Online emulation. RHONE coordinates all models using Python Requests API. The SCA uses `cgroups` to limit CPU resources, and TGS [68] for GPUs. Network connections between nodes are managed using the docker network architecture in StarryNet [43]. The core components of RHONE are implemented in about 4500 lines of Python/C# code.

7 Emulation Evaluation

7.1 Scalability

7.1.1 Experimental Setup

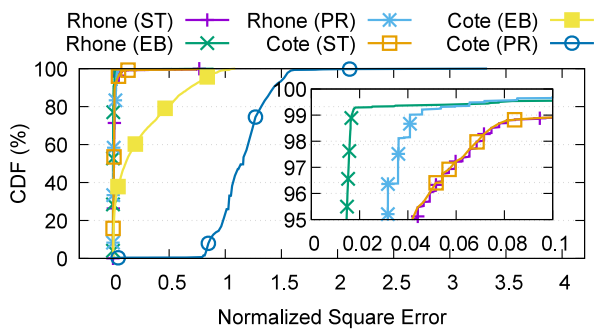
To evaluate the scalability of RHONE, we perform constellation emulations on an enterprise server with both RHONE and StarryNet [43]. Our server is equipped with two Intel Xeon E5-2670 v3 processors, 64GB of DDR4 RAM, 435 GB of disk storage, meeting the requirements of StarryNet.

7.1.2 Results

Performance. As Tab. 2 shows, RHONE supports elastic scaling for large constellations. We demonstrate this by using RHONE to deploy constellations of 172, 348, and 720 satellites, which corresponds to the S3 shell of Starlink, on a single physical machine. This exhibits scalability comparable to StarryNet's performance on a single node. When a multi-node cluster is enabled, RHONE is expected to scale to constellations consisting of thousands of satellites.

System overhead. RHONE exhibits comparable or even lower system overhead in terms of CPU and memory usage. As Tab. 2 shows, CPU and memory usage scale with constellation size, with average CPU usage increasing from 12.1% for 172 satellites to 37.7% for 720 satellites. Similarly, memory usage rises from 8.9% to 24.5% across the same constellation sizes. Notably, these values are consistently comparable to or lower than those observed with StarryNet. This is because RHONE shifts modeling to the offline model-building phase and uses lightweight agents to interact with pre-defined models, resulting in negligible overhead.

Setup time. RHONE exhibits longer setup times than StarryNet due to the calculation of environmental (*e.g.,* energy



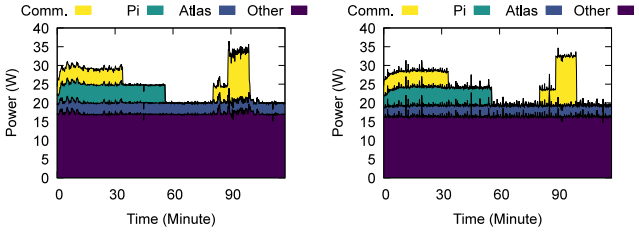


Figure 10: Energy harvesting accuracy.

(a) Real satellite trace. (b) RHONE generated trace.

Figure 11: Energy consumption accuracy.

and thermal) traces and the profiling of COTS computation during the offline phase. Once the setup is completed, the pre-built models can be loaded for subsequent emulations.

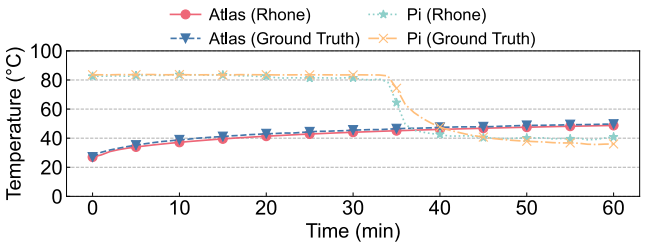
7.2 Fidelity

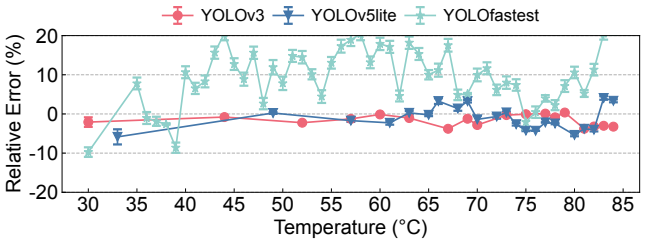
7.2.1 Experimental Setup

To evaluate the emulation fidelity of RHONE in power, thermal, and computation capacity. We conduct our evaluation on two enterprise servers, each equipped with two Intel Xeon E5-2470 v2 processors, 32 GB of DDR4 RAM and 557.9 GB of disk storage. We launch a 25-satellite constellation in a 5×5 grid at 550 km to evaluate RHONE's generated power and temperature traces and computing performance. We use real telemetry data from BUPT-1 and another satellite as ground truth, Cote [13] and StarryNet [43] as baselines.

7.2.2 Power Model Fidelity

Energy harvesting. We evaluate RHONE's energy harvesting behavior by comparing its generated solar array output currents with real data collected from the BUPT1 satellite, alongside a baseline model, CoteSim [13]. We generate 1.5-hour traces for three satellite attitudes: Sun-Targeted (ST), Earth-Backed (EB), and Plane-Rotating (PR) calculate the normalized square error (NSE) between emulated results and ground truth. As shown in Fig. 10, RHONE shows much higher accuracy, especially for EB and PR scenarios where CoteSim's direct solar alignment assumption does not hold. Specifically, RHONE reaches 0.05 NSE at the 99th percentile, outperforming CoteSim (over 1.5 NSE at the 90th





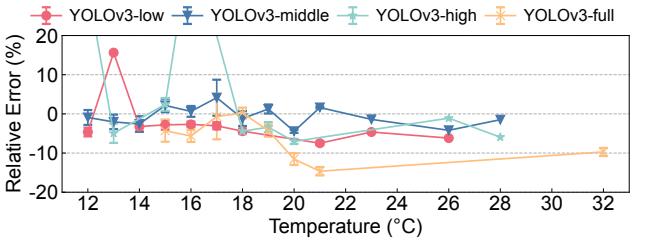


Figure 12: Temperature accuracy.

(a) Raspberry Pi

(b) Atlas 200 DK

Figure 13: Computation accuracy.

percentile) in the PR scenario. These demonstrate RHONE's ability to accurately mimic the energy harvesting behavior of real satellites. Note that both RHONE and CoteSim exhibit long-tail NSEs due to inevitable inaccuracies in orbit calculations. These errors affect the precise timing of satellite transitions between sunlight and eclipse in emulation, which in turn leads to inaccuracies in energy harvesting.

Energy consumption. We compared RHONE's energy consumption component with the actual consumption trace collected from the BUPT1 satellite. To provide a clear view of the power consumption of each component, we show the stacked power usage of different components in Fig. 11. Overall, the models for each component closely simulate the real power trace. Specifically, *Comm.* refers to communication components like X-band, with an average error of 3.0%; *Pi* and *Atlas* are the COTS devices on board, with an average 3.5% and 3.8% error, respectively; *Other* represents all other always-on components with Markov-based consumption pattern, with an average error of 4.1%. Such results demonstrate that RHONE can accurately mimic the energy consumption behavior of real satellites, which indirectly influences the performance of onboard COTS devices.

7.2.3 Thermal Model Fidelity

To evaluate RHONE's thermal model, we use the internal architecture temperature of BUPT-1 and the power consumption trace of the onboard COTS devices as the input of our thermal model. We compare the temperature of emulated COTS devices with that of the real satellite. As Fig. 12 shows, the temperature series of the mirrored chip in RHONE closely matches that of the in-orbit chip, both in terms of values and trends, validating RHONE's accuracy in predicting thermal effects under operational loads, with an average error of 2.5°C and 1.3°C for Pi and Atlas, respectively.

7.2.4 Computation Model Fidelity

To demonstrate RHONE's ability to accurately mimic the computational capacity of onboard chips, we run various DNN applications (YOLOv3-Full/High/Medium/Low, YOLOv5lite, YOLOfastest) from the BUPT-1 open-source dataset [2] on mirrored Raspberry Pi and Atlas 200 DK devices in RHONE with different temperatures. We then compare the inference latency of the emulated results with real-world traces. We show the relative error in Fig. 13, the markers represent the mean, while the upper and lower bounds indicate the standard deviation as we repeat the experiment multiple times. The mean relative error of both Pi and Atlas remains below 5% in most cases with low variations, indicating that RHONE can accurately reflect the impact of thermal throttling on computation capability.

Note that some rare cases exhibit high relative errors (*e.g.,* Atlas running YOLOv3-high at 16°C, and Pi running YOLOfastest). We summarize two possible reasons: *i)* RHONE mirrors COTS chips using on-the-ground profiling data, introducing minor absolute errors compared to the actual latency experienced in space, as shown in Fig. 8. This can be mitigated by thermal vacuum experiments strictly aligned to space, or directly integrating in-orbit satellites to profile the tasks, but both incur high costs and scalability issues; *ii)* Some workloads have short latency (*e.g.,* YOLOfastest completes within 40 ms). Therefore, a small absolute error in emulated inference latency results in high relative errors. This can potentially be addressed by finer-grained container resource tuning, but at the cost of non-trivial scheduling overhead from dynamic quota adjustments.

8 Use Cases

8.1 Satellite Energy Drain Attack

As satellites have limited energy resources, recent studies [27, 28] have explored the effects of energy drain attacks and heavy loads on satellite networks. This combines the emerging focus on satellite-specific network security [69] with longstanding challenges in satellite power management [70, 71]. Using RHONE, we emulate an energy drain attack, demonstrating its strength in accurately modeling energy constraints and evaluating network resilience.

