNAdvisor's SpMMv by 2.87×, outperforms MariusGNN and TC-GNN SpMMv by 14.89× and 56.99× respectively. The reason for its better performance is purely poor design decisions of prior works as discussed above.

7.1.3 Removal of Degree-Norm and Bias Parameter

Fig. 15 shows accuracy drop of 5.1%, 4.4%, 0.7%, 13.1%, and 20.9% in G0, G1, G2, G9, and G10 datasets, respectively, when eliminating the degree-norm and bias parameter for the GCN model. Larger datasets have a larger drop in accuracy. This confirms that such system design issues lower accuracy.

7.2 Framework Level Pitfalls Evaluation

This section focuses on both the framework overheads: runtime and memory. We then use dgNN to discuss the trade-off of its kernel fusion and memory-saving techniques.

7.2.1 Framework-Memory Overhead Impact

Fig. 16 shows that GRAPHPY reduces memory consumption on average by 6.92× on GCN, 3.4× on GIN, and 1.96× on GAT-1 over DGL. We exclude results for G3–G8 as the focus is to study OOM behavior, though we observe a similar pattern for those datasets. On Reddit (G10), GRAPHPY (DGL) consumes only 2.1GB (23.2GB), 4.0GB (23.7GB), 13.3GB (30.3GB), and 30.9GB(OOM) on GCN, GIN, GAT-1, and GAT-3, respectively.

GRAPHPY provides over 20GB of memory saving in GCN for Reddit over DGL. The memory benefit of GRAPHPY is first due to the removal of framework-memory overhead in DGL (§5.2), while other techniques, such as better storage format, removal of dummy edge-level tensor in GCN SpMMv, removal of eShuffle kernel in GAT SpMMve to save the memory of an edge-level tensor, etc., provide true savings.

The true memory consumption allows GRAPHPY *to train GCN on a billion-edge graph (G13: Kron-25), a first on single-GPU*, consuming 29.8 GB only, while DGL cannot even run a graph with around half a billion edges (G12: UK-2002), showing the inefficiencies in DGL.

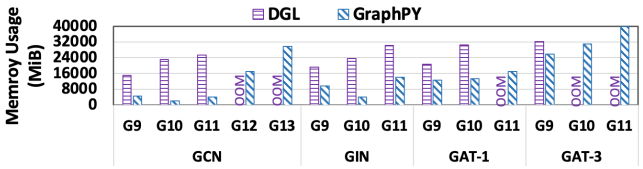

Fig. 16: Memory consumption comparison. OOM=out-of-memory. (Lower is better.)

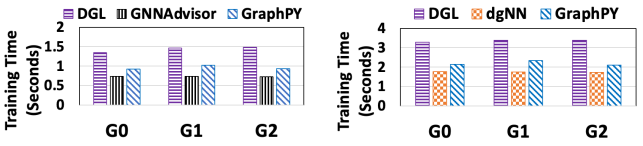

Fig. 17: Training runtime on smaller datasets. **Left:** GCN **Right:** GAT. (Lower is better.)

7.2.2 Framework-Runtime Overhead Impact

Fig. 17 shows training runtime on smaller datasets to focus on runtime overhead. We first notice that GRAPHPY performed much better than DGL when GRAPHPY used the cuSPARSE kernel, same as DGL except for the removal of the message passing. Kindly note that GRAPHPY performed the same irrespective of using cuSPARSE-based SpMM or its vanilla vertex-parallel SpMM (not plotted). Both observations align with our framework-runtime overhead analysis (§5.1).

We also compare with GNNAdvisor and dgNN. The former moved a lot of Python code to C++ (it also has removed bias and performs degree-norm wrongly in the backward). At the same time, the latter uses kernel fusion, resulting in a smaller Python/C++ code footprint than GRAPHPY. Both approaches are expected to reduce overhead, which is proven by the result.

In the absence of knowledge about framework-runtime overhead pitfalls, one can easily claim that GNNAdvisor and dgNN are faster than GRAPHPY as both systems have strong arguments for better performance: GNNAdvisor has workload-balanced SpMMv, while dgNN has a superior kernel-fusion design compared to GRAPHPY. However, both arguments are not valid for mid-sized datasets (see §7.1.2 for GNNAdvisor and §7.2.3 for dgNN) where they matter.

7.2.3 Case-Study: Kernel-Fusion + Memory Saving

GRAPHPY still keeps the baseline characteristics of DGL, hence we use it to benchmark dgNN [66]: superior **kernel fusion** in GAT, whose forward computation stores attention scores ($|E|$) in shared memory to enable its faster fusion with forward SpMMve. The backward phase recomputes the attention (gradient checkpointing) to store in shared memory to fuse it with backward SpMM. Kindly note that the backward recomputation of the attention score in dgNN directly generates a transposed layout of the attention score; hence, fused backward needs SpMMve and not SpMMve^T, which is another way to achieve SpMMve^T.

dgNN is slower than GRAPHPY by 1.48× for datasets G3–G11 (Fig. 18). The SpMMve in GRAPHPY is similar to dgNN,

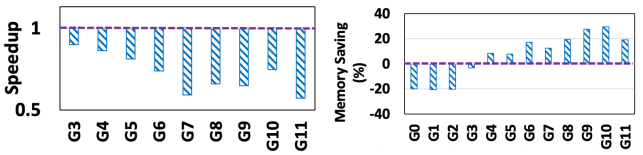

Fig. 18: dgNN GAT training speedup over GRAPHPY. **Left**: Runtime speedup. **Right**: Memory saving speedup. (Higher is better.)

which has been fused with other kernels in dgNN. Hence, the reasoning lies in the trade-off in GNN of kernel fusion.

GRAPHPY has SpMM and SDDMM in vertex-parallel and edge-parallel fashion respectively, like DGL. However, this mixed approach does not allow fusing these two. Hence, dgNN, like other kernel fusion works [9,57], forces SDDMM variants to be performed in vertex-parallel fashion to fuse it with their vertex-parallel SpMM. Our measurements (not plotted) confirm that GRAPHPY has 1.72× speedup over dgSparse [1] (vertex-parallel SDDMM, which is used by dgNN for fusion) on OGBN-Products dataset.

Fundamentally, SDDMM is naturally edge-parallel, as computation on one edge is independent of others. On the other hand, vertex-parallel SDDMM has a workload imbalance as vertices have varying neighborhood sizes. Hence, when one keeps the same SpMM implementation, the advantage of kernel fusion boils down to its benefit versus the loss that occurs by downgrading SDDMM to vertex-parallel. *Hence, even though dgNN is faster than DGL is a correct assertion, it is not faster than the latter's approach of vertex-parallel SpMM + edge-parallel SDDMM, when implemented rightly as by* GRAPHPY. *This represents more fundamental knowledge.*

Average Memory Saving is modest 6.4%. This shows that gradient checkpointing provides memory saving, which we expected. However, dgNN theoretically provides only $|E|$ - $2|V|$ memory saving for state-tensors per GAT convolution layer: $|E|$ memory saving is achieved by not storing attention (edge-level) tensor as a state-tensor, while recomputing is based on introducing two new vertex-level state tensors ($2|V|$). Other kernel fusion techniques save only ephemeral memory as they are not state-tensors.

For some datasets, the saving is negative. Our measurements show that dgNN leaks memory around 150 MB, i.e., the memory consumption around the 200^{th} iteration of training is larger by 150 MB than that of around the first few iterations. GRAPHPY (and DGL) shows the same memory consumption throughout the training procedure. This leak becomes significant in smaller datasets of G0 – G3, leading to negative memory saving in dgNN.

In summary, framework-memory overhead in DGL offered inflated evaluations in dgNN that reported up to 3× memory saving. Our evaluation with GRAPHPY shows its true saving.

8 Related Works

Several papers have uncovered pitfalls or offered alternative perspectives that diverge from established research directions in machine learning (ML) and deep learning (DL) applications. For example, a distinguished award paper [3], systematically describes the ML pitfalls in the security domain. Earlier, another best paper award [11] explains pitfalls in the recommendation system.

From the systems perspective, some studies challenge prevailing assumptions. McSherry et al. [39] show that many graph analytics systems merely parallelized the overhead rather than improving performance when scaling to a distributed deployment. GBench [34] highlights existing pitfalls when benchmarking graph streaming systems. HalfGNN [44] identifies training accuracy flaws in prior GNN systems when they substitute single-precision floating point features with half-precision.

These studies highlight the existence and importance of recognizing pitfalls in the ML/DL domain and beyond, and their recognition by the computer science community underscores their significance. In contrast to these works, our study focuses on system-specific pitfalls in GPU-based GNN systems. Our discussion is based on semantic-preserving GNN models: the model architecture, algorithm, and datasets remain unchanged, and only the underlying system or backend is modified. Under such settings, an ideally optimized system should deliver comparable accuracy while achieving improved performance. Our work investigates why this is often not the case, as we show that design decisions at the system and framework level can lead to significant degradation in both accuracy and performance.

It is important to clarify that while it is widely acknowledged that changes to model architecture or algorithm can affect accuracy and performance, this paper focuses on semantic-preserving models.

Moreover, GNN optimizations have wider applications in exploiting sparsity in the broader DL community, where models are either pruned [10,13,21,22] to make their layers sparse, which requires re-training or defined initially [38] as sparse, thereby requiring similar to GNN sparse kernels. Hence, pitfalls in GNN systems will likely impact this area as well.

9 Conclusion and Future Works

Our in-depth analysis highlighted many critical pitfalls in current GPU-only GNN systems which questions our understanding of system design, implementation, and evaluation. We identified the consequences of ignoring accuracy measurements and unawareness of the role of the framework in training time and memory consumption. We presented their impact, recommendations, and future directions. We also designed a practical and compelling solution to solve some of these pitfalls. The important takeaway is that a simple yet careful design rooted in requirement understanding leads to better runtime and memory usage. We hope our analysis, recommendations, and GRAPHPY can be used by future research to genuinely advance GNN system optimizations. We leave overcoming framework-runtime overhead as a future work.

A Method to Measure Framework Overhead

In this section, we focus on how to measure framework overhead. Though, it has been plotted in the main paper, the main metric to observe in §5.1 is GPU idle time (100 - GPU-Runtime (%)), where overhead runs exclusively. Hence, this section is only for curious reviewers who wants to go deeper.

For reference, the training time is measured as the wall-clock time spent between training start and end. It is a standard practice to insert a "cudaDeviceSynchronize" (barrier) after the last training iteration to make sure GPU finished execution before ending the wall-clock tick due to asynchronous kernel execution as shown in Fig. 19 (left).

Challenges. Give this definition of training time, we discuss following challenges. **a)** One can remove the inserted barrier, and collect the ending wall-clock tick to postulate that it has collected only CPU runtime. However, a limited job queue length in a GPU makes kernel launch synchronous after a few iteration as many kernels are submitted. This blocking behavior make kernel launches includes an indirect wait time spent by CPU. E.g., the profiler shows 90.27% of the total training time as "kernel launch time" for DGL GCN on Reddit for 200 iterations. This is a problem only for mid-size datasets. In smaller datasets, kernels run much faster and hence, job queue never becomes full. However, this methodology cannot be used due to not giving reliable value of overhead time. **b)** Using PyTorch profiler can also not be used as total CPU time is always printed more than GPU total time as the profiler automatically inserts a barrier after the last training epoch even if we do not explicitly write one. Manually subtracting the timing spent on this barrier, which profiler reports, does not give correct overhead cost as kernel launches include the indirect wait time, discussed above.

```
1 start = datetime.now()
2 for epoch in range(200):
3     # training epoch start
4     # training epoch end
5 # end for loop
6 torch.cuda.synchronize()
7 end = datetime.now()
8 trainingTime = end - start
```

```
1 overhead = 0
2 for epoch in range(200):
3     start = datetime.now()
4     # training epoch start
5     # training epoch end
6     end = datetime.now()
7     ovheread += end - start
8     torch.cuda.synchronize()
9 # end for loop
```

Fig. 19: Methodology for measuring training time (left) and framework runtime overhead (right).

Methodology. We propose an automated approach (Fig. 19 (right)) where the idea is to measure the overhead per iteration by introducing a barrier (Line 8). This barrier limits the number of kernel submissions to ensure kernel launch never becomes synchronous. Hence, time spent between Lines 3 and 6 becomes overhead time (CPU) per iteration. The PyTorch profiler shows that time spent on "cudaLaunchKernel" is much lower. Moreover, this printed similar framework overhead per GNN system per model irrespective of dataset size.

The minor issue with this approach is that total training time might increase due to this barrier. Even though our measurement on different datasets shows hardly any such concerns, we continue to rely on actual definitions to measure training runtime (Fig. 19:Left), and not rely on this changed code. For GPU runtime, we always use PyTorch profiler, which print total gpu runtime.

B Systems Suffering from Framework-Runtime Overhead

The main paper discussed how full-batch GNN for smaller datasets, and sampling+mini-batching GNN for all datasets suffer from framework runtime overhead dominating the training runtime. This section outlines other models that suffer from this issue.

Any other model where a small batch size makes computation lightweight will likely suffer from the same framework runtime overhead. As an example, we evaluated LeNet-300-100 model which is a model with just three linear layers of sizes 768×300, 300×100, and 100×10 with ReLU activations, and classifies hand-written digits, such as MNIST dataset. Measurements show framework-runtime overhead to dominate training time even in large batch-size of 4096.

C Code Analysis For Pitfalls

This section presents our code-study results to show that many prior works have pitfalls. These are supporting materials and are optional to convince that pitfalls exist. Kindly note that we have reached out to the authors of their papers to get confirmation. They all have agreed on the issue and we received positive and encouraging feedback.

C.1 GNNAdvisor

https://github.com/YukeWang96/GNNAdvisor_OSDI21/blob/master/GNNAdvisor/GNNConv/GNNAdvisor_kernel.cu#L542 points to backward propagation which performs the SpMMv first, then the degree-norm part within the same kernel. The forward also performs these operations in the same order(line 403), and hence backward should have been done in reverse order.

https://github.com/YukeWang96/GNNAdvisor_OSDI21/blob/master/GNNAdvisor/gnn_conv.py#L98 shows that the bias operator is not there. https://github.com/dmlc/dgl/blob/master/python/dgl/nn/pytorch/conv/graphconv.py#L206 shows that the bias operator is set as True by default in DGL. But https://github.com/YukeWang96/GNNAdvisor_OSDI21/blob/master/dgl_baseline/gcn.py#L12 shows GNNAdvisor did not specifically disable bias in DGL.

C.2 TC-GNN

https://github.com/YukeWang96/TC-GNN_ATC23/blob/atc23ae/TCGNN_conv/TCGNN_kernel.cu#L336 and https://github.com/YukeWang96/TC-GNN_ATC23/blob/atc23ae/gnn_conv.py shows that TC-GNN's GCN implementation does not include degree-norm and bias operator either in the kernel or in Python. But these two URLs (https://github.com/YukeWang96/TC-GNN_

ATC23/blob/atc23ae/dgl_baseline/gcn.py#L20 https://github.com/dmlc/dgl/blob/master/python/dgl/nn/pytorch/conv/graphconv.py#L197) show that TC-GNN uses the default setting for bias and degree-norm in DGL. This means their DGL baseline enables both the degree-norm and bias operator.

One can also see that its AGNN (https://github.com/YukeWang96/TC-GNN_ATC23/blob/atc23ae/TCGNN_conv/TCGNN_kernel.cu) kernels don't do tranpose at all during backward pass.

C.3 FuseGNN

https://github.com/apuaaChen/gcnLib/issues/3 reported an accuracy issue in Github but got no response. Our measurements also show the same accuracy issue.

C.4 Huang et al

https://github.com/xxcclong/GNN-Computing/blob/master/include/aggr_gat.h There is no transpose SpMM function implemented, the kernels work fine for forward but are not workable for backward pass. Their Python code also does not explicitly call/have transposed API from Pytorch/cuSPARSE.

It uses the same copy of edge-level tensor for all the layers of GAT. Hence, in the real-world, they would not be usable in backward propagation. The correct approach would have been to allocate separate memory for each edge-level tensor.

The kernel does not work when the dim is not a multiple of 32, which is a common case for the last layer of GAT. E.g., in Reddit and OGBN-Products, the feature dimensions are 41 and 47 respectively.

For GCN: https://github.com/xxcclong/GNN-Computing/blob/master/include/aggr_gcn.h shows that all the kernels here require an edge-level tensor, i.e. this paper provides SpMMve and not SpMMv, and is the main reason for slower performance despite having a workload-balanced solution.

The kernel does not work for odd dimensions, which is a common occurrence for GCN, specifically for the last layer. E.g., 6 for Cora.

C.5 TLPGNN

https://github.com/charlifu/TLPGNN/blob/main/gat/kernel.cu#L49 shows the fused kernel for GAT forward where the attention-score (edge-level tensor) is computed and stored in a register and not materialized in GPU global memory.

It also neither has backward code for GAT nor transpose code anywhere.

C.6 Seastar

Seastar does not have its code in Github, but it provides a URL to download it. Upon running its training script, it generates the kernel code (in CUDA), compiles it (all automatically), and runs training. We read the generated GCN sparse kernel, which generates a fused version of SpMMv and degree-norm, and suffered from the same set of issues as discussed for GNNAdvisor.

C.7 MariusGNN

https://github.com/marius-team/marius/blob/2f27ffedfbffd405995e8d16d821849db1fe0535/src/cpp/src/nn/layers/gnn/graph_sage_layer.cpp shows its computation kernel for the SpMM kernel. This kernel consists of two parts. The first part scatters the vertex-level features to edges https://github.com/marius-team/marius/blob/2f27ffedfbffd405995e8d16d821849db1fe0535/src/cpp/src/nn/layers/gnn/graph_sage_layer.cpp#L49.resulting in materializing this value. The second part performs the gather procedure https://github.com/marius-team/marius/blob/2f27ffedfbffd405995e8d16d821849db1fe0535/src/cpp/src/nn/layers/gnn/graph_sage_layer.cpp#L52. We use this method to compare its kernel performance.

C.8 GE-SpMM and FeatGraph

These two systems are integrated to DGL. However, due to code reorganization, we could not run Ge-SpMM. For Featgraph, we also could not run its DGL integrated system despite help from authors. We tried many Github branches that their authors suggested.

C.9 DGL

We have reached out to DGL recently through a long email. We are yet to hear from the person. Before this, we had a face-to-face meeting with this person in a conference/workshop, and the employee indicated that they acknowledge that DGL suffers from some issues that we highlighted in the paper. At that time, the manuscript was not fully ready, but we did discuss that their non-standard integration seems to indicate the memory overhead issue.

Bluetooth Low Energy Security Testing with Combinatorial Methods

Abstract

Wireless protocols such as Bluetooth Low Energy (BLE) play a vital role in ubiquitous computing and Internet of Things (IoT) devices. Numerous vulnerabilities in a variety of devices and components of the BLE stack have been uncovered in recent years, potentially affecting millions of customers. Being notoriously difficult to test due to the level of abstraction commonly enforced by the Host Controller Interface (HCI), a recent work successfully implements a fuzzing framework utilizing a custom firmware for a BLE device. However, fuzzing is inherently probabilistic, which may lead to faults remaining undiscovered. In this work, we enhance the aforementioned method with a Combinatorial Security Testing (CST) approach that provides a guaranteed degree of input space coverage. Through an evaluation targeting 10 BLE devices and a variety of firmware versions, we identify a total of 19 distinct issues, replicating findings of the previous work and uncovering additional faults. We additionally provide a performance overview of our tool and the original fuzzer, comparing their execution time and fault detection capabilities.

1 Introduction

BLE [1] is a wireless transmission technology that was first introduced in Bluetooth core specification 4.0 in 2010 as a means of enabling resource constrained entities such as IoT and health care devices to communicate. Despite the similarity in name, it is a separate protocol from Bluetooth classic. According to Berua et al. [4], BLE is the most widely used protocol for IoT devices with 14.2 billion linked IoT devices in 2019. According to forecasts, by 2027, 7.6 billion Bluetooth enabled devices will be shipped annually (most of them supporting BLE and Bluetooth classic).

Because BLE targets battery powered devices with limited computational capabilities and low memory resources, the complexity of the protocol is reduced compared to classic Bluetooth. At the same time, this modification requires adaptations to implement reliable encryption and privacy measures. Due to the widespread adoption of Bluetooth and the fact that it is used in private homes and industrial applications alike, it is important to test applications and protocol implementations in depth.

A variety of approaches have been developed to test different properties of BLE protocol implementations. One aspect of BLE that is often found to be vulnerable is the pairing procedure, especially the "just works" pairing method, which is in general vulnerable to a Man in the Middle (MITM) attack, but was also found to suffer from more severe issues [4, 33].

Other methods focusing on the underlying link layer of Bluetooth protocols have been successful in showing that the firmware controlling Bluetooth chips may harbor vulnerabilities and must be tested extensively [12, 14]. However, these methods are based on fuzzing, which is inherently probabilistic and does not offer guarantees regarding the coverage of the input space. This may lead to bugs remaining uncovered or testing processes incurring infeasibly high execution times. In order to remediate these flaws, we turn to Combinatorial Testing (CT), a black-box testing method based on a model of the input space of a system that features a guaranteed degree of coverage. We adapt the framework used in SweynTooth [14] to execute a combinatorial test set while incorporating feedback from the target BLE device to guide the selection of test cases and evaluate their success in causing unexpected behavior. Our approach features an individual input parameter model per BLE protocol layer. Test sets based on these models are subsequently combined with a granularity as chosen by the practitioner before being submitted to the System under Test (SUT), which is monitored by two separate oracles aiming to identify abnormal operating conditions.

Our primary **contribution** is a CT approach for security testing of BLE devices that offers a guaranteed degree of input space coverage as well as an implementation based on the GreyHound fuzzer. We further provide an experimental evaluation that confirms that the increased coverage permits testers to identify more flaws in total while pointing towards potential avenues for improvement, particularly in terms of execution time and sequence modifications. Our analysis of

detected issues points towards multiple denial of service vulnerabilities as well as further faults that may ultimately lead to memory corruption and potential arbitrary code execution.

The remainder of this work is structured as follows. Section 2 provides relevant background information on BLE, combinatorial security testing, and the GreyHound fuzzer. Subsequently, Section 3 outlines the most important pieces of related work, both in the areas of BLE security testing and combinatorial testing. In Section 4, we provide a detailed description of our methodology, including the overall testing strategy, input modeling considerations, and oracles. Section 5 describes the testing setup, target devices and their firmware versions as well as practical challenges encountered throughout our experiments, followed by a discussion of evaluation results, identified faults, and the differences between the results of GreyHound and our approach in Section 6. We describe the process and results of our responsible disclosure efforts in Section 7. In Section 8, we summarize our work before moving on to a brief outline of potential avenues for future work in Section 9.

2 Preliminaries

This section provides background information on three particular areas that form the focus of our work: Combinatorial Security Testing, the BLE protocol stack, and the GreyHound fuzzer.

2.1 Combinatorial Security Testing

CT is an established black-box testing method that derives tests based on a model of the input parameters of a system under test (SUT). While the underlying concept was explored by Burr and Young in 1998 [8], it received renewed attention after a large-scale empirical study conducted by the National Institute for Standards and Technology (NIST) indicated that all analyzed software faults were triggered by a combination of up to six parameters [22]. This means that exhaustive testing of all combinations of permissible values for each input parameter is often not required to detect faults.

CT utilizes an Input Parameter Model (IPM) containing all externally supplied parameters of a SUT and a list of their possible values. It may further be enhanced with constraints that restrict which combinations of parameter values are allowed to be contained in a single test case (for example, in a test case that encodes the age and age group of a person, a possible constraint could require that if the age group is set to "child", the age must not be greater than 17). A test case assigns one of the permissible values to each of the input parameters. The coverage guarantees of CT stem from its underlying discrete mathematical structure, a Covering Array (CA). A CA is a $N \times k$ array with each of the N rows representing one test case and each of the k columns referring to a parameter. The defining property of a CA is based on an additional value t, which must be between 2 and k (the latter being equivalent to exhaustive testing) and is often referred to as the *strength* in the literature. For every selection of t distinct parameters (columns), a CA is guaranteed to contain every possible parameter-value combination at least once.

Compared to exhaustive testing, the main advantage of CT is a drastic reduction of test set size and thus execution time. Consider, for example, a SUT that accepts 16 binary input parameters. Exhaustively testing this system would require 2^{16} test cases. In contrast to this, a CA with strength $t = 6$ requires merely 179 test cases, a reduction of around 99.997%.

In practice, applying CT usually entails the following steps:

1. Creating an IPM from a description of the SUT, source code or other type of analysis. In this work, IPMs are constructed based on the BLE specification.

2. Generating one or more CAs from the model according to a selected strength. Increasing the strength leads to a larger subset of the input space being explored while also requiring additional test cases.

3. Translating resulting CAs to concrete test sets, as some values may be encoded symbolically and must be transformed to discrete data types.

4. Executing the test cases and gathering the response of the SUT. This may simply be the output of the SUT or more complex behavioral information such as execution traces.

5. Evaluating the SUT's behavior using an oracle to identify whether any faults occurred.

While traditional CT is a type of conformance testing, i.e. seeks to establish whether the SUT processes a wide range of inputs correctly, combinatorial security testing (CST) aims to identify vulnerabilities. This primarily influences the first and last step listed above: In conformance testing, the IPM captures valid values, while in CST, a mixture of valid values and crafted values meant to trigger vulnerabilities (commonly based on expert knowledge on the particular type of attack) is employed. For example, the latter category might encompass overly long sequences, empty values, or particular strings with a special meaning in languages such as SQL (in the context of SQL injections), shell scripts (for command injections) or JavaScript (in the context of XSS). CST additionally utilizes different types of oracles from traditional CT. While a classic CT oracle would seek to identify whether the SUT's output is equivalent to some expected value, CST oracles aim to identify whether a vulnerability has been triggered. Although the findings of the aforementioned NIST fault analysis studies do not directly apply to CST, previous work discussed in Section 3 indicates that the coverage afforded by combinatorial test sets also leads to efficient and effective test sets for the identification of vulnerabilities.

2.2 Bluetooth Low Energy

Bluetooth Low Energy [1] is one of the most widely used communication protocols for IoT devices [4]. It is managed by the Bluetooth Special Interest Group (SIG), consisting of more than 20,000 members, in version 5.6. It operates in the license free 2.4GHz industrial, scientific and medical (ISM) band and is a nearly completely separate protocol from Bluetooth basic rate (BR) and enhanced data rate (EDR). To avoid congestion and collisions, BLE uses Adaptive Frequency Hopping (AFH) to hop between 40 channels (3 advertisement channels, 37 data channels). A BLE network consists of one central device providing a clock and frequency hopping pattern and one or more peripheral devices.

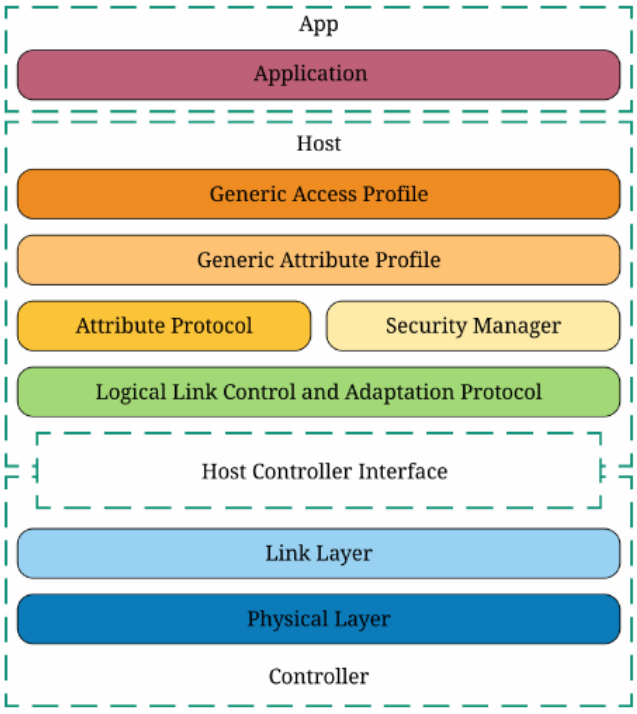

Figure 1: Bluetooth Low Energy stack layers [4]

The BLE stack consists of several protocol layers that interact with each other, each responsible for a different set of functionalities, depicted in Figure 1.

The Host Controller Interface (HCI) represents an isolation layer between lower-layer protocols (Baseband, LMP) and higher-layer protocols (L2CAP, ATT, GATT, GAP, etc.). Higher-layer protocols run on the host operating system, while lower-layer protocols run on a separate hardware called controller, which receives HCI packets from the host that are transformed into appropriate Baseband or LMP packets. The controller also handles timing requirements and checksum calculations. This isolation between components and the inability to access all aspects of the protocol is one of the reasons why the Bluetooth protocol stack is difficult to test.

2.3 GreyHound Fuzzer

Originally, the GreyHound fuzzer framework was developed for testing WiFi protocol implementations [13]. Later, the authors added models for BLE [14] and Bluetooth classic [12], to extend the compatibility of their fuzzer. As our testing approach is built on the GreyHound fuzzer framework, especially its BLE communication functionality, we provide a brief introduction of the hardware and software aspects of this tool in the following paragraphs.

The goal of the GreyHound developers was to find vulnerabilities in BLE protocol implementations [1] and to manipulate and test all their layers. Standards compliant firmware implementations for certified Bluetooth adapters provide only limited access to the inner protocol layers, since they are only accessible through the HCI. The GreyHound fuzzer framework thus utilizes a NRF52840 dongle[1] running a custom firmware implemented in C++ and communicates with it using a USB serial connection. This allows for the use of Python in conjunction with an extension of the scapy [27] framework to craft and dissect arbitrary BLE packets, which are then sent to the dongle. The custom firmware takes care of timing constraints and the CRC calculation and sends the final packet over the air. Contrary to standard HCI implementations, the custom firmware on the dongle provides an unconstrained interface to send raw BLE packets.

The software part of the framework running on the host was implemented using Python 2.7. The framework also includes a state machine, which can initiate the sending of packets and responds according to responses received from BLE peripheral devices. A simplified version of the BLE state machine can be seen in Figure 2. To be compatible with different BLE implementations, the state machine allows for multiple possible paths, since the BLE specification leaves the exact sequence of some interactions open to developers. Because of this, the states depicted in the orange box in Figure 2 can vary in order, depending on the implementation and functionality of the peripheral device.

The state machine starts in the *scanning* state and waits for advertisements from the peripheral. When receiving an advertisement, the central proceeds to the *initiating* state, wherein a connection request is sent to initiate a connection to the peripheral. Now the peripheral can either request GATT services from the central with the central continuing to the *gatt_server* state, or the central and peripheral exchange information about supported features and properties, traversing the states in the orange box in arbitrary order. Subsequently, the central continues on the path after the orange box, negotiating pairing method, exchanging security parameters and keys and finally reading and writing to the GATT services of the peripheral. Finally, if no issues occurred, the central arrives in the *disconnect* state, where it sends a disconnect message to the

[1] https://www.nordicsemi.com/Products/Development-hardware/nRF52840-Dongle

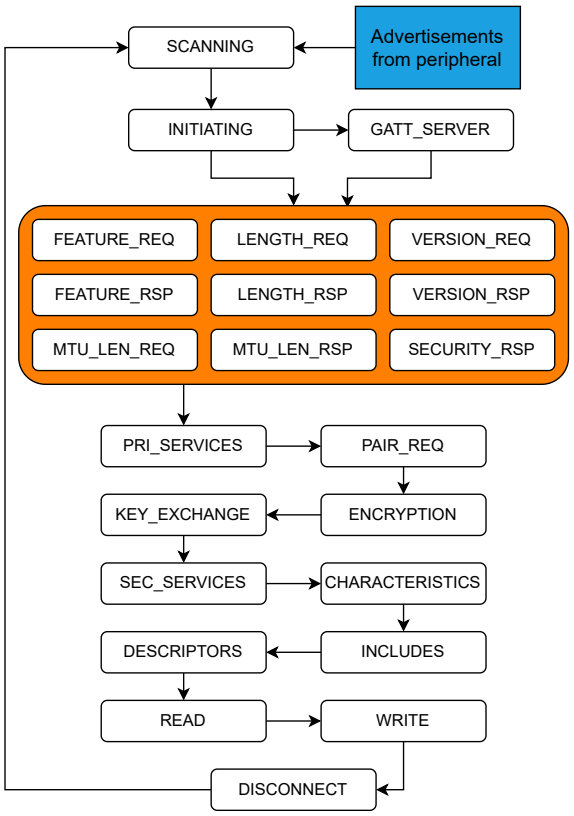

Figure 2: Simplified overview of the BLE state machine [14]. Loops and restrictions regarding state order are omitted.

peripheral and returns to the initial *scanning* state, waiting for advertisements from the peripheral.

Additionally, the GreyHound framework features a fuzzing component that uses the particle swarm optimization (PSO) algorithm of the pyGMO [19] library to guide the probability optimization. The fuzzer module contains two different models, one for WIFI and one for BLE. For every state, the models define what layers a received packet is allowed to contain, which layers of a packet should be fuzzed, what kind of field value mutator should be used for the individual layers and the probability of the individual fields being fuzzed. Initially, all fields and all layers are equally likely to be fuzzed, as long as they are contained in the list of fuzzable layers for that state.

If a field of a layer is selected to be fuzzed, one of the specified mutators is chosen by probability and applied to the field value. The mutator can be either:

- **Random byte:** The field value is replaced by a randomly generated value.
- **Zero filling:** The field value is replaced with zeros.
- **Bit setting:** The most significant bit of every byte is set to zero.

After each iteration through the state machine, the PSO algorithm adjusts the probabilities of the fuzzing model depending on a cost function and which parameters have been fuzzed before. The GreyHound authors wanted to optimize the number of unique anomalies found in a session, which is also chosen as the cost function. For more details of the BLE protocol and its inner workings, we refer the interested reader to the original work [14].

3 Related Work

Due to its popularity, threats to the security and privacy of classic Bluetooth and Bluetooth Low Energy have been studied extensively [4, 9]. Over the years, a variety of vulnerabilities have been discovered [2, 3, 5, 6, 32], often affecting millions of devices. Their impact ranges from simple denial of service attacks to remote code execution or authentication bypasses. Most commonly, finding such vulnerabilities requires significant manual effort such as reverse engineering, code inspection or modification of the source code.

The most closely related work is a more automated BLE fuzz testing approach [14] mentioned in the previous Section, which allows the testing of all layers of the protocol down to the link layer. In addition to custom firmware for the NRF52840 dongle, they constructed a state machine for BLE to utilize as part of a fuzzer guided through probability optimization. This allows for automated testing of peripheral devices with either closed source firmware or BLE development boards, which can be programmed with example applications provided by the vendor of the peripheral chip or other custom implementations. Using this approach, the authors identified 17 previously unknown security vulnerabilities (summarily dubbed *SweynTooth* by the researchers) in the firmware of various BLE controllers. The number of discovered flaws demonstrates the effectiveness of this method, which is further strengthened by the fact that the tool does not need to have access to the source code of the peripheral to test. At the same time, the probabilistic nature of fuzzing may lead to vulnerabilities remaining undiscovered despite extensive testing. This work aims to overcome this restriction through the use of CST methods.

A later work by the same group targets classic Bluetooth devices [12]. This approach is capable of inferring the state machine during execution and features a fuzzer and testing framework similar to their prior work. Instead of using the NRF528400 dongle, which only supports BLE, this research utilizes a ESP32[2] controller.

The use of combinatorial testing in the context of security testing is not new [29]. CST has been successfully used to evaluate web applications with the goal of identifying XSS vulnerabilities [7, 23, 28] and SQL injections [16, 31]. In terms of protocols, prior research attention seems to be focused

[2] https://www.espressif.com/en/products/hardware/esp-wrover-kit/overview

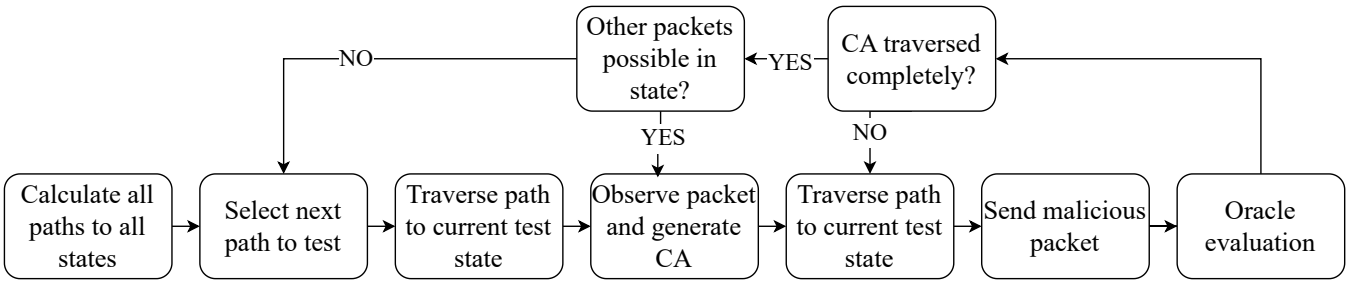

Figure 3: Overview of combinatorial testing strategy.

primarily on TLS. Existing approaches target both X.509 certificate parsers [21, 24] and the flow of protocol messages as well as their contents [15, 30]. While there exist works that aim to identify flaws in IoT devices using CST methods [16, 17], they tend to take a more high-level approach than our contribution, targeting e.g. HTTP REST services instead of lower level protocols.

4 Methodology

This section presents the methodology of our work, including the overall testing strategy, input modeling aspects, CA generation processes and oracles.

Taking into account the considerable success achieved by the authors of the GreyHound fuzzer framework while considering the fundamental drawbacks arising from fuzzing's probabilistic nature, we set out to explore the feasibility of applying CST to generate test cases for BLE implementations. CST has previously been used to perform security testing of TLS implementations [30], but the added complexity of BLE and its interconnected layers requires a more intricate approach. Our work builds upon the aforementioned fuzzing framework, but completely replaces the guided fuzzing component with combinatorial test generation. While this step necessitates the creation of additional models and oracles, our work aims to evaluate whether the guaranteed degree of input space coverage provided by CT leads to the discovery of additional vulnerabilities or bugs.

4.1 Testing Strategy

The original GreyHound fuzzing component traverses the state machine visualized in Figure 2 in an unordered way, guided by probability. In a CST setting, we want to traverse the state machine in a more structured way to ensure that all valid paths (see below) are covered. A simplified overview of our testing strategy is provided in Figure 3, the details of which are discussed in the following paragraphs.

We start by generating a set of all possible paths to every state from the state machine. Subsequently, one path from the set is selected (the exact order is not relevant to our approach, although paths to states closer to the initial state are processed first in our implementation) and we mark all transitions in this path as permissible to traverse by the GreyHound framework. In addition, all transitions that lead to retransmissions and those triggered by timeouts are marked as permitted. The final state of the chosen path is the current state to test. Additionally, we mark all transitions that originate from the current state to test as permitted.

If the current state to test is reachable via this path (which may not always be permitted by the specific SUT), the current path is marked as valid. Invalid paths are currently not tested in our approach, as they are unreachable.

If the path is valid, the next BLE packet that is about to be sent (indicated by the GreyHound framework) is analysed to determine which layers the packet consists of. This packet is the current packet to test. The CST component of our implementation then generates one CA for each of the layers of the current packet to test as well as a meta CA combining these layers, which is used for further testing. Each row in the nested CA represents a test case and contains values for the individual fields of the current packet to test. Details of the CA generation method are given in Section 4.3.

Whenever we reach the current state to test after this point, we select a previously unused row in the CA and change the values of the current packet layers according to the values in the row of the CA in order to create a modified packet which is then transmitted to the SUT. We then continue to send unmodified packets again until an error occurs or we reach the initial state (the scanning state) again, which marks the end of the test. Figure 4 shows an example where the `FEATURE_REQ` state is selected as the current state to test. Unmodified packets (denoted as *Normal Packet*) are transmitted to traverse between all states except for the transition from the state to test to the next state. To traverse further from the state to test, a modified packet is sent, which contains invalid values and is denoted as *Malicious Packet*.

When we reach the end of the CA, we check if there are further outgoing transitions from the current state to itself (i.e. loops). If yes, we generate a new CA for the corresponding packet and proceed as before. Otherwise we continue with another path until all paths to all valid states have been tested.

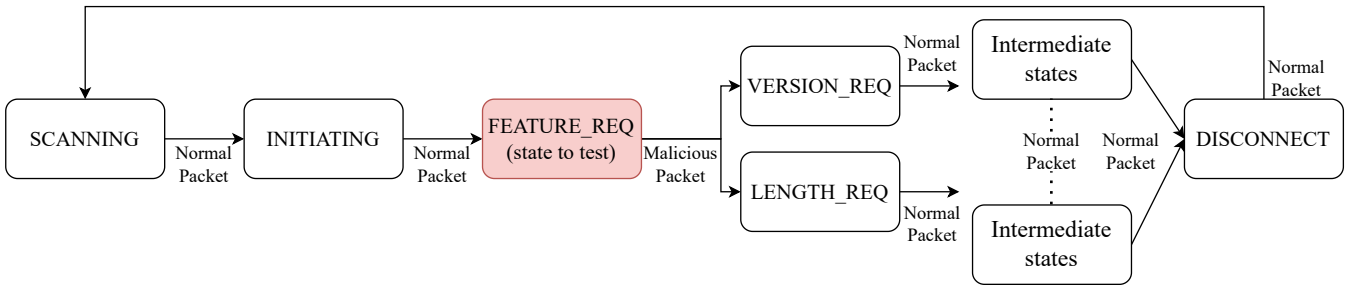

Figure 4: Example testing flow.

4.2 Input Modeling

To generate CAs for testing, we first need to create a model of the input space. This tends to be one of the more challenging tasks in the context of CT, as it commonly requires manual effort to identify all parameters and suitable values.

In this work, we view a BLE packet as a composite system of these layers, with each layer being a component. We utilize the model of layers and their respective fields (which represent our parameters) encoded in the BLE scapy extension contained in the GreyHound framework implementation [14]. For each such field/parameter, we require a set of possible values. To this end, we analyze the source code of the GreyHound framework as well as the BLE specification [1] while considering boundary values [26] of different value ranges. Additionally, we add the symbolic values "LARGER", "SMALLER" or "UNCHANGED" to the parameter values. When applying rows containing these values to a packet, we increment, decrement, or leave unmodified the current value of a field in the original packet. A further symbolic value "RECALCULATE" is added to length parameters and leads to the length value being recalculated based on the current content of the packet.

One individual IPM is constructed for each layer of the BLE protocol. CAs tend to rapidly grow in size when the number of permitted values for a paramater becomes too large. By utilizing multiple smaller models, this effect can be limited, although this slightly reduces overall combinatorial coverage. An example of an IPM for a BLE data layer is shown in Listing 1.

Listing 1: Example of an IPM for a BLE data layer.

```
BTLE_DATA_IPM = {
    'LLID': ["~0", "~1", "~2", "~3", "UNCHANGED"],
    'SN': ["~0", "~1", "UNCHANGED"],
    'NESN': ["~0", "~1", "UNCHANGED"],
    'MD': ["~0", "~1", "UNCHANGED"],
    'RFU': ["~0", "~1", "UNCHANGED"],
    'len': ["~0x00", "RECALCULATE", "~LARGER", "~SMALLER",
            "~0xff"]
}
```

Care must be taken when encoding invalid values for a particular parameter, i.e., values that are not generally permitted to be used for a field. In a process called negative value testing by the authors of PICT [11], it is favorable that only a maximum of one such value be present in a row in the CA. The reasoning behind this choice is that faults or other effects triggered by the presence of an invalid value may mask the effects of additional invalid values. In PICT, it is possible to encode such values by prefixing them with the "∼" symbol.

4.3 Covering Array Generation

The CA generation occurs dynamically during the execution of our CST method. As mentioned in the previous section, we view BLE packets as composite systems, with the layers modeled as subcomponents. To this end, we turn towards a method developed by Kampel et al. [20] that targets composed software systems. Subcomponents are modeled separately, as we have done for the individual packet layers as described in Section 4.2. Using these layer IPMs, so-called seed arrays are constructed (in this work, we selected strength $t = 2$ for all such CAs), the rows of which are subsequently combined based on a meta CA to obtain a resulting combined CA.

To illustrate this approach, we provide an excerpt of three layer IPMs in Listing 2 and the first rows of the resulting seed CAs in comma-separated values (CSV) format in Listing 3. The following paragraphs provide further details on the subsequent steps.

Listing 2: Excerpts of three IPMs used to generate seed CAs

```
BTLE_IPM = {
    'access_addr': ["UNCHANGED", "~0x8e89bed6", "~0xffffffff",
                    "~0x00000000"],
    'crc': ["UNCHANGED"]
}

BTLE_DATA_IPM = {
    'LLID': ["~0", "~1", "~2", "~3", "UNCHANGED"],
    'SN': ["~0", "~1", "UNCHANGED"],
    'NESN': ["~0", "~1", "UNCHANGED"]
}

BTLE_EMPTY_PDU_IPM = {
    'LLID': ["UNCHANGED", "~0", "~1", "~2", "~3"],
    'Length': ["~0x00", "RECALCULATE", "~LARGER",
               "~SMALLER", "~0xff"]
}
```

Listing 3: Excerpts of three seed CAs

```
access_addr,crc
--------
UNCHANGED,UNCHANGED
~0x8e89bed6,UNCHANGED
~0xffffffff,UNCHANGED

LLID,SN,NESN
--------
~0,UNCHANGED,UNCHANGED
UNCHANGED,~0,UNCHANGED
UNCHANGED,UNCHANGED,UNCHANGED

LLID,Length
--------
UNCHANGED,~0x00
UNCHANGED,RECALCULATE
UNCHANGED,~LARGER
~0,RECALCULATE
~2,RECALCULATE
```

At this point, we have obtained an assembly of layer/seed CAs, which provide $t = 2$ coverage for the subcomponents of the composite system. Those seed arrays now have to be combined into a single array. To this end, we first determine the number of rows in each of the seed CAs (in the example above, the first two array excerpts have three rows, while the final array has five rows). Using this information, a meta IPM is constructed wherein each parameter represents a layer CA and takes values between 1 and the number of rows. Indices that refer to rows in the layer CA containing negative values are additionally prefixed with the "∼" symbol in order to prevent masking effects across layers. Listing 4 shows the meta IPM resulting from the sample seed arrays in Listing 3.

Listing 4: Example meta IPM

```
META_IPM = {
    'BTLE_ROWS': ["0", "~1", "~2"],
    'BTLE_DATA_ROWS': ["~0", "~1", "2"],
    'BTLE_EMPTY_PDU_ROWS': ["~0", "1", "~2", "~3", "~4"]
}
```

This meta IPM is subsequently used to generate a meta CA at strength $t = 2$, each row of which references a single row in each of the layer CAs. The meta CA then covers all $t = 2$ combinations of rows from the seed CAs that represent the layers of the current packet. Listing 5 shows an excerpt of a meta CA for our running example.

Listing 5: Excerpt of example meta CA

```

```

By combining the contents of these referenced rows, we obtain a single combined CA that is suitable to be used in our testing flow as described above. Listing 6 shows the first three rows resulting from combining the seed CAs according to the meta CA given in Listing 5. The resulting CA offers not only guaranteed input space coverage within each layer, but also across layers, to a degree that can be adjusted by increasing the strength (at the cost of larger test sets and thus additional execution time).

4.4 Oracles

In order to determine whether the crafted inputs submitted by our approach crashed the SUT, we implement two oracles. The first uses a secondary NRF52840 dongle with the custom GreyHound firmware to receive packets sent by the peripheral device SUT. If no packets are detected for over a second, the oracle marks the test as failed; if the initial state is reached without such a timeout, the test is deemed a success. This oracle aims to detect situations in which the peripheral device becomes unreachable for a longer period than usual. In this case, the peripheral might reboot itself, becoming responsive again after a few seconds, but could also end up in a state in which it requires a manual reboot by cycling the power provided via USB (see Section 5).

Since most development boards we tested have a serial port available, we decided to use it for an additional oracle. If the device under test has a serial port, we connect to it and listen for output from the peripheral device. The received serial output is checked for specific keywords such as "trace", "crash" and "dump". If one of those words is detected, the oracle marks the test as failed.

The first oracle is generally usable for every BLE device. However, the generality of the approach is also a potential problem, since it can lead to false positives if the device merely requires more time than usual to enable advertisements again after a disconnect event.

The second oracle is less general, requiring the device under test to have a serial port and additionally assumes that there is debug output containing specific keywords. Most toolchains of the devices we tested provide settings to enable debug output, which lead to the devices giving more detailed information over the serial connection. During our experiments, we only encountered one device that did not produce serial output.

The oracles we developed are capable of identifying crashes that either lead to a recognizable crash dump being

transmitted via a serial port or to prolonged inactivity of BLE transmissions of the SUT. False negatives may occur if the SUT exhibits incorrect behaviour due to received packets but does not become unresponsive and does not output a crash dump (or outputs it in a manner that is recognized by our oracle). Examples of such cases could be that the peripheral accepts an encryption key that is set to only zeros, which would compromise the privacy of the data exchange, or scenarios in which the peripheral accepts invalid authentication parameters, giving an attacker access to its services.

False positives of our first oracle that listens for transmitted packets of the peripheral could occur if the oracle dongle itself crashes, which is trivial to detect, or the SUT takes significantly longer than expected to transmit packets, which is arguably a denial-of-service condition by itself. False positives of the second oracle, which monitors the SUT's serial output, could occur if the SUT's output contains certain keywords indicating a crash dump without actually having crashed.

To exclude these cases, we constructed automated reproducer scripts for all identified issues, removing cases that did not reliably lead to an unreachable SUT and thus eliminating false positives before reporting them to affected vendors.

5 Setup

Our test setup consists of two NRF52840 dongles running the custom firmware of the GreyHound framework and a laptop running Ubuntu 22.0.4 as the host. The dongles are connected to the host via USB, with one being used for sending and receiving BLE packets from the peripheral device under test, while the other passively listens for packets transmitted by the peripheral device, thus acting as one of the test oracles. Figure 5 depicts a simplified version of our setup.

Submitted test cases and their results are stored in a MongoDB instance. A database entry consists of the CA row used for the test, the packet history recorded during the test, the first received response after the test, the results of both oracles, as well as the current state and path to test. Additionally, we store messages received via the serial port of the BLE peripheral device for post-analysis.

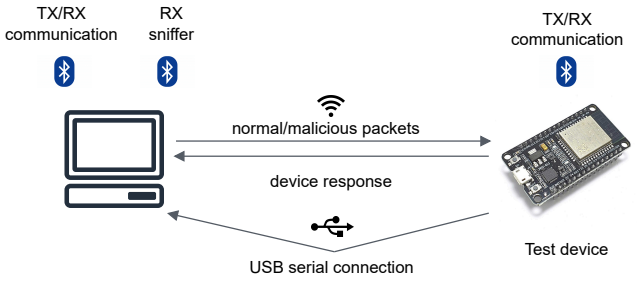

Figure 5: Overview of the test setup.

During testing, we encountered issues with hardware reliability. Some of the evaluated BLE peripheral devices as well as the NRF52840 dongle used for BLE communication crashed or became unresponsive at times, possibly due to race conditions, since we could not reliably reproduce them. We thus implement an automated way of resetting the power to the devices based on relays that interrupt the USB power supply for a few seconds. These relays are controlled via an ESP32 micro-controller that can be communicated with using a REST API. By power cycling the USB devices in this manner, we can reliably reset them to a working and responsive state and repeat the test. Because of the sending dongle occasionally becoming unresponsive, we used a separate receiving dongle as oracle to prevent false positive results in these cases. A test is only logged if a malicious packet was actually sent. Otherwise, the USB devices are reset and the test is repeated.

As the evaluated devices exhibit wide variations in their performance, commonly requiring more than a day to execute a full test set, we parallelize our setup by replicating it four times in total (i.e. using four host computers, each hosting a SUT device and two NRF52840 dongles).

5.1 Target Devices

As we wanted to test the BLE stack implementation of different BLE chips, we needed to source a variety of BLE chips, preferably integrated in development boards. Development boards typically provide easy access to the input and output pins of the chip and ship in a plug-and-play package, integrating the necessary circuitry around the chip such as power supply and serial connections. We further included chips that had previously been tested using the GreyHound fuzzer in order to make a performance comparison. For these devices, we additionally evaluated firmware versions that were newer than those analyzed in the earlier work in order to identify whether the issues that were published as part of the SweynTooth set of vulnerabilities had been successfully remediated. Table 1 shows details of the SDKs and sample applications of the chips we tested.

5.2 Challenges

In addition to the previously mentioned issue of SUTs and dongles becoming unresponsive or crashing, we encountered specific challenges when testing certain devices.

Most notably, the Arduino SDKs of the Apollo3 and MG126 chips were still under development at the time of writing, with their BLE implementations remaining incomplete. This resulted in some unexpected behaviour during testing; devices did not traverse the complete state machine when they reached a state that requires functionality that was not yet implemented, leading to the low number of executed tests shown in Table 2.

For some devices (i.e. ch582m and w801), the onboard USB connectivity was only suitable for flashing new firmware, while capturing the serial output required an additional adapter. In these cases, we utilized an FT232RL USB to serial adapter to enable the use of our second oracle.

In other cases, the testing process was extremely slow due to some states not being reliably reachable via certain paths. This occurred while testing the MG126, CC2640R2 and ESP32 chips. Throughout our experiments, we implemented a routine that identified when paths did not reach the state to test for the last 400 seconds and excluded them from our results, instead proceeding with the next available path.

6 Evaluation

Due to the instability of some of the tested devices, we validated test cases that were marked as failed by either of our oracles using a simple reproducer script that replays the same inputs and records the results. Only those test cases that were deemed reproducible (and therefore not false positives) were selected for further analysis. The following sections present the analyzed results and compare them to those of the previous work based on fuzzing [14].

6.1 Results

While executing the tests, we witnessed crashes and availability issues in most of the devices we tested. Table 2 shows a summary of the reproducible unique faults we encountered in the individual chips and their respective SDK versions. We consider a fault to be unique if the fields/parameters that trigger it have not been identified as part of the trigger of another fault or if the values of overlapping fields/parameters are considered to be semantically different according to the BLE specification or an expert security analyst's opinion (e.g. if a length field's value changes from 1317 to 1318, it would commonly not be considered to be semantically different, while a difference in the packet's `TYPE` code would indicate a separate fault). The column *TO* (short for timeout) lists the number of test cases that led to the SUT becoming unresponsive for at least four seconds, but returning to normal operation after at most two minutes without requiring further intervention. The column *URWF* (Unavailable but Recoverable With Code Fix) details the number of cases where a SUT became unresponsive and required a restart when using the unmodified example code. In these cases, the BLE stack was still properly responding to GAP (General Access Profile) and HCI (Host Controller Interface) commands from the application and despite advertisements not being re-enabled automatically, it was possible to modify the application code to reactivate them. The column *URN* (Unavailable Reset Needed) shows the number of cases in which the SUT became unavailable after receiving a malicious packet and required a reset to function again. When trying to modify the example code to reactivate advertisements in these cases, the BLE functions returned error codes or behaved unexpectedly. Finally, the column *Dump* shows how often a core dump was sent from the SUT to the host PC via serial connection, followed by a restart of the SUT.

Most timeouts and unavailability issues occurred in the *initiating* state, after a connection request with invalid parameters (i.e. a malicious packet) was sent to the peripheral device. An example of such a packet is given in Listing 7, with the invalid value being `0x00000000` for the `access address` (AA) field, a parameter used for handling collisions between peers sharing the same physical radio channel. When sending such a packet to an ESP32 flashed with the `bleprphrl` example application in SDK version 5.0, the BLE stack of the ES32 logs a connection event despite the central not being connected. Because the slave is in a state that indicates that a valid connection has been established, advertisements are not enabled again, which renders the device unusable until the device is reset. Additionally, when trying to re-enable advertisements manually, the following error is logged: "error enabling advertisement; rc=6 (BLE_ERR_PINKEY_MISSING=)". However, a missing PIN error is not consistent with this state in the BLE protocol and can not occur at this point under normal circumstances. This behavior suggests that the BLE

Model	Version	TO	URWF	URN	Dump	Total

Table 2: Identified unique faults per device and software version. The column TO refers to the number of Timeouts, URWF to Unavailable but Recoverable With Code Fix, URN means Unavailable Reset Needed, and Dump indicates a crash dump output by the SUT. The Total column lists the number of executed test cases. Three issues identified in the old version of the CC2640R2 were still present in the later version. For ESP32, one issue was fixed in version 5.0, but a new URN was introduced. In total, 19 unique faults were identified.

stack is in unknown state and currently malfunctioning. When sending the same packet to an ESP32 flashed with the same application in version 4.1, trying to manually re-enable advertisements leads to HCI desync errors and eventually a core dump with controller restart, which indicates an issue with memory management.