Experiment Setup. The experiment involves a constellation of 720 satellites arranged in a 36×20 mesh grid at an altitude of 550 km. To simulate the attack or burst heavy loads, a target satellite is selected to be the victim, and botnets are used to send bulk traffic through it. The effects are tested through daylight (sun side) and night (shadow side) conditions.

Observations. We present the battery level (state of charge) and the network bandwidth of the victim satellite during the attack in Fig. 14. Our emulation process reveals two key events: *i) Rapid energy drain under heavy load.* The saturated link imposes substantial computation overhead on COTS devices for routing and switching from the onset of the attack, leading to a rapid battery drain. The battery level reaches the safety threshold (60%), prompting the onboard system to forcibly shut down the COTS device, signaling a successful attack. Note that satellites are more vulnerable to such attacks at night, as they experience accelerated energy depletion due to the lack of solar power. *ii) Abrupt network performance drop.* The sudden shutdown of onboard COTS devices causes an immediate bandwidth drop to 0. The bandwidth returns to a normal level (similar to that of BUPT-1) once the devices recover from recharging. Such observations highlight the energy concern for future SCN research, including energy-aware SCN task scheduling, traffic load balancing, and energy-related security issues.

8.2 Real-Time Earth Observation

Earth observation constellations (*e.g.,* Planet Dove constellation [11] with 150 satellites) are actively performing Earth imaging tasks. Given the limited bandwidth and computation capacity of satellites, recent studies [72, 73, 14, 74, 75, 76, 15, 13, 66, 19, 77] have explored novel and efficient strategies for in-orbit processing and data transmission. We emulate real-time earth observation in RHONE, highlighting its strength in replicating processing and transmission constraints for strategy evaluation.

Experiment Setup. We launch a 150-satellite constellation at 550 km, with each satellite having a maximum data transmission capability of 200 Mbps. This configuration replicates the constellation of Planet Dove [11], an operational SatEO project. These satellites capture images and process them with four transmission methods: *(i) Direct:* transmit the raw image immediately; *(ii) Compress:* compression the image with three quality levels ($Q = 75, 50, 25$); *(iii) Detect:* detect objects with YOLOv3 and transmit the objects; *(iv) Reasoning:* convert image content to text and transmit the results. We capture 2000 images and transfer data via FTP.

Observations. We present the bitrates of data transmission, the power consumption of the computing device (Atlas 200 DK) and communication (XBand) hardware, and the satellite battery levels in Fig. 15. Our emulation reveals two key observations: *i) Link usage reduction.* In-orbit processing before image transmission can significantly save communication bandwidth by reducing both link usage time and required bandwidth. Specifically, image compression, object detection, and model inference can decrease link usage by

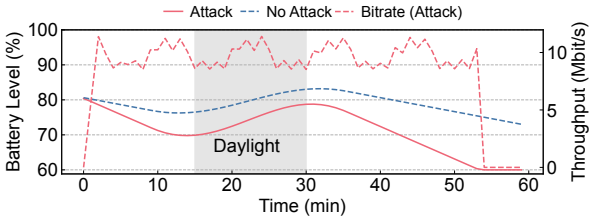

Figure 14: Energy drain attack emulation.

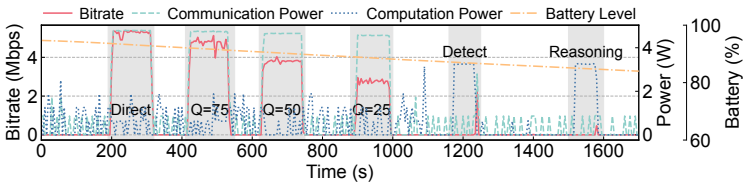

Figure 15: Real-time Earth observation (EO) emulation. Shaded areas indicate the EO working periods.

0.3×, 0.8×, and 0.99×, respectively, compared to direct image transmission. *ii) Energy consumption tradeoffs.* While onboard object detection and reasoning tasks require significantly more computational power than compression tasks, the reduced data transmission size leads to lower communication power consumption. Therefore, performing certain image inference tasks before transmission in SatEO applications is beneficial for both bandwidth reduction and energy conservation. These observations underscore the trade-offs between computation and communication resources in SCN research, especially in-orbit computing for EO tasks.

9 Discussion

Model extendability. While some models in RHONE are built based on telemetry and experimental data from two COTS devices, RHONE allows users to replace or extend models as needed. To expand existing power or thermal models, users can apply the modeling methods provided by RHONE to telemetry data from other satellites or determine model parameters accordingly. Users can also use the hardware-in-the-loop chip mirroring method provided in the computation model to incorporate their own COTS devices.

Other environmental context effects on SCN. Currently, RHONE constructs the energy and thermal context for SCN. While additional system effects on COTS devices – such as radiation failures [34], collision avoidance [78], and physical-layer challenges and security concerns [79] – can also impact SCN performance, these are left for future work.

10 Related Work

In this section, we briefly introduce SCN-related research. The network community is currently focusing on system architecture [80], topology design [81], routing [82, 83], transport-layer congestion control [84], security issues [28], real-world measurements [85], traffic scheduling [72], and on-the-ground emulators [38, 39, 40, 41, 66, 45, 43] for emerging satellite networks. The mobile computing community focuses on verifying the feasibility of satellite image processing applications [86, 87, 88, 89] and on task allocation and resource scheduling algorithms and system design [73, 45, 14, 74, 75, 76]. As satellite networking and computing converge, recent studies investigate SCN applications including real-time EO systems [15], cross-continent satellite video conferencing systems [21], and satellite in-network computing [22, 23]. For example, Li *et al.* [22] explore the feasibility of pushing mobile core network functions to LEO satellite mega-constellations to avoid signaling storm and improve network efficiency. Xing *et al.* [2] conduct a comprehensive in-orbit measurement of satellite COTS computing systems, revealing that energy and thermal contexts in real satellite environments impact satellite behavior and application performance. RHONE serves as a comprehensive emulator accounting for environmental impacts on both computing and networking performance of onboard chips, on which the SCN-related research can be conducted.

11 Conclusion

The growth of SCNs introduces unique characteristics and challenges, which should be carefully considered in designing, building and evaluating SCN applications, demanding accurate, scalable and easy-to-use developing and evaluating tools. In this paper, we introduce RHONE, a full-fledged emulator for SCNs with high satellite- and constellation-level fidelity, high scalability and high usability. It builds models from real in-orbit satellite telemetries, and coordinates the emulation via a Docker container-based environment. Crucially, RHONE provides users with satellite and constellation states (*e.g.,* power, temperature and constellation topology) in real time, and dynamically aligns emulated computing and networking performance with real satellite COTS devices. It enables researchers on Earth to reliably develop, evaluate and optimize SCN applications like satellite earth observation or satellite-backboned global networking without having to access a real in-orbit satellite. We evaluate RHONE 's fidelity using real in-orbit satellite telemetry data, and demonstrate its effectiveness in emulating typical SCN applications as use cases. We believe RHONE will help advance futuristic SCN research, fostering the development of more resilient and efficient space-based systems.

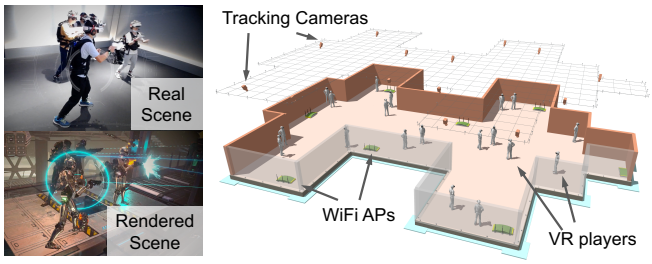
Abstract

Free-roaming VR which allows a group of users to navigate in rooms and even buildings, enhances the VR experience by making it more immersive and interactive. Streaming VR videos over wireless enables unconstrained experiences but raises unprecedented requirements in mobility, efficiency, and scalability. Existing solutions fail in one or more of the following challenges: maintaining low latency during handover, balancing loads on different APs, and stabilizing bitrate for competing users, due to their decentralized nature where each user lacks information about others and makes locally optimal decisions. To address these problems, we present MP^2, a centralized VR streaming system that coordinates multiple Wi-Fi links and video bitrates among users for better QoE. A centralized controller collects cross-layer information from each user and makes better decisions based on global information. It achieves this in a timely manner through accurate modeling and the use of efficient pruning and partitioning algorithms. To our knowledge, MP^2 is the first centrally coordinated VR streaming system that supports multi-user free-roaming. Comprehensive benchmarks including real-world tests, large-scale emulation, and trace-driven user studies, confirm the effectiveness of MP^2 against state-of-the-art solutions. It achieves 35× improvement in tail latency, 1.56× in bitrate, and 1.86× in QoE over state-of-the-art baselines. MP^2 achieves up to a 99.1% improvement in mean opinion scores according to the user study.

1 Introduction

Among the rapidly growing Virtual Reality (VR) ecosystem, free-roaming VR has gained significant traction as it provides a more immersive and interactive experience. In contrast to traditional VR where users are constrained to a small room or seated position, free-roaming VR users can freely walk, run, and explore the virtual world in a much larger physical space. Notable examples include Zero Latency VR [18] with perceptual tricks that enable players to travel up to 1 km to journey through the virtual world within a 400 m^2 room, and Sandbox VR Game [12] that features a group of players collaborating with each other in a shared virtual adventure to defeat aliens, as illustrated in Figure 1. Besides gaming, free-roaming virtual reality has found its way to virtual tourism [17], training [15], and education [13].