        SCA = 0
        hop = 5
```

The core dump issued by the bl602 chip was triggered in the *length request* state, which is part of the initial central peripheral setup procedure and requires the field `max_rx_bytes` to be set to 0. The Apollo3 exclusively became unresponsive in the *pairing request* state, after sending a malicious pairing request to the peripheral device, containing an invalid value for the authentication method.

In addition to the quantitative assessment, we also used the available JTAG ports on the individual SUTs to gather more insight into the identified errors. The results of our analysis indicate that most errors lead to similar behavior. After receiving a malicious connection request, the peripheral devices fail to correctly validate the connection parameters and process the packet as a valid connection request. Since at least one of the parameters is not valid, the BLE central can not communicate with the peripheral device anymore, while the peripheral device is stuck waiting for events from the BLE stack. In this state, the peripheral devices are practically unusable until they are reset, as there is no valid connection established and other devices can not discover them because advertisements can not be re-enabled. The exact impact varies by SUT depending on the field and value of the malicious packet. This is manifested by BLE functions returning different error codes when trying to reactivate advertisements and the sequence of GAP events.

According to the specification, BLE implementations should follow the rule *EffectiveConnectionInterval = ConnectionInterval * (1 + Slave Latency)* [18], and *EffectiveConnectionInterval* must not exceed a maximum of 16 seconds if no packets are received. In our tests, most devices did not drop the connection or were not able to reactivate advertisements after receiving a malicious packet. Simultaneously, applications received a reduced number of GAP events from the BLE stack compared to normal connections. This could indicate an issue in the parameter validation and state transition of the GAP implementation, which could also lead to further corruption of the BLE stack when invalid parameters

Table 3: Comparison of combinatorial security testing (CST) versus GreyHound (GH) fuzzer on current SDK versions. The smallest number of tests for a particular SUT as well as the greatest number of identified issues is highlighted in bold. As discussed in Section 6.2, anomalies are not assessed by the CST approach.

are processed. The MG126 and RTL8720DN were the only devices that were able to automatically recover in some of these cases; they were, however, often unreachable for over a minute, meaning that these inputs led to Denial of Service (DoS) conditions.

Most of the identified faults manifest themselves as timeouts and may be exploited to perform DoS attacks. They are either caused by the device firmware itself or the example application executed on the SUT. Inputs leading to devices transmitting core dumps indicate memory access violations, which may be exploited to gain control over the SUT or leak cryptographic key material or other secrets.

6.2 Comparison

To evaluate the performance of our combinatorial testing approach, we executed the fuzzer as used in the original work [14] against our suite of SUTs. The effectiveness of fuzzing partially depends on the available execution time. As the maximum time required to test a SUT with our approach was just under one day, we ran the fuzzer for 24 hours and then compared its output to that of our method. A summary of the results is given in Table 3.

The oracle of the GreyHound fuzzer not only checks for timeouts and crashes (listed under *Issues*), but also for deviations from the BLE specification (e.g. BLE devices responding to packets in states in which they should not or accepting invalid packets), which the authors call anomalies. Unfortunately, manual analysis indicates that this oracle produces a significant number of false positives. We thus relied on the oracles described in Section 4.4 and opted to not assess anomalies for our approach, leading to their absence from Table 3. Furthermore, due to the aforementioned reliability issues, we created a script that aims to replay inputs indicated by the GreyHound fuzzer as leading to faults and excluded those that were not reproducible.

The column *Tests* indicates the total number of test cases executed. While the execution rate of the fuzzer is higher than that of our approach (often caused by the time required to identify unreliable paths as noted in Section 5.2), it proved unreliable for some devices such as the W801, leading to a lower number of iterations. Additionally, the NRF52 dongle became unstable at times; while our approach implements a reset functionality (see Section 5), the original work does not include this feature.

Overall, the CST approach presented in this work identified more faults than the GreyHound fuzzer in current firmware versions, but did not find any anomalies.

Re-testing

The original work identified several issues that the authors subsequently communicated to vendors. The aforementioned results indicate that most of these bugs have been addressed in current firmware versions. To provide a comparison that is closer to the circumstances of the earlier work, we re-tested some of the devices using old versions offered by vendors.

Table 4 summarizes the results of our approach compared to the results reported by the original work, which always reported results for 1,000 tests. While our method identifies a greater total number of faults, results vary across different devices and types of triggers; most notably, our approach currently makes no attempt to alter the sequence of protocol messages, while the GreyHound fuzzer does offer this functionality. Accordingly, we were unable to identify some of the faults found by the earlier work.

For the ESP32 SUT, one of the identified issues overlaps with the earlier work (the device crashes when receiving a connection request with the `chM` parameter set to `0`), while the second fault found using GreyHound relies on an alteration of

the sequence. In contrast, the second issue identified by our approach is triggered merely through message parameters.

		Tests		Issues		Anomalies
Model	Version	GH	CST	GH	CST	GH
CC2640R2	3.30.00.20	1,000	1,309	2	**5**	1

nRF52	15.3.0	1,000	1,309	**0**	**0**	1

Table 4: Comparison of CST versus GreyHound (GH) fuzzer applied to old firmware versions.

6.3 Lessons Learned

Applying CST to a complex protocol such as BLE occasionally proved challenging, which led us to adapt our models. Earlier models that did not contain markers for invalid values were sometimes unable to detect errors that required only a single value to be triggered due to masking effects. An interesting observation is that all errors identified through our approach only required one parameter to assume a specific value (although the parameter and value varied across SUTs and errors); in other words, even a CA of strength $t = 1$ would have been able to trigger these issues. Since the GreyHound fuzzer was not able to find these faults, it might indicate that the fuzzer tends to alter too many fields and therefore suffers from masking effects.

Another common issue was that higher strengths and covering of interactions between all layers of a packet tends to lead to very large test sets. It might be beneficial to only cover interactions between layers if they have fields that directly influence each other; for example, this includes length or type fields. This could be achieved through the use of variable-strength CAs [25].

Finally, we performed internal experiments to introduce known combinatorial sequence constructions with the goal of varying the ordering of packets. However, the resulting number of test cases was deemed infeasible for practical use. Most issues discovered using GreyHound that rely on reordering of packets occurred in the pairing or encryption processes (which are also the most complex aspects of the protocol and often rely on information exchanged in previous packets). This indicates that it may prove beneficial to only mutate orderings in these states and leave sequences of packets in later states intact. In contrast to variable-strength CAs, we are not aware of existing work that would result in variable-strength sequence coverings.

7 Responsible Disclosure

We notified the vendors of all affected devices 90 days in advance for the purpose of facilitating a coordinated responsible disclosure process. At the time of writing, Espressif and Realtek have been the only two companies that responded. Espressif acknowledged the issues and released fixes for all of the issues we found in all affected software versions and will assign CVEs in the near future. Espressif was the only contacted vendor running a dedicated bug bounty program for software vulnerabilities.

As the 90 day disclosure period has passed, we have uploaded proof of concept code to reproduce the vulnerabilities we found. The example code, together with MongoDB database exports of the test results, is available for download at https://zenodo.org/records/14647110.

8 Conclusion

This work presented a combinatorial security testing approach for modeling and testing Bluetooth LE communications utilizing a modified GreyHound fuzzing framework. Our method provides combinatorial coverage guarantees regarding the input space of wireless devices while minimizing the required number of test cases, leading to the discovery of 19 distinct issues across 13 device/firmware combinations.

A comparative experimental evaluation against the earlier work points towards increased fault detection capabilities of our approach. This is also confirmed when re-testing older firmware versions that contain the bugs uncovered using GreyHound. However, issues that require a modified order of packets to be triggered are currently out of scope of our work. Additionally, the execution rate of our implementation is hampered by the slow identification of unreliable paths.

9 Future Work

A logical extension of our work is the addition of combinatorial sequence modeling and Sequence Covering Arrays (SCAs) [10], an approach that has successfully been used to test protocols [15] and offers additional coverage guarantees. To avoid the problem of combinatorial explosion when generating test sets, it might be beneficial to additionally add a guiding heuristic with adjustable weights, allowing testers to focus their resources on the most interesting components first.

Abstract

Large language models (LLMs) have been increasingly adopted in a variety of application scenarios. However, in spite of the high demand for both tuning and inference, GPUs are often underutilized because they are devoted to a single task. A common argument for single-purpose deployments is the need to meet strict service-level objectives (SLOs). As LLM workloads become more complex, there are, indeed, significant challenges in achieving high utilization while still guaranteeing the necessary low latency. In this paper, we present LLMStation, a flexible spatial-temporal multiplexing and scheduling system for concurrent LLM fine-tuning and inference. LLMStation adopts several novel approaches, including a new iteration-level multitasking scheduling mechanism, an Autograd engine that transforms a tuning task into a suspendable pipeline, and an inference engine capable of batching inference and tuning requests. Our evaluation shows that LLMStation delivers 1.38× to 14.77× the throughput of state-of-the-art systems while meeting inference latency SLOs. These performance gains remain under various setups and workloads, proving LLMStation to be an effective tool to increase the efficiency of LLM deployments.

1 Introduction

GPUs are widely used for AI applications to maximize performance per watt. Due to their high cost [63] and power consumption, operating GPUs at high utilization is critical for minimizing the total cost of ownership and for making optimal use of limited power budgets [50, 58, 59].

However, even resource-intensive LLM workloads struggle to keep GPU hardware highly utilized as applications like LLM inference consist of phases with different resource requirements, which often leave some parts of the GPU idle for a significant fraction of time [30, 50, 52, 58, 59]. For example, during the memory-bound decoding phase of serving a Llama3-8B model on A100 GPUs, Microsoft reports less than 10% GPU compute utilization [16, 33].

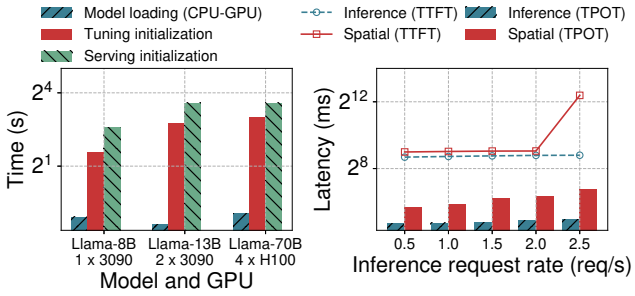

Figure 1: Measured context switch overhead (left). Performance interference between LLM tuning and serving co-located on the same GPU (right).

A natural way to improve resource utilization and cost is to consolidate models and requests on fewer GPUs rather than dedicating a single GPU for each task or model, with time-sharing and/or spatial sharing [23, 43, 52, 58, 59]. Time-sharing the GPU for workloads involving multiple models or tasks can lead to high context-switching overhead, which becomes a critical bottleneck [26, 50]. Figure 1(left) shows the time taken to load models to the GPU memory and initialize the execution engines for inference or fine-tuning (e.g., vLLM [36] and torchtune [54]). As the experiments show, this can take seconds to minutes. In addition to context-switching overhead issues, temporal sharing systems for mixed tasks such as FineInfer [26] may not be able to meet strict latency SLO requirements when models are relatively large, and waste computation resources in the memory-bound decoding phase.

The alternative of spatial-sharing GPUs also faces significant challenges. LLMs require large GPU memory, up to hundreds of GBs, thus preventing strict isolation solutions from being usable, such as the Nvidia virtual GPU [3] which divides the GPU memory into independent small chunks. When relaxing strict isolation, there can be significant interference between processes. Figure 1(right) highlights the performance degradation when tuning and serving tasks on Llama-3.1-8B [22] are co-located on an RTX 3090, with p99

Time to First Token (TTFT) and p99 Time Per Output Token (TPOT) increasing to up to 13.2× and 3.6×, respectively.

To increase the efficiency of LLM systems and reduce resource consumption, in this paper we explore how to share a GPU between LLM parameter-efficient fine-tuning (PEFT) and inference/serving in a spatial-temporal manner, as PEFT creates new opportunities for multiplexing memory and computation resources by sharing base models [26, 29, 44] and co-execution of memory-bound and compute-bound operations [26, 44]. In engineering practice, PEFT is frequently conducted to adapt base models to various tasks and is also commonly performed continuously [10, 13, 15, 31] after deployment to address potential data drift. This scenario is increasingly relevant for applications using on-premise infrastructure, where fine-tuning and model serving compete for limited resources. This is particularly the case when the inference demand fluctuates [21, 50].

To cope with the challenges described above, we propose LLMStation, which employs a novel strategy for spatial-temporal multiplexing. The key insight is that LLM tuning and serving tasks have distinct workload patterns. By spatially batching and temporally reordering tasks, LLMStation simultaneously achieves controllable interference between processes, rapid context switching, maximized LLM fine-tuning throughput, and LLMs serving within the SLO limits.

LLMStation has been implemented in 3k lines of code. It includes a set of novel techniques including an iteration-level multitasking scheduling mechanism, an Autograd engine transforming a tuning task into a pre-emptable pipeline, an inference engine that batches inference requests and tuning requests, and a memory manager that manages base models, adapters, and intermediate states between different tasks. A comprehensive evaluation on Nvidia RTX 3090 and H100 GPUs shows that LLMStation achieves up to 14.77× the fine-tuning throughput of state-of-the-art systems, while maintaining inference latency SLOs. Microbenchmarks confirm that scheduling and context-switching overheads remain minimal. Despite that focusing on the specific but highly relevant use case of LLM tuning and serving, the ideas behind LLMStation can be generalized and the design provides the foundation for future research into GPU virtualization and resource multiplexing to bypass the existing hardware and driver limitations.

2 Background and Motivation

In this section, we provide background on PEFT, LLM inference, and GPU resource multiplexing to motivate our work.

2.1 Parameter-Efficient Fine-Tuning

With the growing adoption of LLMs, fine-tuning becomes more and more frequent in order to adapt base models to different data and downstream tasks [10, 13, 51]. As shown in Figure 2, more than a hundred thousand of adapters were uploaded to Hugging Face in 2024. Even after models are deployed for inference, it is common and important to continue fine-tuning them to adapt to potential data drift [10, 13, 15, 31], as reflected in the continuously changes in model weights for these Hugging Face model repositories.

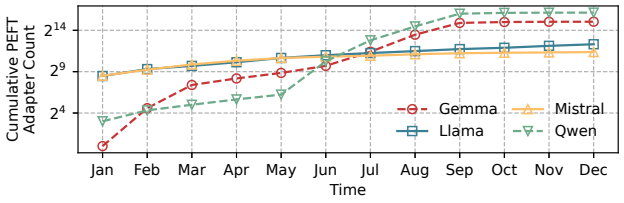

Figure 2: The number of PEFT adapters based on popular open-source model series uploaded to Hugging Face in 2024.

To make fine-tuning cost-effective, various PEFT techniques [29, 37, 39, 41, 42] have been proposed to reduce its memory requirements while retaining comparable statistical performance. The core idea of PEFT technique is to freeze most parameters of the pre-trained model and only update a small part of the model parameters (i.e., adapters), which can greatly reduce the memory footprint of the optimizer state during fine-tuning. A representative PEFT technique is Low-Rank Adaptation (LoRA) [29] that freezes the whole pre-trained model and only fine-tunes extra rank decomposition matrices injected in each transformer layer. The output of a LoRA layer can be formulated as:

$$h(x) = Wx + \Delta Wx = Wx + BAx,$$

where $W \in \mathbb{R}^{d\times k}$ is a pre-trained matrix, and $B \in \mathbb{R}^{d\times r}$ and $A \in \mathbb{R}^{r\times k}$ are trainable matrices. By setting the rank $r \ll min(d,k)$, the number of trainable parameters in LoRA fine-tuning can be reduced by a factor of 1000 compared to full parameter fine-tuning.

2.2 LLM Inference

LLM inference is an auto-regressive process that, given an input sequence $(x_1, \cdots, x_n)$, generates an output sequence $(x_{n+1}, \cdots, x_{n+T})$ according to:

$$p(x_1, \cdots, x_{n+T}) = p(EOS|x_1, \cdots, x_{n+T}) \prod_{t=1}^{n+T} p(x_t|x_1, \cdots, x_{t-1}),$$

where EOS is the end-of-sequence symbol. Mainstream LLM serving systems [36, 62] divide the process into two phases: (1) The prefilling phase generates the first new token x_{n+1} and stores the KV cache tensors representing the model states of the input tokens; (2) The decoding phase takes the latest generated token as input, computes and stores its KV cache tensors. Then it utilizes all KV cache tensors to generate a new token. The decoding phase will execute multiple decoding steps until the generation length limit T is reached or the EOS symbol is encountered.

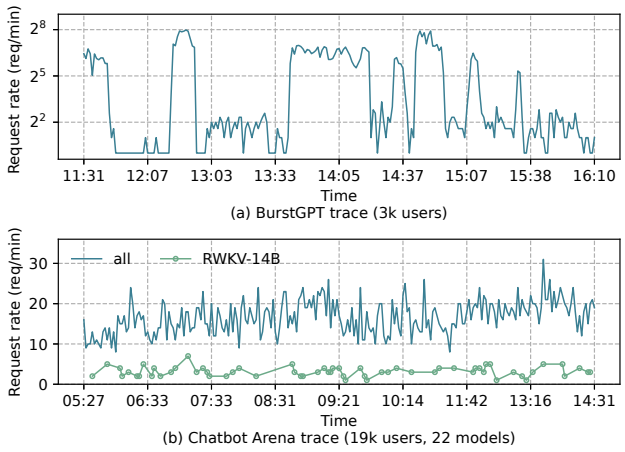

Figure 3: Real-world LLM inference workloads, BurstGPT [57] and Chatbot Arena [65].

2.3 Resource Multiplexing in LLM Workloads

The characteristics of LLM workloads reveal opportunities to improve GPU utilization by colocating LLM tuning and serving tasks as described in Section 2.3.1. However, in the presence of SLOs, present systems struggle to achieve high utilization while still guaranteeing the necessary low latencies as discussed in Section 2.3.2.

2.3.1 Opportunities

The advances of open-source LLMs make self-hosting LLMs in on-premise or cloud servers an attractive alternative to cloud APIs. These deployments usually over-provision GPU resources based on peak load, but the huge minute-to-minute fluctuations [21, 50] in request load lead to inevitable underutilization of resources during certain short and discrete time periods. Figure 3 shows the request loads of two real-world LLM inference workloads from thousands of users (i.e., BurstGPT [57] and Chatbot Arena [65]). The underutilization of GPU resource will be more serious if the request loads to multiple LLMs are unbalanced as shown in Figure 3(b). This observation reveals an opportunity to utilize idle GPU cycles of the highly fluctuating LLM serving workloads.

On the other hand, the Model FLOPs Utilization (MFU) of the LLM decoding process is typically less than 5% [64], because each decoding step loads and evicts the entire model between HBM and SRAM, yet the computation involves only the last generated token rather than the whole sequence. This observation reveals an opportunity to co-execute compute-intensive PEFT and memory-intensive LLM inference to maximize GPU computation utilization.

Tuning base LLMs for downstream tasks often only requires hundreds [51] or thousands [11] of labeled data samples, which can be completed in ten minutes to an hour using one or a few GPUs. The high frequency of computation-intensive LLM fine-tuning, along with its relatively low to moderate time and resource demands, makes it an ideal task for utilizing otherwise idle GPU capacity.

In addition to utilizing spare computing resources in the fluctuating LLM serving workloads, the growing popularity of AI PCs [12, 14] has also made resource multiplexing of PEFT and serving an emerging requirement. AI PCs enable users to locally run inferences on LLMs and regularly finetune them using their personal data [12, 26], highlighting the need for optimized resource multiplexing between these tasks.

2.3.2 Challenges

Previous studies have explored various resource multiplexing techniques to improve GPU utilization. However, existing solutions cannot maximize GPU utilization while meeting the SLO when co-executing PEFT and LLM inference, as illustrated in Figure 4.

Base model multiplexing. The increasing size of LLMs renders out-of-the-box solutions [1, 3, 8]—where each task or fine-tuned LLM must hold an exclusive copy of the base model—less practical, as even a single LLM can exhaust the entire GPU memory capacity, preventing the sharing of compute and memory bandwidth across different tasks or fine-tuned LLMs. Therefore, recent frameworks [18, 26, 31, 44, 48, 61] combine base model multiplexing (i.e., sharing the base model across different tasks and fine-tuned LLMs) with temporal multiplexing and/or spatial multiplexing to create opportunities for GPU resource multiplexing.

Temporal multiplexing. FineInfer [26] proposed *Deferred Continuous Batching* to schedule PEFT and LLM inference tasks in a temporal multiplexing manner [8]. The advantage of temporal multiplexing in co-execution is that it does not interfere with LLM decoding, thus ensuring that the TPOT of LLM inference meets the SLO. However, as the input sequence length of PEFT becomes longer or the model size becomes larger, TTFT will experience a significant delay because LLM inference cannot start until the current step of PEFT ends, as shown in Figure 4(a). Figure 5(left) shows that fine-tuning latency increases with input sequence length and model size, exceeding the commonly used TTFT SLOs.

Spatial multiplexing. An out-of-the-box solution is to use Nvidia MPS [1] with high-performance LLM serving and fine-tuning frameworks to schedule PEFT and LLM inference tasks in a spatial multiplexing manner. By carefully configuring `CUDA_MPS_ACTIVE_THREAD_PERCENTAGE` to partition the computing units (i.e., streaming multiprocessors), spatial multiplexing can maximize GPU utilization while ensuring SLOs when processing static LLM workloads. Besides inheriting the aforementioned drawbacks of out-of-the-box solutions, its main limitation is that the percentages are fixed at framework startup and cannot be adjusted dynamically during task execution. Figure 4(b) shows that, if the percentage of computing units allocated to PEFT is not restricted, the TPOT

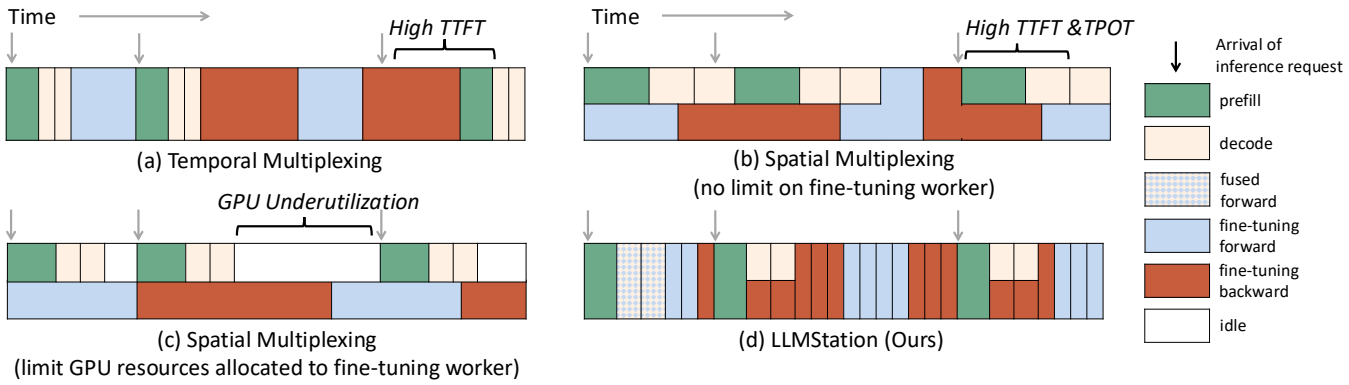

Figure 4: Illustration of different task scheduling strategies.

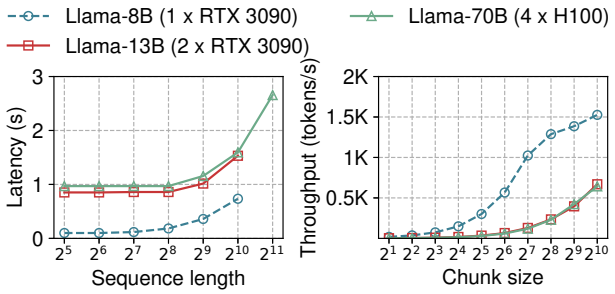

Figure 5: Latency for LoRA fine-tuning per sample for different sequence lengths and model sizes. (left) Throughput of chunked-training for different chunk sizes and model sizes. The complete input sequence length for each sample is fixed to 1024. (right)

of LLM inference becomes very high with many LLM inference requests. If one restricts the percentage of computing units allocated to PEFT, GPU resources will be underutilized when the LLM inference request load is low (Figure 4(c)).

FlexLLM [44] leverages chunked-training [40] to further break down the PEFT tasks. It divides the input sequence into several chunks and performs forward and backward passes on each chunk separately. By storing and reusing the results and states of each chunk required by rest chunks, chunked-training can achieve the same results as regular PEFT. Nevertheless, it is subject to two significant limitations. First, as shown in Figure 5(right), shorter input sequences cannot fully utilize the computing resources of the GPU [19, 34, 35, 38, 56] and it incurs additional data movement overhead. If the input sequence is divided into N chunks, the whole LLM needs to be loaded from slow HBM to fast SRAM $2N$ times. Second, it may degenerate into simple temporal or spatial multiplexing in real-world workloads and suffers from the same problems as the latter. For example, if chunked training does not split the input sequence to avoid incurring additional overhead when no LLM inference requests are running, it cannot ensure the SLO for newly arrived LLM inference requests while processing the current PEFT step.

3 LLMStation Overview

In this section, we give a brief overview of LLMStation, whose architecture is illustrated in Figure 6. LLMStation follows three design principles: (1) *SLO-guarantee*. The co-execution of PEFT and LLM inference should not violate the performance SLOs of LLM serving. (2) *GPU utilization maximiazion*. Our primary objective is to maximize the GPU utilization in each short time slice to improve PEFT throughput under the highly fluctuating real-world LLM serving workload. (3) *Memory efficiency*. The system should be able to reduce memory consumption by sharing common base model weights, adapter weights, and states between PEFT and inference. The principal components are as follows and details in Section 4 and Section 5:

1. SLO-aware task scheduler (Section 4). LLMStation is built around an iteration-level multi-tasking scheduling mechanism that improves PEFT throughput by assigning proper number of PEFT tasklets to be executed with the current inference iteration according to the SLOs. Before the execution of each iteration, the scheduler obtains the latencies of the different kinds of tasks using profiling results, cached runtime records or its own latency predictor, and then uses its planner to adaptively determine the number of PEFT tasklets to execute together.

2. Suspendable automatic differentiation engine (Section 5). Achieving our proposed scheduling mechanism requires system support to decompose the PEFT task into tasklets that can be executed together with the inference iterations without violating the SLO. We do so by taking an existing automatic differentiation engine (PyTorch Autograd [46]) and transforming its backward path to coroutines.

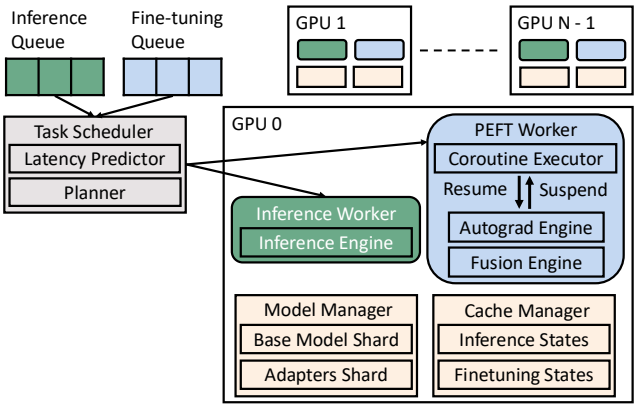

Figure 6: LLMStation overview.

3. Workers. LLMStation divides the workers into PEFT workers and inference workers to handle different parts of the co-execution in different situations: (1) If inference workers are in the prefilling phase, the PEFT workers will be suspended. (2) If the inference workers are in the decoding phase and PEFT workers are in the forward pass, the PEFT workers will fuse their forward pass and the decoding step of the inference workers. (3) If the inference workers are in the decoding phase and PEFT workers are in the backward pass, the PEFT workers will run PEFT tasklets in parallel.

4. Memory manager. Leveraging base model multiplexing, LLMStation's GPU-CPU memory manager only keeps one copy of the base model, adapter, and inference state, which is shared by PEFT workers and inference workers. Only the fine-tuning state is exclusive to PEFT workers. When the available GPU memory is insufficient to hold the new inference states, LLMStation can swap some GPU tensors to CPU memory and swap back when GPU memory is sufficient.

4 LLMStation Scheduler

In this section, we describe the detailed design of LLMStation's scheduler. At its core is a new iteration-level multitasking scheduling mechanism that improves PEFT throughput by co-executing PEFT tasklets with inference requests without violating SLOs, as illustrated in Figure 4(d).

4.1 Scheduling Strategy

The pseudocode in Algorithm 1 shows how LLMStation's scheduling strategy co-executes PEFT and LLM inference. Whenever new inference requests arrive (lines 8 - 11), the scheduler dispatches them to the inference workers to perform the prefilling step (line 18) while suspending the PEFT workers. Before performing the decoding step, the scheduler will send the batch size and length of input sequences, the current phase of PEFT workers, and the hardware and model configurations (e.g., GPU types and numbers, parallelism strategies, model sizes, and adapter types) to the latency predictor. If the PEFT workers are performing the forward pass, the latency predictor estimates the latency of fused execution of LLM decoding and PEFT forward tasklets (line 17). If the PEFT workers are performing the backward pass, the latency predictor estimates the latency of running LLM decoding step and PEFT backward tasklets in parallel (line 21). After obtaining the latencies, the scheduler's planner calculates the number of PEFT tasklets that can be executed together with the LLM decoding step without violating the SLOs (lines 18 and 22). Finally, the scheduler dispatches the tasks to corresponding workers (lines 19, 23 and 24).

When the fine-tuning request queue is empty, our scheduling strategy degenerates to continuous batching [62]. When the inference request queue is empty, our scheduling strategy

Algorithm 1 Iteration-level multitasking scheduling.

Input: hardware and model configurations c, prefilling SLO_p, and decoding SLO_d
1: let Q_i and Q_f denote inference request queue and fine-tuning request queue
2: let W_i and W_f denote inference workers and fine-tuning workers,
3: let $B_i, B_f \leftarrow \emptyset, \emptyset$ denote the current batch of inference requests and the current batch of fine-tuning samples
4: let $B_{new} \leftarrow \emptyset$ denote the batch of new inference requests
5: **while** True **do**
6: $B_{new} \leftarrow \emptyset$
7: **if** $B_f = \emptyset$ **then** $B_f \leftarrow$ get_first_batch(Q_f)
8: **for all** $r \in Q_i$ **do**
9: **if** r cannot fit in the memory **then**
10: Break
11: $B_{new} \leftarrow B_{new} \cup r$
12: **if** $B_{new} \neq \emptyset$ **then**
13: $Q_i \leftarrow Q_i \setminus B_{new}$
14: prefill(W_i, B_{new}, SLO_p)
15: $B_i \leftarrow B_i \cup B_{new}$
16: **if** W_f is in forward pass **then**
17: latencies $\leftarrow$ latency_predictor(forward, c, B_i, B_f)
18: budget $\leftarrow$ planner(latencies, SLO_d)
19: forward_fused(budget, W_f, B_i, B_f)
20: **else**
21: latencies $\leftarrow$ latency_predictor(backward, c, B_i, B_f)
22: budget $\leftarrow$ planner(latencies, SLO_d)
23: async_decode(W_i, B_i)
24: async_backward(budget, W_f, B_f)
25: $B_i \leftarrow B_i \setminus$ finished_requests(B_i)
26: $B_f \leftarrow B_f \setminus$ finished_samples(B_f)

degenerates to normal fine-tuning. In actual implementation, LLMStation also seeks to optimize GPU utilization during the prefilling phase (line 14) by: (1) selectively co-executing PEFT and prefilling steps, as some prompts are short; and (2) scheduling the prefilling step using *Deferred Continuous Batching* from FineInfer [26]. When there is no running inference request, *Deferred Continuous Batching* defers newly arrived requests according to their arrival time and prefilling SLO, thus improving their chance of being able to batch up with other requests.

4.2 Planner and Latency Predictor

Considering that the workloads of LLM inference vary significantly across different short time periods, the scheduler needs to make decisions based on the information of the next iteration adaptively to maximize the PEFT throughput.

Objective. Let SLO_d denote the decoding SLO, l_d and l_{d0} denote the latencies of running a decoding tasklet with and without PEFT tasklets, and l_p denote the latency of running a PEFT tasklet with decoding tasklets. The objective and the SLO constraint can be formulated as

$$\begin{aligned} \max \quad & N_p \\ \text{s.t.} \quad & N_d \cdot l_d + (N_{d,all} - N_d) \cdot l_{d0} \leq SLO_d \\ & N_p \cdot l_p \leq N_d \cdot l_d \end{aligned}$$

where N_p and N_d are the number of PEFT tasklets and decoding tasklets to be executed together, and $N_{d,all}$ is the total number of decoding tasklets that need to be completed in the upcoming iteration. We can further derive the following inequality about N_p:

$$N_p \leq \frac{(SLO_d - N_{d,all} \cdot l_{d0}) \cdot l_d}{(l_d - l_{d0}) \cdot l_p}. \tag{1}$$

Besides the SLO constraint, the planner also calculates the peak memory usage of PEFT and LLM inference, respectively, to check whether the planned tasks can meet the memory constraints before execution.

Latency predictor. In Eq. 1, although SLO_d and $N_{d,all}$ are user-configured constants, the remaining variables (i.e., l_{d0}, l_d and l_p) are highly dependent on the hardware and software environment, the length of the input sequence, the distribution, number, and architecture of adapters and models, etc. Furthermore, l_d and l_p differ in the forward and backward passes and are highly dependent on the tasks executed in parallel with them. Therefore, for co-executed tasklets without cached runtime records or profiling results, the planner adopts a learned latency predictor to estimate the three different types of latency mentioned above. The latency predictor used to estimate the latencies can be defined as:

$$\mathbf{l} = \mathbf{y}(\frac{computation}{FLOP/s_{GPU}}, \frac{communication}{bandwidth_{interconnect}}, \frac{memory_access}{bandwidth_{memory}}, \mathbf{w}),$$

where $\mathbf{l}$ are predicted latencies, $\mathbf{y}$ are prediction models, and $\mathbf{w}$ of each prediction model are parameters that need to be learned. Similar to recent works in LLM performance prediction [32, 40], the current implementation of LLMStation adopts linear models for $\mathbf{y}$ and uses simple feature engineering to obtain computation, communication, and memory access from raw input features (e.g., the batch size and sequence length of inference requests and PEFT samples, and the architecture of models and adapters).

Note that we only use the learned latency predictor when the system does not have any profiling results or cached runtime records. Therefore, after a few initial iterations, the prediction error and runtime latency of the simple linear regression models have little impact on performance, as the actual co-execution latencies are stored in the system's cache, which is organized as a nested index. At the top level, records are grouped and keyed by the (hardware, model, adapter) tuple. Within each group, the records of decoding tasklet latency and PEFT tasklet latency are further keyed by (decode batch size, PEFT input length). Since the required information is available at the start of each iteration, caching and usage of latencies are straightforward. When co-locating PEFT-based LLM inference tasks and PEFT tasks, LLMStation additionally includes the adapters used by PEFT-based LLM inference as a key in the index.

5 LLMStation Engines

Now we describe the design of LLMStation's execution engines. For inference requests, the prefilling step is handled by the inference engine and the decoding step is selectively handled by the inference engine or the fusion engine. For PEFT samples, the backward pass is handled by the Autograd engine and the forward pass is handled by the fusion engine.

5.1 Autograd Engine

In the PyTorch Autograd engine, the backward pass is done synchronously by the PEFT workers and the gradients are calculated from the last layer to the first layer according to the computation graph constructed in the forward pass. As shown in Figure 7(a), once the backward pass starts, the PEFT workers cannot adjust their execution according to the current workload of the inference workers. As a result, it can not realize the iteration-level multitasking scheduling algorithm (See Algorithm 1) to ensure that the SLOs of inference requests are met.

The key to splitting the backward pass into tasklets is transforming nested functions on the backward path into coroutines [2], which are functions that can be suspended voluntarily and be resumed later. In the LLMStation Autograd engine, the functions involved in the function call chains of the backward pass are implemented as coroutines, instead of "normal" functions. We use `co_await` to invoke other coroutines and

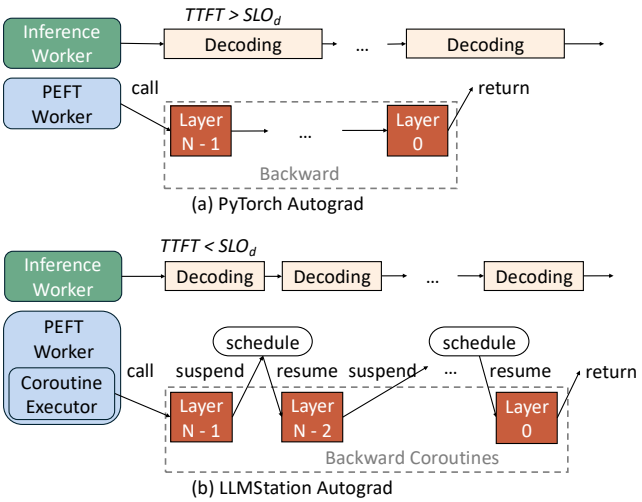

Figure 7: An illustration of Pytorch Autograd engine (a) and LLMStation Autograd engine (b) running backward pass while the inference engine is running the decoding phase.

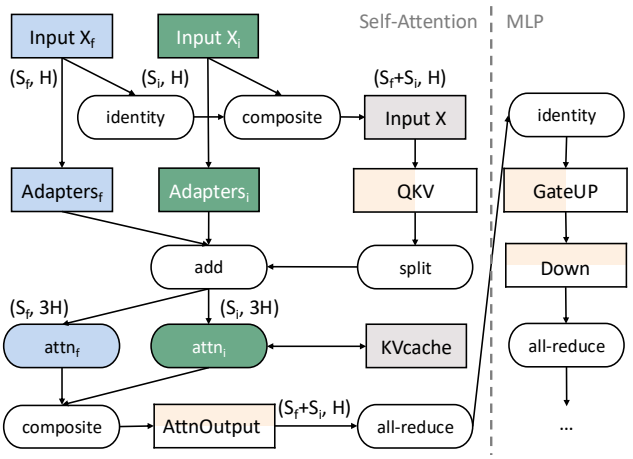

Figure 8: An illustration of LLMStation Fusion engine co-executing inference requests and fine-tuning samples on a Transformer layer. We only depict the QKV projection, the Attention, the Attention Output projection, and the multilayer perceptron (MLP) for simplicity.

replace return with `co_return`. After this transformation, the PEFT worker can use its coroutine executor to voluntarily suspend and resume the backward pass. Figure 7(b) illustrates the end-to-end control flow. When a new backward task is created, LLMStation starts to execute it in a coroutine. According to the workload of the next LLM decoding step, LLMStation scheduler uses its planner to estimate how many layers of the backward pass could be executed together without violating SLOs. After the PEFT tasklets are completed, the LLMStation Autograd Engine returns control to the PEFT worker. The scheduler will then estimate the number of PEFT tasklets to run in the next iteration based on the next LLM decoding step and resume the backward coroutine. Finally, after the backward pass of the current batch is completed, the scheduler starts a new batch and performs a forward pass on it, which we will discuss in the next subsection. The above design enables LLMStation Autograd engine to help users flexibly generate suspendable backward passes for different models and adapters.

5.2 Inference and Fusion Engines

When the PEFT workers are in the backward pass, the current iteration of that inference request will be fully processed by the inference worker. The inference engine in the inference workers is similar to the inference engine in the mainstream LLM serving systems. When an inference request is in the decoding phase and PEFT workers are in the forward pass, LLMStation uses the Fusion engine to amortize the data movement, communication, and kernel launch overheads in the PEFT forward pass. Previous works leverage prompt and generation composition strategies [16, 27] to amortize the overheads of the prefilling phase, but we found that less than 5% of decoding iterations are mixed with prefilling when running real-world workloads, which leaves room for us to composite the decoding phase and the PEFT forward pass.

Figure 8 describes the execution flow of the Fusion engine, where computational operations are represented by ellipses and weight matrices, input sequences, and intermediate states are represented by rectangles. Instead of processing inference requests of shape (S_i, H) and fine-tuning samples of shape (S_f, H) separately, the Fusion engine processes them as the following procedure: (1) composites them to an input tensor of shape $(S_f + S_i, H)$ which is then fed to QKV projection; (2) adds up the results from the base model and the adapters required by inference and PEFT; (3) splits the results and performs self-attention operation separately; (4) composites them again and then performs AttnOutput projection, GateUP projection and Down projection. With the Fusion engine, we can utilize the computing resources in decoding phases without violating the decoding SLO. For distributed co-execution, LLMStation adopts tensor model parallelism [49] and partitions the weight matrices of QKV projection and GateUP projection along columns (output dimension), and the weight matrices of AttnOoutput projection and Down projection along rows (input dimension). All-reduce operations are performed after AttnOutput projection and Down projection during the forward pass and before QKV projection and GateUP projection during the backward pass.

Similar to the co-execution of the decoding phase and the backward pass, the LLMStation scheduler estimates the number of layers that the decoding phase and the forward pass can run together. The remaining layers of the decoding phase are executed in the normal decoding way. Alternatively, the LLMStation Fusion engine can composite the inference requests

and the PEFT samples for every layer and let the LLMStation scheduler estimate the number of tokens that can be batched.

6 Evaluation

We empirically evaluate the performance of LLMStation on both synthetic and real-world workloads. Through experiments, we answer the following questions:

- How does LLMStation compare to other specialized frameworks and out-of-the-box solutions for co-execution of PEFT and LLM inference?
- What are the throughput-latency tradeoffs in LLMStation?
- What are the overheads of LLMStation 's scheduler and Autograd engine?

6.1 Experimental Setup

Here we describe the setup used throughout the experiments.

Hardware. The experiments are conducted on various hardware settings, including a server with four RTX 3090 GPUs and servers with four H100 GPUs. The RAM capacities of these servers range from 256 GB to 512 GB, and all are equipped with intra-node NVLink.

Models and adapters. We use representative open-source LLMs, the Llama series [22], and one of the most popular PEFT methods, LoRA [29]. As listed in Table 1, we considered three different sizes of Llama models, 7B, 13B, and 70B, and three different sizes of LoRA adapters, with ranks of 8, 16, and 32, respectively.

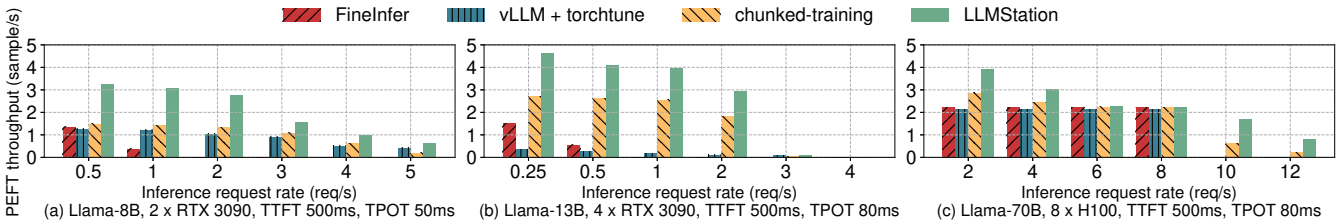
Datasets and traces. For input sequences, we use the ShareGPT [6] datasets for LLM inference and the Alpaca [53] dataset for PEFT, both are real-world datasets. For inference request rates, synthetic workloads send inference requests at a steady rate and real-world workloads send inference requests according to the BurstGPT [57] trace.

Implementation. LLMStation is implemented in about 3k lines of code and combines multiple components from different systems. We modified PyTorch Autograd [46] using C++ stackless coroutines and used it as the Autograd engine for LLMStation. The inference engine, memory manager and cache manager are built atop vLLM [36]. The fusion engine is built atop FineInfer [26], and the implementation of different parallelism strategies refers to Nanotron [4]. Also, we align the fine-tuning results of LLMStation with Hugging Face PEFT [5] to ensure the correctness of our implementation.

Baselines. We compare LLMStation with three baselines. We use the combination of vLLM [36] + torchtune [54] as the out-of-the-box solution. vLLM is a SoTA LLM serving system with the batching mechanism of adapter computation from Punica [18] and an optimized GPU memory allocation mechanism. torchtune is a high-performance fine-tuning system that integrates a range of commonly used performance optimization techniques. In the category of specialized frameworks, we evaluate FineInfer [26] and chunked-training [44], which are discussed in Section 2.

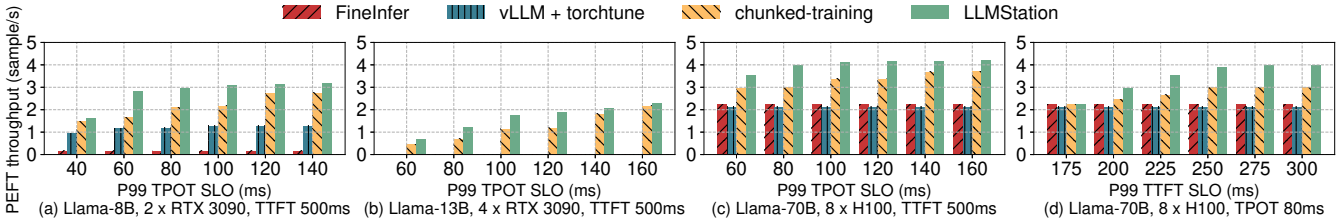
Table 1: Model and GPU configurations.

Model	GPU	# Layers	TP Degree
Llama-3.1-8B	2 RTX 3090	32	2
Llama-2-13B	4 RTX 3090	32	4
Llama-3.1-70B	2×4 H100	80	4



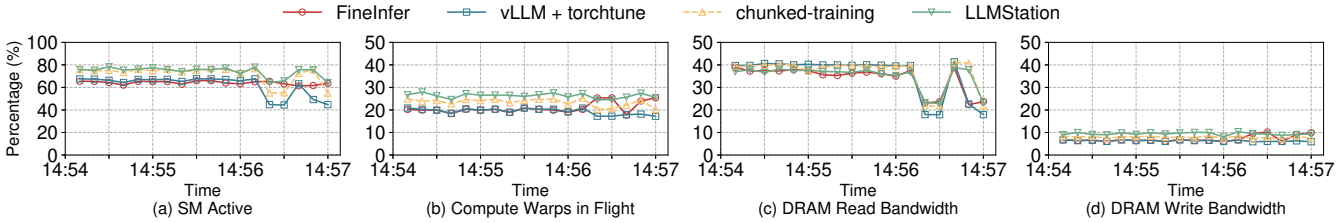
Metrics and SLOs. In end-to-end comparison, we report the throughput (i.e., samples/s) of PEFT that each system can achieve while the given P99 TTFT SLO and P99 TPOT SLO are not violated. Unless otherwise specified, the P99 TTFT SLO is set to 500 ms for all configurations, and the P99 TPOT SLO is set to 50 ms for Llama-3.1-8B and 80 ms for larger models. To compare latencies, we report the latency for different systems to achieve a given PEFT throughput.

6.2 End-to-End Comparison



In this section, we evaluate the end-to-end performance using both synthetic and real-world workloads. To get the best performance of baselines, we carefully tune their configurations such as deferral bound for FineInfer, `CUDA_MPS_ACTIVE_THREAD_PERCENTAGE` for vLLM + torchtune, and chunk size for chunked-training.

Synthetic workloads with varying request rates. Our first experiment evaluates the PEFT throughput that different systems can achieve at different inference request rates under commonly used SLO targets. Figure 9i shows the results on the synthetic workloads with different inference request rates. When the inference request rates are relatively low (i.e., $\leq$ 0.5 req/s) in serving Llama-8B and Llama-13B with RTX 3090, LLMStation outperforms FineInfer/vLLM + torchtune/chunked-training by 2.38∼8.17×/2.53∼14.77×/1.57∼2.18×. As a temporal multiplexing solution, FineInfer does not co-execute the decoding phase and PEFT, and therefore cannot fully utilize the computational power of the GPU. As a spatial multiplexing solution, vLLM + torchtune needs to limit the `CUDA_MPS_ACTIVE_THREAD_PERCENTAGE` of the PEFT workers at launch time to ensure SLOs, but this also reduces their PEFT throughput when no inference requests are being processed. Chunked-training does not suffer from the above two problems, and its slowdown is mainly due to the inherent additional data movement overhead. As the inference request rate increases, FineInfer's PEFT throughput quickly drops to zero since it cannot guarantee TTFT. The PEFT throughput of the other systems gradually becomes very close, until it drops to zero when TPOT cannot be guaranteed.



When using two servers equipped with four H100 GPUs

(i) PEFT throughput under synthetic workloads and varying inference request rates.

(ii) PEFT throughput under real-world workload and varying SLO targets.

(iii) Case study of GPU utilization under real-world workload.

Figure 9: End-to-end comparison of LLMStation and baselines.

and built-in node NVLink to serve Llama-70B, the performance difference also comes from the flexibility of deployment and service. Considering the low interconnection bandwidth between servers and the high PEFT latency per sample on Llama-70B, we need to deploy a 4-way tensor-parallel base model for FineInfer on each server instead of partitioning the model to two servers via pipeline parallelism or 8-way tensor parallelism. Considering that the vLLM + torchtune cannot share the base model, and the GPU memory of a server is only enough to place the basic model and state of vLLM or torchtune, we need to deploy vLLM and torchtune on different servers respectively. For a fair comparison, LLMStation and chunked-training are deployed in the same way. Therefore, when inference requests cannot saturate a single server, LLMStation outperforms FineInfer/vLLM + torchtune/chunked-training by up to 1.77×/1.8×/1.38×. This is because FineInfer and vLLM + torchtune can only use the resources of one server for PEFT, while LLMStation can use the total remaining resources of two servers. When executing inference requests requires two servers to guarantee the SLOs, the PEFT throughput of FineInfer and vLLM + torchtune drops to zero. On the contrary, LLMStation can still leverage the remaining resources of one server to perform PEFT until inference requests saturate two servers.

Real-world workloads with varying SLO targets. Our second experiment tests how different approaches perform under varying SLO targets under real-world workloads. The trace was extracted from BurstGPT [57], with an average request rate of 4.15 req/s. Figure 9ii(a - c) show results under varying P99 TPOT SLOs, where the performance differences can be attributed to similar reasons discussed previously. In real-world workloads, more requests arrive at similar times, so the decoding phases of more requests can be batched together, which leaves more room for PEFT. However, vLLM + torchtune and FineInfer may perform worse on real-world workloads with fluctuating request loads than on synthetic workloads with stable request loads. Since more requests arrive at similar times, vLLM + torchtune needs to impose stricter resource constraints on PEFT workers to avoid violating SLOs, while FineInfer may always violate TTFT SLOs in some cases. As the P99 TPOT SLO increases, the PEFT throughput of LLMStation and chunked-training gradually becomes very close, since chunked-training can use a larger chunk size. As shown in Figure 9ii(d), the performance of LLMStation is also limited under strict P99 TTFT SLOs since the prefilling step can only be executed after the current decoding step is finished. Therefore, the number of PEFT tasklets that can be executed together is now limited by the time remaining in the

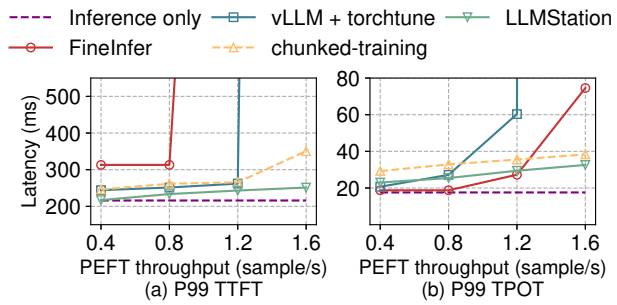


Figure 10: P99 TTFT and P99 TPOT of running Llama-3.1-8B on two RTX 3090 GPUs under real-world workloads and varying PEFT throughput settings.

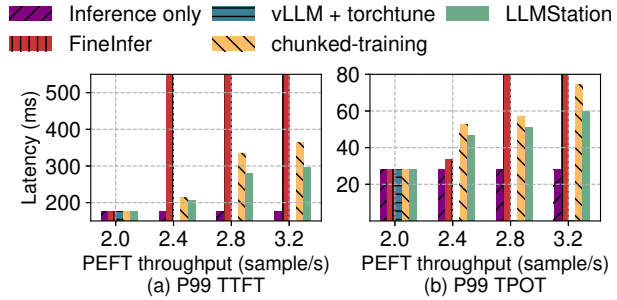

Figure 11: P99 TTFT and P99 TPOT of running Llama-3.1-70B on eight H100 GPUs under real-world workloads and varying PEFT throughput settings.

prefilling phase (rather than the decoding phase).

Case study of GPU utilization. We replayed a 3-minute segment of trace from Figure 9ii(a) using Llama-70B on eight H100 GPUs, with P99 TTFT and TPOT SLOs set to 500 ms and 80 ms, respectively. As shown in Figure 9iii, LLMStation achieves high `SM Active`, `Compute Warps in Flight`, and `DRAM Write Bandwidth` during most of the time. FineInfer only achieves high utilization when inference request loads are low since it cannot execute PEFT tasks when inference tasks are running and vLLM + torchtune can not utilize half of the GPU resources even when inference request loads are low since it cannot share the base model. Chunked-training achieves high `SM Active` and `DRAM Read Bandwidth` but low `Compute Warps in Flight`, reflecting that it suffers from additional data movement overhead.

6.3 Throughput-Latency Tradeoff

In this section, we do not consider SLOs and use real-world traces to explore how inference latency is affected under varying PEFT throughput settings. For the experiment using two RTX 3090s to serve Llama-8B, we extracted another trace from BurstGPT [57] with an average inference request rate of 0.88 req/s. As shown in Figure 10, LLMStation achieves up to 33.13×/52.64×/1.4× lower P99 TTFT and 2.29×/362.49×/1.29× lower P99 TPOT than FineInfer/vLLM + torchtune/chunked-training. FineInfer's P99 TTFT is always higher than other variants because its scheduling algorithm postpones the execution of prefilling phases to obtain higher PEFT throughput. When the PEFT throughput is 1.6, the P99 TTFT of inference requests even exceeds 8 seconds, which is unbearable for users. But its P99 TPOT is up to 36% lower than LLMStation when PEFT throughput is low. Both P99 TTFT and P99 TPOT of vLLM + torchtune are higher than LLMStation because it underutilizes GPU resources when no inference request is being processed and needs to pay more at the expense of latency for inference requests. The trend of latency variation for chunked training is similar to LLMStation, but slightly higher due to its additional data movement overhead. For the experiment using eight H100 GPUs to serve Llama-70B, we use the same real workload as in Section 6.2. As shown in Figure 11, LLMStation achieves up to 180.48×/1.23× lower P99 TTFT and 14.22×/1.24× lower P99 TPOT than FineInfer/chunked-training. Similarly, FineInfer's P99 TPOT is up to 28% lower than LLMStation when PEFT throughput is low but its P99 TTFT exceeds 25 seconds when PEFT throughput is high. In this experiment, if the PEFT throughput needed exceeds what a server with four H100 GPUs can handle, vLLM + torchtune is unable to perform LLM inference since we need to use all eight H100 GPUs to deploy torchtune.

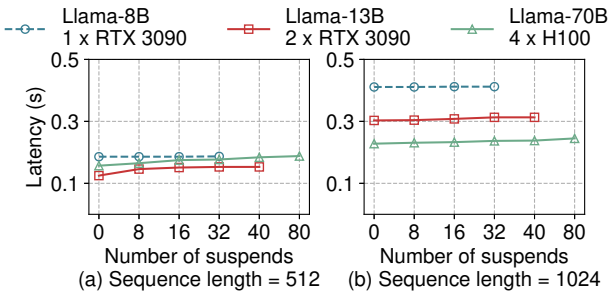

Figure 12: The time of backward pass with varying numbers of suspends.

6.4 LLMStation Autograd Engine and Scheduler Overheads

Now we study the overheads of the scheduler and Autograd.

Autograd engine. Llama-3.1-8B, Llama-2-13B and Llama-70B have 32, 40 and 80 layers respectively, and we selectively suspend and resume after each layer to evaluate the overhead of context switch in this experiment. Figure 12 shows the latency of the backward pass under different sequence lengths, model sizes, and GPUs and varying numbers of suspends. For single-GPU fine-tuning, our Autograd engine incurs less than 0.5% additional latency thanks to the low overhead of

C++ stackless coroutines [2]. For multiple-GPU fine-tuning, our Autograd engine incurs up to 18% additional latency. We attribute this to the extra inter-GPU and inter-process synchronization and a slight amplification in synchronization overhead due to execution variability.

Scheduler. On an AMD EPYC 7313 16-Core processor, the average latency of the planner and the latency predictor of LLMStation scheduler is 18 microseconds per iteration, and the average latency is less than 1 microsecond when profiling results or cached runtime records are available since we need not to call the latency predictor. For the latency predictor, we train the prediction models with our profiling results from RTX 3090 GPU servers and H100 GPU servers and test them on A100 GPU servers. For Llama-3.1-8B and Llama-2-13B with the rank of LoRA adapters set to 8, the overall average Coefficients of Determination [7] (i.e., R^2 score), are 0.73 and 0.69. The R^2 score is the default score function for many regression models in scikit-learn [47]. By definition, the score ranges from $-\infty$ and 1.0, with scores closer to 1 indicating that the model explains a large portion of the variance.

6.5 Impact of Access Distribution and Sizes of Adapters

The final set of experiments analyzes the impact of adapter access distribution and adapter size on PEFT. We run Llama-3.1-8B and the LoRA adapters on two RTX 3090 GPUs and use the same real-world workload as in Section 6.3. For the adapter access distribution experiment, we set the rank of LoRA adapters to 32 and the number of LoRA adapters to 8 and use three different access distributions: (1) None: None of the LoRA adapter is accessed. (2) Skewed: 50% of LoRA adapters are uniformly accessed. (3) Uniform: All LoRA adapters are uniformly accessed. As shown in Figure 13(left), LLMStation outperforms FineInfer/vLLM + torchtune/chunked-training by up to 2.98×/2.41×/1.74×. The performance of all variants decreases slightly when the percentage of accessed LoRA adapters increases from 0% to 50%. The performance of all variants drops to zero in the uniform distribution, since serving inference requests alone violates the P99 TTFT SLO.

For the adapter size experiment, we vary the rank of LoRA adapters and set the number of LoRA adapters to 8 and the percentage of accessed LoRA adapters to 50%. As shown in Figure 13(right), LLMStation outperforms FineInfer/vLLM + torchtune/chunked-training by up to 2.98×/2.41×/1.73×. The performance of all variants decreases slightly when the rank of LoRA adapters increases from 8 to 32. The results of these two experiments match the observations from Punica [18]. They found that as the rank of the LoRA adapter increases, the performance is more sensitive to the access distribution. When the rank equals to 32, the latency in their distinct distribution (i.e., our uniform distribution) is up to 2.5× higher than in skew distribution.

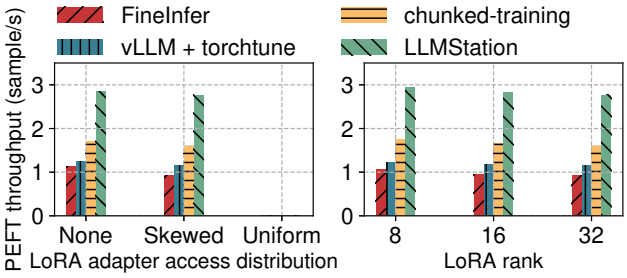

Figure 13: PEFT throughput with varying access distribution to adapters (left) and varying sizes of adapters (right).

7 Discussion and Limitations

Operator-level suspend. LLMStation's Autograd Engine is natively able to suspend and resume between operators (i.e., nodes of the backward computation graph). Considering that the backward computation graphs of LoRA fine-tuning on Llama-3.1-8B and Llama-3.1-70B have about 4k and 10k nodes respectively, the average latency per tasklet can be as low as a few microseconds. Therefore, if the latency of each layer in backpropagation is too high, LLMStation can switch to a combination of iteration-level scheduling and operator-level suspends. For the PEFT of ultra-long context LLMs (i.e., millions of tokens), a potential solution is to integrate LLMStation and chunked-training [40, 44], which we leave as future work.

Decoding SLO, TPOT and disaggregated LLM serving. TTFT and TPOT are common SLOs used in today's LLM serving. In our scheduling mechanism, the definition of prefilling SLO is the same as TTFT, but the definition of decoding SLO is slightly different from TPOT. Decoding SLO is defined as the latency of each decoding iteration while TPOT is defined as $TPOT = (e2e_time - TTFT)/number_of_generated_tokens$, where $e2e_time$ represents the time between the arrival and completion of a request. They are identical in disaggregated LLM serving systems, and only these systems can strictly meet the TTFT and TPOT SLOs in theory, since there is no interference between prefilling and decoding. For common monolithic deployments, we need to set the decoding SLO slightly smaller than the TPOT SLO. To transform the scheduling mechanism into a TPOT-aware algorithm, one needs to continuously update the respective TPOTs of all running inference requests and make decisions based on them.

Parallelization. LLM serving typically parallelizes models across different models via tensor model parallelism (TP) [49] and pipeline model parallelism (PP) [40, 45]. Since tensor model parallelism performs better in servers with NVlink and most open source models can be accommodated by 8 GPUs on a single server, we consider only TP in the paper and plan to incorporate PP into LLMStation in the future. Dy-

namoLLM [50] observes that the most cost-beneficial tensor parallelism strategy is different for workloads with different request rates, request input lengths and output lengths. Therefore, they adjust tensor parallelism every five minutes if it is necessary since per adjustment might take up to several seconds. The current implementation of LLMStation does not consider workload-aware dynamic parallelization. We assume that the parallelization is controlled by the inference worker and the PEFT worker performs fine-tuning accordingly based on the given settings.

Applicable models. Our approach can be seamlessly applied to large auto-regressive vision, time-series, tabular, DNA, and multimodal models that share similar memory-bound characteristics of the decoding phase, as well as other workloads [28] that have both compound-bound and memory-bound phases. For models or workloads that are purely memory-bound or compute-bound, the benefit will only come from the utilization of idle GPU cycles of the fluctuating serving workloads.

8 Related Work

LLMStation builds upon many techniques from LLM serving and tuning, GPU resource multiplexing and scheduling.

System optimizations for LLM serving. A flurry of optimizations has been proposed recently to enhance LLM serving from various aspects. Orca [62] proposed continuous batching that batching requests at the iteration level and interleaving prefill and decoding phases to amortize data movement overhead. vLLM [36] reduces memory fragmentation in KV cache management with PagedAttention to maximize throughput. Punica [18] and SLoRA [48] explored efficient batch processing of requests for multiple PEFT models with Segmented Gather Matrix-Vector Multiplication and Multi-size Batched Gather Matrix-Vector Multiplication, respectively. DeepSpeed-FastGen [27] and Sarathi-Serve [16] proposed chunked prefill to batches prefilling and decoding requests to improve GPU utilization. Our work adopts all the above optimizations to improve serving performance, but further focuses on improving GPU utilization without violating SLOs by multiplexing GPU resources between LLM tuning and serving and fine-grained scheduling.

GPU resource multiplexing. Beyond the works covered in Section 2, a substantial body of research has also explored GPU computation multiplexing [8, 24, 52] to improve GPU utilization, which can also be divided into temporal multiplexing and spatial multiplexing. In addition, some studies leverage software-hardware co-design to enable GPU memory multiplexing [3, 55, 60].

Temporal multiplexing shares exclusive GPU cycles by context-switching between multiple jobs. Time-Sliced NVIDIA vGPU [8] schedules vGPUs to run in series. However, out-of-the-box solutions using temporal multiplexing solutions with existing tuning frameworks and serving frameworks suffer from significant context switching overhead.

Spatial sharing allows multiple processes to run on the same GPU simultaneously, eliminating task switch overheads and enhancing GPU utilization. NVIDIA MIG [3] provides applications with exclusive access to a dedicated memory space and streaming multiprocessor, which prevents fine-tuning systems and serving systems from sharing the same base model. However, this will sacrifice statistical performance because they can only use smaller models due to memory constraints. Reef [24] and Orion [52] enable fine-grained spatial multiplexing by padding kernels that have no performance interference on each other together based on their computation and memory access characteristics and then co-execute them. Given that they can only see kernels that have been submitted to the GPU work queue and do not consider interference from interconnect (i.e., NVlink and PCIe), this is a safe execution strategy that does not violate the SLOs. However, they cannot maximize PEFT throughput due to excessive constraints for co-execution. LLMStation is a user-space solution for spatial-temporal GPU resource multiplexing. The iteration-level multitasking scheduling mechanism allows LLMStation to achieve fine-grained spatial multiplexing and optimal co-execution plan since it has the information of all kernels to be executed in the next iteration as well as the SLO constraints.

Co-locating tuning and serving. Recent studies [17, 31] have pointed out the emergent requirements and benefits of co-locating LLM tuning and inference tasks. Several pioneers [26, 44] proposed approaches that multiplex GPU resources for this specific application scenario and are the most relevant works to LLMStation. Since they have been covered in Section 2, we do not repeat them here.

GPU cluster scheduling. Numerous cluster-level GPU resource allocation and management frameworks [20, 30, 58, 59] have been proposed in recent years to improve resource utilization for GPU clusters. AntMan [59], Gandiva [58], and Lucid [30] observe the fluctuating resource demands of deep learning (DL) training jobs and explore opportunities for sharing GPUs across multiple training jobs. GSLICE [20] co-locates DL inference jobs by apportioning the GPU% among them with MPS according to their throughput and latency at varying GPU%. The resource allocation granularity of these frameworks is coarser than LLMStation, and they do not consider the base model multiplexing and specific optimizations between fine-tuning and serving tasks for three reasons. Firstly, unlike LLM workloads, the input size of the inference workload of general DL models is relatively consistent and only one iteration is performed for each request. Therefore, for this relatively stable workload, coarse-grained resource allocation is sufficient. Secondly, the training of general DL models is less expensive or time-consuming so there is no need to reuse base models for fine-tuning or serving. Thirdly, the inference of general DL models is less memory-bound so the benefits from co-executing tuning and serving of them would be limited. Given the growing requirements

in tuning and serving LLMs, applying the optimizations in LLMStation to cluster-level scheduling would be interesting and viable future work.

Systems using coroutines. Much recent work has devised cooperative scheduling to improve the utilization of computation resources. CoroBase [25] models transactions as coroutines, thus enabling overlapping data fetching and computation within transactions. LuisaRender [66] proposes a GPU coroutine model for flexible splitting and scheduling of sophisticated rendering tasks. NVIDIA [28] leverages Boost [9] coroutines to overlap the processing of multiple molecular dynamics simulations, improving GPU utilization without complex code restructuring.

9 Conclusion

We highlighted the gap between resource multiplexing and its adoption in existing systems for LLM workloads. Prior approaches often underutilize GPU resources due to dedicated service and solutions for colocating LLM serving and other tasks were not ready. To fill this gap, we proposed LLMStation, a flexible spatial-temporal multiplexing and scheduling system concurrent LLM fine-tuning and inference. LLMStation achieves high performance via a new iteration-level multitasking scheduling algorithm, an Autograd engine that enables lightweight context switch via stackless coroutine, and an inference engine that merges memory-bound operation in inference and computation-bound operation in PEFT. Evaluation results show that LLMStation can achieve 1.38–14.77× higher PEFT throughput than highly-optimized baselines while meeting inference latency SLOs.

Acknowledgments

We would like to thank Timothy Roscoe and Shivaram Venkataraman for their valuable discussions. We also thank the anonymous reviewers from the Program Committee and the Artifact Evaluation Committee of USENIX ATC '25, as well as our shepherd, Ashish Panwar, for their insightful reviews and feedback.

Colocating ML Inference and Training with Fast GPU Memory Handover

Jiali Wang, Yankui Wang, Mingcong Han, Rong Chen
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

This paper presents SIRIUS, an efficient colocation system that enables spatial sharing of GPU resources between machine learning (ML) inference and training tasks. To meet strict latency SLOs, SIRIUS prioritizes inference tasks, allowing them to utilize all GPU resources without restriction and interference. Meanwhile, it concurrently runs training tasks on leftover resources to improve throughput and GPU utilization. SIRIUS is novel in three ways. First, it leverages the characteristics of gradient computation in a batch to adjust the memory consumption of training tasks in a few milliseconds. Second, it explicitly manages memory reclamation for training, ensuring a thorough and safe memory handover process. Third, it employs an SLO-aware memory reallocation strategy to mitigate memory initialization overhead and prevent thrashing when facing frequently fluctuating workloads. Our evaluation shows that SIRIUS outperforms existing state-of-the-art colocation approaches, improving inference SLO compliance by an average of 57.0% (up to 97.0%) and training throughput by 2.2× (up to 13.7×).

1 Introduction

Serving machine learning (ML) inference and training workloads has become one of the most critical workloads in cloud data centers. High-performance GPUs serve as the predominant accelerators in ML-as-a-Service (MLaaS) platforms, catering to the growing computational demands for ML tasks [7, 8, 42, 47, 87]. However, these costly GPUs are often inefficiently utilized when serving inference with dynamic and bursty workloads. Inference serving is latency-sensitive and must adhere to strict Service-Level Objectives (SLOs) for latency (e.g., 100 ms [34]). To meet these SLOs even during sharp bursts—which can surge to 50× the average [56]—MLaaS platforms typically allocate dedicated, over-provisioned GPU resources for inference serving [33, 93]. This strategy, however, results in severe GPU underutilization (e.g., below 15% [44]) for ML inference workloads [32, 37, 49, 87].

Colocating heterogeneous workloads, such as latency-sensitive online services and throughput-intensive batch jobs, is a common practice to enhance resource utilization [60, 80]. Industrial products, such as Google Kubernetes Engine [14] and Tencent Cloud qGPU [15], demonstrate this by colocating high-priority inference tasks with low-priority training tasks to improve GPU utilization, serving as a selling point for MLaaS platforms. Furthermore, colocating ML inference and training workloads has also been explored in recent research work [16, 62, 63, 75, 97]. One approach, known as *temporal sharing*, enables inference and training tasks to share GPU resources in different time slices. For example, Lyra [53] colocates inference and training workloads within the same GPU cluster by dynamically allocating varying numbers of GPU servers for each task. Similarly, PipeSwitch [16] alternates between inference and training execution on a single GPU.

However, both inference and training tasks are memory-intensive, consuming substantial GPU memory to store models and intermediate states [12, 21, 28, 57, 91, 92]. Consequently, temporal sharing inevitably incurs significant overhead due to time-consuming context switching between these tasks. Unlike CPUs, GPUs require memory switching because of their limited capacity (typically tens of GBs). For inference tasks, reinitializing contexts and reloading models into GPU memory can cause significant latency overhead—up to a few seconds [16, 26, 91]—likely violating inference SLOs. For training tasks, preempting execution without saving context for fast switching can result in starvation or even failure. More importantly, temporal sharing cannot improve GPU utilization during inference serving.

Concurrently running ML inference and training tasks on the same GPU, known as *spatial sharing*, is an attractive alternative with the potential to fully utilize GPUs and avoid context switching. Modern GPUs allow dynamic partitioning of GPU compute units (i.e., Streaming Multiprocessors, SMs) between multiple tasks (e.g., ML training and inference) by setting SM masks within 1 millisecond [17]. Furthermore, recent studies have demonstrated the feasibility of preventing interference between inference and training tasks when sharing GPU computing resources [17, 36, 72, 75, 89].

Spatially sharing GPU memory between inference and training tasks remains challenging. *Statically partitioning* GPU memory for these memory-intensive tasks inevitably compromises performance for both, even with carefully tuned proportions. This approach is particularly ineffective for dynamic workloads—a hallmark of inference serving. An alternative is *dynamic swapping*, which transfers data between GPU and host memory as needed. This can be done either proactively through CPU offloading [16, 48, 51, 91] or passively via memory oversubscription mechanism (i.e., Unified Memory, UM [29, 39]). However, data transfer between GPU and host memory can significantly degrade performance due to limited PCIe bandwidth. For example, UM-based colocation suffers 93% degradation in inference SLOs, compared to running inference tasks alone, even under low workloads.

Our approach. We observe that the actual memory requirements of inference tasks fluctuate with the dynamic inference workloads. Without compromising inference SLOs and training throughput, the inherent elasticity of training tasks [58, 61, 66] provides an opportunity for *dynamic GPU memory sharing* between inference and training tasks—reconfiguring training tasks at runtime to meet the varying memory requirements of inference tasks.

This paper presents SIRIUS, an efficient colocation system that enables spatial sharing of GPU resources between ML inference and training tasks. SIRIUS treats inference tasks as first-class citizens to utilize all GPU resources without restriction and interference, satisfying strict latency SLOs. Meanwhile, it concurrently runs training tasks on leftover resources as much as possible to improve throughput and GPU utilization.

Key challenges. The handover of GPU memory from a training task to an inference task involves three steps: (1) waiting for the current training batch to complete, (2) transferring the released memory from the training task to the inference task, and (3) initializing the memory for the inference task. This process usually takes several hundred milliseconds (typically 250 ms, see §3), which hardly meets the inference SLOs (e.g., 100 ms). Therefore, we introduce a millisecond-scale reallocation mechanism for dynamic GPU memory sharing between inference and training tasks, built on three key techniques:

Instant memory adjustment (§4.1). We discover that the execution of a training batch can be divided into two distinct phases: gradient computation (GC) and model updating (MU). GC dominates the training execution time (over 95%) but does not change the training states. In contrast, MU requires atomic execution but commonly takes less than 10 ms. Therefore, SIRIUS can adjust the memory consumption of training tasks in just a few milliseconds (5 ms on average) by either instantly discarding the executing batch during GC phases or briefly waiting for MU phases to complete.

Safe memory handover (§4.2). To reduce memory handover time, SIRIUS directly transfers GPU memory released by training tasks to inference tasks, bypassing the memory cache in training frameworks and costly processes in the GPU runtime (e.g., 34 ms). However, this approach may result in *data pollution* due to synchronization issues between allocation and computation. To remedy this, SIRIUS explicitly manages memory reclamation, ensuring a thorough and safe memory handover process.

SLO-aware memory reallocation (§4.3). To guarantee inference SLOs under fluctuating workloads, SIRIUS reallocates memory between inference and training tasks in an SLO-aware manner. SIRIUS reserves GPU memory for inference tasks to tolerate memory re-initialization overhead caused by memory thrashing. Moreover, SIRIUS reallocates memory in a coarse-grained way to minimize disruptions to training tasks (e.g., 1.4% overhead caused by reallocation).

We implemented SIRIUS as a new inference engine with a plugin for training frameworks [55], aiming to colocate inference and training tasks on GPUs while ensuring inference SLOs and improving training throughput. We evaluate SIRIUS with four generated and two real-world traces [71, 85], comparing it with different GPU memory sharing approaches. Our experimental results show that SIRIUS outperforms these approaches by an average of 57.0% (up to 97.0%) improvement in inference SLO compliance and 2.2× (up to 13.7×) speedup in training throughput. Furthermore, SIRIUS can achieve up to 98% of inference SLO compliance of running inference tasks alone, even under a high-intensity workload.

2 Background and Motivation

Inference and training are two major tasks in machine learning services. To clarify the problem of colocating inference and training in MLaaS platforms, we begin by analyzing the unique characteristics and demands of both workloads.

2.1 ML Inference

Underutilized GPU computing resources. To ensure strict latency SLOs of inference services (i.e., on the order of milliseconds [34, 73]), GPU servers are typically overprovisioned. However, due to the dynamic and fluctuating nature of inference workloads, GPU resources are often underutilized when there are insufficient inference requests to saturate all GPU computing units [23, 94, 95]. Figure 1(a) shows that GPU utilization can often remain low during serving with the MAF trace.[1] This underutilization presents a necessity to colocate inference services with training tasks to effectively saturate GPU resources.

Inefficient GPU memory consumption. To maintain low inference latency, GPU memory is typically dedicated to storing inference models. The growing number of deployed models (e.g., more than one million models in HuggingFace model hub [10]) incurs considerable pressure on GPU memory resources. Additionally, the recent emergence of Large Language Models (LLMs) further intensifies this memory pressure due to their KV caches for requests [51, 67, 76]. However, we observe that the dedicated GPU memory (11.9 GB) often surpasses the actual memory requirements (4.4 GB on average), as shown in Figure 1(a). This overconsumption of GPU memory prevents the opportunity to share GPU resources with training tasks, despite the fact that computing resources may remain underutilized.

Dynamic memory requirements. Memory requirements of inference workloads fluctuate over time (e.g., from 1.8 GB to 10.3 GB). This is presented by the changes in the number of requested models, or the volume of generated KV caches. Statically allocating memory that is less than the peak requirement, e.g., based on the *average* memory consumption, can

[1] Similar to prior work [34, 48, 56], we simulate inference model requests using serverless functions. As the original trace is collected from serverless functions, we set the maximum requests per second as 150 reqs/s.

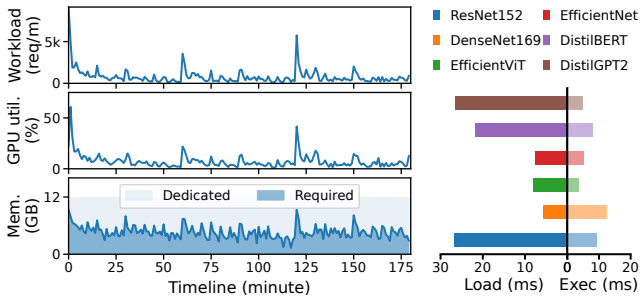

Figure 1: *(a) The GPU utilization and memory consumption during serving 64 different models with MAF [71] trace.* Total *stands for the memory consumption of all deployed inference models, and* Required *stands for the actual memory consumption required to serve inference requests. (b) The model loading (*Load*) and inference execution (*Exec*) time of six different models on NVIDIA V100.*

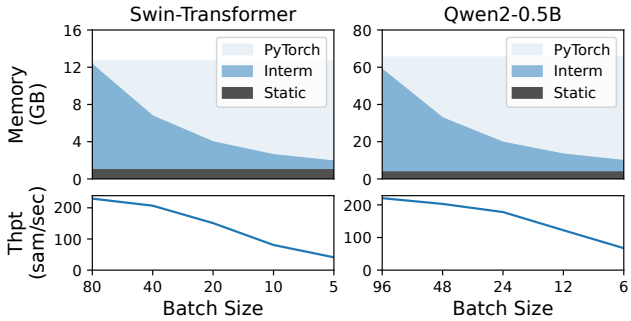

Figure 2: *The memory consumption (GB) and throughput (samples processed per second) for training Swin-Transformer [59] on NVIDIA V100 and Qwen2-0.5 [13] on NVIDIA A100 with different batch sizes.*

severely violate SLOs. Because inference tasks must queue up to use GPU memory when their requirements exceed the allocation. For example, when the allocated GPU memory fails to store all requested models, inference tasks must swap models between GPU memory and host memory, which introduces slow model loading (aka. *cold start*) in the critical path of inference services. Figure 1(b) shows that loading DistilGPT2 [70] (26.6 ms) takes 5.3× longer than its execution (5.0 ms).

2.2 ML Training

To avoid wasted GPU resources of inference serving under low load, colocating inference services with computing-intensive training tasks can ideally saturate GPU resources, which has gained significant attention in recent years [16, 75, 88, 89, 92, 97]. However, due to the large memory consumption of inference services, there is often not enough memory reserved for training tasks, making the colocation inefficient or even infeasible. Fortunately, we observe that the unique characteristics of training tasks bring an opportunity to efficiently share GPU resources with inference tasks.

Memory consumption breakdown. An ML training task iteratively computes gradients (i.e., forward and backward) and applies them to update the model parameters. Figure 2 shows memory consumption during the training of Swin-Transformer (Swin-T) [59] and Qwen2-0.5B models [13].[2] The memory consumption of a training task can be categorized into two types: (1) the static training states, which includes model parameters and optimizer states that store training progress, representing the minimum memory required for training; and (2) the intermediate results, which are consumed during the computation of gradients.

Elastic memory consumption. It can be found that the memory consumption of training is primarily dominated by the intermediate results (91% for Swin-T with batch size of 80). Furthermore, by reducing the batch size during training execution, the memory consumption of intermediate results can be effectively controlled (proportional to the batch size), finally adjusting the training memory consumption. This makes it possible to align the memory consumption of training tasks with the varying memory requirements of inference services by configuring the batch size. To guarantee training convergence, the hyper-parameters of training tasks (i.e., the effective batch size[3]) must remain unchanged. Fortunately, a widely-adopted technique—gradient accumulation—enables gradients to be accumulated over multiple smaller batches, maintaining a constant effective batch size for model parameter updating [31, 78].

However, the memory caching mechanism of ML frameworks (e.g., PyTorch [65]), which reduces the memory allocation overhead to improve training performance, leads to the unchanged memory occupation of training tasks even when the batch size is reduced. This causes the unused memory of training tasks invisible to inference tasks.

Memory demand for high throughput. As shown in Figure 2, having more memory resources enables training tasks to use larger batch sizes, which enhances training throughput by fully utilizing the GPU. However, colocating inference and training tasks can restrict the available memory for training, ultimately impacting training performance.

2.3 Colocation of ML Inference and Training

We review and discuss various approaches to colocating inference and training tasks, as illustrated in Figure 3, which contains two inference models (M_x) and one training task.

Task switching (temporal sharing). This approach enables inference and training tasks to temporally share GPU resources by switching GPU memory between tasks [16]. Therefore, an ML task can utilize the entire GPU memory and avoid memory contention, achieving the optimal performance during execution. However, this approach comes with significant context switching overhead. In Figure 3(a), to handle the first two inference requests (R_1 and R_2), GPU memory must be

[2]The constant memory consumed by the CUDA context is excluded.

[3]The effective batch size, also known as the global batch size in distributed training, represents the total number of samples used to compute gradients before updating model parameters.

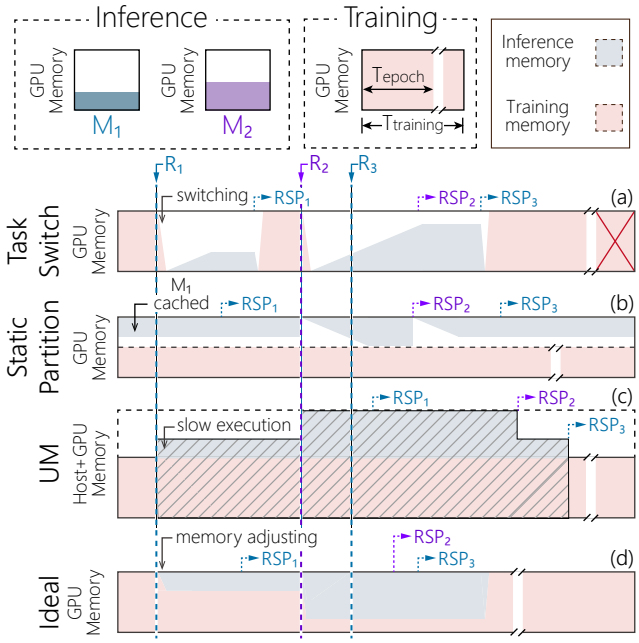

Figure 3: *An example of GPU memory consumption when using different approaches to colocate two inference models (M_x) and one training task. The illustrated time slice contains 3 inference requests (R_x) of two models. RSP_x marks the completion time of requests.*

switched from the training task to the inference tasks, leading to cold starts for inference models (M_1 and M_2). To guarantee inference SLOs, the training task may be preempted to facilitate fast switching. However, this can result in starvation, where training batches are rarely completed due to the frequent context switching when inference requests arrive continuously. Such frequent switching also causes additional cold starts for inference tasks (e.g., M_1 needs to be reloaded to serve R_3). Moreover, during inference serving, unused GPU resources may be wasted.

Static GPU memory partition. This approach statically partitions GPU memory for inference and training tasks to spatially share the GPU. Each task is restricted to using the memory allocated to it. This alleviates the interference between inference and training tasks due to memory contention, and avoids the overhead of task switching. However, the available memory for inference and training tasks is limited and fixed. In Figure 3(b), to serve the requests R_1 and R_2, the inference task must swap models between GPU memory and host memory, increasing the inference latency due to cold starts. Furthermore, training throughput is constrained by the limited memory. On the other hand, such static memory allocation can mismatch with the memory requirements of inference workloads, leading to memory waste under low load or inference SLO violations under high load.

Dynamic GPU memory swapping. This approach provides unlimited memory resources for inference and training tasks by swapping between GPU memory and host memory. Therefore, it not only meets the memory requirements of inference and training tasks but also ensures the optimal GPU utilization. However, executing ML tasks on both GPU memory and host memory significantly degrades performance. For example, as shown in Figure 3(c), the data traffic over PCIe (60× slower than GPU memory on NVIDIA A100) caused by memory swapping of Unified Memory (UM) significantly decelerates both tasks.

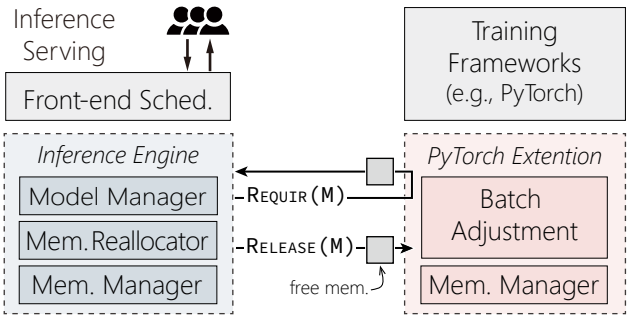

Figure 4: *The architecture of* SIRIUS. *Modules in boxes with dashed borders are the key components of* SIRIUS *for ML inference (blue) and training (red), other modules (gray) can be reused from existing ML frameworks. The interfaces for memory handover are labeled as* REQUIRE*(M) and* RELEASE*(M), where M represents the memory size.*

3 Overview of SIRIUS

Our approach: dynamic memory sharing via training elasticity. SIRIUS enables inference and training tasks to spatially share a GPU by exploiting the elasticity of training tasks. As shown in Figure 3(d), SIRIUS dynamically adjusts training memory consumption by reconfiguring the batch size to accommodate fluctuating inference tasks. As a result, inference tasks can fully utilize all GPU memory during high workloads, ensuring latency SLO. Meanwhile, training tasks can still utilize the remaining GPU memory, executing alongside inference tasks. This approach improves training throughput without compromising inference performance.

For example, to serve the requests R_1 and R_2 in Figure 3(d), the memory consumption of the training task will be swiftly adjusted by reducing the batch size. This allows inference tasks to utilize the released memory to store the model M_1 and M_2 to complete serving. Once all inference requests are finished, the training task can utilize all GPU memory to enhance the throughput by increasing the batch size.

System Overview. SIRIUS is designed as a comprehensive system for existing ML software stacks, which colocates inference and training tasks on multiple GPUs. On each GPU, the inference service process cooperates with the training task process to dynamically share GPU memory. As shown in Figure 4, SIRIUS consists of an inference engine and a plugin to the training framework. SIRIUS introduces the memory handover interface—REQUIRE(M)/RELEASE(M)—to enable

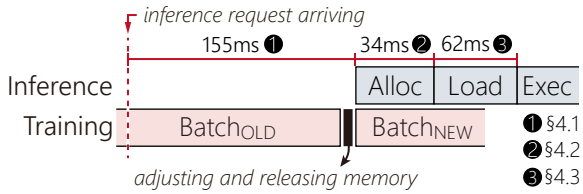

Figure 5: *The breakdown of the time for GPU memory handover from training to inference tasks.*

dynamic GPU memory sharing between ML inference and training tasks. When inference tasks require more memory, the inference engine calls REQUIRE(M) to meet the requirement by adjusting the training memory. Conversely, when less memory is required, the inference engine notifies the training task to utilize idle memory resources by calling RELEASE(M).

Inference Engine. The inference engine uses a standard ML-as-a-Service (MLaaS) interface, the same as existing inference servers (e.g., NVIDIA Triton [12]). To handle dynamic workloads effectively, the inference model manager monitors the memory requirements of online inference services. Memory resources consumed by unrequested models (i.e., idle models) and unused LLM KV caches will be reclaimed for training tasks. Furthermore, the fluctuating memory requirements of inference tasks lead to memory thrashing between inference and training tasks. This incurs cold start delays for inference tasks and frequent interruptions for training tasks. Therefore, SIRIUS introduces an SLO-aware memory reallocator to mitigate memory thrashing.

Extensions on Training Engine. The training plugin extends the popular training frameworks (i.e., PyTorch) to dynamically adjust the training task, while minimizing the training development effort. The main component of training extension is the batch adjustment, which provides a mechanism to adjust training memory consumption by reconfiguring the batch size. When receiving REQUIRE(M) from the inference engine, it swiftly and safely reconfigures the training tasks (i.e., decreasing the batch size) to hand over the memory to inference tasks. When receiving RELEASE(M), it will increase the batch size at the beginning of the next iteration to improve training throughput. To let training tasks utilize multiple GPUs efficiently, the effective batch is distributed across all GPUs with the consideration of load balancing.

Key challenge: fast GPU memory handover between training and inference tasks. When additional inference models are requested, memory must be reallocated from training to inference tasks timely to ensure SLO compliance. As shown in Figure 5, the memory handover process—consisting of adjusting training memory (❶, see §4.1), transferring memory to inference (❷, see §4.2), and initializing inference memory (❸, see §4.3)—takes approximately 250 ms. This delay significantly reduces inference SLO compliance.

Table 1: *Execution time (in milliseconds) breakdown of one training batch for different models on NVIDIA V100.*

Phase	ResNet-152	Swin-T-b	BERT-b	GPT2
Gradient Compute	323.7	344.2	241.5	188.7
Model Update	9.6	9.0	10.0	9.8

4 Fast GPU Memory Handover

In this section, we elaborate on the design of SIRIUS for reallocating GPU memory from ML training to inference.

4.1 Instant Memory Adjustment

To adjust training memory consumption through batch size reconfiguration, inference tasks must wait for the currently running batch to complete. Since training batches take hundreds of milliseconds while inference runs in just milliseconds, this waiting period is unacceptable for latency-sensitive inference tasks.

Based on the characteristics of model training, we propose an approach to instantly adjust memory consumption by discarding the currently running batch. We found that the execution of a training batch can be divided into two phases: gradient computation (i.e., forward and backward) and model parameter updating. During the gradient computation phase, the model parameters typically remain unchanged. However, the model updating phase must be executed atomically to prevent inconsistent training states. Therefore, discarding the running batch to achieve instant memory adjustment is safe as long as it is not in the model updating phase.

As shown in Table 1, gradient computation takes significantly longer than model parameter updating, dominating the training time (e.g., 97% for ResNet-152). This is because model updating involves only a few lightweight addition operations. During memory adjustments, most of the time, the training task is engaged in gradient computation. If an adjustment arises during model updating, waiting for this short phase to complete is acceptable.

We first introduce the execution process of a training batch before discussing how to discard the executing training batch. The execution of the training task involves both the host CPU and the GPU accelerator. The host CPU is responsible for the control plane, and the computation-intensive operators in the training computational graph are dispatched to the GPU. The GPU is responsible for the computation plane, where those operators are executed as asynchronous GPU kernels.

However, asynchronous execution makes it challenging to discard the training batch instantly. Since the CPU operator dispatching is much faster than GPU computation, numerous uncompleted kernels are executing on the GPU when the training task is notified of the memory adjustment. Therefore, simply synchronizing the GPU to halt model training incurs a lengthy wait for these in-flight kernels to complete. Ultimately, this delay causes inference tasks at risk of violating SLOs due to waiting for memory adjustments.

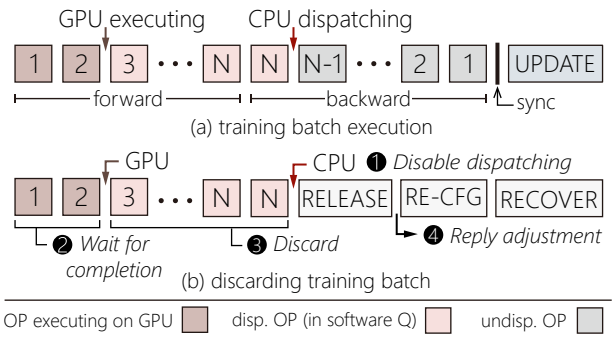

Figure 6: *Instant training memory adjustment.*

To harness the training asynchronous execution, SIRIUS employs the software GPU kernel management technique [36, 72, 75]. As shown in Figure 6(a), instead of directly launching training operators to GPU hardware, SIRIUS adds these operators to a software queue maintained by the host CPU. The operators in the software queue are gradually launched to the GPU for execution. Consequently, only a few in-flight operators are executing on the GPU, whereas most are in the software queue.

Furthermore, SIRIUS leverages the host CPU as the oracle to determine the training stages (i.e., GC or MU), as it manages the training control plane. However, the GPU can lag behind the host CPU and not fully complete gradient computation when the host CPU enters the model updating phase. Therefore, SIRIUS inserts a synchronization between the host CPU and GPU before model updating, ensuring their consistency in the training phase.

Figure 6(b) shows the process of discarding the training batch. When the memory adjustment occurs during the gradient computation, SIRIUS disables operator dispatching by refusing the operators to be added to the software queue (❶). SIRIUS then waits for a few executing GPU kernels to complete (❷). As training kernels are generally short, it only takes a short time. After this, SIRIUS discards the operators in the software queue to fully discard the training batch in the computation plane (❸).

Next, SIRIUS must ensure the training control plane is aware of the adjustment to release the training memory. To achieve this, SIRIUS lets the host CPU actively check for adjustments at each training operator. Because the operator dispatching on the host CPU is very fast, checking for adjustments will not become a bottleneck for the training task. Furthermore, as operators are the basic units of the computational graph, they are fine-grained enough to notify the host CPU of the adjustment in a timely manner.

Once the training memory is released, the memory adjustment will be replied (❹). Before recovering the training task, SIRIUS reconfigures the training task by reducing the batch size. SIRIUS then re-enables the operator dispatching and resets the control plane to the next iteration to recover the training task, where data samples of the discarded batch will be reprocessed.

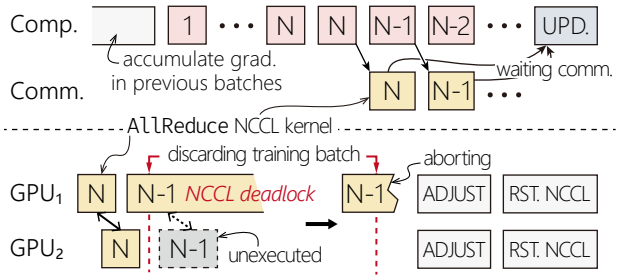

Figure 7: *The memory adjustment with data parallel training.*

To fully release the memory resources occupied by the discarded training batch, SIRIUS must traverse the training computational graph to release the corresponding intermediate results. This is necessary because discarding the training batch disrupts the normal training execution, causing the training task to fail to release these intermediate results during the backward stage.

Support for multi-GPU training. Data parallelism (DP) is a widely used technique to improve training throughput by distributing data samples across multiple GPUs [55]. Unlike single-GPU training, multi-GPU training with DP involves gradient synchronization (i.e., `AllReduce`[4]) across all GPUs in the backward stage, as shown in Figure 7. The training task must wait for gradient synchronization to complete before updating model parameters. When gradient accumulation is incorporated, the gradients are accumulated locally without initiating communication until the effective batch size is reached.

SIRIUS extends its memory adjustment approach from a single GPU to multiple GPUs, supporting training tasks with data parallelism. When memory adjustment is needed, the training task on every GPU receives notifications to initiate the process. Similar to single-GPU training, if a training task is computing gradients, the current batch will be discarded.

However, the execution speed of training varies slightly across different GPUs, leading to inconsistencies in the number of `AllReduce` NCCL kernels launched at any given timestamp. As shown at the bottom of Figure 7, one more `AllReduce` NCCL kernel is launched on GPU_1 when SIRIUS starts to discard the training batch. This presents an NCCL deadlock because the NCCL kernel on GPU_1 cannot receive the required data from GPU_2, which will not launch the corresponding `AllReduce` NCCL kernel after the discarding process starts. This ultimately causes the SIRIUS to fail at waiting for the completion of in-flight GPU kernels to finish discarding the training batch.

To address this issue, SIRIUS must abort the in-flight NCCL kernels. Simply aborting NCCL kernels by terminating NCCL connections between GPUs (i.e., calling `ncclCommAbort`)

[4] `AllReduce` is one of the collective communication primitives provided by NCCL [11]. When the training task initiates `AllReduce`, NCCL submits a GPU kernel to complete the communication.

hurts training throughput. It typically takes hundreds of milliseconds to re-establish NCCL connections to recover the training task.

Contrarily, SIRIUS leverages the NCCL communication mechanism to abort NCCL while retaining NCCL connections. NCCL maintains a counter between GPUs to ensure the order and correctness of collective data transmission. Moreover, to support the basic functionality of collective communication—connection termination, an abort flag is designed to let NCCL kernels exit despite ignoring the correctness of data transmission.

Therefore, SIRIUS sets the abort flag to abort NCCL kernels to fulfill training memory adjustment. To avoid NCCL deadlock or data pollution caused by incorrect NCCL states, SIRIUS resets the NCCL counter on all GPUs before starting the next training iterations, after which the training task will be recovered similarly to the single GPU case.

Batch distributing. The memory requirements for inference tasks can vary across different GPUs, which causes data parallel training to suffer from memory resource imbalances, resulting in a degradation in training throughput due to the straggling GPU. Therefore, SIRIUS must ensure the effective batch processing time is similar across all GPUs. SIRIUS achieves this by dynamically distributing the batch across GPUs to balance the effective batch processing time. SIRIUS uses training batch size to model the training throughput for each GPU through online profiling. SIRIUS redistributes the batch to maintain a balanced training time when the memory adjustment occurs, assigning more samples to faster GPUs. Furthermore, to prevent communication deadlock during training, SIRIUS ensures that all GPUs progress the training tasks (i.e., the training batch size of each GPU is non-zero), or none of GPUs progress the training task. The latter happens when all adjustable memory is allocated for inference tasks.

4.2 Safe Memory Handover

To transfer the released memory from the training task to the inference task, the simplest method is to return the memory cached by the training task to the GPU, then allocate memory from the GPU for the inference task. However, GPU memory allocation (i.e., `cudaMalloc`) is notoriously inefficient [16, 35, 83, 96], which incurs significant overhead to inference latency (see §3). Therefore, SIRIUS maintains a shared memory pool between inference and training tasks to bypass the memory caching mechanism of training frameworks and the inefficient GPU memory management, minimizing the overhead of memory handover. Furthermore, to protect data privacy, the memory transferred from the training task is filled with zeros before being allocated to the inference task, and vice versa. Due to high GPU memory bandwidth, the impact of zero-filling on memory handover latency is negligible. Nevertheless, the shared memory resources must be carefully managed to avoid data pollution.

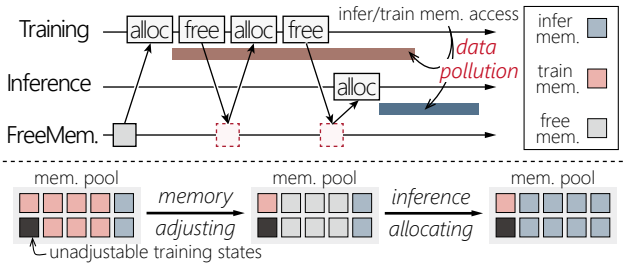

Figure 8: *The illustration of data pollution and memory handover between inference and training tasks.*

Data pollution. In the conventional training, the memory allocation and computation are asynchronous. Typically, the training tasks first allocate memory and then launch computational operators. Rather than waiting for the operators to complete, the memory is promptly released to training internal memory cache after launching. This design reduces GPU synchronization overhead and potentially lowers memory consumption by reusing memory across training operators (e.g., the second training memory allocation at the top of Figure 8).

However, when inference and training tasks allocate memory from the shared memory pool, such behavior can lead to *data pollution* between two tasks. As shown in Figure 8, once the training task releases its memory to the memory pool in the second free operation, this memory immediately appears to be available for the inference task. Then the inference task allocates this memory to serve inference requests. At the same time, however, the training task is still accessing this memory, leading to data pollution. This issue does not occur in solo training execution because no concurrent computation streams using the same memory area.

The root cause of data pollution is that the memory released by the training task is prematurely seen by the inference task, making the inference task mistakenly treat the memory being accessed by the training task as free memory. To address this issue, instead of aggressively polling for the real availability of training released memory, which incurs synchronization overhead to the training task. As shown at the bottom of Figure 8, SIRIUS maintains the memory ownership and only explicitly reclaims the training released memory for inference tasks when the memory adjustment occurs. Because there is no in-flight training operator after training memory adjustment (see §4.1), the safety of memory handover is guaranteed. If the memory adjustment does not occur, the memory released by the training task still belongs to the training task and is not visible to inference tasks.

4.3 SLO-aware Reallocation

When serving multiple inference models under fluctuating workloads, an idle model may soon be requested again. If such a model's memory is reclaimed for the training task, it can lead to memory allocation thrashing. On the one hand, this incurs frequent model loading to initialize memory for inference tasks, degrading the quality of inference services. On the

Algorithm 1: SLO-aware Memory Reallocation

Input: The maximum liveness time of idle models, $\mathcal{T}_{idle}$;
The watermark of memory reallocation, $\mathcal{W}$.
$\mathcal{M}_{rsv}$**:** The volume of reserved memory for inference tasks.