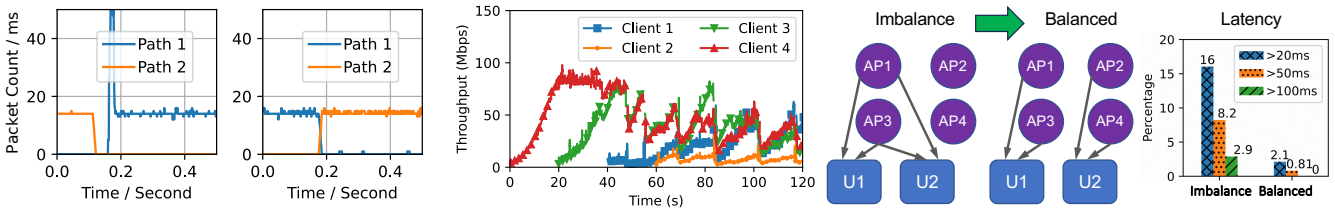


Figure 1: Real-world/rendered scenes and settings of a free-roaming VR scenario. Although existing commercial systems still require users to carry a heavy backpack (top left), a wireless streaming system would remove the burden.

Existing on-device VR rendering solutions necessitate that users either carry a heavy backpack or wear a bulky headset and battery pack for the rendering hardware, which limits immersion. Wireless streaming offloads rendering but needs to meet several requirements in free-roaming VR scenarios: *(1) Mobility*: The system must support wireless operation and allow users to roam freely across different access points (APs) without experiencing significant latency or disconnections, as a single AP cannot provide sufficient coverage and bandwidth. *(2) Scalability*: The system should be capable of supporting multiple users simultaneously, each with its own control loop, without compromising the quality of service. *(3) Efficiency*: It is crucial for the system to schedule available bandwidth resources efficiently to accommodate a large group of users.

It is not surprising to find that existing solutions often fail to meet the requirements of free-roaming VR as they are not specifically designed for such use cases. To better understand the challenges, we build a VR streaming system

(a) Large (≈50 ms) packet gap during handover (left) *vs.* seamless handover (right).

(b) Bitrate fluctuation of four competing streams.

(c) Example of uneven AP traffic load and how balancing improves latency.

Figure 2: Challenges of supporting free-roaming VR with state-of-the-art streaming system.

with XLINK [110], a state-of-the-art multipath transport, and ALVR [2], the most popular open-source VR streaming solution. The experiment results are shown in Figure 2. We summarize the challenges as follows:

• *High handover latency*: Handover between APs can lead to significant performance degradation [85]. While the baseline uses a multipath protocol designed to mitigate latency spikes during handover, it fails to account for the fact that Wi-Fi radios require time to wake up and achieve their optimal throughput. This oversight results in a substantial packet gap compared to the ideal seamless migration scenario, as illustrated in Figure 2a.

• *Unstable bitrate*: Deciding which encoding bitrate to use is already considered challenging over dynamic wireless links. This becomes more complex when coupled with multipath transport, which is known as the double-control loop problem [24,50]. The problem is further exacerbated in the context of multiple players competing for resources, resulting in unstable bitrates for players, as shown in Figure 2b.

• *Imbalance of loads*: Although the baseline solution can distribute traffic between different connected APs, it lacks control over which AP to connect to, nor does it have a global view. This results in an imbalance of loads with users concentrated on a subset of the APs, leading to sub-optimal performance, as shown in Figure 2c.

Similar to the baseline solution, current systems fall short in addressing one or more of the above challenges, as detailed in Table 1. We attribute the root cause to a lack of coordination in their architecture design, including 1) no horizontal coordination among competing users and APs; 2) no vertical coordination across different layers including link, transport, and application layers. Users have to rely on probing to make decisions in a decentralized manner, which is inefficient in free-roaming VR scenarios. While certain solutions manage to tackle some of the challenges, they often require kernel modifications or the use of special hardware, complicating the deployment, as shown in Table 1.

Our answer to these problems is **MP^2** (Multi-Path for Multi-Players), *a centralized overlay system that has a global view of the entire stack and coordinates link/path/bitrate decisions across free-roaming VR users on different APs*. MP^2 can be separated into a data plane and a control plane. The data plane of MP^2 is built around multipath QUIC tunnels that create a virtualized interface to route VR traffic according to the control plane's decisions. The control plane, on the other hand, obtains a global view of the system by gathering cross-layer information, including Wi-Fi PHY and VR application data from all users. By leveraging global knowledge, it orchestrates link-level AP association, transport-level path selection, and application-level bitrate adaptation to optimize Quality of Experience (QoE), and judiciously coordinates different streams to avoid performance degradation when enforcing the arrangement. MP^2 is practical to deploy as both its control and data planes operate in the user space thus requiring no modifications of the kernel, and can be implemented with low-cost commercial Wi-Fi hardware.

In addition to its unique centralized architecture, MP^2 incorporates two significant advancements to achieve its objective. The first is an efficient decision algorithm that optimizes global QoE for large-scale systems in a timely manner. We combine mathematical observations and algorithms optimization including Gaussian Mixture Modeling (GMM) of frame statistics, Modulation and Coding Scheme (MCS)-aware pruning, location-based partitioning, and adaptive topology stabilization. The second advancement is the coordinated seamless migration method which utilizes a combination of path warmup, bitrate guidance, and redundant transmission to smooth out latency spikes during migration.

We conduct comprehensive evaluations including real-world tests, large-scale emulation, and trace-driven user studies on commercial devices to benchmark and understand the performance gain of MP^2. Real-world tests confirm the effectiveness of seamless migration that reduces tail latency by more than an order of magnitude. Large-scale emulation results indicate that MP^2 consistently outperforms state-of-the-art solutions at all scales, achieving a 35× improvement in terms of tail latency, a 1.56× improvement in bitrate, and a 1.86× QoE improvement. The improvements in bitrate and latency translate into significant perceptual quality gain over different VR scenes, resulting in up to a 99.1% improvement in Mean Opinion Scores (MOS) according to our user study.

Our major contributions can be summarized as follows:

- We are the first to identify the requirements and challenges of wireless video streaming for free-roaming VR, and pro-

pose the first centralized multipath multiplayer orchestration system as an alternative to existing decentralized solutions that fail to meet the needs.
- We present the design and implementation of MP^2's data and control planes, along with key enablers including an efficient scheduler and seamless migration mechanism to solve the challenges of mobility and scalability. MP^2 is implemented in the user space, ensuring easy deployment without the need for special hardware.
- We perform extensive evaluations on MP^2 through real-world testing, large-scale emulation, and trace-driven user studies to demonstrate its superior supports for mobility, scalability, and improvements in latency, bitrate, as well as perceptual quality over state-of-the-art baselines.

2 Background and Motivations

2.1 Requirements of Free-Roaming VR

QoE requirements: Creating life-like, immersive VR experiences is the holy grail for multimedia technology. Ideally, to match human perception, a resolution of 9720×8100 per eye is needed, assuming a 162 × 135 degree field of view and 60 pixels per degree, thus requiring a whopping 4 Gbps of bandwidth [30]. Although the peak/average bitrates are 140/80 Mbps on Oculus Pro and Quest 2, we anticipate higher bitrates with next-generation, higher-resolution headsets. Latency is equally important. The optimal motion-to-photon latency should be 20 ms or less [52, 89–91, 103], which poses significant challenges to the entire video pipeline, including rendering, encoding, transport, decoding, and display. As a result, we report percentages of frames with >20/50/100 ms as the latency metric, though MP^2 is designed to be flexible with different latency targets (§6.2.3). Ideally, all these percentages should be zero. We also include a user study for a more subjective understanding of the performance (§6.3).

Number of players and APs: An example setup of the free-roaming VR is shown in Figure 1. Current free-roaming VR supports 4 to 12 players per venue [12, 18], and there is a growing demand to support even more players [108] in the building scale. This not only accommodates larger groups, but also helps to increase sales per unit area. Considering the aforementioned bandwidth requirement for each user and the maximum throughput supported by modern Wi-Fi [7], we estimate that each AP can reliably serve up to three users. Taking a 48-user scenario as an example, this requires at least 16 APs, or more, to accommodate redundancy and account for varying and uneven user distribution. Given the number of users and APs, it is crucial to keep scalability in mind. MP^2 is designed to achieve this goal, and we present large-scale studies in §6.2.

2.2 Key Observations

The following key observations motivate the design of MP^2:

Observation I: Centralization beats decentralization. Existing decentralized systems cannot effectively manage the complex dynamics of free-roaming VR scenarios due to their inability to coordinate decisions across users and network layers. This can lead to high handover latency, unstable bitrates, and imbalanced loads, all of which degrade the quality of experience for VR users. In contrast, the centralized design of MP^2 not only solves these problems, but also simplifies deployment and maintenance.

Observation II: Single Wi-Fi is insufficient. Handover and reliability are limiting factors for a single Wi-Fi link in free-

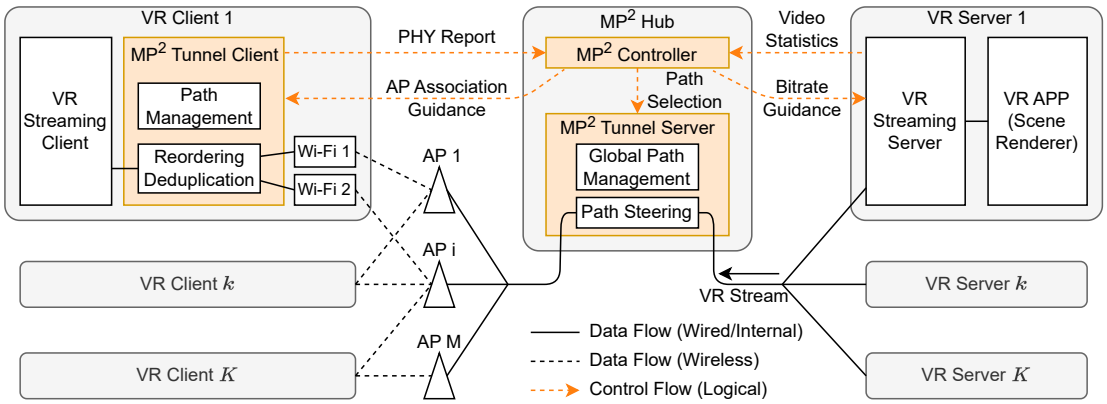

Figure 3: System architecture of MP^2 consists of multi-homed VR clients, MP^2 Hub, and VR servers.The data flows are represented in black lines, with solid lines for wired data, and dotted lines for wireless data. The logical control flows are indicated by colored, dotted arrows.

roaming VR. Wi-Fi handover involves hundred-ms level network outages even with fast handover mechanisms [21,35,88], which is not acceptable for the free-roaming VR experience. Another factor to consider is reliability. A single Wi-Fi link can be prone to interference, congestion, and signal degradation, leading to packet loss, jitter, and increased latency. Recent studies [33,41,46,65,79,80,110,112] show that combining multiple links provides better stability and quality for mobile users. We present a more detailed discussion in §8.