```
1  Function InferRelease(model)
2      if the model has been requested in the last T_idle then
3          return;
4      M_rsv += model_sz
5      if M_rsv < 2 × W then
6          reserve the model
7      else
           /* reallocate memory to training task */
8          release_sz = M_rsv − W
9          release the coldest models
10         M_rsv = W
11 Function InferRequire(model)
12     if M_rsv ≥ model_sz then
           /* use the reserved memory */
13         M_rsv −= model_sz
14     else if training task does not reach the adjustment limit then
           /* reallocate memory to inference task */
15         adjust_sz = (model_sz − M_rsv) + W
16         AdjustTrainingTask(adjust_sz)
17         M_rsv = W
18     else
19         fallback to model swapping
```

other hand, the training task will be frequently interrupted by inference tasks to fulfill memory adjustment, hurting training throughput. To address these issues, we present an SLO-aware reallocation approach, as shown in Algorithm 1.

To reclaim memory resources from inference tasks (i.e., `InferRelease`), SIRIUS maintains a maximum liveness time ($\mathcal{T}_{idle}$) of idle models. An idle model will be reclaimed if it has not been requested for $\mathcal{T}_{idle}$ time. Furthermore, SIRIUS reallocates memory in a coarse-grained way to minimize the disruptions to training tasks. SIRIUS maintains a watermark ($\mathcal{W}$) to control the minimum granularity of memory reallocation. Instead of directly releasing the memory resources of idle models to the training task, SIRIUS reserves these models until the volume of reserved memory ($\mathcal{M}_{rsv}$) reaches the releasing threshold—$2\mathcal{W}$ (`L5`). Therefore, when these models are requested again, SIRIUS can quickly complete the serving. When the releasing threshold is reached, SIRIUS releases the coldest model in the reserved memory until the volume of reserved memory is reduced to $\mathcal{W}$ (`L8-L10`).

When inference tasks require more memory to serve requested models (i.e., `InferRequire`), SIRIUS first uses the inference reserved memory (`L12`). If this reserved memory is exhausted, SIRIUS reallocates memory resources between inference and training tasks (`L15-L17`). Besides meeting the current memory requirements of inference tasks, SIRIUS adjusts $\mathcal{W}$ more memory resources to reduce the impact of the memory adjustment on training throughput. However, suppose the training task has reached the adjustment limit (e.g., the batch size has already been adjusted to zero). In that case, SIRIUS will serve inference requests by swapping models between GPU memory and host memory (`L19`). Finally, to mitigate model loading overhead, SIRIUS employs a pipelined execution scheme [16, 26] to overlap the inference execution with model loading.

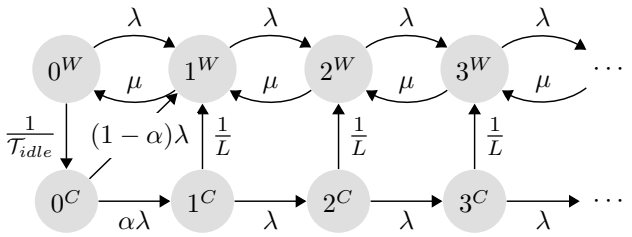

Figure 9: *The M/G/1 model for inference SLO compliance. x^W and x^C represent the state where there are x queueing inference requests without cold start and with cold start, respectively. λ is the arrival rate of inference requests. μ is the execution rate of inference tasks. α is the cold start ratio of state 0^C. L is the re-initialization time of the released model.*

To effectively mitigate cold start overhead for inference tasks and not hurt training throughput due to insufficient available memory, SIRIUS needs to be configured with the rational values of $\mathcal{T}_{idle}$ and $\mathcal{W}$ (see §6.4). Therefore, we leverage queueing theory to model the inference SLO compliance, finally determining SIRIUS's configuration.

To simplify modeling, we assume inference models are homogeneous (i.e., inference execution time and loading time are the same across models) and independent of each other. Consequently, the system can be modeled as a single-server queueing system, specifically M/G/1 [38]. In this model, inference requests follow a Poisson process with arrival rate λ, and the processing time of inference tasks follows a general distribution, accounting for potential re-initialization.

Figure 9 shows the M/G/1 model for inference SLO compliance. The expiration of the liveness time $\mathcal{T}_{idle}$ is represented by the transition from state 0^W to state 0^C with rate $\frac{1}{\mathcal{T}_{idle}}$. The watermark $\mathcal{W}$ is modeled by the cold start ratio α of state 0^C, which can be approximated as $1 - \frac{\mathcal{W}}{\sum \text{model_sz}}$, assuming the reserved memory follows a uniform distribution. Consequently, when the inference request arrives at state 0^C, the probability of transitioning to state 1^W and state 1^C is $1-\alpha$ and α, respectively. Finally, the re-initialization of the released model triggers the transition from state x^W to state x^C. The re-initialization time L includes the model loading overhead, and potential training adjustment time due to the coarse-grained reallocation, which can be approximated as the training adjustment time multiplied by α.

For every system state s, the inference response time is the sum of the waiting time for queueing inference requests and the processing time of the current inference request,

$$X_s \sim \begin{cases} \sum_{i=0}^{x} \exp(u) & s = x^W \\ \sum_{i=0}^{x} \exp(u) + \exp(\frac{1}{L}) & s = x^C \end{cases} \quad (1)$$

where X_s is the inference response time, following the hypo-exponential distribution. Finally, the inference SLO compliance—the percentage of inference requests that are served within the SLO—can be calculated by conditioning on states of the system,

$$P_{\text{SLO}} = \sum_s \pi_s P(X_s \leq \text{SLO}) \quad (2)$$

where π_s is the probability of state s, which can be calculated using the matrix method [38]. Therefore, given the inference SLO and compliance requirements, we can leverage the above model to search for a suitable configuration of $\mathcal{T}_{idle}$ and $\mathcal{W}$.

5 Implementation

For inference tasks, we built the inference server from scratch with approximately 6,000 lines of C++ code. The inference engine employs TVM [20, 98] as the backend for DNN models and vLLM [50] for LLMs. For training tasks, SIRIUS extends PyTorch with a Python library that contains around 5,000 lines of both Python and C++ code. The GPU memory and computing resource management is implemented as a common component of inference and training tasks, comprising roughly 6,000 lines of C++ code.

Memory management. SIRIUS uses GPU Virtual Memory Management (VMM) [1] to maintain a shared memory pool for both inference and training tasks, offering more flexibility than the native GPU memory management (i.e., `cudaMalloc`/`cudaFree`). SIRIUS establishes a contiguous memory area constituted by all available memory pages to form this shared memory pool. For inference tasks, SIRIUS allocates memory by directly dividing the memory area to avoid costly VMM calls. To prevent the memory fragmentation caused by the interleaving memory allocation of inference and training, SIRIUS allocates memory for the training task by mapping free, potentially non-contiguous memory pages in the memory pool to form a separate contiguous memory area.

When inference tasks request the memory adjustment, SIRIUS unmaps the unused memory pages from the training task to transfer memory resources to inference tasks, leading to the unmapping overhead in the adjustment critical path. To address this, SIRIUS merely updates the ownership of memory pages, postponing the actual unmapping until the next training memory allocation.

Dynamic GPU SM sharing. SIRIUS leverages the GPU hardware mechanism, specifically the SM mask [17], to allocate GPU computing resources between inference and training tasks. This mechanism enables dynamic specification of the Streaming Multiprocessors (SMs) used by GPU kernels, overcoming the limitation of static SM allocation of MPS [4].

Table 2: *Inference trace description.*

Workload	LIGHT	HEAVY	BURST	SKEWED
Request Rate	LOGN_L	LOGN_H	LOGN_{L+H}	LOGN_{L+H}
Model Dist.	Uniform	Uniform	Uniform	Zipfian

SIRIUS offline profiles the number of SMs that each inference model needs without degrading inference performance. To minimize the inference SLO violation during colocation, SIRIUS enables inference tasks to utilize all SMs. To reduce computation interference between inference and training tasks, SIRIUS limits the number of SMs allocated for the training task by subtracting the SMs required by inference tasks from the total number of SMs. When SIRIUS is about to execute inference for a request, SIRIUS decreases the number of SMs allocated to the training task by the amount needed for inference tasks. Upon completion of the inference task, SIRIUS restores these SMs to the training task.

6 Evaluation

Testbed. The experiments are conducted on a GPU server with two Intel Xeon Gold 6138 CPUs (total of 80 cores), 503 GB of DRAM, and four NVIDIA Tesla V100 GPUs with 16 GB of memory. The GPUs are fully connected by NVLinks. The GPU and CPU are connected by PCIe 3.0×16. The software environment of the server is configured with Ubuntu 20.04, Python v3.10, CUDA v11.6, PyTorch v2.1.2, TVM v0.14.

Comparing targets. We compare SIRIUS with the following memory resource sharing approaches in inference and training colocation. **TaskSwitch** represents systems like PipeSwitch [16], where GPU is temporally shared by inference and training tasks. We do not directly compare with vanilla PipeSwitch because it lacks support for multi-GPU training. Moreover, PipeSwitch terminates the entire training task when switching to inference tasks, degrading training performance significantly. Instead, we implement TaskSwitch based on SIRIUS and support switching from the training task to inference tasks by preempting the training batch. **Static Partition** refers to the approach of statically partitioning GPU memory for inference and training tasks. For this approach, we use NVIDIA Triton [12] for serving inference tasks and PyTorch [65] for running training tasks. We compare SIRIUS against two configurations of static partition: **SP-50** (50% GPU memory for inference tasks and 50% for training tasks) and **SP-75** (75% GPU memory for inference tasks and 25% for training tasks). **UM+MPS** represents the dynamic memory swapping approach, which extends GPU memory with the host memory using CUDA Unified Memory [39] and concurrently runs tasks using NVIDIA MPS [4]. We also use NVIDIA Triton and PyTorch to serve inference and training tasks for this approach, respectively.

Workloads. Table 2 shows four generated inference traces

Table 3: *ML model description.*

Inference	Model	Model Size	Exec. Time
DNN	ResNet-152 [40]	319 MB	9.4 ms
	DenseNet-169 [43]	84 MB	12.6 ms
	EfficientNetV2-s [77]	86 MB	5.3 ms
	EfficientViT-b2 [19]	109 MB	3.7 ms
	DistilBERT [70]	254 MB	8.0 ms
	DistilGPT2 [70]	317 MB	5.0 ms
LLM	Llama2-13B [79]	26 GB	170.2 ms (TTFT) 20.7 ms (TBT)
Training	**Model**	**Batch Size**	**Exec. Time**
DNN	Swin-T [59]	72	318 ms (1 batch)
LLM	Qwen2-0.5B [13]	72	346 ms (1 batch)

used for DNN model serving: LIGHT (L), HEAVY (H), BURST (B), and SKEWED (S). In these traces, the inference serving timeline is sliced into 20-second intervals. During each interval, inference requests arrive following a Poisson distribution [68, 69]. LIGHT represents a low-intensity workload where the request rate of each interval is sampled from a LogNormal distribution [64] with μ=1 and σ=1 (LOGN_L), yielding an average request rate of 3.4 requests per second (reqs/s). HEAVY represents a high-intensity workload where the request rate of each interval is sampled from a LogNormal distribution with μ=4.5 and σ=0.3 (LOGN_H), yielding an average request rate of 98.2 reqs/s. BURST represents a bursty inference workload by combining LIGHT and HEAVY workloads [90], with 30% of request rates sampled from LOGN_H and 70% from LOGN_L. The average request rate is 29.9 reqs/s. LIGHT, HEAVY and BURST workloads distribute inference requests uniformly on all models, and SKEWED assigns requests to various models following a Zipfian distribution (α=1.05). Furthermore, we use a real-world trace from Microsoft Azure Functions (MAF) [71] to simulate a realistic arrival distribution in cloud data centers. We compressed the MAF workload by scaling one minute to 5 seconds. All workloads run for a total of 300 seconds.

For inference tasks, we use six widely-deployed DNN models, as shown in Table 3. All models are compiled using TVM before deployment. To simulate different customized variants of standard models, we duplicate these models up to 56 instances in a round-robin manner. For the training task, we use Swin-Transformer (Swin-T) [59]. To evaluate the performance of SIRIUS with LLMs, we employ Llama2-13B for inference tasks and Qwen2-0.5B for the training task using the BurstGPT [85] trace (see §6.6 for details).

Metrics. For inference, we measure the P99 latency and SLO compliance of all requests. The inference SLO is set as four times of inference model standalone execution time (see Table 3). For training, we measure the value of training throughput (i.e., samples per second).

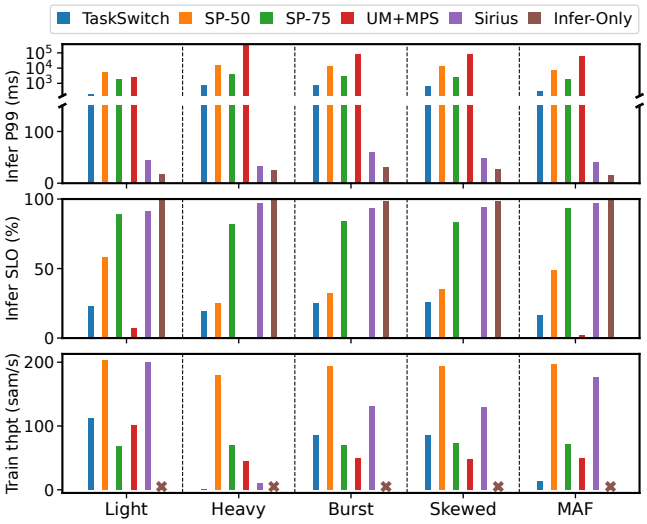

Figure 10: *The comparison of inference P99 latency, SLO compliance, and training throughput for different approaches with various workloads on one GPU.*

6.1 Overall Performance on A Single GPU

We compare the overall performance of SIRIUS with its competitors using various workloads (see Figure 10). To configure SIRIUS with the above SLO requirement, we use the queueing model with averaged inference model attributes to find values of $\mathcal{T}_{idle}$ and $\mathcal{W}$ that achieve an averaged SLO compliance of 90% across all workloads. The result configuration is $\mathcal{T}_{idle}$ = 5 seconds and $\mathcal{W}$ = 1 GB. Overall, SIRIUS improves the inference SLO compliance by an average of 57.0% (up to 97.0%) and improves the training throughput by an average of 2.2× (up to 13.7×) compared with all competitors.

First, compared with TaskSwitch, SIRIUS improves the P99 latency and SLO compliance by averagely 12.6× and 72.6% respectively. The low inference serving quality of TaskSwitch is mainly caused by the cold starts due to the context switch. For example, the inference task suffers a 38% higher cold start ratio than SIRIUS under BURST workload. For training throughput, SIRIUS outperforms TaskSwitch by averagely 4.6×. Due to preempting the training task, TaskSwitch degrades training throughput by 13.7× under MAF workload compared with SIRIUS, despite the GPU is not fully utilized by inference tasks. Contrarily, only 1.4% of computation time is wasted due to the discarded batch in SIRIUS.

Second, compared with SP-50, SIRIUS improves the P99 latency and SLO compliance by averagely 261.9× and 54.6% respectively. Although SP-50 has higher training throughput, it fails to meet the memory requirements of inference tasks, resulting in only 25% SLO compliance under HEAVY workload. Compared with SP-75, SIRIUS improves the P99 latency and SLO compliance by averagely 64.3× and 8.2% respectively. We found that inference model cold start overhead of Triton can be as high as 2 seconds, leading to high inference latency of SP-75 even with LIGHT workload. SP-75 allocates

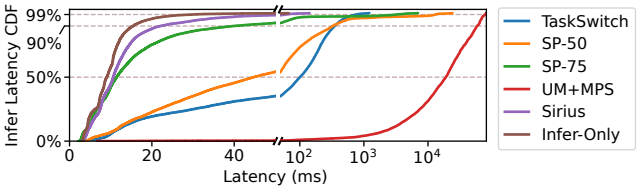

Figure 11: *Inference latency CDF for different approaches with* BURST *workload.*

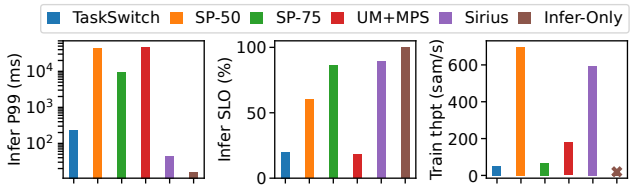

Figure 12: *The comparison of inference P99 latency, SLO compliance, and training throughput with* LIGHT *workload on four GPUs.*

more memory for inference tasks, leading to 3.0× training throughput degradation with LIGHT workload.

Third, compared with UM+MPS, SIRIUS improves the P99 latency and SLO compliance by $3.1k\times$ and 92.6%, respectively. The poor performance of UM+MPS is mainly caused by memory swapping, presenting significant pressure on the PCIe bus. Even under LIGHT workload, UM+MPS can only achieve 7% SLO compliance. The memory swapping also causes 2.2× degradation of training throughput.

Furthermore, we compare SIRIUS with the ideal case, i.e., **Infer-Only**, which is based on SIRIUS but solely executes inference tasks on GPU. The evaluation result shows that SIRIUS achieves averagely 95.3% (up to 98%) of inference SLO compliance of Infer-Only. The decrease in SLO compliance is mainly caused by additional cold start overhead (e.g., 9.1% cold start ratio under BURST workload).

Additionally, Figure 11 shows the CDF of inference latency with BURST workload, illustrating that SIRIUS improves overall inference latency. For more relaxed SLO targets, such as 10× of the standalone execution time, SIRIUS also improves SLO compliance by 48.8% on average compared with all competitors.

Finally, we evaluate the impact of dynamic batch size on training convergence. To evaluate the impact of randomness, we train Swin-T with and without dynamic batch size on CIFAR-100 [9] dataset for five times. We compare the number of epochs required to achieve the same accuracy of 75%. The evaluation result shows that the averaged number of epochs are 210.6 and 206.2 (the standard deviation are 1.5 and 3.7) for each case respectively. This confirms that SIRIUS can ensure training convergence.

6.2 Performance on Multiple GPUs

We next evaluate the performance of SIRIUS with four GPUs. To evaluate the inference and training colocation on multiple GPUs, we scale the request rate and the number of inference

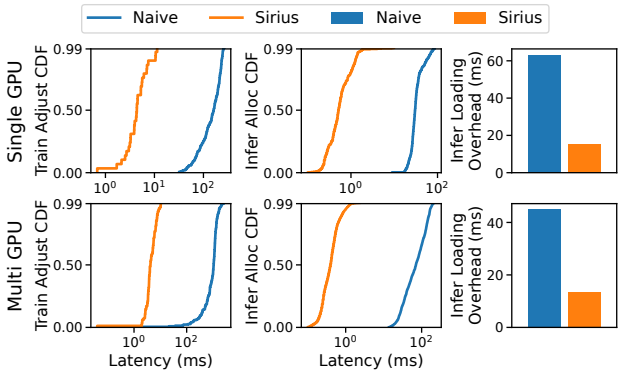

Figure 13: *The comparison of adjustment time for different approaches with* MAF *workload on one and four GPUs.*

models of the LIGHT workload by the number of GPUs. As shown in Figure 12, compared with all competitors, SIRIUS improves the inference P99 latency and SLO compliance by averagely $558.4\times$ and 43.0% respectively, and improves the training throughput by averagely $6.1\times$. The reason for the performance improvement of SIRIUS is similar to the single GPU case. Furthermore, SIRIUS achieves 89.0% of inference SLO compliance of Infer-Only.

6.3 Adjustment Breakdown

We next compare the memory handover performance of SIRIUS with the naive memory handover, which adjusts memory at the end of training batches. Figure 13 shows the breakdown of memory handover, which is evaluated over a mixture of 32 ResNet-152 with MAF workloads on both single and four GPUs. First, for training adjustment, the naive memory handover can take over 250 ms because it must wait for the completion of the training batch. Due to the synchronization across multiple GPUs, the naive adjustment has to wait for the effective batch to complete on all GPUs, resulting in latency exceeding 1 second. In contrast, SIRIUS can adjust training memory in less than 5 ms ($121\times$ faster than the naive on average) for both single and multiple GPUs, with P99 latencies of 11.4 ms and 10.5 ms respectively. Moreover, thanks to the coarse-grained reallocation, the average memory adjustment intervals are 10.3 seconds and 3.6 seconds for single and multiple GPUs, respectively. Second, by bypassing inefficient GPU runtime, SIRIUS accelerates memory allocation to averagely 0.8 ms (including zero-filling overhead), $89.2\times$ faster than the naive. Third, thanks to the SLO-aware reallocation and pipeline loading, SIRIUS reduces the waiting time for model loading by $3.7\times$ than the naive. Finally, compared with the naive adjustment, SIRIUS improves memory reallocation by $148\times$ and inference SLO compliance by 38% on average.

6.4 Ablation Study

We next evaluate the configuration of SIRIUS that affects the memory adjustment.

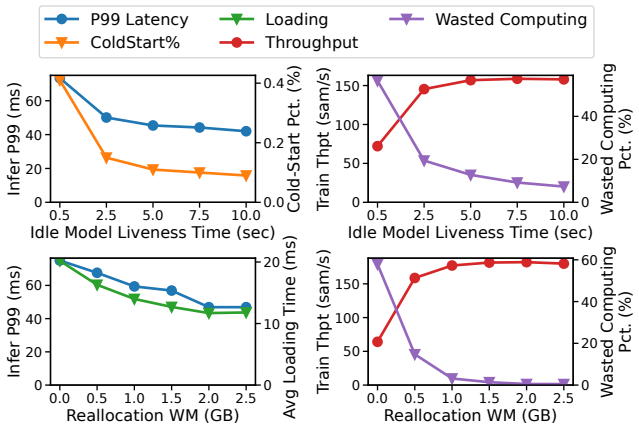

Figure 14: *The effect of maximum model liveness time and reallocation watermark on inference and training performance.*

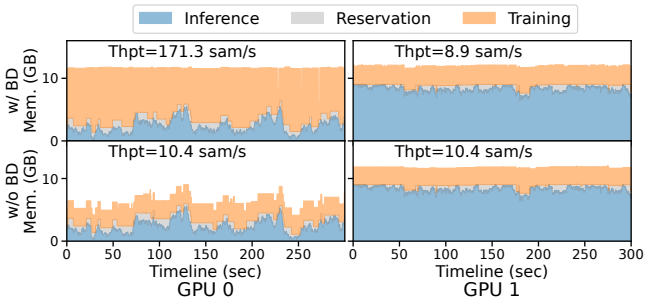

Figure 15: *The training throughput and GPU memory utilization of* SIRIUS *with an unbalanced workload.*

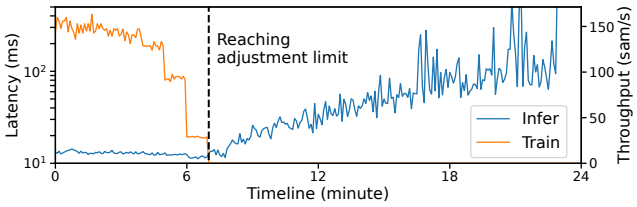

Figure 16: *The inference latency and training throughput of* SIRIUS *with varying the number of requested ResNet-152 models.*

Maximum liveness time ($\mathcal{T}_{idle}$). This configuration determines when idle inference models should be released. We evaluate the cold start ratio and P99 latency for inference tasks, as well as the wasted computation time spent on discarded batches and throughput for training tasks, using different $\mathcal{T}_{idle}$. In this experiment, we use the MAF workload and set the reallocation watermark to zero (i.e., no memory reservation for inference tasks). As shown at the top of Figure 14, with the increase of $\mathcal{T}_{idle}$, both the cold start ratio and P99 inference latency decrease. For training throughput, it first increases due to fewer wasted computing resources from discarded batches. However, for larger $\mathcal{T}_{idle}$, training throughput slightly decreases due to reduced memory resources. This suggests a sweet spot for aggressive levels of dynamic memory sharing.

Memory reallocation watermark ($\mathcal{W}$). The watermark impacts inference model loading and the frequency of adjustments. We evaluate the model loading time and P99 latency for inference tasks, as well as the wasted computation time and throughput for training tasks, using different memory reallocation watermarks. In this experiment, we use the MAF workload and set $\mathcal{T}_{idle}$ to 500 ms. As shown at the bottom of Figure 14, the finding is consistent with that of inference model liveness time. A larger watermark leads to a reduction in model loading time, P99 inference latency, and wasted training computation. However, training throughput may decrease if the watermark is too large.

6.5 Case Study

Memory imbalance. We evaluate the training throughput and GPU memory utilization of SIRIUS with an unbalanced workload on multiple GPUs. To construct the unbalanced workload, we colocate inference and training tasks on two GPUs, where one GPU serves LIGHT inference workload and the other serves HEAVY workload. To demonstrate the issue of memory imbalance, we set the adjustment limit of training batch size to one. Figure 15 shows memory utilization (excluding the CUDA context) without and with the batch distributing (BD) of SIRIUS. It can be found that without batch distributing, the training task must use the same batch size for both GPUs, resulting in memory underutilization on GPU_0 and suboptimal training throughput. In contrast, batch distributing allows the training task to use different configurations to fully utilize GPU memory and achieves 8.7× higher throughput.

Memory pressure. We next evaluate the performance of SIRIUS under memory pressure. We start with 4 ResNet-152 and gradually add 4 ResNet-152 every minute. There are 50 requests per second evenly distributed across these models. Figure 16 shows the evaluation result, where the inference latency and training throughput are averaged over 5 seconds. Before reaching the adjustment limit, inference tasks can get memory from the training task and maintain low latency while training throughput decreases. However, once all training adjustable memory is reallocated for inference tasks, SIRIUS adopts model swapping to serve more models, resulting in increasing inference latency.

6.6 LLM Inference

We further investigate the performance of SIRIUS with Large Language Models (LLMs). The memory consumption of LLMs fluctuates due to their KV caches, which typically dominate their memory requirements [41, 76]. Therefore, we dynamically allocate GPU memory for the LLM's KV cache and the training task to enable memory sharing. The LLM is pinned in GPU memory to minimize inference SLO violations. In our experiments, we use BurstGPT [85] trace and scale the maximum request rate to 10 req/s. We use Llama2-13B as the

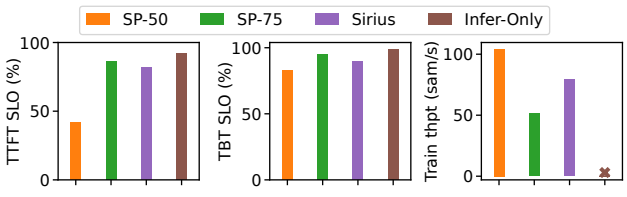

Figure 17: *The comparison of SLO compliance of TTFT (Time To First Token) and TBT (Time Between Tokens) of LLM serving, and training throughput.*

inference model and colocate it with training Qwen2-0.5B. We compare SIRIUS with **SP-50**, **SP-75**, and **Infer-Only**. All systems use vLLM [50] to serve inference requests. For SP-50 and SP-75, we set the KV cache size as 50% and 75% of that of Infer-Only, which configures the KV cache to utilize the GPU memory fully. For LLM inference, we evaluate the SLO compliance of TTFT (Time To First Token) and TBT (Time Between Tokens). Similarly, we set the SLO to be four times the average latency of an inference request standalone execution (see Table 3). Figure 17 shows the evaluation result on an NVIDIA A100 GPU with 80 GB memory. Compared with SP-50, SIRIUS improves the SLO compliance of TTFT and TBT by 40% and 7% respectively. Compared with SP-75, SIRIUS improves training throughput by 1.5×. This performance improvement stems from the same reason discussed in the previous evaluation—dynamic GPU memory sharing. Finally, in comparison to Infer-Only, SIRIUS achieves 89% and 91% of its SLO compliance for TTFT and TBT, respectively.

7 Discussion

Modern inference and training systems are scaled out across multiple GPUs and nodes to enhance their performance. To support memory handover for multi-GPU and multi-node inference tasks, Sirius could allow the inference engine on each GPU to notify the training task of the memory adjustment. The inference task will be processed once the memory adjustment is complete on all GPUs.

For multi-GPU and multi-node training tasks, the memory adjustment can still be completed immediately. However, such training tasks, which typically incorporate data parallelism, pipeline parallelism, and tensor parallelism [18, 74], must be reconfigured and resumed after the memory adjustment. Currently, SIRIUS has explored the elasticity of training tasks with data parallelism to adjust memory consumption, enabling fast GPU memory handover. To support model parallelism (i.e., pipeline parallelism and tensor parallelism), SIRIUS can reshard pipeline stages [30, 45, 81] and reshape tensors [86], respectively. We leave this to future work.

8 Related Work

Improving GPU cluster utilization. To address the underutilization of GPU clusters [27, 87], prior work [33, 69, 93] auto-scales GPU resources based on dynamic workloads. Differently, SIRIUS focuses on colocating ML tasks to improve GPU utilization. While Lyra [53] schedules inference and training tasks within the same GPU cluster, SIRIUS colocates two types of tasks on the same GPU in a fine-grained manner. Observing the dynamic resource utilization of training tasks, AntMan [89] co-designs the GPU cluster scheduler and the ML framework to colocate training tasks, which reconciles the GPU memory resources between training tasks by unifying GPU and host memory. Compared with AntMan, SIRIUS instantly adjusts the memory consumption of training tasks to meet inference SLOs.

Elastic training and dynamic batch. To utilize dynamic GPU resources, elastic training has gained increasing attention recently [2, 3, 6, 46, 54, 61, 66, 82, 84]. Different from these approaches, which mainly focus on improving utilization and accelerating training tasks, SIRIUS exploits the elasticity of training tasks to colocate with latency-sensitive inference tasks under dynamic inference workloads.

GPU sharing for machine learning. Fully utilizing GPU becomes increasingly challenging for more powerful GPUs [87, 88, 92, 97]. NVIDIA GPU offers several techniques to enable GPU sharing, including MPS [4] and MIG [5]. MIG is a hardware mechanism for static partitioning, dividing the GPU into multiple isolated instances. While prior work [22, 24, 25, 36, 52, 72, 75] has primarily focused on computational resource sharing, SIRIUS targets GPU memory sharing. Different from PipeSwitch [16] and Zico [57], SIRIUS dynamically allocates GPU memory between ML tasks to achieve efficient colocation.

9 Conclusion

In this paper, we present SIRIUS, a colocation system that leverages training elasticity to dynamically share GPU memory between ML inference and training tasks. SIRIUS prioritizes inference tasks to meet strict latency SLOs, allowing them access GPU memory without interference. Meanwhile, it concurrently runs training tasks on remaining resources to maximize throughput and GPU utilization. The key innovation behind SIRIUS is a millisecond-scale GPU memory handover mechanism between training and inference tasks. Our experiments demonstrate the efficacy and efficiency of SIRIUS in colocating inference and training tasks. SIRIUS is open-source and publicly available at https://github.com/SiriusInfTra/Sirius.

AssyLLM: Efficient Federated Fine-tuning of LLMs via Assembling Pre-trained Blocks

Shichen Zhan, Li Li*, Chengzhong Xu
State Key Laboratory of Internet of Things for Smart City, University of Macau

Abstract

Federated Learning (FL) provides a promising way to fine-tune Large Language Models (LLMs) to downstream mobile tasks while preserving data privacy. However, the intensive memory footprint prevents large amount of edge devices from contributing to the fine-tuning process with their own private data.

To this end, we introduce AssyLLM, an innovative framework that conducts fine-tuning in a memory-efficient manner through directly assembling the pre-trained transformer blocks. The core idea of AssyLLM is to decompose a pre-trained LLM into discrete blocks. These blocks are iteratively selected based on the local corpus distributed across various devices, and subsequently assembled to form a novel LLM tailored for downstream tasks. In this way, high fine-tuning efficiency can be achieved through avoiding the backpropagation process adopted in traditional fine-tuning approaches. Specifically, AssyLLM features four core components: 1) Block Comparator, 2) Elastic Adapter, 3) Block Quanter, and 4) Block Swapper. Block Comparator is designed to assess the compatibility between two blocks, facilitating the selection of appropriate blocks for assembling. After that, Elastic Adapter creates customized adapter configurations that address the specific structural differences between the blocks for seamless concatenation between the selected blocks. Meanwhile, Block Quanter is proposed to adjust precision of related weights based on the block output activation in order to reduce the extra memory overhead caused by retaining the candidate blocks while preserving the performance of the assembled model. Moreover, in order to further increase the scalability of the candidate blocks for better fine-tuning performance while guaranteeing fine-tuning progress, Block Swapper is designed to optimize the swapping pipeline by incorporating block correlation metrics. AssyLLM is comprehensively evaluated on multiple benchmark datasets of varying complexity. Compared to traditional methods, AssyLLM improves accuracy by up to 18.26%, achieves up to 30.04× speedup, and significantly reduces memory consumption by up to 92%.

1 Introduction

Recently, Large Language Models (LLMs) have demonstrated remarkable proficiency in language understanding and generation and are promising to widely support different mobile applications [17, 32]. Fine-tuning pre-trained LLMs using specialized domain-specific corpus has been proven to effectively enhance their applicability to downstream tasks [43]. However, those data are often located across various edge devices, leading to privacy concerns during the collection process. Federated Learning (FL) provides a promising way to fine-tune the LLM while guaranteeing data privacy, e.g. FedLLM [4, 5, 33, 40, 44]. Instead of collecting the data to the central server, FedLLM coordinates the participants to fine-tune the LLM locally on their private data and share only the updated model parameters with the server for aggregation.

Despite its benefits, the high memory footprint of local fine-tuning prevents resource-limited devices from contributing private data in real-world scenarios. For example, full fine-tuning a pre-trained Llama-7B model [39] with a batch size of 16 requires over 40GB of memory, whereas edge devices typically have memory capacities ranging from 4 to 16GB [1]. Even with mainstream parameter-efficient fine-tuning (PEFT) methods like LoRA [14] and adapter-based approaches [28], fine-tuning Llama-7B still requires over 15GB of memory, which still cannot be afforded by most edge devices. The significant disparity between the memory demands of model fine-tuning and the limited memory capacities of edge devices results in a substantial number of low-end devices being excluded from the fine-tuning process. Consequently, these devices are unable to contribute their locally stored data, diminishing the diversity and richness of the fine-tuning dataset. This, in turn, negatively impacts the performance of the LLM.

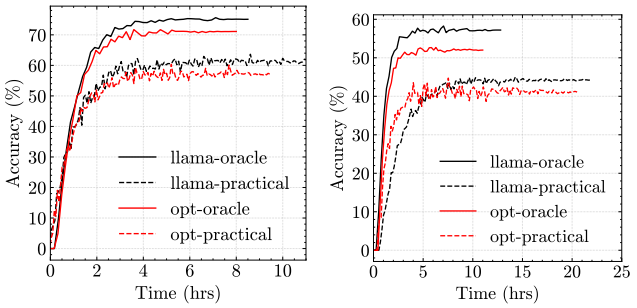
Limitation of Prior Arts. In order to reduce the memory footprint during the fine-tuning process, several approaches have been proposed which can be mainly divided into the following categories. The first category of work applies quantization to PEFT [8, 14] or adopts adapter tuning with layer freezing [4] to further reduce the resource consumption of

PEFT. Although these methods reduce model size and memory usage, incomplete model updating often degrades performance, and higher compression results in greater accuracy loss. The second category employs zeroth-order optimization [29], or forward gradient [42] to reduce the memory footprint caused by backpropagation (BP-free). However, these methods can lead to unstable model performance due to reliance solely on forward gradient estimation. The third category tackles the memory issue from the system perspective. For instance, gradient recomputation [6, 16, 19] and swapping [15, 30, 31, 38] have been introduced to manage memory usage by dynamically trading off computation and I/O overhead. While both recomputation and swapping effectively reduce memory consumption, they incur higher training time and computational overhead, which ultimately diminishes overall training efficiency. Hence, a new fine-tuning paradigm is urgently required to surmount the memory constraints while guaranteeing the fine-tuning performance and efficiency for the deployment of FedLLM in real-world cases.

Our Design. To tackle these challenges, this paper proposes AssyLLM, an innovative framework that addresses memory constraints in federated fine-tuning by leveraging a pool of pre-trained LLMs instead of relying on a single model. The main idea of AssyLLM is to break down multiple pre-trained LLMs into smaller blocks and select the most appropriate block segments for the downstream tasks. By systematically combining these blocks from various pre-trained LLMs, we create a custom-assembled model that draws on the unique strengths of each block. Specifically, it coordinates the participating clients to select optimal blocks using inference operations, with the help of block compatibility analysis. On the server side, these selected blocks are aggregated to form a global LLM. By dynamically selecting and assembling the most relevant blocks for each task, AssyLLM eliminates the need of repetitive finetuning, thereby accelerating the adaptation of LLMs to diverse applications. Moreover, through avoiding the BP process, this block-wise strategy significantly lowers memory demands during fine-tuning, enabling more devices to participate in the fine-tuning process.

Challenges and Techniques. However, designing such a new learning paradigm is non-trivial and presents several key challenges.

1) How to compare the compatibility between blocks? For effective assembling, it is crucial to select a compatible counterpart from the block pool. A higher compatibility between the selected blocks leads to improved performance of the resulting assembled model. We propose Block Comparator to evaluate the compatibility between blocks using meticulously designed metrics, enabling the selection of the most suitable blocks for concatenation and thereby improving the performance of the assembled model.



2) How to ensure the appropriate assembly of two blocks while guaranteeing the model performance and fine-tuning efficiency? Blocks from different pre-trained models vary in structure, features, and dimensions, rendering simple concatenation ineffective and potentially harmful. To address this challenge, we introduce Elastic Adapter, an adaptive lightweight fine-tuning approach with adapter that resolves mismatches by aligning the inputs and outputs of blocks from heterogeneous models, ensuring cohesive functionality in the assembled model.

3) How to reduce the excessive memory footprint of the block pool? Compared to a single LLM, constructing a block pool from multiple LLMs incurs substantial memory overhead, adding additional pressure on devices. Hence, we introduce Block Quanter, a mixed-precision quantization method applied at the block level. Since block selection depends on the output activation from each block's inference pass (see Section 3.1), our method applies varying precision levels based on impact of weight inside the block on the output. We prioritize higher precision for critical weights and lower precision for less impactful ones by analyzing the correlation between weights and output activations.

Although Block Quanter effectively reduces the block pool size, it remains too large for deployment on edge devices when handling billion-scale LLMs (e.g., the Llama series). Additionally, incorporating more pre-trained LLMs into a larger block pool improves adaptability and performance across downstream tasks, but also increases related memory costs. Further compression could degrade model performance, making it insufficient for edge deployment. To address these challenges, we introduce Block Swapper, a block-based swapping method that reduces memory usage by dynamically swapping blocks between internal and external storage. Traditional swapping methods face significant I/O latency. In contrast, Block Swapper utilizes a block correlation-aware pipeline strategy, along with pre-loading and pre-swapping mechanisms, which substantially reduce latency during the swapping process.

To the best of our knowledge, we are the first to address fine-tuning memory optimization in FL by leveraging multiple pre-trained LLMs and inference passes. Our approach significantly reduces BP-related overhead, lowering memory cost, energy consumption, and data requirements. This allows resource-constrained clients to participate while achieving performance comparable to state-of-the-art methods. The main contributions are summarized as follows:

- We propose AssyLLM, an FL framework that employs a new LLM generation method, splitting pre-trained models into blocks and assembling them together for downstream tasks.
- We design and implement the four core components, Block Comparator, Elastic Adapter, Block Quanter, and Block Swapper to interact with each other and guide the whole block selection process.
- Extensive experiments evaluate the effectiveness of As-

2 Background and Motivation

2.1 The Memory Wall of FedLLM

One important question required to be explored is: *how does the memory wall impact the federated fine-tuning process of LLM?* In order to make the investigation, we conduct the following experiments. To emulate the federated fine-tuning environment, we set 200 clients and split them into five groups with different memory budgets, as 10% (64GB), 15% (32GB), 15% (16GB), 30% (8GB), and 30% (4GB). We perform fine-tuning for Llama-7B [35] and OPT-6.7B on BoolQ [7] and OpenBookQA (OBQA) [9] datasets. Specifically, BoolQ is a binary question-answering dataset and OBQA focuses on multiple-choice reasoning questions. For data distribution, we follow [41], using a Dirichlet distribution [12] with concentration parameter $\alpha = 1$ to allocate fine-tuning samples for each client. The *oracle* baseline assumes all clients have sufficient memory for full local fine-tuning, while *practical* reflects experiments under memory constraints. As shown in Figure 1, memory limitations cause accuracy drops of up to 14.7% for Llama-7B and 19.1% for OPT-6.7B, as their fine-tuning requires over 45GB and 32GB of memory, respectively. This leaves 85% of Llama-7B clients and 60% of OPT-6.7B clients unable to participate, reducing data diversity and resulting in underperformed fine-tuning results.

2.2 Exploring Existing Techniques in FedLLM

In this section, we explore several techniques that are commonly used in LLM fine-tuning for memory saving.

2.2.1 Parameter-efficient Fine-Tuning.

Parameter-efficient fine-tuning (PEFT) techniques like LoRA [8, 14] and Adapters [4] enable task-specific adaptation of LLMs with minimal retraining. LoRA injects trainable low-rank matrices into attention and feed-forward layers, reducing the number of updated parameters. Adapters introduce task-specific modules between transformer layers, keeping the main model frozen while fine-tuning only these adapter layers.

Using the same experimental settings, we evaluate LoRA, QLoRA [8] (extending LoRA with quantization), FedAdapter [4], and FwdLLM [42] (will be introduced later) in an FL scenario with Llama-7B. As shown in Figures 2 and 3, for example, QLoRA reduces at most 79% memory consumption, decreases the aggregation time by 67%, and increases the participation rate to 70%, but it still comes with a 5.3% accuracy drop compared to oracle scenario. Similarly, other baselines also experience varying degrees of performance drop. This decline is due to two key factors. Firstly, incomplete model updates often lead to performance degradation, with higher compression levels causing greater accuracy loss. Secondly, while PEFT reduces memory usage compared to full fine-tuning, it still requires storing and updating low-rank matrices or adapters, and a portion of resource-constraints clients still remain unable to participate in the fine-tuning

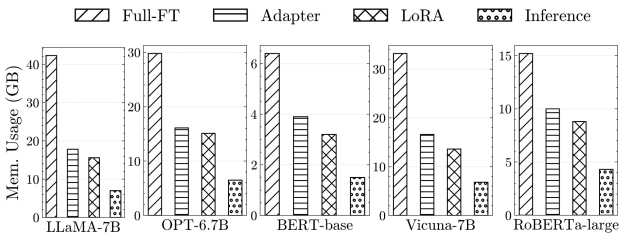

Figure 4: Memory overhead of different fine-tuning technologies and inference.

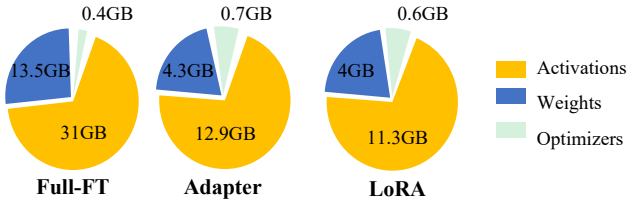

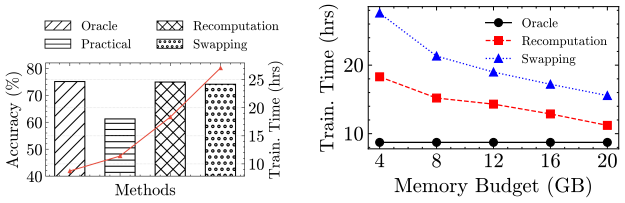

Figure 5: Memory breakdown. Model: Llama-7B. FT denotes fine-tuning.

process, resulting in fewer data contributions to the global model and further impacting overall performance.

2.2.2 Backpropagation-free Fine-tuning.

As shown in Figure 4, LoRA and Adapter effectively reduce the memory overhead of Llama-7B by 62.1% and 53.9%, respectively. However, they still require more than 15GB of memory, which remains insufficient to deploy certain large models on real edge devices. Figure 5 shows the breakdown of memory footprint and analyzes the reason: these activations generated during forward pass account for most of the memory usage, and existing PEFT methods cannot eliminate this overhead. To address this, BP-free fine-tuning methods, such as zero-order optimization [2], have gained attention. BAFFLE [10] and FedZeN [25] apply BP-free training in FL but are not designed for LLMs. FwdLLM [42] is a recent BP-free method tailored for LLMs, requiring only "perturbed inferences" instead of full fine-tuning. By updating parameters directly from gradients computed during the forward pass, FwdLLM reduces memory consumption, making it more suitable for resource-constrained FL environments. From Figure 2, FwdLLM reduces fine-tuning memory requirements from 45~58GB to 3.8GB, enabling 100% client participation. However, this comes with an approximate 5.8% performance drop compared to the oracle baseline.

The decline mainly stems from the inherent limitations of forward gradient estimation, which sacrifices fine-tuning accuracy for computational efficiency. Unlike BP, which provides precise error-correcting feedback through gradients, forward gradient estimation relies on approximate updates, making parameter adjustments less accurate. This imprecision tends to accumulate over time, especially across multiple fine-tuning rounds. Without the precise gradient flow that backpropagation provides, small errors introduced in each update step may compound, resulting in cumulative error that degrades the overall model performance. In non-IID scenarios, this issue becomes more pronounced because non-IID data, which require more precise model adaptation to account for diverse patterns.

(a) Performance comparison with memory budget 4GB. (b) Fine-tuning time under different memory budget.

Figure 6: System-level memory saving techniques analysis. Model: Llama-7B; Dataset: BoolQ.

2.2.3 System-level Memory Saving Techniques.

System-level memory optimization techniques are widely used to enable model fine-tuning on memory-constrained devices. Recomputation [6, 16] (or gradient checkpointing) reduces memory usage by discarding intermediate activations and recomputing them during BP pass. While effective for memory savings, it incurs additional recomputation overhead, prolonging training time and reducing efficiency. Swapping [15, 30, 31] transfers model components or activations between memory and storage. Though it minimizes in-memory usage, swapping introduces significant I/O overhead, slowing down training due to frequent memory-to-disk transfers. As shown in Figure 6a, both techniques achieve accuracy near the oracle baseline, but the fine-tuning time increases from 8.73 hours to 27.6 hours. This can be attributed to their ability to achieve the same client participation rate as the oracle by efficiently reducing memory overhead, but at the expense of substantial additional I/O operations and computational costs. From Figure 6b, as the memory budget decreases, the required additional time increases from 1.78× to 3.17× due to the need for more recomputation and swapping.

Summary. Although existing techniques effectively reduce the memory overhead of fine-tuning, they either compromise accuracy or introduce additional computational costs, extending the aggregation time. This highlights the necessity of a method that achieves a balanced trade-off across three critical dimensions: reducing memory usage, maintaining model performance, and ensuring process efficiency.

2.3 Opportunity

To address these limitations, we propose a new perspective by leveraging multiple pre-trained LLMs to construct a task-specific model through block-level assembly. Leveraging multiple models with distinct architectures provides better expressive capabilities for different downstream tasks, enabling im-

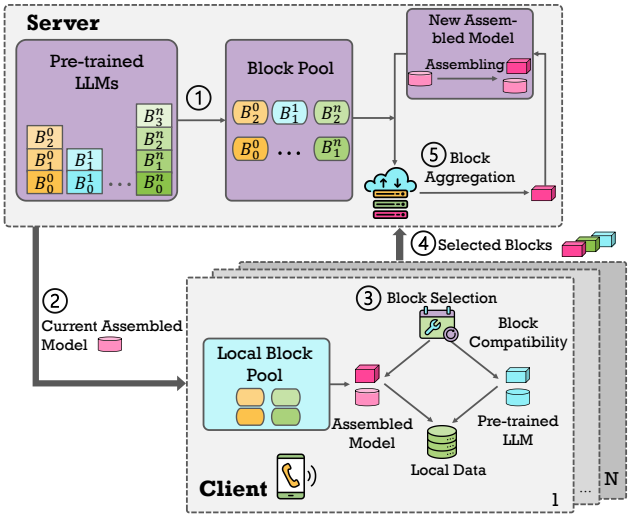

Figure 7: Workflow of assembled model generation.

proved performance for task-specific objectives. First, we divide multiple LLMs into modular transformer blocks, forming a block pool. Then, based on local data characteristics, each client dynamically selects relevant blocks from the shared block pool and assembles them into a task-specific model. This process is accomplished through simple inference operations without the need for BP.

The proposed learning paradigm builds on two key insights: 1) **using pre-trained models as modular building blocks** and 2) **enabling dynamic block assembly for task flexibility**. By selecting blocks based on local data and resources, it tailors model generation to diverse tasks. The block-level optimization reduces memory usage, allowing even low-end devices to participate in FL.

3 AssyLLM Design

3.1 The Fine-tuning Paradigm

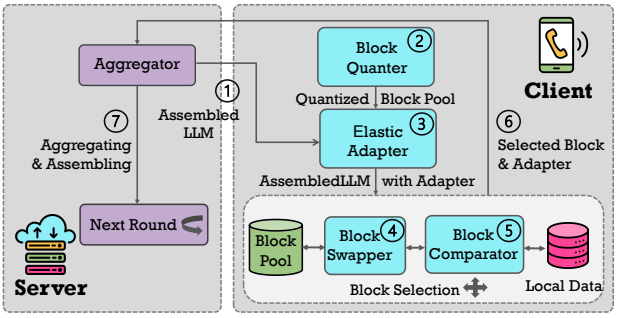
Figure 7 represents the overall fine-tuning paradigm of AssyLLM, which can be mainly divided into the following steps. ① **Initialization:** Pre-trained LLMs are manually split into blocks categorized as starting blocks (embedding layer), intermediate blocks (groups of transformer layers), and terminating blocks (output layers). These pre-trained models and candidate block pools are distributed to participating clients. ② **Model Downloading:** In each round, participants receive a candidate assembled model. ③ **Local Block Selection:** Given the current model N_s, each client searches the block pool for compatible blocks. For a candidate block B_{nl}, derived from a pre-trained LLM n up to layer l, clients assemble N_s with B_{nl} and perform two inference passes with the same batch of local data: one on the new assembled model and another on the originating LLM up to layer l. The resulting activations X and Y are compared to compute the compatibility score for B_{nl}. This process is repeated for all candidate blocks. ④ **Block Uploading:** Each client selects the K blocks with the highest compatibility scores and uploads. ⑤ **Server-Side Aggregation:** The server aggregates the uploaded blocks using a weighted voting mechanism (similar to FedAvg). The voting process is based on compatibility scores. A higher score indicates better adaptability to the current assembled model. The K selected blocks with the highest votes, whose parameters are averaged across relevant clients, are sequentially stacked onto the current model N_s to construct the candidate model for the next round. The process continues until a terminating block is selected, the model depth limit is reached, or all paths are explored. The block selection process requires only inference on a small data batch, significantly reducing the data needed.

However, deploying this paradigm in real-world environments presents several challenges that warrant further investigation.

- Q1: *How to compare the compatibility between two blocks?* For a given block, selecting a compatible counterpart from the block pool is essential for effective concatenation in downstream tasks. Higher compatibility between the selected blocks enhances the performance of the resulting assembled model.
- Q2: *How to assemble two different blocks together?* Blocks derived from different pre-trained LLMs exhibit varying features and structures. Directly combining them without careful consideration can negatively impact overall performance, necessitating a more deliberate integration strategy.
- Q3: *How to reduce the additional memory overhead caused by multiple LLMs.* As the block pool comprises multiple LLMs, maintaining it in memory during the block selection process introduces additional memory overhead.

3.2 System Overview

To tackle these challenges, we introduce AssyLLM, an FL system for deploying LLMs that optimizes memory and performance. Furthermore, we design four core techniques: Block Comparator (Section 3.3), Elastic Adapter (Section 3.4), Block Quanter (Section 3.5), and Block Swapper (Section 3.6), as shown in Figure 8. For **Q1**: 1) Block Comparator introduces a well-defined metric to assess block compatibility, facilitating the selection of appropriate blocks for concatenation. For **Q2**: 2) Elastic Adapter addresses model heterogeneity by integrating blocks from different pre-trained LLMs using lightweight adapters, ensuring seamless assembly with minimal information loss. For **Q3**, we design two components to optimize the memory overhead of block pool: 3) Block Quanter applies mixed-precision quantization at the block level to block pool, balancing resource allocation by



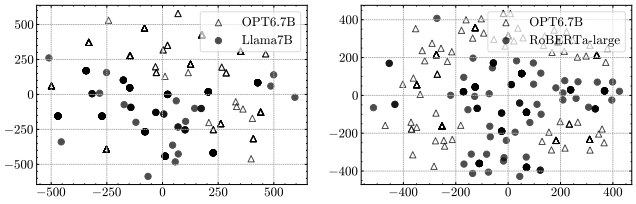


Figure 8: AssyLLM architecture.

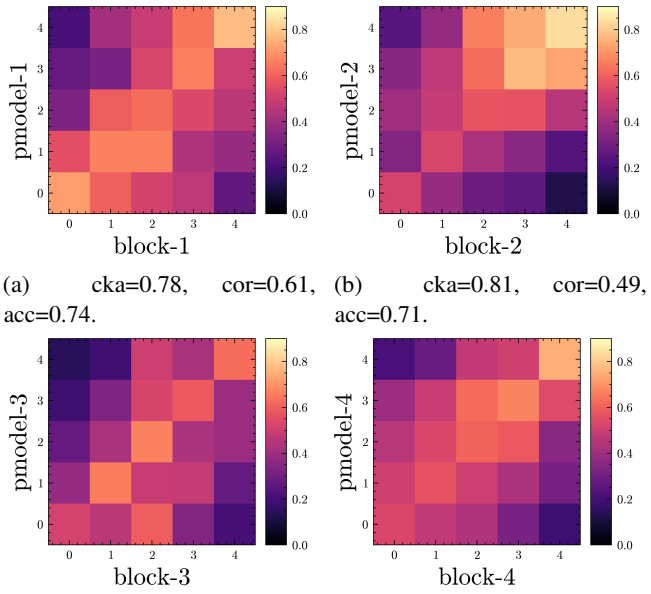
(a) OPT-6.7B vs Llama-7B. (b) OPT6.7B vs RoBERT-large.

Figure 9: Feature differences visualization using t-SNE [36].

assigning lower precision to less critical weights and higher precision to key components; 4) Block Swapper further optimizes the swapping pipeline by leveraging the correlation between blocks. Additionally, its pre-loading and pre-swapping mechanisms reduce I/O delays, enabling efficient model assembly on low-resource devices. Together, these techniques enable AssyLLM to overcome memory, fine-tuning efficiency, and computational challenges in FL, enabling real-world FL applications of state-of-the-art billion-scale LLMs.



3.3 Block Comparator

Block compatibility is critical when assembling a model from block pool. To guide block selection, robust comparison metrics are necessary. Centered Kernel Alignment (CKA) [18] is a widely used method for measuring the similarity between activation sets, commonly applied to analyze layer representations in neural models. We extend CKA to LLMs by comparing activations from different transformer blocks, providing insights into feature evolution across layers and models. In this work, CKA serves as a key metric to evaluate block compatibility. Specifically, we compute the CKA score using activations K and L from the candidate assembled LLM and corresponding pre-trained LLM (detailed in Section 3.1). A higher CKA score indicates better alignment, aiding in selecting the most compatible blocks to optimize model performance. The CKA score is calculated as follows:

$$CKA(K,L) = \frac{\mathbf{HSIC}(K,L)}{\sqrt{\mathbf{HSIC}(K,K)\mathbf{HSIC}(L,L)}} \quad (1)$$

where **HSIC** is Hilbert-Schmidt Independence Criterion [13]. For the linear kernels, **HSIC** is:

$$\mathbf{HSIC}(K,L) = ||cov(X^T X, Y^T Y)||_F^2 \quad (2)$$

(a) cka=0.78, cor=0.61, acc=0.74. (b) cka=0.81, cor=0.49, acc=0.71.

(c) cka=0.63, cor=0.41, acc=0.65. (d) cka=0.72, cor=0.53, acc=0.69.

Figure 10: CKA Heatmaps for four various candidate blocks; *pmodel* denotes pre-trained LLM where the block originates from; *cor* denotes layer-correlation metrics; *acc* denotes final assembled model performance; Dataset: BoolQ.

CKA helps evaluate block compatibility but focuses only on final activations of block, overlooking intermediate layer differences in LLMs, which can lead to suboptimal block selection and reduced model performance. To explore these differences, we conducted an experiment on BoolQ by feeding the same input to various LLMs and extracting their intermediate features. We visualized them using t-SNE [36], as shown in Figure 9. The results highlight that, despite identical inputs, different architectures produce distinct intermediate feature distributions. To address CKA's limitation, we propose layer-correlation (COR), a new metric that compares activation distribution similarities across layers using KL divergence [20]. Given two activation distributions P and Q for a specific layer, KL divergence is defined as:

$$D_{KL}(P \parallel Q) = \sum_i P(i) \log\left(\frac{P(i)}{Q(i)}\right) \quad (3)$$

Where $P(i)$ denotes the probability of activation i in the first distribution, and $Q(i)$ denotes the probability of activation i in the second distribution.

To calculate COR, we sum the KL divergence between corresponding layers within two blocks. This is done once during initialization. To validate the effectiveness of these metrics, we conduct experiments on BoolQ using the LLMs described in Section 2.3. Given an assembled LLM composed of four blocks, we set four different candidate blocks to assemble and record corresponding CKA, COR scores, and accuracy of the generated assembled model. Figure 10 shows the heatmap for CKA distributions, revealing key insights: 1) Blocks with

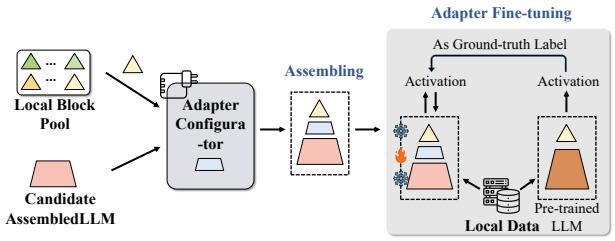


Figure 11: Elastic Adapter fine-tuning.

high CKA and COR achieve better performance (e.g., *Block 1* vs *Block 3*); 2) High CKA alone doesn't ensure optimal selection (e.g., *Block 1* vs *Block 2*); 3) High COR alone is also insufficient (e.g., *Block 2* vs *Block 4*). These findings motivate us to integrate CKA and COR to block compatibility score for reliable block selection in each round to identify the best candidate (e.g., *Block 1*) that maximizes accuracy.

3.4 Elastic Adapter

Assembling blocks from different pre-trained LLMs is non-trivial due to structural and semantic mismatches, which can significantly degrade performance. Specifically, there are three primary types of mismatches in LLMs: dimensional misalignment, semantic inconsistency, and attention mechanism differences. We introduce Elastic Adapter, an adaptive adapter fine-tuning approach that addresses these mismatches by introducing adapters that align the outputs and inputs of blocks from heterogeneous models. 1) *Dimensional Misalignment*: This issue arises when the output of one block does not match the input dimensions of the next. To overcome this, we introduce lightweight linear transformations to project outputs into the correct dimensional space. 2) *Semantic Inconsistency*: Even when block structures align, the features they extract may differ semantically, causing further mismatches. To address this, we implement a cross-attention mechanism that uses one block's output as the query and the next block's output as the key and value. This process aligns semantic content between blocks, reducing feature mismatches and ensuring smoother block integration. The cross-attention alignment process is defined as:

$$\mathbf{O}_{cross} = softmax\left(\frac{\mathbf{Q}\mathbf{K}^{\top}}{\sqrt{d_k}}\right)\mathbf{V}, \tag{4}$$

where $\mathbf{Q} = \mathbf{W}_Q\mathbf{H}_{out1}$ is the query matrix derived from the output of the first block $\mathbf{H}_{out1}$, $\mathbf{K} = \mathbf{W}_K\mathbf{H}_{out2}$ and $\mathbf{V} = \mathbf{W}_V\mathbf{H}_{out2}$ are the key and value matrices derived from the output of the second block $\mathbf{H}_{out2}$. Here, $\mathbf{W}_Q$, $\mathbf{W}_K$, and $\mathbf{W}_V$ are learnable projection matrices, and d_k is the attention dimension used to scale the dot-product for numerical stability.

Optionally, a linear transformation can be applied to ensure dimensional consistency for subsequent processing:

$$\mathbf{H}_{aligned} = \mathbf{W}_{out}\mathbf{O}_{cross}, \tag{5}$$

where $\mathbf{W}_{out}$ is a learnable projection matrix.

Table 1: Assembled model performance and memory overhead of the block pool with different quantization methods comparison. BP denotes the block pool. Dataset: BoolQ. Block pool: Llama-7B, OPT-6.7B, Vicuna-7B, BERT-base, and RoBERT-large.

Precision	BP Overhead	Model Accuracy (%)
FP16	42.2GB	75.8 ± 2.5
INT8	21.1GB	73.1 ± 4.7
INT4	11.5GB	67.3 ± 8.9

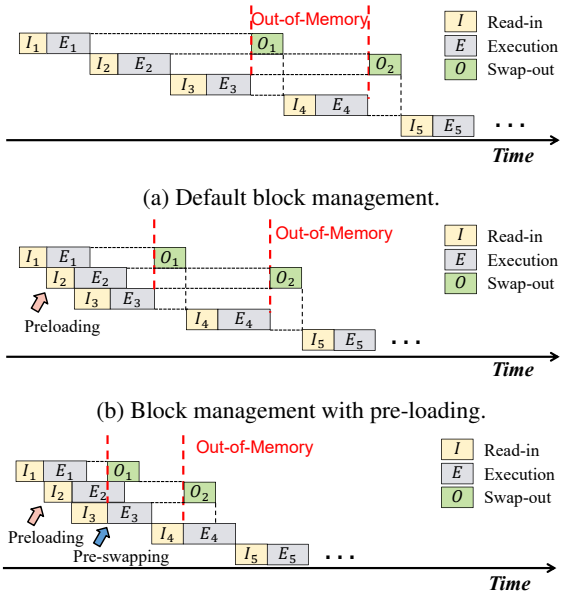
3) *Attention Mechanism Differences*: the last challenge is handling different attention mechanisms, such as multi-head versus single-head attention. We address this by designing adapters that pool or expand attention outputs based on block configurations, ensuring compatibility without altering model structures. We apply lightweight fine-tuning by freezing most model parameters and training only adapters with local client data. Notably, not all block assemblies require trainable adapters. In most cases, the mismatch between blocks primarily falls into the first category of challenge (*Dimensional Misalignment*), where a simple projection matrix is often sufficient to address it without introducing additional complexity. Furthermore, trainable adapters are used only for significant mismatches, primarily in the final blocks. As a result, most intermediate activations can be discarded during forward propagation, reducing memory overhead. Figure 11 illustrates the Elastic Adapter workflow.

3.5 Block Quanter

For **Q3**, the block pool size equals the combined size of multiple pre-trained LLMs and need to remain in memory throughout the block selection process, leading to substantial memory overhead. Quantization [11, 22] is a common technique to reduce memory usage, but excessive compression can harm accuracy. As shown in Table 1, FP16 precision results in over 40GB of memory usage, far exceeding edge device limits. INT8 reduces memory to 21GB with minor performance loss, while INT4 significantly degrades accuracy, resulting in a 5.8% accuracy drop with an 8.9% fluctuation. On the other hand, mixed-precision techniques [22, 37] apply varying precision levels at the layer level, requiring layer-wise sensitivity analysis to assess the impact of precision changes. This process involves additional forward passes or statistical measurements, resulting in significant computational overhead during model preparation and fine-tuning.

To address this, we propose Block Quanter, a block-wise mixed-precision quantization method. Unlike prior work [22, 37], which typically applies layer-wise precision adjustments, our approach focuses solely on the impact of internal weights on block output activations, which directly affects block compatibility and selection. By evaluating the sensitivity of weight to the entire block's output rather than individual

Algorithm 1 Block Quanter



Input: Pre-trained LLM M, block pool $\mathcal{B} = \{b_1, b_2, ..., b_n\}$, block activation $\mathbf{A}_b$, sparsity threshold τ_s, sensitivity threshold τ_a.
Output: Weight importance scores $\mathcal{S}_w$.

// Weight Sparsity Analysis

  for *each weight* $w \in b$ **do**
    $S_s(w) \leftarrow SparsityMetric(w)$
    if $S_s(w) < \tau_s$ **then**
      Mark w as unimportant
    end if
  end for
end for
// Activation Sensitivity Analysis
for *each block* $b \in \mathcal{B}$ **do**
  for *each remaining weight* $w \in b$ **do**
    $\Delta\mathbf{A}_b \leftarrow RandomPerturbation(w)$ or $Masking(w)$
    $S_a(w) \leftarrow ActivationImpact(\Delta\mathbf{A}_b)$
    if $S_a(w) < \tau_a$ **then**
      Mark w as unimportant
    end if
  end for
end for
// Bottom-Up Sensitivity Analysis
for *each block* $b \in \mathcal{B}$ **do**
  $L \leftarrow$ *Number of layers in block b*
  for $l = L$ **down to** 1 **do**
    for *each remaining weight* $w \in layer\ l$ **do**
      $C(w, \mathbf{A}_b) \leftarrow Correlation(w, \mathbf{A}_b)$
      $\mathcal{S}_w(w) \leftarrow C(w, \mathbf{A}_b)$
    end for
  end for
end for
return $\mathcal{S}_w$

layers, Block Quanter avoids the need for layer-level precision tuning across multiple Transformer layers. This block-wise granularity significantly reduces the computational overhead compared to layer-wise methods, as it requires fewer forward passes and sensitivity analyses, making it more efficient and practical for resource-constrained devices. Block Quanter performs offline multi-step quantization by first analyzing weight sparsity in block and then evaluating activation sensitivity through random perturbations and masking to identify critical weights for higher precision allocation. For the random perturbation method:

$$S_a(w) = \frac{\|\mathbf{A}_b(w) - \mathbf{A}_b(w+\Delta w)\|_2}{\|\mathbf{A}_b(w)\|_2}, \quad \Delta w \sim \mathcal{N}(0, \sigma^2), \quad (6)$$

where $\mathbf{A}_b(w)$ represents the block's original output activation,

(a) Default block management.

(b) Block management with pre-loading.

(c) Memory-aware block management with pre-loading and pre-swapping (ours).

Figure 12: Different pipeline strategies for block swapping.

$\mathbf{A}_b(w+\Delta w)$ is the activation after adding random perturbation Δw, and $\|\cdot\|_2$ denotes the L_2 norm.

For the weight masking method:

$$S_a(w) = \|\mathbf{A}_b(w) - \mathbf{A}_b(w=0)\|_2, \quad (7)$$

where $\mathbf{A}_b(w=0)$ is the output activation after masking weight w to zero.

Based on the results, insignificant weights are discarded. A bottom-up sensitivity analysis then re-evaluates the correlation between the remaining weights and the output, starting from the block's output layer to its input layers. This refined analysis ensures that critical weights are retained at high precision, while less important ones are quantized to lower precision. The entire process is performed offline, ensuring minimal additional resource consumption during the block selection phase and significantly reducing memory usage of block pool without compromising performance. The complete process is outlined in Algorithm 1.

3.6 Block Swapper

While BlockQuanter reduces block pool memory usage, it remains insufficient. As shown in Table 1, a block pool composed of five pre-trained LLMs still requires over 11GB of memory, even with INT4 compression, exceeding the typical capacity of edge devices (4~8GB). Furthermore, incorporating additional LLMs improves adaptability across diverse downstream tasks and enhances the assembled model's performance, but it also significantly increases the block pool size, resulting in higher memory costs. To address this, we propose Block Swapper, a system-level solution to further optimize memory usage. The Block Swapper design begins

Algorithm 2 Block Swapper.

Input: Block Pool $\mathcal{B}$, Memory Budget M_{max}, Current assembled LLM $\mathcal{M}_{assembled}$.