Observation III: User-space implementation simplifies deployment. Operating in user space allows MP^2 to be deployed without OS kernel modifications or special hardware, which significantly lowers the barrier to adoption (see Table 1). This also facilitates easier updates and maintenance allowing quick adaptation to evolving technologies and user needs. We explain the design of MP^2 in §3.1.

Inspired by these observations, we then explain how we build MP^2 to overcome challenges and meet the requirements of free-roaming VR in the following sections.

3 Overview of MP^2

MP^2 orchestrates VR streams for multi-homing users by collecting cross-layer and cross-user information, then performing path assignment and migration for optimal overall QoE. The system architecture, depicted in Figure 3, consists of endpoints including VR clients and servers, as well as network infrastructure components including Wi-Fi APs and Ethernet switches. MP^2 incorporates a centralized hub, namely MP^2 hub, to coordinate between multiple paths and users. Note that the MP^2 hub can run on one of the servers, eliminating the need for additional hardware. Also, we focus on downlink traffic (from server to client) as uplink traffic, which primarily comprises of VR tracking and control messages, requires minimal bandwidth.

The VR client (headset) is equipped with multiple Wi-Fi radios, runs a VR streaming client application, and integrates a tunnel client built on top of multipath QUIC (MPQUIC [59]). It sends PHY layer reports to the MP^2 controller running on the MP^2 hub, and receives AP association guidance from the controller. The VR servers run a VR scene renderer that generates raw video streams, a GPU/CPU video encoder that compresses the frames, and a VR streaming server that controls the sending rate. The video streams are sent to the tunnel server inside the MP^2 hub and then distributed to clients via Wi-Fi APs according to the path selection decision from the MP^2 controller. Similar to the client, the VR servers also send video statistics to the MP^2 controller which generates bitrate guidance based on the statistics.

The bitrate guidance works by setting a cap on top of the target bitrate input for codec while keeping the original Adaptive Bitrate (ABR) algorithm functioning if its suggested bitrate is lower. This provides two-fold benefits: 1) it guarantees that no stream will exceed its optimal bitrate (flattening the curve), and 2) it allows MP^2 to make use of any advanced ABR algorithm that may respond faster than the MP^2 control loop or even provide more advanced features [45,63,92,104].

We first introduce the MP^2 data plane (§3.1), including the tunnel server and clients that carry video traffic, and then present techniques for seamless connection migration in MP^2 (§3.2). We describe the MP^2 controller which makes centralized routing decisions according to cross-layer information in the next section (§4).

3.1 MP^2 Data Plane

The goal of the MP^2 tunnel is to provide the data plane for handling VR traffic while facilitating real-world deployment by masking the complexity of the underlying links. It consists of a tunnel server and client:

Tunnel Server: It uses a virtual tunnel interface to receive VR video streams and conduct path steering based on decisions from the MP^2 controller. It encapsulates all incoming packets with a tunnel header, assigning new IPs and ports for diverse

path forwarding. Additionally, it manages a global path table for tracking client-server mappings and IP/port details for each stream's paths.

Tunnel Client: It is positioned between the VR streaming client and the Wi-Fi radio on each VR client. On the control plane, the tunnel client is responsible for local path management by maintaining a local path table. It collects PHY layer information and transmits it to the MP^2 controller. Additionally, it relays the AP association guidance received from the MP^2 controller to the Wi-Fi radios to establish association on-demand. On the data plane, the tunnel client exposes a virtual tunnel interface to the VR streaming client as the egress port for video streams.

3.2 Coordinated Seamless Migration

The centralized architecture of MP^2 is required by the Client-Server model of the QUIC protocol, but it also provides a coordinated scheduler to maximize overall QoE as described in the previous section. In fact, we find that the benefit of a centralized architecture goes beyond that: it enables a coordinated workflow for seamless connection migration:

Path warmup: Before initiating a connection migration, the MP^2 controller sends a small amount of probing traffic (*e.g.,* one packet per 10 ms) over the target link for a short period to warm up the Wi-Fi radio. While the Wi-Fi beaconing mechanism may also help keep the radio active to some extent, it is primarily intended for network management and typically with over 100 ms intervals, which is insufficient for seamless handover (confirmed empirically by our observation in Figure 2a).

Redundant transmission: During connection migrations, we adopt a transient full-redundant transmission on both paths to minimize packet loss and latency. The path warmup and redundancy mechanisms introduce a fractional overhead, but they are only required for a short time window (100 ms for path warmup and 50 ms for redundant transmission based on our practice), and therefore negligible. Our evaluation in 6.2.1 also shows significant empirical gains from both.

Bitrate guidance: Migration can disrupt streams on an AP by breaking the original equilibrium. Instead of waiting for the underlying ABR algorithm to achieve the new equilibrium, which can take over 10 seconds according to our evaluation 8a, the MP^2 controller proactively issues bitrate guidance that enforces a maximum bitrate cap for all users on the AP. The guidance value is calculated by MP^2 controller (§4) to optimize global QoE. As a result, the new user quickly reaches the ideal bitrate, enabling higher overall bitrates along with lower latencies. Note that bitrate guidance functions as a cap, only intervening when the existing ABR attempts to use excessive bitrate. This allows MP^2 to coexist seamlessly with other traffic, as the ABR continues to adapt when bandwidth is occupied by competing traffic.

While not all these techniques are surprising, a combination of them forms the perfect recipe. To understand the performance of coordinated seamless migration, we present a comprehensive evaluation of seamless migration and ablation study in §6.1. Next, we introduce the MP^2 controller that performs all the heavy lifting behind the scenes.

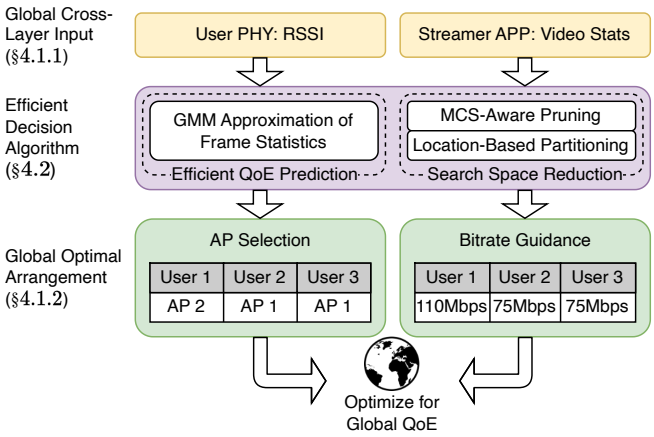

Figure 4: Overview of the MP^2 controller.

Table 2: Notations used in the controller design, in each timestamp.

Notation	Definition for user k
$\boldsymbol{L}_{k,m}$	Matrix of link rates from clients (Mbps).
$\boldsymbol{S}_{k,t}$	Matrix of frame sizes from clients (Byte).
$\boldsymbol{A}_{k,m}$	Binary matrix of user-AP connections.
$\boldsymbol{B}_{\boldsymbol{k}}$	List of bitrate guidance for each user.
$\boldsymbol{P}_{k,i}$	% of frames with latency $>$ threshold.
w_i	Weight for the corresponding P.

4 MP^2 Controller

The MP^2 controller acts as the brain of the control plane, positioned atop the tunnels within the data plane. Figure 4 shows an overview of the controller. We start with the design of MP^2 controller, including control objectives, inputs, and outputs. Then, we present an efficient decision algorithm enhanced through mathematical observations and algorithms including approximation, pruning, and partitioning.

4.1 Control Problem Formulation

In this section, we define the control input/output and optimization goal. The notations used can be found in Table 2.

4.1.1 Control Inputs

The MP^2 controller collects cross-layer information from both clients and servers during each decision-making round. It focuses on adapting to changes in user/AP topology rather than fine-grained Wi-Fi link fluctuations. Consequently, the decision interval need not be long and is adjusted based on mobility levels[1]. The collected data includes:

[1]In this paper, the control interval is set to a default of one second to accommodate walking or jogging users with speeds between 0 to 3 m/s.

Link rate from clients: The MP^2 tunnel client periodically collects Wi-Fi `SSID` and `RSSI` information using `iw dev wlan link` and `iw dev scan` for connected and nearby Wi-Fi APs. We then convert the RSSI to link capacity using standard MCS (Modulation and Coding Scheme) table [1, 7] and AP configurations such as generation (*e.g.,* Wi-Fi 5/6), bandwidth, number of spatial streams, and guard interval [2]. While raw CSI information or dedicated measurement streams could provide more accurate capacity estimates, these approaches are either impractical due to special firmware/driver requirements [39] or too resource-intensive for tight bandwidth budgets. RSSI strikes a balance, offering both practicality and decent estimation [102]. The MP^2 hub aggregates PHY reports from all clients as a link rate matrix $\boldsymbol{L}_{k,m}$ with values in Mbps where $k \in [1,K]$ and $m \in [1,M]$ for K clients and M APs. We fill $\boldsymbol{L}_{k,m}$ with zeros if AP m is out of range for client k.