```
// Step 1: Initialize Memory Budget
M_used ← 0
for each block b ∈ B do
    // Step 2: Check if block b is in memory
    if b ∈ Memory then
        Continue with assembly
    else
        // Step 3: Perform Swap-In
        if M_used + size(b) ≤ M_max then
            Pre-loading b from external storage
            M_used ← M_used + size(b)
        else
            // Step 4: Perform Swap-Out
            b_out ← BlockCorrelation(b, B)
            Pre-swapping out b_out to external storage
            M_used ← M_used − size(b_out)
            Load b from external storage
            M_used ← M_used + size(b)
        end if
    end if
    // Step 5: Assemble Model
    Assemble block b into M_assembled
    BlockCompatibilityCalculation(b, M_assembled)
end for
```

by setting a memory budget for each device, determining how many blocks can be stored in memory. When a required block is missing, a swap-in operation is initiated. If memory is full, a swap-out unloads less relevant blocks to storage. **Block correlation.** The block swapping decision combines a Least Recently Used (LRU) strategy with block correlation metrics. The relevance of blocks is determined by their feature correlation, previously analyzed in Section 3.3 and directly applied here. Blocks with lower correlation to the current model are prioritized for swapping out.

To mitigate I/O overhead from frequent swaps (Figure 12a), we further introduce a pre-loading mechanism, pre-loading blocks into memory to ensure smoother execution (Figure 12b). Additionally, a memory-aware pre-swapping strategy estimates upcoming memory needs and performs swap-out operations in advance to reduce I/O waiting times (Figure 12c). In summary, Block Swapper optimizes the pipeline by leveraging block correlations and further reduces delays through pre-loading and pre-swapping, enabling efficient memory management. Algorithm 2 outlines the process.

Table 2: Specifications of tested devices.

Device	Mem	GPU	CPU
Nvidia Jetson TX2	8G	256 CUDA Cores (Pascal)	A57 (6C)
Nvidia Jetson Nano	4G	128 CUDA Cores (Maxwell)	A57 (4C)

4 Evaluation

4.1 Experimental Setup

LLMs, Block Pool, and Datasets. We select five pre-trained LLMs: Llama-7B, OPT-6.7B, BERT-base, Vicuna-7B, and RoBERTa-large from Huggingface [39], which are chosen for their widespread adoption and distinct characteristics on edge devices, covering diverse architectures, parameter sizes, and training objectives. Table 3 presents the model sizes of the tested LLMs. To optimize block-based assembly, we use an adaptive segmentation strategy. Shallow and deep layers, which have minimal semantic differences, are grouped into larger blocks (e.g., 6–8 layers per block) to reduce complexity while maintaining functionality. Conversely, middle layers with more significant semantic variation are divided into smaller blocks (e.g., 2–4 layers per block) to improve flexibility and minimize mismatch during assembly. As a result, Llama-7B, OPT-6.7B, BERT-base, Vicuna-7B, and RoBERTa-large consist of 6, 6, 4, 6, and 6 blocks, respectively, forming a block pool with 28 blocks.

We evaluate our approach on three benchmark datasets: BoolQ [7], PIQA [3], and OpenbookQA (OBQA) [9]. BoolQ is a question-answering dataset focused on yes/no questions based on a passage. PIQA involves physical reasoning tasks, challenging the model's ability to predict plausible solutions for real-world scenarios. OBQA tests commonsense knowledge and reasoning, requiring answers based on general science facts. These datasets were selected for their diversity in task types—reading comprehension, physical reasoning, and commonsense knowledge—ensuring a comprehensive evaluation of our method's adaptability.

Baselines. We evaluate our method against two groups of baselines to demonstrate its effectiveness across both algorithmic and system-level aspects. Algorithm-level baselines include **FT-oracle**, representing full-parameter fine-tuning under ideal memory conditions as the upper bound; **FT-practical**, which accounts for memory limitations; **LoRA** [14], a widely used PEFT technique; **QLoRA** [8], which extends LoRA with quantization; **FedAdapter** [4], an FL approach utilizing adapter tuning with layer freezing; and **FwdLLM** [42], the SOTA BP-free method for memory constraints in FL. System-level baselines include **Recomputation** [6, 19], which reduces memory usage by recomputing activations during BP, and **Swapping** [15, 30], which offloads computations or parameters to external storage to save GPU memory. These baselines offer a comprehensive comparison of AssyLLM's performance in terms of both algorithmic flexibility and system-level efficiency.

Implementation Details. We implement AssyLLM on a hy-

Table 3: Model size (FP16).

Model	Size
Llama-7B	14GB
OPT-6.7B	13.4GB
BERT-base	220MB
Vicuna-7B	14GB
RoBERT-large	710MB

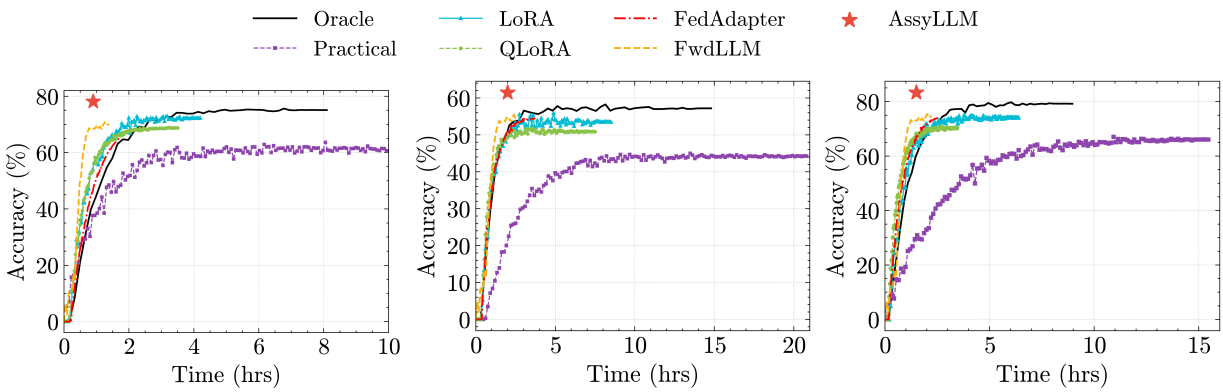
brid platform combining simulation and hardware. Simulation experiments are conducted on two Nvidia A100 GPUs to emulate clients with high memory budgets, while on-device experiments are performed on Nvidia Jetson TX2 and Nano, representing memory-constrained edge devices. Device specifications are provided in Table 2. We use Hugging Face Transformers [39] and PyTorch [27] for on-device fine-tuning and inference, monitoring memory usage with htop. For FL, we follow the setup in Section 2.1, with 200 users split into 4 groups based on memory budgets, as shown in Figure 13. Aggregation uses FedAVG [26]; the maximum sequence length of 512 for OBQA and 256 for others. A minimum 4GB memory budget is allocated for *Swapping*, *Recomputation*, and *AssyLLM* to ensure client participation. Baseline fine-tuning needs 5 local epochs with a batch size of 16 and 500 global epochs. For AssyLLM, the process of selecting the next block for the current candidate model is repeated for 5 rounds, with 3 blocks evaluated per round. It is important to note that block type does not directly influence the aggregation outcome, as all blocks are evaluated using the same compatibility metric. In practice, assembling blocks of different types naturally tends to produce lower compatibility scores due to larger feature distribution mismatches, making them less likely to be selected. We use a learning rate of 0.01, which is higher than the standard (e.g., 5e-5) used for full-model fine-tuning. This is intentional and empirically justified, as only lightweight adapters are trained while the backbone remains frozen. The higher rate accelerates convergence and mitigates underfitting due to limited adapter capacity. Sensitivity analysis confirms this setup achieves efficient training with minimal impact on accuracy. The batch size for CKA computation is 32. The assembly process typically requires fewer than 100 epochs, with each epoch taking less time than baseline methods. For Block Quanter, we use the INT8/INT4 combination for mixed-typed quantization with GPTQ [11].

4.2 Overall Performance

Throughout the assembling process, 21 assembled LLMs are generated, with statistics shown in Figure 14, demonstrating the diversity of models created from various block combinations. All generated models are stored on the server, and each client receives one model per round for block selection, minimizing additional memory overhead for edge devices. After model generation, we select models with high block compatibility, as it typically leads to better accuracy and ensures top-performing models are chosen. We use llama-7B as the LLM for baseline methods, applying INT8 quantization with GPTQ. Table 4 and Figure 15 present the comparison results with algorithm-level baselines and Table 5 and Figure 16 for the system-level baselines.



Superior Accuracy. From Table 4 and Figure 15, compared to full fine-tuning, AssyLLM achieves 16.75%, 17.16%, and 18.26% absolute improvements across three datasets due to reducing memory requirements and enabling contributions from users previously constrained by memory limitations. For parameter-efficient fine-tuning baselines like LoRA, QLoRA, and FedAdapter, AssyLLM shows improvements of up to 8.24%, 13.09%, and 11.57%, as these methods reduce weight precision or limit fine-tuning, causing performance degradation. Compared to BP-free methods like FwdLLM, AssyLLM improves by 6.14%, 8.88%, and 7.58%, as FwdLLM's reliance on inference perturbations leads to instability during aggregation. AssyLLM's concatenation method avoids these issues while maintaining superior performance. From Table 5 and Figure 16, AssyLLM outperforms existing memory-saving techniques by up to 3.77%, 5.26%, and 6.18%. This is due to constructing a block pool with multiple LLMs of diverse structures, enriching the model pool, and enhancing the adaptability and expressiveness of the generated models for downstream tasks.

Speedier Convergence. From Table 4, for algorithm baselines, AssyLLM achieves up to 12.92×, 14.67×, and 10.97× speedup across three datasets, thanks to the elimination of BP-related computations, which drastically reduces fine-tuning time. From Table 5, for system-level baselines, the speedup is even more significant, reaching up to 30.04×, 28.71×, and 26.75×. This improvement is due to the substantial additional time introduced by I/O exchanges or activation recomputations, which greatly extend the overall aggregation process.

Robustness to non-IID data. We evaluated performance under various non-IID settings and conducted multiple experiments with different initialization settings. AssyLLM and baselines both utilized the FedAvg aggregation algorithm, with results shown in Figure 17. As depicted, as the local data distribution becomes more skewed, the baseline experiences varying degrees of performance degradation, with accuracy drops of up to 14% and increased bias. In contrast, while AssyLLM also faces some impact (a 4.6% absolute accuracy drop), it still demonstrates up to a 27.2% improvement

Table 4: Test results (top-1 accuracy and speedup) of **algorithm-level memory saving schemes** on BoolQ, PIQA, OBQA in non-IID scenario. *FT-oracle* represents the experiment conducted without memory limitation, denotes as the upper bound.

Dataset	FT-practical		FT-oracle		LoRA		QLoRA		FedAdapter		FwdLLM		AssyLLM	
	Speedup	Acc	Speedup	Acc	Speedup	Acc	Speedup	Acc	Speedup	Acc	Speedup	Acc	Speedup	Acc

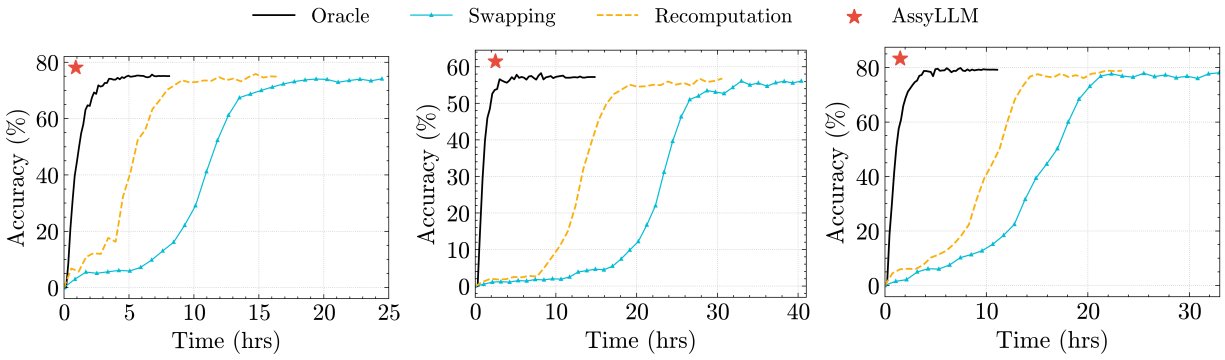
Table 5: Test results (top-1 accuracy and speedup) with **system-level memory saving baselines** on BoolQ, PIQA, OBQA in non-IID scenario. See Table 4 for further reference.

Dataset	Recomputation		Swapping		AssyLLM	
	Speedup	Acc	Speedup	Acc	Speedup	Acc
BoolQ	0.65×	74.91	0.43×	74.35	**12.92**×	**78.12**
PIQA	0.68×	78.96	0.51×	78.13	**14.67**×	**83.39**
OBQA	0.51×	56.88	0.41×	56.19	**10.97**×	**62.47**

over the baseline, offering more stable performance. This improvement stems from the fact that, in our method, local data only guides block selection and fine-tunes lightweight adapters, without altering the blocks themselves. As a result, the generated LLM is less affected by the local data distribution compared to baselines. Furthermore, our approach is orthogonal to other methods that address non-IID issues, like Harmony [34] and Oort [21], and can be seamlessly integrated with them for further optimization.

4.3 System Cost



Memory overhead reduction. As shown in Figure 18, AssyLLM reduces memory consumption by 92% compared to full fine-tuning and 63.6% compared to PEFT baselines. This is due to AssyLLM's design, which limits operations to the forward pass, reducing memory cost to only the block pool and lightweight adapter fine-tuning. In contrast, while other system-level and BP-free methods reduce memory usage and also achieve 100% client participation, they often sacrifice accuracy or prolong training time, limiting their real-world efficiency. Moreover, mainstream inference optimization techniques [23, 24] can be integrated with our approach to further reduce memory overhead.

Energy and communication cost reduction. As shown in Figure 19, AssyLLM reduces energy consumption by 95.01% and inter-device communication overhead by 99.1% compared to full fine-tuning. Our method is also highly efficient relative to PEFT or BP-free methods, achieving up to 88.1% energy reduction and 94.2% decrease in communication overhead. This reduction is due to the fact that, unlike traditional training methods, our approach only requires clients to upload block selection results and a lightweight adapter each round. Since the block pool is shared between the server and clients, the block selection results are transmitted as an index, typically requiring only a few bytes. In contrast to traditional methods, which require uploading entire or partial model weights or updates, our method significantly reduces communication overhead.

4.4 Effectiveness of Each Component

Impact of Block Comparator. We compared the impact of using two individual metrics (CKA and COR) for block selection on the final performance. As shown in the Figure 10, neither metric alone can identify the optimal blocks, resulting in a 9.1% and 3.4% performance drop.

Impact of Block Quanter. We compare Block Quanter with different precision schemes. As shown in Figure 20a, compared to FP16, AssyLLM reduces memory consumption by 70.2% with only a 1.1% accuracy loss. For INT4, our method increases memory overhead by 10.1% but improves accuracy by 8.1%. This shows that Block Quanter effectively reduces block pool memory overhead while preserving accuracy through block-specific mixed-precision quantization.

(a) BoolQ. (b) OBQA. (c) PIQA.

Figure 16: Efficiency comparison with **system-level baselines**. Model: Llama-7B.

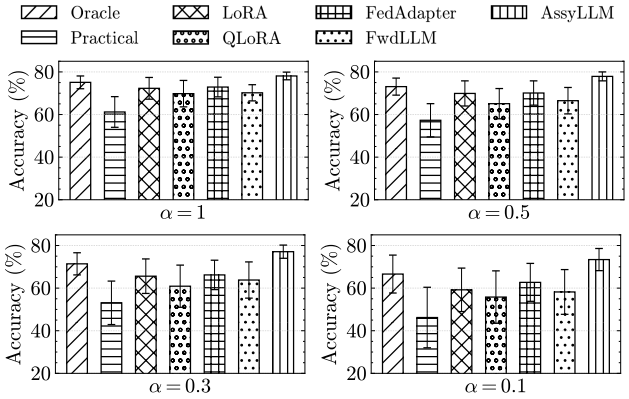


Figure 17: Performance comparison under various non-IID settings in BoolQ. α denotes the concentration parameter in Dirichlet distribution.

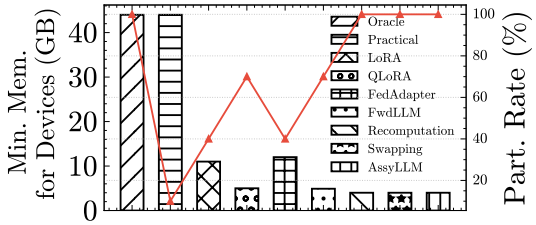

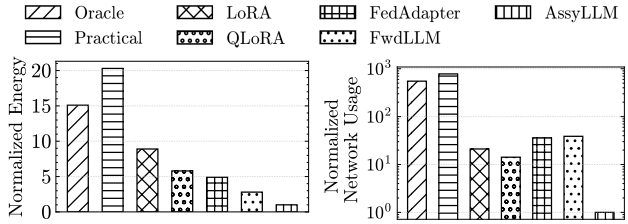

Figure 18: Peak memory footprint and client participation rate comparison on BoolQ. *Min. Mem. for Devices* denotes the minimum memory required for the participant to apply the corresponding methods.

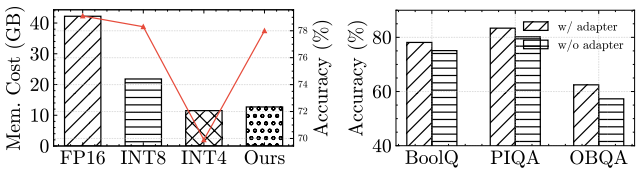

Impact of Elastic Adapter. We compare AssyLLM with a baseline approach that uses a simple dimensional transformation matrix to connect blocks. As shown in Figure 20b, adding the assembling adapter improves performance by 3.02%, 3.19%, and 5.17% on datasets. The improvement demonstrates the effectiveness of our method in facilitating seamless block integration and enhancing performance.

Impact of Block Swapper. To verify the effectiveness of Block Swapper, we evaluated two pipeline management strategies: one without pre-loading and pre-swapping (system default), and another without pre-swapping, as shown in Figure 12. The results in Figure 21 show that as the number of block swaps increases, incorporating pre-loading reduces local time by up to 30.21% compared to the default pipeline. Additionally, adding pre-swapping on top of pre-loading further reduces total time by 68.12%. This significantly minimizes the additional latency from block swapping, improving overall system efficiency.

(a) Total energy cost. (b) Total network cost.

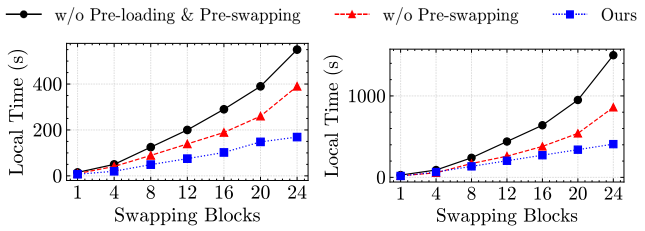

Figure 19: Resource cost of AssyLLM and baselines. Dataset: BoolQ.

(a) Block Quanter on BoolQ. (b) Elastic Adapter.

Figure 20: Ablation study for Block Quanter and Elastic Adapter.

Component-wise Contribution Summary. Each component in AssyLLM contributes to overall performance. Block Comparator selects compatible blocks using CKA and COR scores. Elastic Adapter integrates mismatched blocks by activating adapters only when significant semantic divergence is detected. Block Quanter reduces memory via mixed-precision quantization; INT8/INT4 yields ~70% savings with ~1.1% accuracy loss, while maintaining robust compatibility metrics. Block Swapper improves memory efficiency through correlation-aware prefetching and pre-swapping. Together, these modules enhance accuracy, memory usage, and convergence, as confirmed by our ablation results.

5 Discussion

Criteria for selecting pre-trained models. While AssyLLM shows promising results, selecting the appropriate combination of pre-trained LLMs for the block pool remains a non-trivial task. We prioritize architectural diversity to ensure the assembled model captures a broad spectrum of representational patterns, incorporating both decoder-only models (e.g., LLaMA, OPT, Vicuna) and encoder-only models (e.g., BERT, RoBERTa). Empirical results indicate that such heterogeneity improves generalization across downstream tasks. However, expanding the block pool increases memory and computation overhead, and not all combinations yield consistent performance. Our experiments reveal fluctuations across different LLM sets, highlighting the need for a more principled strategy to guide model selection. In future work, we plan to explore adaptive construction methods based on task embeddings, domain-aligned pretraining, or proxy task performance to optimize block pool composition.

System Robustness and Scalability. While AssyLLM consists of four interacting components—Block Comparator, Elastic Adapter, Block Quanter, and Block Swapper—each is implemented as an independent and lightweight module (300~600 lines in Python), coordinated through shared interfaces without tight coupling. For example, the Comparator and Quanter operate purely on forward activations, while the Adapter is only triggered when structural mismatches occur. This modularity enhances robustness against architectural variations and supports easy reuse across different LLM workflows.

In terms of scalability, while the current design targets edge devices, AssyLLM can be extended to larger LLMs (e.g., LLaMA-13B or 30B) with minimal architectural changes. The primary challenges lie in the memory overhead due to increased block pool size and potential I/O pressure during block swapping. These can be addressed via hierarchical block indexing, storage prefetching, or streaming-based execution, which we leave as promising directions for future work.

Why block-level assembly works better? Traditional fine-tuning incurs high memory overhead, restricting participation to high-resource devices and reducing data diversity in FL. In contrast, our method removes most BP-related memory costs, enabling participation from low-resource devices. By assembling blocks from diverse pre-trained LLMs, our framework captures a broader range of representational patterns. Moreover, the inherent redundancy in LLMs allows them to tolerate moderate structural or semantic inconsistencies, so the assembled model can still perform effectively even if individual blocks are not perfectly aligned.

6 Conclusions

In this paper, we propose AssyLLM, a memory-efficient federated fine-tuning framework using pre-trained LLMs block assembly, effectively reducing BP-related overhead. The four key components—Block Comparator, Elastic Adapter, Block Quanter, and Block Swapper—effectively enhance the method's efficiency by addressing block compatibility, mismatches and reducing the memory footprint of block pool. Experiments demonstrate that AssyLLM reduces memory requirements, enhances model accuracy, and accelerates training compared to conventional FedLLM methods.

Abstract

Pattern matching is critical in various network security applications. However, existing pattern matching solutions struggle to maintain high throughput and low cost in the face of growing network traffic and increasingly complex patterns. Besides, managing and updating these systems is labor intensive, requiring expert intervention to adapt to new patterns and threats. In this paper, we propose *Trochilus*, a novel framework that enables high-throughput and accurate pattern matching directly on programmable data planes, making it highly relevant to modern large-scale network systems. Trochilus innovated by combining the learning ability of model inference with the high-throughput and cost-effective advantages of data plane processing. It leverages a *byte-level recurrent neural network (BRNN)* to model complex patterns, preserving expert knowledge while enabling automated updates for sustained accuracy. To address the challenge of limited labeled data, Trochilus proposes a *semi-supervised knowledge distillation (SSKD)* mechanism, converting the BRNN into a lightweight, data-plane-friendly *soft multi-view forest (SMF)*, which can be efficiently deployed as match-action tables. Trochilus minimizes the need for expensive TCAM through a novel entry cluster algorithm, making it scalable to large network environments. Our evaluations show that Trochilus achieves multi-Tbps throughput, supports various pattern sets, and maintains high accuracy through automatic updates.

1 Introduction

Pattern matching is essential to many network applications, such as network intrusion and prevention systems (NIDS/NIPS) [41, 45, 61], web application firewalls [48], network censorship systems [19], and application identification systems [37]. These applications rely on pattern-matching systems to scan packet headers and payloads to check if they match a given set of rules (i.e., patterns or signatures) containing a series of strings and regular expressions.

A recurring theme in pattern-matching systems literature is the gap between the high bandwidth workloads they need to handle and the scalability or cost of existing hardware/-software implementations. Prior pattern-matching systems have attempted to alleviate this gap via algorithm optimization [5, 17, 42, 51, 54, 58, 59, 62] and hardware (GPU/FPGA/NPU) acceleration [22, 24, 35, 44, 49, 50, 64]. For algorithm optimization which is mainly deployed on CPUs, a server is unable to reach more than 70Gbps [52, 53, 58]. While servers optimized with FPGA/GPU/NPU may achieve a higher throughput (i.e., at most 100Gbps under state of the art [64]) thanks to their inherent parallel computation, they significantly increase the complexity in system management and make the updates extremely challenging [11, 32].

The emerging programmable switching ASICs in the network community provide an unprecedented opportunity to bridge this gap. A programmable switch can easily handle multi-Tbps traffic at a line rate with lower cost than GPU/FPGA/NPU/CPU, offering a new possibility for addressing the performance bottlenecks of pattern-matching systems.

Existing works have integrated programmable switches but they still suffer from the issues of accuracy. Multi-string matching [25, 30, 52] employs Nondeterministic Finite-state Automata (NFA) relevant matching algorithms and is constrained by the limited memory available on the programmable data plane, and thus can only support a limited number of string patterns. Besides, multi-string matching can only detect exact and simple patterns (e.g., digital sequence), which consists of a small subset of pattern matching. Regular expression matching is a more powerful tool for matching complex patterns, attributing to regular expression's representative syntaxes (e.g., Kleene star and counting constraint). However, the aforementioned methods can not extend to deploy complete pattern matching on programmable switches. This is because the serialized state transitions of automaton utilized in [25, 30, 52] cause the problem of resource explosion when deploying the complex syntaxes in regular expressions (e.g., range matching "$[a\text{-}f]$"). Today, we are still faced with the need to build a pattern-matching system that

Table 1: Trochilus v.s. prior arts. Hardware includes GPU, FPGA, and NPU. Switch represents programmable switch.

Platform	Method	Solution	High throughput	Accuracy	Manag ability
Software	Automaton-based (Rule-based)	[51,53,54]	×	✓	×
Hardware		[13,49,64]	✓	✓	×
Switch		[25,52]	✓	×	×
	Model inference-based	Trochilus	✓	✓	✓

can support line rates on the order of 100Gbps [64]. This paper answers this challenge with the Trochilus Programmable Data Plane-based complete pattern matching system.

Moreover, current pattern-matching systems are focused on enhancing performance while managing cost and power consumption, but they do not allow for the efficient updating of pattern sets to ensure sustained accuracy. In practical deployment, pattern-matching systems require not only an initially high-accuracy pattern set but also regular updates to maintain high accuracy, in order to address new traffic patterns (e.g., new cyber attacks and new applications). However, current rules are typically obtained through offline techniques (e.g., crafted by experts or obtained from proprietary vendor algorithms) [64], which is labor-intensive and induces high maintenance costs. Trochilus addresses this challenge by replacing traditional pattern matching with model inference.

In designing Trochilus, we argue that an ideal system for pattern matching should meet three requirements: R1: High Throughput (Capable of achieving high throughput at a low cost). R2: Accuracy (consistently able to accurately identify traffic patterns). R3: Manageability (efficiently updating the system to accommodate new network traffic patterns). Unfortunately, prior pattern matching schemes [13,25,49,51–54,64] fall short on at least one requirement, as shown in Table 1. Tochilus fulfills all three requirements by incorporating the learning abilities of model inference with the low-cost and high-throughput advantages of programmable switches.

To meet the requirements of accuracy and manageability, Trochilus designs a pattern modelization method that can losslessly transform given patterns to a byte-level recurrent neural network (BRNN). BRNN preserves expert knowledge from the patterns, thereby achieving high initial accuracy. Compared with traditional pattern-matching systems, the BRNN enables automatic updating with labeled data for higher accuracy and supports easy manageability over ever-changing traffic patterns. Further, concerning limited or even no labeled data, Trochilus introduces a semi-supervised knowledge distillation (SSKD) mechanism to transform the BRNN into a lightweight yet accurate model, called the soft multi-view forest (SMF), whose inference process only requires simple operations supported by the switches' match-action paradigm. By training multiple biased decision trees, the SMF can better represent complex traffic patterns and achieve higher accuracy compared to other tree-based models [55,65,66].

To achieve high throughput with programmable switches, Trochilus develops a model representation to efficiently deploy SMFs on the data plane. Trochilus converts SMFs to match-action tables through tree encoding. Specifically, we formulate an optimization problem that aims at finding a partition of table entries to minimize the TCAM requirement. To this end, we propose an entry cluster algorithm, which heuristically aggregates table entries into clusters based on the similarity among features represented by table entries so that each cluster only requires a more compact table. Moreover, a sliding window mechanism is introduced to effectively inspect the incoming data packet payload.

We evaluate Trochilus extensively with various pattern sets (Snort [41] and Suricata [45]) and workloads (captured in one of the largest public cloud providers). Evaluations show that Trochilus effectively preserves the accuracy of original patterns without labeled data and maintains even higher accuracy through training with labeled data. Moreover, Trochilus achieves multi-Tbps throughput and supports various pattern sets with limited resources.

Contributions. 1) We design a novel framework that integrates model inference with low-cost high-throughput data plane processing to address the pressing challenges of scalability, accuracy, and manageability faced by pattern matching systems. 2) We design pattern modelization, SSKD, and entry cluster optimization to convert patterns into accurate and lightweight models and deploy them on resource-constrained programmable data planes. 3) We implement a prototype of Trochilus using the Tofino switch as the programmable data plane and make its source code available [3]. We conduct testbed experiments to show its performance superiority.

2 Background and Motivation

In this section, we introduce the background of pattern matching, propose the design requirements of pattern matching, and highlight the limitations of the prior arts in this field.

2.1 Pattern Matching

The key goal of a pattern-matching system is to identify when network traffic triggers any of up to tens of thousands of signatures, also known as rules. In network applications (e.g., network intrusion and prevention systems), patterns typically include strings for exact matching and regular expressions for complex patterns. Formally, given an alphabet σ, an input string $x = x_0, \cdots, x_n$ and a set of patterns $P = \{p_1, \cdots, p_k\}$, where each element $p_i = r_1 \cdots r_m$ is a predefined pattern and each x_i or r_i is a character belonging to σ, pattern matching can check whether each p_i is a substring of x. Since Finite-state Automata (FA) provides a formal and flexible framework for representing and processing regular languages, converting patterns to Nondeterministic Finite-state Automata (NFA)

and deterministic finite-state automata (DFA) is a common method for practical pattern matching [52].

2.2 Design Requirements

Requirement 1 (R1): High Throughput. Recently, the network bandwidths at traffic aggregation points in regional ISPs have already surpassed multi-hundred Gbps. Many network device providers [46] and standard organizations [2] are moving towards the era of 800 Gbps bandwidth. An ideal pattern-matching system should keep up with the current network bandwidth requirements. Moreover, the financial cost of the system must be low enough to be affordable for the majority of companies.

Requirement 2 (R2): Accuracy. An ideal pattern-matching system should have high initial accuracy upon deployment and consistently maintain accurate identification of network traffic patterns during operation.

Requirement 3 (R3): Manageability. In practical deployment, pattern matching systems need to continuously update their pattern sets to identify new traffic patterns (e.g., new applications and new cyber attacks). However, updating patterns requires experts to analyze large-scale network traffic and extract representative patterns, which is labor-intensive. An ideal pattern-matching system should be manageable and be able to update and maintain patterns with low overhead.

2.3 Limitations of Prior Studies

Many efforts have been made to accelerate pattern matching, including software-based algorithmic optimization, hardware acceleration, and programmable switch acceleration.

Software-based algorithmic optimization. Algorithmic optimization boosts throughput by reducing memory consumption [5, 10, 59] or increasing the number of characters per state transition in NFA [42, 51, 54, 62]. However, since servers' CPUs are not designed specifically for high-throughput packet processing, the performance of software-based packet processing is still constrained. Actually, a server-based pattern matching engine still can not achieve 70 Gbps packet processing throughput [53, 54, 58]. Although scaling up the number of servers can achieve higher throughput, it also induces high capital and management costs [15]. To sum up, software-based algorithmic optimization methods do not satisfy R1.

Hardware acceleration. Some works leverage GPUs for pattern matching as the single instruction multiple threads (SIMT) architecture can effectively parallelize an algorithm, providing multi-10 Gbps throughput [24, 49, 50, 60]. However, it is difficult to maintain GPU's performance at the peak rate as it requires all computational units to have the same instruction stream [34]. Additionally, GPUs also come with higher power costs. FPGA-based solutions utilize circuit-level parallelism to accelerate pattern matching. While these methods improve the overall throughput of pattern matching [13, 35, 44, 64], they do not support dynamic updates well due to the FPGA programming process. Such inflexibility increases the investment in capital and research and development efforts. Furthermore, the performance of these hardware alternatives still struggles to keep pace with the rapidly increasing network traffic since these hardware alternatives are typically connected to servers via PCIe which provides limited bandwidth [44]. To sum up, the traditional hardware acceleration does not satisfy R1.

Traditional Programmable switch acceleration. Programmable switches, centering around Protocol-Independent Switch Architecture (PISA) [7], provide flexible packet processing capabilities at high throughput, presenting opportunities for network functions offloading [26, 32, 33, 56]. They exhibit similar power consumption and capital costs as traditional fixed-function switches, significantly reducing costs compared to CPUs or other hardware. However, PISA faces computation and storage constraints. Complex instructions such as multiplications and divisions are not allowed. PISA has limited match action unit (MAU) stages (e.g., Tofino 1 has 12 stages) to implement the main calculation logic. In addition, storage is limited, e.g., on Tofino 1, the SRAM of each pipeline is 120MB and the TCAM is 6.2MB. Previous works utilize programmable switches to accelerate multi-string matching [25, 52]. They mainly convert the multi-string matching patterns into NFAs and then perform optimization on state encoding and state transition. However, prior works perform sequential state transitions, where the number of MAU stages and TCAM requirements increase linearly as the average length and the total number of multi-string patterns grow. As a result, they are unable to achieve a complete deployment toward large-scale multi-string patterns. Moreover, prior works can not be extended to more general and complex pattern matching. To sum up, traditional programmable switch solutions do not satisfy R1 and R2.

Common limitations of prior studies. The deployed patterns can not always remain effective over ever-changing traffic patterns. However, prior arts primarily focus on the acceleration of pattern matching and do not provide efficient mechanisms for pattern update. Therefore, existing pattern-matching systems can not meet R3.

3 Trochilus Overview

3.1 Target Scenarios

Trochilus acts as a functional instance of network applications, inspecting payloads at the byte level and taking corresponding actions (such as alerting, forwarding, and dropping). Via network data planes, Trochilus can be deployed as a link middlebox or as a dedicated application for traffic analysis, such as redirecting traffic to Trochilus. The current mainstream data plane includes programmable switches and SmartNICs [36].

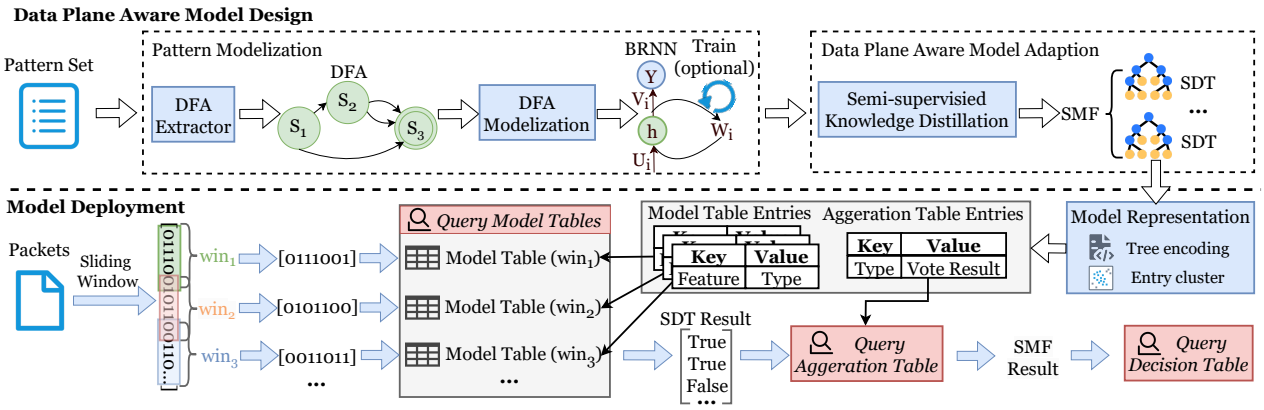

Figure 1: Trochilus framework.

These two types of hardware have drastically different characteristics: programmable switches have much higher throughput, with much limited computation capability. In this paper, we focus on PISA-driven pattern matching design, which can be integrated into other data plane hardware (e.g., SmartNICs) with minor changes. Note that when the depth of the payload exceeds the single pipeline processing capability of the programmable switch, Trochilus will recirculate the packets and discard the inspected parts of the packets.

In this paper, we assume that a processed packet contains an Ethernet header, an IP header, a UDP or TCP header, and a payload to be inspected. Note that our approach can support other header and payload fields (e.g., ICMP). The packet payload can be encoded in any form, such as ASCII and UTF-8. In this paper, we adopt ASCII encoding, where each character is encoded as one byte. Our approach is devoted to scenarios where the payload only contains plain text that is not encrypted. For processing encrypted traffic, Trochilus can be combined with previously proposed decryption mechanisms [43] to handle encrypted traffic.

3.2 Trochilus Workflow

As illustrated in Figure 1, Trochilus consists of two components: *data plane aware model design* and *model deployment*.

Data plane aware model design combines *pattern modelization* and *data plane aware model adaption* to generate data plane-friendly learning models from patterns, enabling Trochilus to replace traditional pattern matching with model inference. Given patterns extracted from the signature database (e.g. Snort community rules [41]), Trochilus first utilizes the *DFA extractor* to convert the patterns to a DFA. Second, the *DFA modelization* transforms the DFA into a BRNN, which can effectively preserve the patterns' expert knowledge and achieves high initial accuracy. When labeled data is available, the BRNN can automatically capture underlying patterns in the data through training to improve accuracy. Although the BRNN is effective, it cannot be deployed in the data plane. To generate a data plane aware model, Trochilus then leverages semi-supervised knowledge distillation (SSKD) to distill a soft multi-view forest (SMF), which consists of multiple soft decision trees (SDTs), under the instruction of the BRNN.

The key component of *model deployment* is *model representation*, which targets efficiently translating an SMF into multiple model tables and one aggregation table through *tree encoding*. Each model table is encoded from an SDT in the SMF, and the aggregation table stores the SMF inference results voted by each model table. When deploying model tables, Trochilus designs an efficient *entry cluster* algorithm to greatly reduce the TCAM requirements.

For incoming packets, Trochilus first utilizes a sliding window mechanism to extract payload segments for different windows as features. Then, these features are used to query model tables to obtain inference results of SDTs. The SMF result is voted by inference results of SDTs through querying the aggregation table. Finally, based on the SMF result, users can design post-processing actions encoded in the decision table, such as dropping, passing, alerting, or forwarding.

The conversion of the SMF model into data-plane table entries is lossless. Trochilus supports online updates of the pattern matching system by collecting new labeled attack traffic, incrementally training the model offline, and converting the updated rules into table entries. These entries can then be installed on the switch without interrupting ongoing services. This allows Trochilus to adapt to new attack patterns with minimal impact on system operations.

4 Data Plane Aware Model Design

In this section, we show how we convert patterns to byte-level recurrent neural networks (BRNNs) and how we further transform the BRNNs to soft multi-view forests (SMFs) with semi-supervised knowledge distillation (SSKD).

4.1 Pattern Modelization

In this subsection, we utilize the byte-based DFA extractor to construct a DFA from patterns. Then we leverage the DFA modelization to convert the DFA into a BRNN as the teacher model in SSKD. Compared to other existing teacher models, BRNN is the most suitable for pattern matching. Specifically, compared to DFAs, when labeled data is available, the BRNN can capture new undefined patterns in the data through training, leading to an improvement in accuracy and boosting the performance of the following knowledge distillation. Compared to other learning models (e.g., LSTM [20], GRU [12]), the BRNN preserves the provided patterns' expert knowledge and retains a high accuracy under cold start.

Byte-based DFA extractor. Network security applications, e.g., Suricata [45] and Snort [41], usually use Perl-compatible regular expression (PCRE) [39] syntax to define patterns. We also use the PCRE syntax as the standard syntax, which can easily be extended to other syntax flavors (e.g., POSIX [16]). The supported PCRE syntax is shown in Appendix A.

Consider an example pattern in Snort "$\backslash x26cvv\backslash x3d[0\text{-}2]\{3,5\}$". Since this pattern can appear anywhere, we first convert the pattern to "$.*\backslash x26cvv\backslash x3d[0\text{-}2]\{3,5\}.*$". Here, '.' is the wildcard that can match any character. '$*$' is the Kleene star operator to match the preceding subexpression zero or more times. Braces "$\{a,b\}$" are the range matching to match the preceding subexpression a to b times. To make this pattern consistent with the packet payload format (i.e., bytes), we convert each character in the pattern except the special operators in PCRE (e.g. '$*$') into its corresponding one-byte ASCII code. So the final converted pattern is "$.*$ $0x26$ $0x63$ $0x76$ $0x76$ $0x3d$ $[0\text{-}2]\{3,5\}$ $.*$".

Next, we construct the DFA for the converted pattern. We use Thompson's construction algorithm [47] to transform a pattern into an equivalent NFA. Then we convert the NFA to a DFA with the powerset construction algorithm [40]. We minimize the number of states of the DFA by the DFA minimization algorithm [21]. Formally, a DFA consists of a 5-tuple $\mathcal{A} = (\Sigma, \mathcal{G}, \mathcal{W}, \alpha_0, \alpha_\infty)$, whose elements are defined as follows. Σ: the input vocabulary, whose size is $V = 2^8 = 256$; $\mathcal{G}$: a finite set of states, where $|\mathcal{G}| = K$; $\mathcal{W} \in \mathbb{R}^{V\times K\times K}$: transition weights; $\mathcal{W}[\sigma, g_i, g_j]$: the weight of transferring g_i to g_j according to the input σ; α_0: initial weight; $\alpha_\infty[i]$: the final weight of g_i after reading the whole input; α_∞: final weights; $\alpha_\infty[i]$: the final weight of g_i after reading the whole input. Consider an input sequence $\mathcal{X} = \{x_1, x_2, ..., x_N\}$ and a path $\mathcal{P} = \{u_1, u_2, ..., u_{N+1}\}$, where u_i is the index of state concerning x_i. The score $\mathcal{B}(\mathcal{A}, \mathcal{P})$ of path $\mathcal{P}$ is defined as:

$$\mathcal{B}(\mathcal{A}, \mathcal{P}) = \alpha_0[u_1] \cdot \left(\prod_{i=1}^{N} \mathcal{W}[x_i, u_i, u_{i+1}] \right) \cdot \alpha_\infty[u_{N+1}]. \quad (1)$$

Let $\pi(\mathcal{X})$ be the set of all paths starting from any state in $\mathcal{G}_0$ and ending at any state in $\mathcal{G}_\infty$, where $\mathcal{G}_0$ is the set of start states and $\mathcal{G}_\infty$ is the set of final states. The sum of path scores, $\mathcal{B}_{fw}(\mathcal{A}, \mathcal{X})$, can be computed by the Forward algorithm [4]:

$$\mathcal{B}_{\text{fw}}(\mathcal{A}, \mathcal{X}) = \sum_{\mathcal{P}\in\pi(x)} \mathcal{B}(\mathcal{A}, \mathcal{P}) = \alpha_0^T \cdot \left(\prod_{i=1}^{N} \mathcal{W}[x_i] \right) \cdot \alpha_\infty. \quad (2)$$

DFA modelization. The DFA is parameterized by Θ, which is defined as $< \mathcal{W}, \alpha_0, \alpha_\infty >$. Let $h_t \in \mathbb{R}^K$ be the forward score vector after considering the first t words $\{x_1, x_2, ..., x_t\}$ of $\mathcal{X}$. We can rewrite the forward score into a recurrent form:

$$h_0 = \alpha_0^T, \quad (3)$$

$$h_t = h_{t-1} \cdot \mathcal{W}[x_t], 1 \le t \le N, \quad (4)$$

$$\mathcal{B}_{\text{fw}}(\mathcal{A}, \mathcal{X}) = h_N \cdot \alpha_\infty. \quad (5)$$

Here, we treat matching on a pattern as a binary classification task. To this end, we expand $\mathcal{B}_{\text{fw}}(\mathcal{A}, \mathcal{X})$ to a vector $[1, 0]$ when $\mathcal{B}_{\text{fw}}(\mathcal{A}, \mathcal{X})$ is 0, and $[0, 1]$ otherwise. It can be easily generalized to multi-classification tasks as well. Recall that the hidden state computation in the forward propagation of a recurrent neural network (RNN) is given by $h_t = \theta(Ux^t + Wh^{t-1} + b)$, where θ denotes the activation function. When $U = 0, b = 0, W = \mathcal{W}$, and θ is the identify function, the forward score computation of the DFA (as shown in Equation 4) becomes analogous to the forward propagation process of the RNN. On this basis, we convert the DFA with byte-format transitions into an RNN with Θ, called BRNN. In practice, fine-grained classification may be desired, which considers the different combinations of final states, i.e., different terminal state combinations correspond to different output categories. In this case, we can use an MLP after BRNN as the aggregation layer. The BRNN can retain the accuracy of the original patterns and be put into production immediately without waiting for data collection. When enough labeled data is collected, the performance of the BRNN can be further improved through training.

4.2 Data Plane Aware Model Adaption

The BRNN obtained in the previous step is difficult to directly deploy on the data plane, since it involves float and nonlinear operations, and requires huge storage resources. To promote easy deployment on the data plane, we further convert BRNN, an unwieldy teacher model, into a lightweight ensemble model called SMF using SSKD.

Existing knowledge distillation approaches face two major problems when applied in network scenarios. First, labeled data only accounts for a very small proportion. It is challenging to distill a student model with high accuracy in such data-scarce scenarios. Second, due to the limited computational and memory resources on programmable switches, there are stringent restrictions on the selection of student models. Specifically, prior studies mostly deploy tree-based models (e.g., decision trees) [55,57,65]. However, the generalization of the decision tree is too limited to represent complex

traffic patterns. Training decision trees on large-scale data are prone to overfitting, resulting in poor classification accuracy.

Algorithm 1: Data Plane Aware Adaption.

Input: Teacher model $BRNN$, Labeled data D_l, Unlabeled data D_u, Tree set T_{set}

1 $\mathcal{Y}_l^{soft}, \mathcal{Y}_u^{soft}, \mathcal{Y}_u^{hard} \leftarrow BRNN(D_l, D_u)$;
2 $\mathcal{Y}_l^{mix} \leftarrow \beta \cdot \mathcal{Y}_l^{hard} + (1-\beta) \cdot \mathcal{Y}_l^{soft}$;
3 $\mathcal{Y}_u^{mix} \leftarrow \beta \cdot \mathcal{Y}_u^{hard} + (1-\beta) \cdot \mathcal{Y}_u^{soft}$;
4 $\mathcal{Y}^{mix} \leftarrow \mathcal{Y}_l^{mix} \cup \mathcal{Y}_u^{mix}$;
5 $w \leftarrow [1] * (D_l.size + D_u.size)$;
6 $\mathcal{X}_{filtered}, \mathcal{Y}_{filtered}^{mix} \leftarrow \mathcal{X}, \mathcal{Y}^{mix}$;
7 **for** m **in** $range(n_t)$ **do**
8 $\quad T_m \leftarrow TrainSDT(\mathcal{X}_{filtered}, \mathcal{Y}_{filtered}^{mix}, w)$;
9 $\quad T_{set} \leftarrow T_m \cup T_{set}$;
10 $\quad error \leftarrow TestSDT(\mathcal{X}, \mathcal{Y}^{mix}, T_m)$;
11 $\quad w \leftarrow UpdateWeight(error, w)$;
12 $\quad \mathcal{X}_{filtered}, \mathcal{Y}_{filtered}^{mix} \leftarrow SampleFilter(\mathcal{X}, \mathcal{Y}^{mix}, w)$;
13 **end for**
14 **return** T_{set}

In Trochilus, we propose SSKD and SMF, which overcome the above-mentioned problems with two key ideas. First, we introduce the semi-supervised learning strategy into the knowledge distillation. Attributing to the cold start characteristic, the BRNN can effectively preserve the expert knowledge from patterns and hence offers adequate accuracy without training data. Moreover, when enough labeled data is collected, BRNNs' performance can be further improved. As a result, we jointly utilize the ground truth of labeled data and inference results of BRNN on both labeled and unlabeled data to train the student model. Second, we propose SMF as the student model instead of the decision tree (DT) used in the previous studies [55]. SMF is an ensemble model which is composed of multiple soft decision trees (SDT). Each SDT is trained in a weight-based iterative manner and is applied with binary features to adapt to programmable switches. The submodels (SDTs) of the ensemble model (SMF) are trained with samples with different weights to achieve multi-view observation and learn the inherent patterns.

SSKD aims to generate soft labels that contain knowledge of the teacher model and applies the soft labels to train the student model. We define the labeled data as $D_l = \{(\mathcal{X}_1, \mathcal{Y}_1), \ldots, (\mathcal{X}_n, \mathcal{Y}_n)\}$ and unlabeled data as $D_u = \{\mathcal{X}_{n+1}, \mathcal{X}_{n+2}, \ldots, \mathcal{X}_{n+m}\}$, where each $\mathcal{X}$ is composed of the bit sequences extracted from the packet payload (binary feature).

The training phase of SSKD includes three steps as shown in Algorithm 1. First, we acquire the output logits of BRNN (line 1 in Algorithm 1), which are the output values of the Softmax layer, for both labeled and unlabeled data, and define them as the soft labels ($\mathcal{Y}^{soft}$). Second, we calculate the mixed label $\mathcal{Y}^{mix} = \beta \cdot \mathcal{Y}^{hard} + (1-\beta) \cdot \mathcal{Y}^{soft}$ of a sample, where β is a hyperparameter ranging from 0 to 1, $\mathcal{Y}^{hard}$ is the hard label of the sample (line 2-4 in Algorithm 1). For labeled data, the hard label is its ground truth; for unlabeled data, the hard label is the output label of BRNN. Third, we use all data obtained in the second step to train the SMF (line 5-13 in Algorithm 1). We define the number of iterations (number of trees in SMF) as n_t. The SMF training process includes four steps, as illustrated in Algorithm 1.

(1) We initialize each sample weight w to 1 so that all samples have the same significance at the beginning (line 5-6 in Algorithm 1).

(2) We train an SDT referred to as T_m using the weighted samples for m-th iteration rounds (line 8-9 in Algorithm 1). w affects the training process of SDT including the calculation of the *Gini* index, node partition, and the label selection of leaf nodes. The training process of *TrainSDT* is similar to that of the CART decision tree [9], which utilizes purity to split nodes. The purity after splitting the node via feature A is

$$P(D,A) = \frac{|D_l^A|}{|D|} Gini(D_l^A) + \frac{|D_r^A|}{|D|} Gini(D_r^A), \tag{6}$$

where D is the sample set of the parent node, and D_l^A and D_r^A are the sample sets of the left and right child split by feature A, respectively. The feature with the smallest $P(D,A)$ will be used for node splitting. Different from the calculation of the *Gini* index for hard labels, for the sample set D that contains mixed labels, we calculate its *Gini* index $Gini(D)$ as

$$Gini(D) = 1 - \sum_{y^i \in \mathcal{Y}} \left(\frac{\sum_{(\mathcal{X},\mathcal{Y}) \in D} w \cdot y^i}{|D|} \right)^2, \tag{7}$$

where $\mathcal{Y} = (y^0, y^1, ..., y^C)$, y^i represents the mixed label of type i, and $\mathcal{N}_C$ is the number of classes. The end condition of the SDT training process is consistent with the CART.

(3) In lines 10-11, we test the T_m trained in step (2) on all training sets and update w according to

$$w_i = \frac{w_i^{former}}{Z} exp(-\log \frac{1-error}{error} \cdot \mathcal{Y}_i^{hard} \cdot T_m(\mathcal{X}_i)), \tag{8}$$

where w_i is the weight of sample i, $error = 1 - accuracy$, and Z is the normalization coefficient to make the sum of weight constant. Intuitively, the weights for misclassified samples will be increased.

(4) We filter out samples with weights smaller than tw to reduce the complexity of a single SDT (line 12 in Algorithm 1). The above training is conducted for n_t iteration rounds.

5 Model Deployment

Trochilus deploys trained models onto the resource-limited data plane through model representation and efficiently identifies target patterns using the sliding window algorithm.

Algorithm 2: Entry Cluster.

Input: Entry set E, Maximum table number $\mathcal{T}$, Maximum iterations l, Subset number k

1 Randomly init the center set $c^{(1)} = \{c_1^{(1)}, ..., c_k^{(1)}\}$;
2 Init the target entry set $S = \{S_1, ..., S_k\}, S_i = \emptyset$; iteration round $h = 1$;
3 **while** $h < l$ & $c^{(h)} \neq c^{(h-1)}$ **do**
4 **for** e_i **in** E **do**
5 **for** $c_j^{(h)}$ **in** $c^{(h)}$ **do**
6 $d_j \leftarrow Jaccard(e_i, c_j^{(h)})$;
7 **end for**
8 Assign e_i to the cluster with smallest d;
9 **end for**
10 **for** $c_i^{(h)}$ **in** $c^{(h)}$ **do**
11 Update $c_i^{(h)}$ for S_i;
12 **end for**
13 $h \leftarrow h + 1$
14 **end while**
15 **return** $S^{(h)}$

5.1 Data Plane Model Representation

We present how to represent SMFs in the data plane. Our SMF consists of multiple SDTs. We start with the data plane representation of a single SDT. Prior studies often adopt decimal features to train tree-based models [57, 65, 66]. When converting the rules of these trained models into table entries on the data plane, we need to perform range matching for each feature. Since range matching is not supported by all programmable switches, it has to be expanded into multiple ternary matching using the traditional prefix method [31]. However, when concatenating multiple feature ranges within a classification rule, the number of extensions is multiplied, leading to the problem of entry explosion [66].

Tree encoding. Trochilus solves the above entry combinatorial explosion problem by introducing binary features [55]. For an SDT with binary features, a sequential decision process classifies a given example by selecting a path from the root node to a leaf node. Starting from the root node, a branch is selected by checking the value (0/1) of the current node's bit feature. The tree repeats this process until reaching a leaf node and then returns the classification result. Each path corresponds to a classification rule, and for each rule, we only need to check the bit values of different features. Trochilus converts an SDT to a model table that conducts ternary matching with the concatenation of binary features and extracts table entries from the classification rules of the SDT.

Formally, given the input feature vector $\mathcal{X} = x_0 \cdots x_n$, where $x_i \in \{0,1\}$, the entry set extracted from the SDT model is denoted as $E = \{e_1, e_2, \cdots\}$, where $e_i = (M_i, V_i)$ is a ternary matching rule, with $M_i = m_0 \cdots m_n, m_i \in \{0,1\}$ being the ternary mask, and $V_i = v_0 \cdots v_n, v_i \in \{0,1\}$ being the ternary value. If the condition of $\mathcal{X} = M_i \; AND \; V_i$ is satisfied, a hit in e_i is indicated and the corresponding action will be executed. This implies that for each e_i, we only need to consider the indices $pos(e_i) = \{p | M_{ip} = 1\}$, and $\forall j \in pos(e_i), x_j = v_{ij}$. For example, let $\mathcal{X} = x_0 x_1 \cdots x_7$ denote an input sequence, which is an 8-bit feature. The path to leaf node 5 in Figure 2 is: If $x_1 = 1$ *and* $x_4 = 1$ *and* $x_8 = 0$; Then $class \leftarrow 5$. As feature values in positions 1, 4, and 8 need to be considered, the ternary masks M is $0b10010001$ and the corresponding ternary value V is $0b10010000$. By employing wild card matching denoted by $*$, we can specify this entry as "$1**1***0$".

Model table resource minimization problem. In model deployment, we observe that most table entries converted from SDTs have redundant information. Based on our statistics, over 90% of the binary data in the masks are zero, indicating that most entries do not require the full matching width of n. Therefore, we can further optimize our algorithm by splitting the original model table that requires the matching of all features into k sub-tables, so that each table only has to match a subset of the features, thereby reducing the overall TCAM usage. We formalize this process as a model table resource minimization problem as follows:

$$\min_{\{S_1,...,S_k\}} \sum_{i=1}^{k} \left| \bigcup_{e_i \in S_i} pos(e_i) \right| \cdot |S_i| \quad s.t. \begin{cases} C_1 : \bigcup_{i=1,...,k} S_i = E, \\ C_2 : S_j \cap S_j = \emptyset, \forall 0 \leq i, j \leq k, i \neq j, \\ C_3 : k \leq \mathcal{T}. \end{cases} \tag{9}$$

Object and Constraints: The optimization goal is to find a k-subset partition of E that minimizes the total TCAM requirement. The total TCAM requirement of each subset can be calculated as the product of the required match length and the number of entries in the subset. There are three constraints. C_1 ensures that the union of all subsets S_i is E. C_2 ensures that there is no overlap between any two subsets S_i and S_j. C_3 ensures that the number of subset k does not exceed the allowed maximum number of tables $\mathcal{T}$, as each subset requires a match-action table.

Entry cluster. The task of partitioning N table entries into k subsets to minimize the overall TCAM requirement is computationally NP-hard. We design a highly efficient heuristic algorithm to solve the aforementioned problem. As depicted in Algorithm 2, we first randomly select k entries from E, each as a cluster center, initialize k clusters of entries as empty sets, and set iteration round h to 1 (line 1-2). Entry cluster proceeds by alternating between two steps.

(1) In the assignment step (line 4-9 in Algorithm 2), we apply the Jaccard distance to measure the dissimilarity between each e_i and each center c_j. Afterwards, the entry e_i is assigned to the closest center in Jaccard distance.

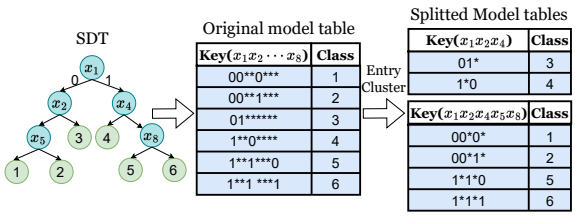

Figure 2: Entry cluster.

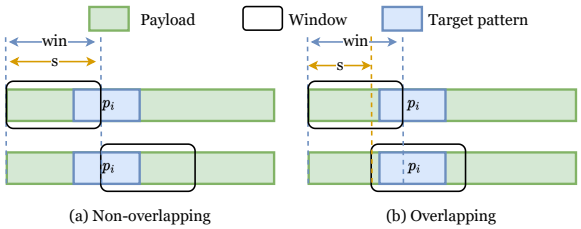

Figure 3: Sliding window.

(2) In the update step, the cluster center is reassigned by summing the distances from each element in the cluster to other elements and selecting the element with the minimum sum (line 10-11 in Algorithm 2).

The algorithm terminates when the entry assignment no longer changes or the maximum iteration number is reached.

Complexity analysis: Let z denote the number of entries, k the number of clusters, n the average feature size for computing Jaccard distance, and l the maximum number of iterations. Each iteration requires computing Jaccard distances between n entries and k centers, resulting in a time complexity of $O(zkn)$. The total worst-case complexity is therefore $O(lzkn)$. In the best case, the algorithm converges after a single iteration, with complexity $O(zkn)$. In the worst case, the Entry Cluster algorithm performs no merging, resulting in the same resource usage as the original SMF. In the best case, all rules are merged into a single wildcard entry, reducing storage usage by a factor of $(z-1)/z$.

Taking the SDT in Figure 2 as an example, the original model table encodes from the SDT takes an 8-bit vector as the ternary match key and has six entries, thus requiring $8*6=48$ bits TCAM at least. Through the entry cluster algorithm, it can be partitioned into two new tables. These two tables respectively utilize a 3-bit and a 5-bit vector as the match key, requiring a total of $3*2+5*4=26$ bits TCAM.

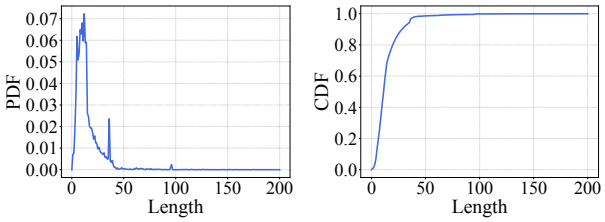
Inference aggregation. We aggregate the results of each SDT through a voting mechanism. We append an aggregation table behind the model tables to match the concatenation of the inference classes of each SDT and obtain the majority of individual inference classes. Since the number of SDTs and inference classes is small, the aggregation table will not induce the problem of excessive entries caused by the combination.

5.2 Sliding Window

The length of the input sequence of each SDT must be limited within the maximum matching length supported by the ternary matching table (e.g., 66 bytes for the Tofino 1). However, the maximum packet length is typically 1500 bytes, which means a packet payload may have to be matched across multiple windows. A naive solution can utilize multiple non-overlapping windows to inspect continuous segments of the payload. However, a target pattern p_i (described in Section 2.1) may occur at arbitrary positions in the packet payload, as shown in Figure 3(a). In this scenario, p_i may span across windows, resulting in a failure to detect p_i in any window.

To address this issue, we propose a sliding window mechanism. The window size is denoted as win, and the maximum length of a pattern is denoted as $\mathcal{L}$. As depicted in Figure 3(b), each time we move the window for s bytes, and hence retain a $win-s$ overlap with the previous window. To ensure that any p_i can be matched, $\mathcal{L} \leq win-s$ must be satisfied.

The maximum payload length that can be inspected by a single pipeline with the sliding window is $win+MS\cdot s$, where MS is the maximum number of MAU stages that can be utilized. Different win and s will influence the depth that can be inspected in a single pipeline and subsequently affect the overall throughput, as recirculation is required for data packets that have not been matched completely. As will be shown in Section 6.6, the sliding window mechanism can significantly enhance the accuracy of pattern matching. This mechanism introduces some additional inspection of packet segments, which can increase resource overhead and affect throughput. Network administrators can deploy Trochilus with carefully chosen window sizes based on the available resources in the target scenarios to achieve the desired trade-off between accuracy, resource overhead, and throughput.



6 Evaluation

We conducted extensive experiments to demonstrate that:

- Trochilus can achieve high initial accuracy comparable to existing pattern-matching systems and can further improve accuracy by around 10% through training (R1).
- Trochilus can achieve Tbps-level throughput for pattern matching while consuming minimal data plane storage resources. (R2).
- Trochilus can automatically update its rules, thereby consistently maintaining high pattern-matching accuracy in the face of changing traffic patterns (R3).

6.1 Dataset and Pattern Set

The pattern sets used are constructed from Snort 2.9.7.0 and Suricata 5.0 provided by ET-OPEN [28]. We collected packet-level traces at gateways of a large data center, which belongs

(a) PDF (b) CDF

Figure 4: Matched packet segments lengths statistics.

to one of the largest public cloud providers and serves tens of Tbps traffic for customers with diverse cloud access requirements. The collected traces are labeled by the advanced attack detection system and application identification system deployed in the data center. We use 10 minutes of traffic traces collected in different time periods of a week. The collected traffic traces mainly cover five categories of the pattern sets, including *info*, *web specific app*, *malware*, *sql*, and *exploit*, containing around 4000 patterns. The total size of collected traffic traces is 534GB. We divide them into the training, test sets with a ratio of 7 : 3. We use the patterns to match the collected traces. The PDF and CDF of matched packet segment lengths are illustrated in Figure 4. The patterns with a length of fewer than 50 accounts for more than 95%.

Ethical Considerations. All data analysis was approved by our cooperation units. We did not investigate human behavior, surface or investigate any individual flows or IP addresses, or store any traffic or individual records to disk. To protect user privacy, all packets in the collected traces are anonymized. We restricted all analysis to aggregate network statistics directly output by Trochilus.

6.2 Baselines and Metrics

Baselines. To evaluate Trochilus's accuracy, throughput, and overhead, we conducted experiments under both, full pattern matching and multi-string matching scenarios. We compared Trochilus with several solutions:

- Traditional Pattern Matching System (TPS): It represents the system implemented by Snort [41] or Suricata [45] based on the given pattern set.
- To evaluate the effectiveness of pattern modelization, in addition to TPS, we also compare BRNN with traditional RNNs, including LSTM [20] and GRU [12], as well as a 4-layer CNN [27] and DAN [23].
- For data plane aware model adaption, we compare our SMF with decision tree (DT) [9], random forest (RF) [8], multi-view forest (MF), soft decision tree (SDT), and soft random forest (SRF). Note that SDT and SRF are the results of distilled DT and RF via SSKD.
- BOLT [52]: As far as we know, no solution currently can support full pattern matching in the data plane. Only BOLT can effectively implement multi-string matching in the data plane. We extract multi-string matching rules from the pattern sets to implement BOLT. To maximize the throughput of BOLT, we set the number of bytes consumed per state transition to 5 and the number of MAU stages used to 12.
- T-MSM-*i*: a trimmed version of Trochilus that only implements multi-string matching rules from the pattern set. Trochilus-*i*: a full version of Trochilus that implements full pattern matching. Here, *i* denotes the number of MAU stages used on the programmable switch.

Metrics. *Accuracy* is the weighted ratio of correctly classified packets in all packets. The weight of each category is the product of the other categories' packet numbers, addressing the imbalance of collected traces. # *table entries* is the number of table entries. *TCAM requirement* is the product of the table entry number and the width of the matching key.

6.3 Experimental Setup

Implementation. We develop a Trochilus prototype which includes about 2000 lines of $P4_{16}$ [6] code for the data plane and 4000 lines of Python code for the control plane. In the data plane, to implement the sliding window mechanism, we replicate both the model and the aggregation table for each window. For an incoming packet, the switch first extracts the payload segments for different windows into customized headers. Afterward, each model table takes different payload segments as the match field, and its action is to obtain the classification result of an SDT. In the next stage, the aggregation table matches the results of each model table and flags the packet if some patterns get matched. In the control plane, we use *automata_tools* library [29] to convert patterns to DFAs, *Pytorch* library [38] to implement BRNN, and Python's *Numpy* library [18] to implement SSKD and SMF.

Resource breakdown. We deployed Trochilus and BOLT to a 12-stage 6.4Tb/s EdgeCore wedge 100BF-65X Tofino switch with a local CPU of Intel (R) Xeon (R) Gold 5218 CPU @ 2.30GHz. Two Dell R230 servers (Intel XeonE2620 v4, 64GB RAM, 40Gbps Intel Network Interface Card) are used for data transmission. We install the DPDK Pktgen [1] on each server to achieve high-performance traffic replay. We run Snort 3 and Suricata 7 software experiments on a Dell R230 server. For pattern modelization, we set the learning rate to 10^{-4}, the batch size to 500, and the hidden state size to 100 for each model. We use the cross-entropy loss as the objective function. We train each model for 200 epochs and use early stopping to avoid overfitting. For data plane aware model adaption, we set β to 0.5 in SSKD. To achieve a balance between model complexity and accuracy, we set n_t to 5, and $thre_w$ to 0.5 in SMF. In each SDT we set *minimum samples* to 15, which is the minimum number of samples required to be at a leaf node. For model deployment, we set $k = 5$ in the entry cluster algorithm, and $s = 30, w = 64$ in the sliding

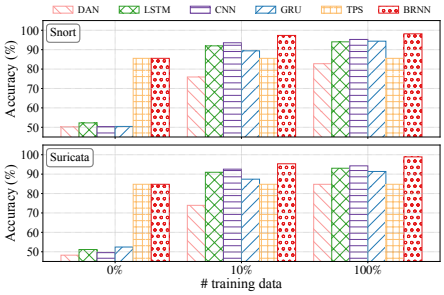


Figure 5: Teacher model accuracy of pattern matching (Snort and Suricata).

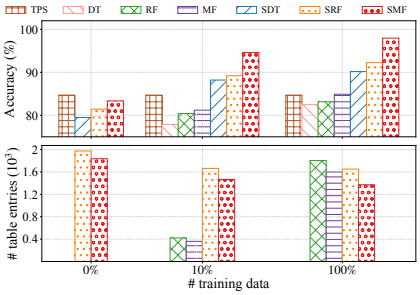

Figure 7: Student model performance of pattern matching (Suricata).

window.

6.4 Data Plane Aware Model Performance

Pattern matching accuracy. Trochilus achieves initial accuracy comparable to TPS. Moreover, through training with labeled data, both the teacher model BRNN and the student model SMF improve accuracy by over 11% compared to TPS.

For pattern modelization, we compare the performance of BRNN and baseline models trained with 0%, 10%, 100% training data. Figure 5 shows the average accuracy of BRNN and each baseline on all categories, and details are shown in the Appendix A. In zero-shot scenarios (i.e., 0% training data), both BRNN and TPS perform the best among all, achieving 85.2% accuracy, demonstrating that BRNN can effectively preserve the full knowledge of original patterns to achieve high initial accuracy. On the contrary, the other baselines only have 50% accuracies since they literally perform random guesses. In few-shot scenarios (i.e., 10% training data), BRNN boosts the accuracy to 96.3%, showing superior accuracy over all baselines. Among the baselines, TPS performs the worst since current pattern matching systems like Snort and Suricata cannot improve accuracy through training like machine learning models do. DAN also performs poorly, only obtaining an accuracy of 74.9% when given 10% training data. The best-performing one among the baselines, i.e., CNN also underperforms BRNN. For full training, BRNN is again the best performing one among all, achieving an accuracy of 98.5%. DAN only achieves 83.7% accuracy. LSTM, CNN, and GRU achieve accuracies of around 93%, which are still inferior to that of BRNN. In a word, BRNN achieves the best accuracy in all scenarios. This justifies the selection of BRNN as the teacher model in the following SSKD.

For data plane model adaption, we compare SMF with baselines trained with 0%, 10%, 100% training data, as shown in Figure 6 and Figure 7, and details are shown in the Appendix A. In the zero-shot scenario, SMF also preserves the expert knowledge of original patterns, achieving an initial accuracy of 83.7%, which is comparable to TPS. DT, RF, and MF are not available in zero-shot scenarios since there is

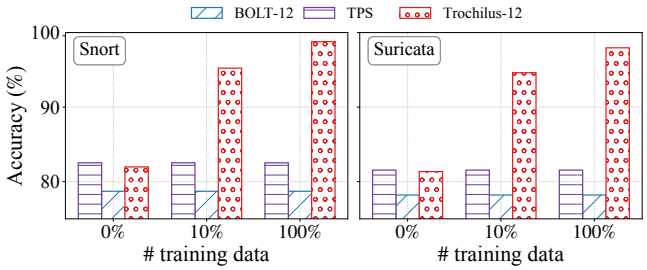

Figure 8: Accuracy comparison of multi-string matching.

no labeled data. In the few-shot scenario, attributing to the SSKD, the accuracy of SMF is more than 12% better than all non-distilled models. Compared with SRF, our solution still presents an advantage of about 5% in accuracy. When trained with full data, SMF achieves over 97.1% accuracy. More importantly, compared to TPS, SMF can achieve an accuracy improvement of over 11% through data training.

We also evaluate # table entries converted from RF, MF, SRF, and SMF. As shown in Figure 6 and 7, # table entries in SMF are less than that in SRF, indicating the lightweightness of the SMF. In the few-shot scenario, SMF and SRF introduce more table entries compared to RF and MF since the SSKD leverages more unlabeled data to train to boost the accuracy. Therefore, SMF is the best choice for the data plane aware model in terms of accuracy and resource efficiency.

Multi-string matching accuracy. Since existing solutions can only perform multi-string matching in the data plane rather than complete pattern matching, we compared the trimmed version of Trochilus, T-MSM-12, with BOLT on multi-string matching. T-MSM-12 consistently achieves higher accuracy than BOLT. Additionally, T-MSM-12 still achieves an initial accuracy comparable to TPS, and through data training, it can improve accuracy by over 10%.

Figure 8 illustrates the accuracy of T-MSM-12, BOLT, and TPS based on the given multi-string pattern set under different training data proportions. In zero-shot scenarios (0% training data), T-MSM-12 achieves similar accuracy with TPS, which is 2% higher than BOLT. Because BOLT matches rules based

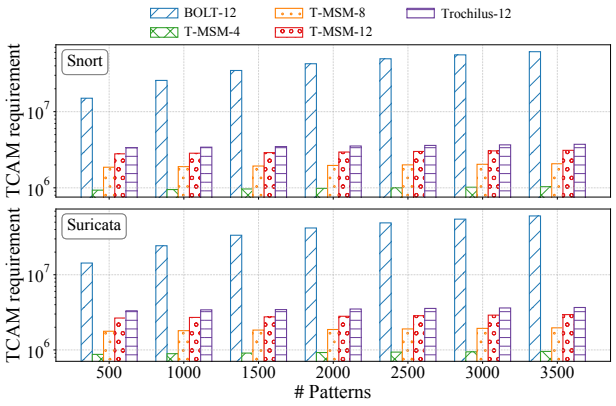

Figure 9: Comparison with BOLT on TCAM requirement. BOLT only supports multi-string matching and uses 12 stages. T-MM-*i* represents Trochilus using *i* stages for multi-string matching. Trochilus-12 represents Trochilus using 12 stages for complete pattern matching.

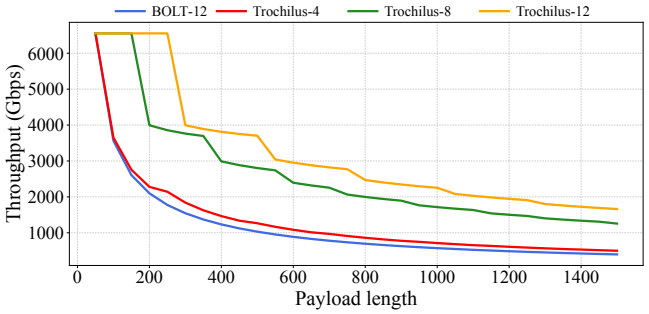

Figure 10: Comparison of throughput. Note that BOLT utilizes 12 MAU stages to achieve maximum throughput and only supports multi-string matching. Trochilus supports full pattern matching.

on serialized state transitions of automaton, it can not handle complex and elongated rules in programmable switches with limited storage and computing resources. In contrast, T-MSM-12 transforms rule matching into model inference, which allows it to handle complex and elongated rules with high effectiveness. In the few-shot and the full training scenarios, T-MSM-12's accuracy is more than 15% higher than BOLT's and more than 10% higher than TPS's. Obviously, like TPS, BOLT is also unable to improve its accuracy through training. Specifically, BOLT cannot expand its state machine converted from multi-string patterns via learning from training data, so its accuracy remains at 82%. Meanwhile, the accuracy of Trochilus can be significantly improved through training attributed to its learning ability.

6.5 Model Representation Performance

We conducted experiments on pattern matching and multi-string matching with varying pattern numbers to evaluate the TCAM requirement. We also conducted experiments with varying payload lengths to evaluate the throughput.

TCAM requirement. Figure 9 shows a comparison of TCAM requirements by Trochilus and BOLT on multi-string matching. T-MSM-4, T-MSM-8, and T-MSM-12 reduce the 97.8%, 95.6%, and 93.4% TCAM requirement of BOLT, respectively. The TCAM requirement of BOLT increases rapidly with the increase of the pattern number, due to the dramatic increase of the state number after the patterns are converted to automatons. Specifically, when the number of patterns reaches 3500, the TCAM requirement of BOLT is 4 times that of when the number of patterns is 500. However, Trochilus only increases about 10% TCAM requirement on average. Although more patterns add complexity to the BRNN model, SSKD can effectively distill the knowledge and add it to the data plane aware model, resulting in limited TCAM requirements. Note that T-MSM-4 achieves a similar throughput with BOLT. However, Trochilus can further improve its throughput using more MAU stages, which will be discussed in Section 6.6.

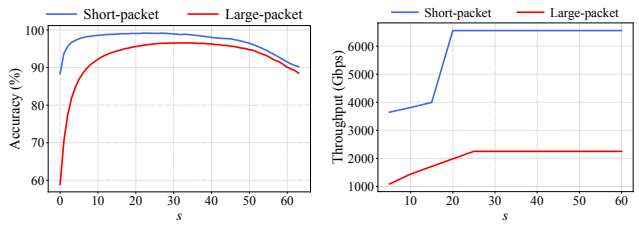

Figure 9 also shows the TCAM requirements of Trochilus for pattern matching under different pattern numbers. We can find that the TCAM requirement for pattern matching is about 15% higher than that for multi-string matching since full patterns have more complex syntax. However, the TCAM requirements of Trochilus on pattern matching are still much less than that of BOLT on multi-string matching. Meanwhile, there is still adequate space for other services after Trochilus has deployed all the patterns in the programmable switches.

Throughput. Trochilus achieves multi-Tbps throughput when processing packets of varying sizes. Restricted by the capability of our traffic generator, we can not fully cover the bandwidth of the Tofino switch used. We use a similar method in BOLT [52] to simulate the theoretical upper limit of the throughput of Trochilus under different pattern sets and workloads. We set the total number of multi-string patterns in Trochilus and BOLT to 3500. For the deployment of Trochilus, we set s to 30 bytes, and use 4, 8, and 12 MAU stages. As shown in Figure 10, with the increasing payload length, both Trochilus and BOLT experience a decrease in throughput due to more recirculations. Nevertheless, even with just 4 stages, Trochilus's single pipeline is able to detect deeper depths than BOLT, thus having higher throughput. Leveraging more MAU stages can improve the inspection depth of a pipeline. Therefore, Trochilus-8 and Trochilus-12 achieve 2.3, and 2.8 times the throughput of BOLT, demonstrating their ability to achieve high throughput in various scenarios.

6.6 Trochilus Deep Dive

We explored the hyperparameters affecting Trochilus in the sliding window and the entry cluster. Note that we extend Trochilus to 12 MAU stages.

Sliding window parameters s and win. The window size

(a) Accuracy (b) Throughput

Figure 11: Analysis of the sliding window step s.

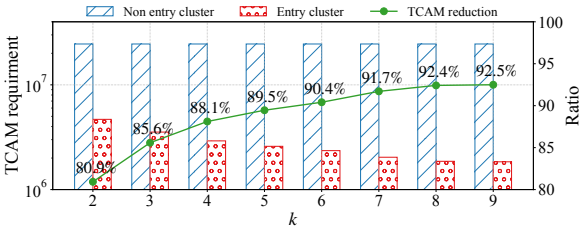

Figure 12: TCAM reduction achieved by entry cluster under different cluster number k.

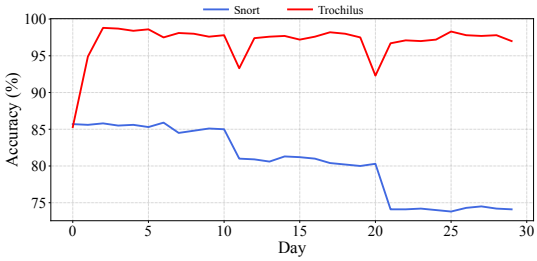

Figure 13: Comparison of accuracy over a 30-day experiment.

win and moving step s are important parameters affecting Trochilus's accuracy and throughput. The larger the *win* is, the larger the packet length that can be inspected by a single window. However, since the key length supported by a ternary match-action table is limited (e.g., no more than 66 bytes in Tofino 1), we fixed the *win* at 64 bytes. Afterward, we apply different s to demonstrate how s affects accuracy and throughput. The short-packet traces and large-packet traces are selected from our dataset, with an average length of 200 bytes and 1000 bytes, respectively. Figure 11(a) shows the impact of different s on accuracy under two traces. As s increases, accuracy first increases and then decreases. The reason behind this is that as s increases, the number of inspection windows decreases, reducing the probability of misclassification. However, it also reduces the probability of a single window capturing patterns, thus decreasing the accuracy.

The throughput of Trochilus over two traces are shown in Figure 11(b). Trochilus can provide high throughput for short packets under different s because they require only a few or even no recirculations which consume negligible bandwidth. However, Trochilus provides relatively low throughput for large packets due to more recirculations. Meanwhile, the PHV resource for storing the extracted payload in the switch restricts the maximum depth that can be resolved in a single pipeline. As a result, the overall throughput for large packets has an upper bound.

Entry cluster parameter k. To further evaluate the performance of the entry cluster, we vary k from 2 to 9 and illustrate the results of the TCAM requirements in Figure 12. When k increases, the TCAM reduction ratio improves from 80.9% to 92.5%, revealing the superior performance of the entry cluster on saving resources. However, the increase of k results in that more tables should be defined and configured in the data plane, introducing a trade-off between the complexity of table management and the TCAM requirement. However, an increase in k results in the need to define and configure more tables in the data plane. Users need to make a trade-off between the complexity of table management and the TCAM requirements.

6.7 Why is Trochilus Easy-to-maintain?

We evaluated Trochilus over multiple weeks of traffic to assess its low maintenance requirements through continuous training. We sampled packet-level traffic for 30 consecutive days at gateways of a large data center and replay the traffic to the Trochilus system and the Snort system. When replaying traffic, we continuously injected different types of zero-day attack traffic on the 10th and 20th days, where the amount of the new attack traffic accounts for 10% of the original attack traffic. On the initial day, Trochilus employed the original pattern set to cold-start since there was no labeled data. At the end of each day, Trochilus was automatically updated based on labeled data collected offline that day.

As shown in Figure 13, Snort exhibits a significant accuracy decline of about 4% and 6% on the 10th and 20th days, respectively. This is because the existing rules are unable to cover new attacks. While Trochilus experiences an accuracy drop of 3% and 4% on the 10th and 20th days, respectively, its accuracy rebounds to about 97% on the 11th and 21st days. Through training with labeled data, Trochilus can automatically mine data patterns and update the transition weights $\mathcal{W}$ of the BRNN. Based on $\mathcal{W}$, we can reconstruct the DFA by mapping the weights into $\{0,1\}$ and convert a trained BRNN back to patterns. Therefore, updating Trochilus parameters through training is equivalent to adding representative new rules. However, Snort requires manual rule extraction from attack traffic to detect new threats, which is both labor-intensive and necessitates special expertise. Conversely, the automated updating process of Trochilus is not dependent on expert knowledge or human efforts, which significantly enhances the system's manageability compared to existing

pattern-matching systems.

In summary, in long-term deployments, traditional pattern-matching systems face challenges in adapting to emerging attacks, while Trochilus sustains a stable accuracy through automatic updates.

7 Discussion

Security analysis. We discuss several adaptive (or white-box) attacks targeting Trochilus. The first type is a throughput exhaustion attack, in which the adversary sends a large volume of jumbo frames (Ethernet packets with payloads exceeding the standard maximum transmission unit (MTU) of 1500 bytes). These oversized packets trigger excessive recirculations within the programmable switches, rapidly depleting their processing capacity. To mitigate such attacks, we propose integrating existing network measurement techniques [14,63] to track both the size and recirculation count of network flows. When statistical indicators surpass predefined thresholds, the system can promptly block the attack traffic and alert network administrators.

The second type is the adversarial attack, where the attacker feeds adversarial inputs to the model to cause model misclassification due to small adversarial perturbations. For example, attackers can add benign bytes to malicious packets to bypass network intrusion detection systems. To tackle this problem, Trochilus can be extended to fuzzy matching to improve its robustness against adversarial attacks. Fuzzy matching (also called approximate pattern matching) is a technique that evaluates the similarity between an observed traffic payload and known malicious patterns, rather than requiring exact matches. Specifically, we can modify our SSKD and use the probability values output by BRNN to train the regression tree instead of the SDT as the fundamental unit of the SMF. We then compare the probability values output by the SMF with a predefined threshold to achieve fuzzy matching.

Scalability analysis. As the number of patterns increases, the required storage may exceed the capacity of a single programmable switch. To address this, the model can be distributed across multiple switches. During packet processing, switches cooperate by forwarding packets to other nodes based on intermediate detection results, thereby forming a complete pattern matching system. We plan to further investigate and optimize this distributed approach in future work. Real-world network applications also require support for encrypted traffic and emerging transport protocols. To handle encrypted traffic, Trochilus can be integrated with existing decryption mechanisms (e.g., [43]). For new protocols, Trochilus can collect relevant packets and update the model accordingly. As data collection is performed offline and model updates are incremental, the system's operation remains unaffected by peak traffic conditions.

8 Related Work

Intelligent model deployment in the data plane. To leverage both the inference ability of the learning model and the line-rate processing ability of the programmable switch, existing methods try to embed learning models into the data plane [55, 57, 65, 66]. However, they need to train the model for a long time using large-scale datasets. The current frameworks and models can not adapt to pattern matching that involves parsing of payloads.

Using programmable switches to accelerate pattern matching. As for the existing methods using programmable switches to accelerate pattern matching, some of them can only support simple multi-string matching [25, 52], while others just use switches for packet forwarding and offload complex pattern matching functions onto additional dedicated hardware (e.g., network processors [22]). Trochilus is the first to implement complex pattern matching entirely in the programmable switches and can be integrated into other data plane hardware (e.g., SmartNICs [36]) with minor changes.

9 Conclusion

In this paper, we propose Trochilus, a learning-enhanced, high-throughput pattern matching framework that leverages programmable data planes to address the pressing challenges of scalability, accuracy, and manageability in modern network pattern matching systems. By integrating model inference with low-cost data plane processing, Trochilus delivers a significant improvement in throughput, achieving multi-Tbps throughput without compromising on pattern matching accuracy. Through innovative techniques like BRNN-based pattern modelization, semi-supervised knowledge distillation, and entry cluster optimization, Trochilus efficiently deploys high-performance models in resource-constrained data planes while ensuring automatic system updates, crucial for real-time adaptation to emerging network traffic and threats. As network bandwidth continues to grow and new applications emerge, Trochilus provides a future-proof pattern matching framework that can adapt and scale to meet the evolving needs of next-generation network infrastructures. Looking ahead, our framework opens several avenues for future research, including the integration of Trochilus with encrypted traffic analysis, SmartNICs, and other hardware-accelerated platforms.

A supplementary materials

We show supported PCRE syntax in Table 2. The detailed results of pattern modelization and data Plane aware model under different pattern sets are shown in Table 3-6.

Table 2: PCRE syntaxes supported in this paper.

Syntax	Description
α	Matches a single character.
$\alpha\beta$	CONCAT operation. Matches $\alpha\beta$.
$\alpha\|\beta$	OR (|) operation. Matches α or β.
$\alpha*$	Kleene ($*$) star. Matches α zero or more times.
.	Wildcard. Matches any character.
$\alpha+$	PLUS ($+$) operation. Matches α one or more times.
$\hat{}\alpha$	Matches α only appears at the beginning of the string.
$\$\alpha$	Matches α only appears at the ending of the string.
$[\alpha-\beta]$	Character class. The character class uses OR operation to match a character included in the character class.
$\alpha\{\beta,\delta\}$	Range Matching. Matches α subexpression β to δ times.
$\alpha\{\beta,\}$	AtLeast Matching. Matches α subexpression β or more times.
$\alpha\{\beta\}$	Exactly Matching. Matches α subexpression β times.
$\backslash d$	Matches any number, equivalent to $[0-9]$.
$\backslash D$	Matches any non-number.
$\backslash w$	Matches any letter, equivalent to $[a-zA-Z]$.
$\backslash W$	Matches any non-letter.
$\backslash s$	Matches any non-whitespace character.
$\backslash S$	Matches any whitespace character.