Statistics of VR frames from servers: The actual frame size of the VR video stream varies from frame to frame, as shown in Figure 5. Simply dividing the bitrate by the frame rate can lead to significant inaccuracies [49], particularly when the QoE function is sensitive to transient or tail latency, as is often the case in VR streaming. To more accurately characterize VR traffic at the per-stream level, we collect recent T video frame size information from all users as $\boldsymbol{S}_{k,t}$ with values in Bytes where $k \in [1,K]$ and $t \in [1,T]$ for K clients and T samples. Instead of using raw frame size for scheduling, we use the Gaussian function to approximate the size, as also depicted in Figure 5. We will discuss Gaussian approximation in detail in §4.2. The system also includes an empirical preset to help cold-start the system.

4.1.2 Control outputs

The MP^2 controller generates the following control outputs:

Arrangement of Path/AP selection: As mentioned in §3.1, the tunnel server needs to select a path (AP) for each user denoted as a logical matrix $\boldsymbol{A}_{k,m}$ with values in the Boolean domain $\{0,1\}$, where 1 means establishing or maintaining a connection between user k and AP m. To ensure all users have exactly one active connection, $\sum_{m=1}^{M} \boldsymbol{A}_{k,m} = 1$ for all $k \in \{1,K\}$. There are two cases when executing $\boldsymbol{A}$: in the first case, all users have connections to APs ($\sum_{k=1}^{K}\sum_{m=1}^{M} \boldsymbol{A}_{k,m} = K$) so the data plane can switch the path directly; in the second case, a user k may not satisfy the aforementioned condition, thus requiring one of the Wi-Fi NICs on user k to associate with the AP first and then apply the path switch. As a result, MP^2 operates with a minimum number of two Wi-Fi radios[3], one for the active link that carries the VR stream, and the other for scanning AP downlink MCSs passively.

Bitrate guidance: With the centralized framework, MP^2 is able to steer the encoder target bitrate on each VR server by overriding ABR with a global bitrate guidance $\boldsymbol{B_k}$ for $k \in [1,K]$. This approach has several advantages: 1) Decentralized ABR tends to achieve fairness among streams passing through the same AP, while MP^2 can apply different bitrates on each stream for better overall QoE. 2) It is generally hard to tune a decentralized ABR algorithm to settle on the optimal bitrate for high-bandwidth, low-latency applications (as depicted in Figure 2b). 3) We can enable seamless path migration by coordinating bitrate between contending users, which we explain in detail in §3.2.

[2]Although it is possible to get AP to client MCS directly using the `iw/nmcli` command, we find RSSI tends to be more stable as it is resilient to whether the link is in use or not.

[3]We discuss the possibility of using a single Wi-Fi radio in §7.

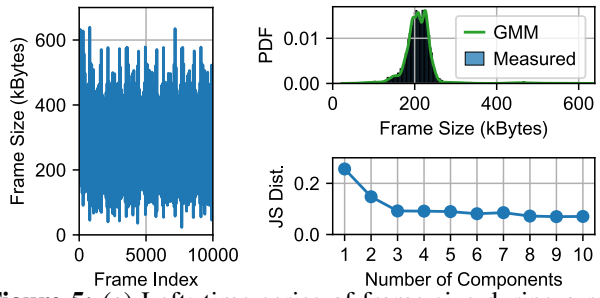

Figure 5: (a) Left: time series of frame size during a real VR session. (b) Top Right: GMM approximation. (c) Bottom Right: Jensen-Shannon distance of the approximation *vs.* number of components in GMM, where 0 means identical and 1 means completely different.

4.1.3 Optimization Goal

MP^2 uses a flexible QoE goal that can be customized for various VR scenarios from fast-paced first-person shooting games to slow-paced leisure games:

$$\boldsymbol{Q} = \sum_{k=1}^{K} \boldsymbol{B}_k * (1 - \sum_{i=1}^{3} w_i * \boldsymbol{P}_{k,i}) \quad (1)$$

where $\boldsymbol{P}_{k,1}, \boldsymbol{P}_{k,2}, \boldsymbol{P}_{k,3}$ represent the percentage of frames with latency $>$ 20/50/100 ms for user k, and w_i represent their respective weights that can be tailored for different needs[4].

4.2 The MP^2 Decision Algorithm

Optimizing the QoE goal shown in Equation 1 is non-trivial. A brute-force approach would require searching across all possible combinations of $(\boldsymbol{A},\boldsymbol{B})$, then running a simulator with recorded video traces to compute $\boldsymbol{P}$ by counting the delayed frames. The time complexity for K clients and M APs is $M^K \cdot B^K \cdot C$, where B is the number of discrete bitrate levels, and C is the time needed to run the simulator once. For example, with $M = 4$, $K = 12$, $B = 10$, and $C = 0.1$ seconds, the total running time would be 1.67×10^{18} seconds, making this approach computationally infeasible. The core issues here are the *lack of closed-form prediction for tail latency* and the *intractable search space*. To address this challenge, MP^2 incorporates two key components: Gaussian Mixture

[4]The frame rate is not considered part of the QoE function since most VR headsets are running at a constant, pre-configured frame rate.

Modeling (GMM) of frame statistics to provide a closed-form solution for calculating $\boldsymbol{P}$, and pruning and partitioning based on MCS and user locations to exponentially reduce the search space.

Gaussian Mixture Modeling (GMM) of frame statistics: The decision engine should be able to estimate tail latency ratio $\boldsymbol{P}$ for a given candidate arrangement and bitrate guidance $(\boldsymbol{A}, \boldsymbol{B})$. While this could theoretically be achieved with a simulator or a complex prediction model, the exponentially growing search space makes such non-closed-form predictions impractical. Therefore, an efficient yet effective prediction method with a closed-form solution is essential. Our intuition for solving the problem is to approximate the VR frame size statistics using Gaussian approximation. However, since videos usually contain different types of frames such as intra/inter frames with varying size distributions, a single Gaussian distribution may be insufficient. Instead, we adopt GMM [64] which is a mixture of several Gaussian distributions. We use the Expectation-Maximization (EM) algorithm [69] to find parameters in the GMM model and experiment with different numbers of components. The result shown in Figure 5 confirms our approach: the GMM closely tracks the distribution of measured frame size. We further calculate the distance of two distributions using Jensen-Shannon (JS) divergence [57] and experiment with different components of the GMM. From the figure, we conclude that a small number of components such as three, is sufficient to bring the JS distance below 0.10, which indicates accurate modeling.

We then realize a nice property of Gaussian modeling: a linear combination of Gaussian distribution is also Gaussian distributed, which can be demonstrated using convolutions or characteristic functions [16]. Such property helps to *solve two problems at once* of generating closed-form solutions for both $\boldsymbol{L}$ and $\boldsymbol{B}$, eliminating the need to run a simulator. Assuming that there are N users streaming through an AP and the total link bandwidth $\boldsymbol{W}$ (also assume fair time-sharing between Wi-Fi clients), the sum of distribution $\boldsymbol{S}$ would be:

$$\boldsymbol{B} = \alpha \boldsymbol{W} = N * (\sum_{k=1}^{N} L_k^{-1})^{-1}, \quad \boldsymbol{S} \sim \mathcal{N}(\sum_{k=1}^{N} \mu_k, \sum_{k=1}^{N} \sigma_k^2) \quad (2)$$

where α is a discounting variable $(0 < \alpha < 1)$ to trade-off between bitrate and latency. As a result, we can calculate $\boldsymbol{P}$ directly:

$$\boldsymbol{P}_{k,i} = \frac{1}{2}\left[1 - erf\left(\frac{x_i - \sum_{k=1}^{N} \mu_k}{\sqrt{2\sum_{k=1}^{N} \sigma_k^2}}\right)\right] \quad (3)$$

where erf is the Error function and x is the size of frames that take more than 20/50/100 ms to transmit, *e.g.,* $\boldsymbol{W} * 0.1$ for >100 ms latency. Using binary search or Newton's method we can find the best α that maximizes the QoE function.

Pruning and Partitioning: Despite the advantages of GMM, the problem remains challenging as there are still M^K possible arrangements. Our solution is two-fold: *(1) MCS-aware Pruning*: We sort the MCS for all users and apply pruning by skipping a certain percentage p of links with low MCS. The percentage p is adjusted according to computation resources. *(2) Location-based Partitioning*: We group co-located APs into cells. Handover between cells is handled in a way that is adapted from traditional cellular networks: if there exists an AP in another cell with MCS higher than the current AP by a certain threshold, MP^2 calculates the performance gain and initiates the cell switch only if there is significant QoE gain.

With these strategies, we reduce the time complexity to $E * (p * (M/E))^{K/E}$ where E is the number of cells. MP^2 is able to handle system as large as $M = 16$, $K = 48$, $E = 4$, $p = 0.6$ with a running time of less than 1 second. Assuming a fixed cell size with a fixed AP-to-client ratio of $M : K : E$, the complexity of the MP^2 decision algorithm grows linearly as the total number of cells/total users.

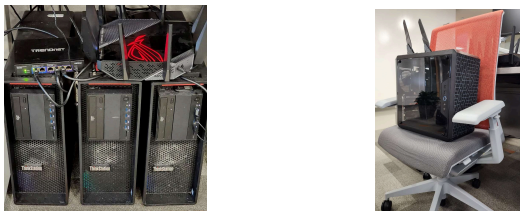
In practice, we also observe that link bandwidth fluctuates frequently. Blindly applying the optimal client configuration at each control interval can cause excessive link switching, leading to instability. To address this, MP^2 employs an adaptive topology stabilization mechanism based on a configurable threshold $V_{\text{thresh-qoe}}$, which prevents unnecessary topology changes that offer only marginal benefits but pose significant risks of service disruption. This mechanism acts effectively as a dual-threshold strategy: a handover is triggered only when the estimated global QoE gain exceeds $V_{\text{thresh-qoe}}$, ensuring that topology changes are made only when the benefit is substantial. In scenarios where clients frequently move between neighboring AP cells, this approach prevents oscillation by favoring stability unless a meaningful performance gain is predicted. The threshold is tunable based on user dynamics: a higher value improves stability in volatile scenarios, while a lower one allows more responsive adaptation to user movements. By default, the threshold is set proportional to the number of links being changed in a given attempt ($|A^{\text{cand}} - A^{\text{cur}}|$).

The complete decision algorithm of MP^2 is shown in Algorithm 1. By combining all the optimizations, the control loop takes less than one second to run, which is sufficient for the target scenario.

5 Implementation

It requires non-trivial effort to build a free-roaming VR system as it is relatively new. Most VR streaming systems operate on special hardware with constrained software and OS access, complicating the development. We describe the implementation details of MP^2 and highlight the major challenges we have encountered.

VR streaming platform: The platform should satisfy the following requirements: 1) hardware support for multiple Wi-Fi radios; 2) a software platform that runs MP^2; 3) detailed metrics from VR applications to facilitate evaluation of both the server and client sides. The Oculus ecosystem has the largest user base, but unfortunately, it does not satisfy any of



Algorithm 1: The MP^2 Decision Algorithm

Input: Link rates $\boldsymbol{L}$, approximated framesize $\boldsymbol{S}$, current AP selection $\boldsymbol{A}^{cur}$ and bitrate $\boldsymbol{B}^{cur}$.
Output: Arrangement of AP selection $\boldsymbol{A}$, bitrate guidance $\boldsymbol{B}$

      for $u \in U^a$ **do**
        $\boldsymbol{B}_u^{cand} \leftarrow \alpha \times (\sum(\boldsymbol{L}_{u \in U^a})^{-1})^{-1}$
      $QoE^{cand} \leftarrow QoE^{cand} + QoE^a$
    if $QoE^{cand} > QoE^{max}$ **then**
      $\boldsymbol{A}^e, \boldsymbol{B}^e, QoE^{max} \leftarrow \boldsymbol{A}^{cand}, \boldsymbol{B}^{cand}, QoE^{cand}$
  $\boldsymbol{A}$.merge($\boldsymbol{A}^e$)
  $\boldsymbol{B}$.merge($\boldsymbol{B}^e$)
return $\boldsymbol{A}, \boldsymbol{B}$

these requirements. Instead, we choose to implement MP^2 with ALVR/ALXR [2] as it not only runs on Linux PCs as well as commercial headsets but also comes with source code that allows for the collection of all necessary metrics. On the server side, we have the Steam gaming platform [14] for VR scene rendering and ALVR for VR video streaming. On the client side, we run the headset application using Linux ALXR on top of Monado [8], an open-source XR runtime.

MP^2 tunnel and controller: We implement the MP^2 tunnel in C, following the IETF draft of QUIC [59] with 10k lines of code. It is an event-driven framework that responds to registered events such as read/write file descriptors and timers. We enable multithreading for packet forwarding with dedicated threads for logging and monitoring. The MP^2 system involves orchestrating multiple clients/servers on different layers of the stack. As a result, we choose to build the centralized controller and the VR client/GPU software around Redis [11], as it provides us with a robust, efficient, and scalable method to synchronize messages across devices with versatile interfaces to modules built in different languages. For example, we use

(a) GPU servers and AP/switch. **(b)** Mobile client.

Figure 6: Hardware testbed of the real-world test.

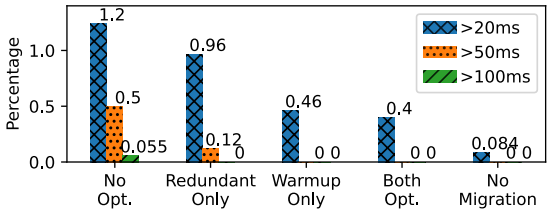

Figure 7: Lag rate comparison of different stream migration methods. MP^2 with both redundant transmission and path warm-up led to significant improvement in the >20 ms lag rate and eliminated >50/100 ms lag completely, which is very close to the upper bound, no migration scenario.

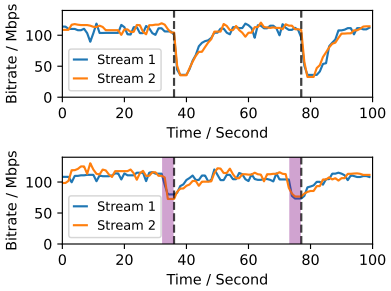
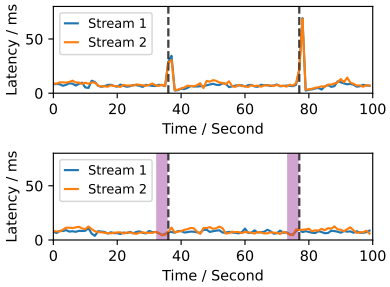
`hiredis` for the C binding with the tunnel, `tokio-rs` for the Rust binding with the ALVR application, and `redis-py` for the Python binding with Wi-Fi information collection and the centralized controller.



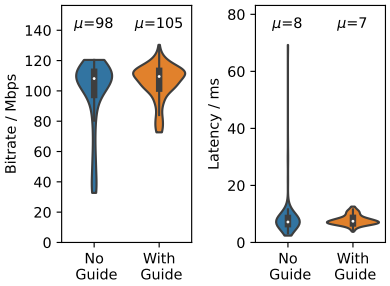
Hardware testbed: The streaming server is equipped with an Intel Xeon 18-core 36-thread CPU and NVIDIA RTX 3070 GPU. The MP^2 tunnel server and the streaming clients are each equipped with an Intel i5 6-core 12-thread CPU. The tunnel server is equipped with one Intel 2*10 Gbps NIC, and one Intel 4*1 Gbps NIC. We connect the tunnel server, and two Asus ROG Rapture GT-AXE11000 Wi-Fi 6 APs via a TEG-S762 six-port, 10 Gbps switch. The streaming clients each connect to the APs with two Intel AX211 Wi-Fi 6E radios and two external antennas, as shown in Figure 6[5].

6 Evaluation



In this section, we present a comprehensive evaluation for MP^2 to answer the following questions:

- **How does MP^2 perform in real-world?** We evaluate the handover performance of MP^2 against state-of-the-art systems in the real world under single/multiuser scenarios.
- **How does MP^2 perform in large-scale emulation?** We perform Mininet emulations that run MP^2 data and control plane to evaluate MP^2 in large-scale deployments that are required to unleash the full potential of MP^2 as well as ensure repeatability and facilitate reproducibility.
- **How does MP^2's performance translate into real players' experience?** We put MP^2 to the ultimate test by conducting



[5]Current mobile platforms offer limited support for dual Wi-Fi radios, so we run clients on standard desktops. They are powered by 100-foot extension cables and are made mobile by placing them on chairs.

a user study with VR headsets and emulation traces to understand how MP^2 performs from players' perspective.

Baselines. As we have mentioned in §5, it is not easy to build free-roaming VR systems that require setting up both application and transport software on different platforms. We intend to compare as many state-of-the-art solutions as possible, but unfortunately, many works are yet to be open-sourced, which prohibits faithful replication and greatly increases the development effort, or does not support the target platform, or require special hardware. By carefully evaluating recent works, we select the industry standard MPQUIC [32, 60] with four state-of-the-art schedulers as the transport layer for our baselines: minRTT (the default and wide adopted scheduler for MPTCP and MPQUIC) [78], fully redundant (RE) [36], Earliest Completion First (ECF) [56], and XLINK [110] (a recent advancement in MPQUIC optimized specifically for video streaming in mobile environments). The application layer of our baselines is ALVR, and we use high-end commercial Wi-Fi and compute hardware as described in §5. For a fair comparison, we have tailored and optimized these baselines to perform at their best.

6.1 Real-world Performance Test

We benchmark the real-world performance of MP^2 by initially testing with a single user and then introducing additional competing users. Through an ablation study and detailed trace analysis, we closely examine and explain the reasons for the performance improvement.

6.1.1 Handover Latency.

We conduct an ablation study to demonstrate the effectiveness of path warmup and redundant transmission in enhancing path migration latency in a single-user scenario.

In this experiment, we allow a client to move freely between two APs, which triggers a handover every 20 seconds, and record the frame latency for a total duration of 75 minutes. The findings of this study are presented in Figure 7. Compared with XLINK + ALVR (No Opt.), MP^2 with both optimizations could reduce the >20 ms lag rate (percentage of frames with over 20 ms latency) from 1.2% to 0.4% and eliminate >50/100 ms latency completely. The performance of applying both optimizations is the closest to the no migration baseline (achieving minimal latency by sacrificing bitrate) with normal Wi-Fi fluctuation while using a single optimization method leads to worse performance.

6.1.2 Bitrate Guidance.

We further demonstrate the performance of MP^2 in scenarios involving multiple users. We arrange for stream 1 to repeatedly join and depart from the AP with 20-second intervals, while stream 2 remains active. One representative period is depicted in Figure 8. It is important to note that the departure of stream 1 does not cause significant fluctuation. However, when we move stream 2 to the same AP as stream 1, the ABR algorithm responds drastically, reducing the bitrate by more than half and taking over 10 seconds to recover. This is evident in the upper half of Figure 8a.

In contrast, the bitrate guidance method proactively reduces the bitrate, thereby avoiding a drastic drop and recovering to the normal bitrate much quicker. As expected, this preemptive guidance also significantly reduces the latency during the switch, as shown in Figure 8b. This is because the traditional reactive method relies on a delay increase as the signal for bitrate adaptation, which is often too late.

Consequently, bitrate guidance contributes to a 120% increase in the minimum bitrate, from 32.7 to 72.7 Mbps, and a 4.5-fold reduction in the maximum latency, from 68.9 to 12.6 ms. These improvements are illustrated in Figure 8c.

6.2 Larger Scale Emulation

Mininet Wi-Fi Emulation Testbed: Our emulation testbed is based on Mininet Wi-Fi [37], which is a Wi-Fi extension of the network emulator Mininet [51]. It can create isolated containers for each server and mobile client and faithfully emulate the behavior of Wi-Fi. We choose Mininet-based

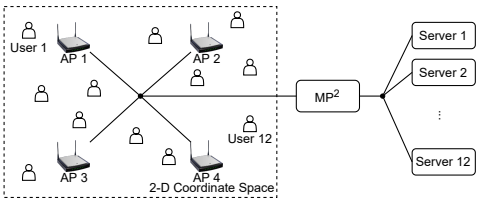

Figure 9: Topology of the large-scale Emulation with Mininet Wi-Fi, using 4 AP $\times$ 12 clients as an example.

emulation because MP^2 is designed as an end-to-end system that tightly integrates real-time components. Mininet allows us to run the MP^2 software stack without abstracting the core components to evaluate.We overcome two major hurdles to set up the testbed:

(a) VR streams: Due to the limitation of computation resources, it is not possible to start enough VR encoding sessions for the emulation. To maximize emulation fidelity, we record real VR packet traces and replay them using a UDP-based streamer, which implements the same ABR algorithm as ALVR.

(b) Wmediumd: `wmediumd` is the built-in physical layer emulator of Mininet Wi-Fi. Our test results show that its max throughput is less than 30Mbps, which is far away from the aggregated throughput of multiple VR streams. To solve the problem, we approximate a high bandwidth link by scaling the packet count by 40$\times$ to balance between performance and practicality that each frame still consists of a few packets. Furthermore, since the implementation of `wmediumd` cannot emulate the effects during handover, we focus solely on emulating the periods between handovers. Although this may understate the full advantages of MP^2, it will accurately demonstrate the contribution of the MP^2 controller.

Figure 9 shows an example of the Mininet Wi-Fi deployment featuring 4 APs and 12 clients. In this setup, the APs and their antennas remain stationary. To simulate player movements, we generate a set of random walk trajectories with random speeds between 0 to 3 m/s for each individual player, which. Both the traffic pattern and player movements are kept consistent across comparisons. We carry out the emulation for a cumulative total of 300 hours for all the experiments in this section.

6.2.1 Comprehensive Performance Evaluation.

In this section, we carry out an extensive and thorough performance evaluation involving 16 APs and 48 clients. The results are displayed in Figure 10. MP^2 consistently reduced latency throughout the tests, with only 0.26% of the time where latency exceeded 20 ms outperforming all baseline metrics by a large margin. It achieves an impressive reduction in the 20 ms lag rate by 97.3% to 98.9%. Moreover, it completely eliminates cases where the latency exceeds 50 ms.

MPQUIC + ALVR with RE scheduler exhibits the weakest performance, primarily due to its design of full redundancy. This design, while intended for occasional severe network disruptions, is not well-suited for multi-user scenarios. The

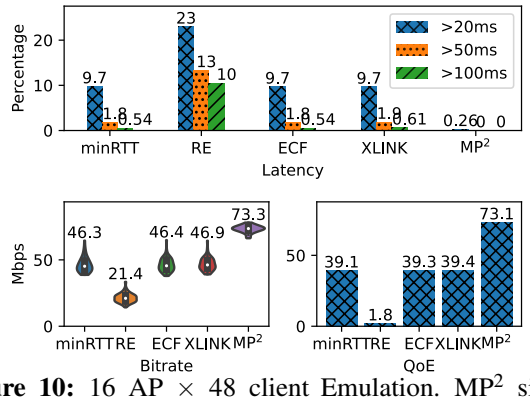

Figure 10: 16 AP $\times$ 48 client Emulation. MP^2 significantly outperforms XLINK + ALVR and different flavors of MPQUIC (MinRTT, RE, ECF) + ALVR on both latency (35$\times$ improvement over 2nd place), bitrate (1.56$\times$), and QoE (1.86$\times$).

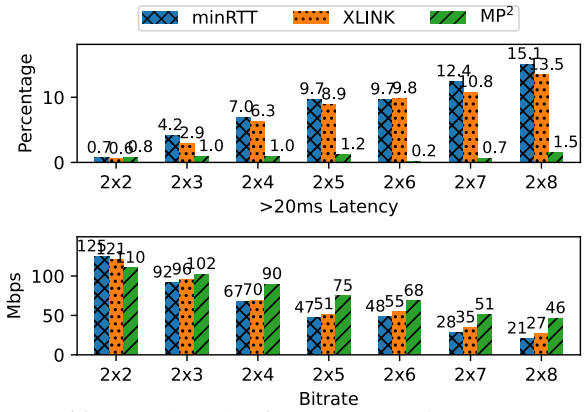

Figure 11: Benchmark of MPQUIC (minRTT) + ALVR, XLINK + ALVR and MP^2 under different AP$\times$user ratio. MP^2 is able to maintain a steady low latency while baselines keep increasing as there are more users while keeping a high bitrate with up to 8 users.

unnecessary redundant packets congest the system, leading to an increased queue buildup and consequently compromising QoE for all players. XLINK and other MPQUIC schedulers including MinRTT, and ECF display similar latency patterns.

MP^2 achieves an average bitrate of 73.3 Mbps, notably improving the overall network capacity by 56.3% to 242.5%. We adopt a sample QoE with latency penalty weights $w_1, w_2, w_3 = 1, 2, 4$ in this experiment to show consideration of the combined effect of latency and bitrate. It is not surprising that MP^2 also achieves outstanding performance in terms of QoE, which is 1.86$\times$ the closest contender.

6.2.2 Scalability Evaluation.

In this experiment, we compare MP^2 with other competitors under different user/AP densities and scales to show its scalability advantages. Figure 11 shows the performance variation in a 2-AP setup where the number of users grows from 2 to 8. In 2×2 deployment, MP^2 performs similarly to its competitors. This is expected since most multipath schedulers are naturally optimized for such cases. When the user den-

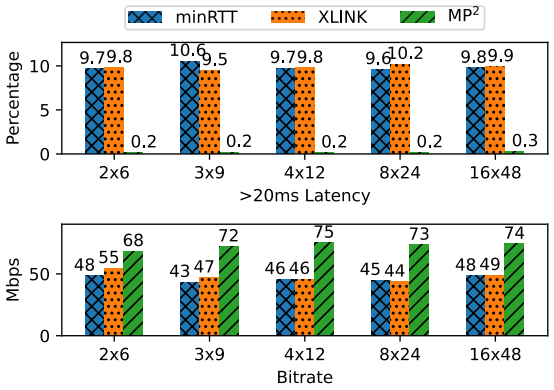

Figure 12: Benchmark of MPQUIC (minRTT) + ALVR, XLINK + ALVR, and MP^2 with the same AP to client ratio but different scales. MP^2 consistently outperforms baselines.

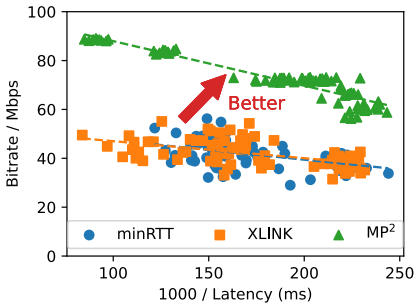

Figure 13: Latency *vs.* bitrate under different ABR algorithm targets. MP^2 achieves a clearly better trade-off than minRTT + ALVR and XLINK + ALVR.

sity grows, as expected, both latency and bitrate performance of both MPQUIC (minRTT) + ALVR and XLINK + ALVR degrade drastically due to unmannered competing for bandwidth. On the other hand, MP^2 successfully keeps the >20 ms lag rate below 1.5%, achieving up to 48× lag rate improvement over the 2nd place. In terms of bitrate, MP^{2}s able to maximize the utility of limited bandwidth and achieves 1.7 × improvement over the 2nd place.

Figure 12 illustrates the variations in latency and bitrate across different scales ranging from 2×6 to 16×48. Overall, MP^2 consistently delivers a substantial performance boost irrespective of the scale. The lag rate exceeding 20 ms remains below 0.6% across all scales, while the bitrate improvement ranges from 51.0% to 71.4% over the baseline. The performance of MP^2 remains relatively stable when the system scale grows, demonstrating its capability for VR streaming with a larger number of users.

6.2.3 Evaluation under Different ABR Latency Targets.

MP^2 is designed to cooperate with ABR algorithms, enabling flexible adjustments to meet various latency objectives. To understand its performance, we conducted experiments with latency target settings of 5/10/20 ms and compared the results with minRTT/XLINK + ALVR baselines. The experiments are performed 70 times in a 4 AP × 12 client setup. Figure 13 clearly illustrates the trade-off between median latency and bitrate for each of the three ABR targets. MP^2 ranges from 4 ms/61 Mbps to 12 ms/92 Mbps while minRTT and XLINK ranges from 4 ms/38 Mbps to 12 ms/50 Mbps. Regardless of the latency target, MP^2 consistently achieves a better Pareto frontier between latency and bitrate.

(a) Sample VR scenes (indoor and outdoor). **(b)** Oculus Pro VR headset and controllers.

Figure 14: Software/hardware setup of the user study.

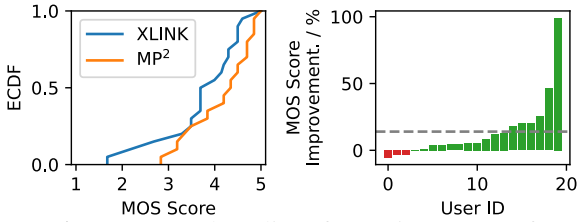

Figure 15: Perceptual quality of experience score for MP^2 and XLINK + ALVR, the higher the better. MP^2 consistently outperforms the baseline and is significantly preferred by the vast majority of users.

6.3 Trace-driven User Study

A fundamental limitation of current commercial VR headsets is their lack of support for additional network adapters, in both hardware and software, which constrains the evaluation of MP^2. In order to assess the benefits MP^2 could bring to the VR experience from the viewpoint of the players, we conduct a user study which is based on packet-level traces collected from the previous large-scale emulation, by randomly selecting client-side traces from both XLINK + ALVR and MP^2.

System Setup: The setup is shown in Figure 14. We construct the user study platform using the ALVR backend, the Steam VR gaming engine, and the Oculus Quest Pro, a high-end consumer VR headset. To emulate network impact, we use MahiMahi [71] to replay the collected packet-level traces between the headset and a container running Steam VR and the ALVR streamer on a GPU server.

Methodology: We recruit 20 unpaid volunteers, ranging in age from early 20s to 40s, with varied technical and VR experience. We distribute invitations for the user study via a public channel within our organization, and include all interested individuals in the experiment and results. Each participant is exposed to both the MP2 and XLINK + ALVR conditions in randomized order, across visually distinct indoor and outdoor scenes. In each setting, participants freely explore three

30-second segments per condition and rate their overall VR experience on a 1–5 scale (bad to excellent), yielding a total of 240 ratings. The evaluation is based on the question: "How would you rate your overall VR experience?" While the scale labels are explained qualitatively, no formal training or dimension-specific criteria are provided.

Figure 15 shows the distribution and improvements of Mean Opinion Scores (MOS). MP^2 consistently outperforms the baseline in terms of MOS distribution. Additionally, MP^2 is preferred by the vast majority of users, with an improvement of up to 99.1%. Even among users who do not perceive an improvement, MP^2 matches the baseline performance, with no more than 5.5% drawbacks.

7 Limitations and Discussion

Next, we discuss MP^2's limitations and future directions.

7.1 Practical Concerns

Larger scale deployment: Due to hardware (no support for multiple Wi-Fi interfaces) and software (unable to run a customized tunnel application) constraints (§5), in the real-world experiments, the client-side testbed for MP^2 is implemented on PC rather than actual headsets. These constraints are largely due to the relatively closed nature of current VR headset ecosystems. We look forward to a large-scale deployment with actual VR headsets. In fact, we anticipate that MP^2 can be easily deployed on any headset by simply connecting an extra Wi-Fi NIC and installing a user-plane application.

Hardware Gap: The only hardware gap between MP^2 and current commercial VR systems is the addition of a second Wi-Fi interface (with the corresponding antenna). However, we argue that this is practical: (1) Multiple Wi-Fi interfaces have long been commercially available on the AP side [22], and there are no technical difficulties on the client side either. In fact, the industry [5, 6, 9] is moving towards Dual Band Dual Concurrent (DBDC) Wi-Fi, which enables simultaneous operation on different bands; (2) Wi-Fi radios are relatively inexpensive compared to the cost of VR headsets, with entry-level models available for as little as USD $2 [10], and even advanced Wi-Fi radios can be obtained for $10 to $20 [3, 4].

Additional Power Consumption: While the second Wi-Fi interface introduces some power overhead, our estimation shows it is minimal, contributing less than 2% of the total headset power consumption. The interface remains idle most of the time (for PHY info collection) and activates only during migration periods, which occur for at most 100 ms per second (10% duty cycle). According to open measurements [68], it consumes up to 750 mW when active and 25 mW when idle. Based on this, the weighted average overhead is $\leq$97.5 mW. Given that typical VR headsets draw 5–13 W during operation [66, 67], the additional consumption remains within 0.75%–2%.

Scalability Limits: Scalability is an important consideration in MP^2's centralized architecture. To address this, MP^2 adopts a partitioning strategy (§4.2) in which the environment is divided into geographic cells. This reflects the observation that resource contention in multiplayer VR primarily occurs among users who are physically close. By optimizing QoE within each cell independently, global optimization is reduced to a set of localized sub-problems. Inter-cell handovers are handled using lightweight heuristics inspired by cellular network designs. As a result, the computational overhead of the MP^2 Controller scales linearly with the number of users and APs. Nonetheless, scalability within a single partition is bounded by the CPU and NIC capacity of the MP^2 Hub. Our prototype demonstrates support for up to 48 users per partition using a single server. Beyond this scale, the hub may become a bottleneck. While partitioning enhances scalability, it can weaken global optimality. Thus, partition size should be carefully selected based on server capability, or alternatively, multiple servers can be deployed to scale out the MP^2 Hub horizontally, managed by containerized cloud [28, 98, 99].

7.2 Future Works

Handling Failures: As a centralized system, MP^2 is built with failure resilience in mind. In the event of a data plane failure, such as a tunnel disconnection, clients will immediately fall back to a direct connection with VR servers. While AP and bitrate guidance remain functional, handovers are no longer seamless under this fallback mode. To detect control plane failures, clients periodically send heartbeat packets, allowing the system to revert to a baseline solution when needed. Partial failures may result in some clients/servers being unresponsive to AP association and bitrate guidance, leading to reduced performance for unaffected clients. However, addressing these failure scenarios comprehensively requires careful design and rigorous testing.

Full redundancy and network coding: MP^2 does not replicate streams unless during migration for better efficiency as we observe there is nontrivial overhead to do so, which may result in much worse performance, such as RE mode of MPQUIC in §6. This result aligns with previous works [81]. However, if bandwidth permits, network coding [38, 44, 48] based redundant transmission through two or more links may offer higher flexibility, especially for less stable links.

Experiment with other ABR algorithms: although MP^2 is designed to work with any ABR algorithm due to the fact that we impose a cap for the bitrate only, it may be interesting to see how it works with state-of-the-art real-time ABR algorithms [25, 34].

8 Related Work

While we have presented a comparison of MP^2 with related works in Table 1, we delve into them with greater detail:

Reducing latency during handover. Latency experienced during handover between APs represents a significant challenge [74] that attracted substantial attention: SCTP [86] dynamically updates a user's address list for handover from one interface to another. MPTCP [74, 78, 95] and MPQUIC [32, 94], multipath extensions of TCP and QUIC, can adapt to changing network conditions and provide smooth handover leveraging multiple channels. Efforts have been made to improve multipath transport [40, 55, 72, 73] and apply multipath for various cases, such as path dynamics, heterogeneity, and handovers [43, 53, 77, 110, 111]. These systems primarily focus on single-user perspectives while MP^2 targets a group of VR users sharing the common bottleneck and optimizes for overall performance. There are also multipath solutions designed for Wi-Fi networks. Sheriff *et al.* [83], Musher [81], MPWi-Fi [75] and DiversiFi [47] aim to exploit multiple Wi-Fi paths simultaneously for improved throughput. Croitoru *et al.* [29] connects mobile clients with all visible APs and splits traffic among them. Again, they do not address multiple contending users. Our approach optimizes global QoE for a group of users with coordination among different user streams.

Streaming optimizations for mobile VR. Collaborative VR is a real-time streaming application without an explicit playback buffer and thus cannot utilize existing buffer-aware ABR algorithms on video-on-demand (VoD) tasks [45, 63, 70, 100, 104]. Adaptive real-time streaming solutions like GCC [25] and Converge [34] optimize both latency and bitrate, but their applications (*e.g.,* video conferencing) do not involve user competition at the edges. Nevertheless, they are orthogonal and can be integrated with MP^2. Given the positional and link-quality dynamics of mobile VR users, VR-specific ABR algorithms and streaming strategies like Firefly [58], MoVR [19], M5 [107], Habitus [105], and CollaborativeVR [26] have been developed. However, they either focus on single-user scenarios, potentially compromising other users' performance, or are limited to single-AP scenarios that are unsuitable for free-roaming VR. Recent advancements including MuV2 [61], Dasari *et al.* [31] leverage the correlation across VR users to optimize rendering, which are also orthogonal and can be integrated with MP^2.

Multi-AP coordination for load-balancing. Multi-AP coordination techniques like C-OFDMA [93], coordinated spatial reuse [62], coordinated beamforming [20, 42], and joint transmission [106] have been explored. There is also a growing interest in using a centralized controller for WLAN management such as Smartassoc [97], NEMOx [109], SWAN [54], OpenSDWN [82], MUSE [87], BigAP [113], Wi-Fi Goes to Town [84], ClientMarshal [23], LATTE [76], LMA-ABC [96], and OpenCarrier [101]. However, these approaches often require either low-level access to Wi-Fi devices or customized hardware. Additionally, they may fail to meet the stringent demands for handover latency and bandwidth required by free-roaming VR.

9 Conclusion

We design, implement, and evaluate MP^2, a centralized overlay system with a global view of the entire stack that coordinates link/path/bitrate decisions across free-roaming VR users. With a carefully engineered data plane and an intelligent control plane, MP^2 orchestrates VR streams that compete for bandwidth to achieve global optimal QoE and steer traffic between paths seamlessly. Our real-world tests, large-scale simulations, and trace-driven user studies confirm the effectiveness of MP^2, with up to an order of magnitude improvement in latency metrics, as well as consistent QoE gain under different settings, making it a promising solution for future immersive VR experiences.

STORM: a Multipath QUIC Scheduler for Quick Streaming Media Transport under Unstable Mobile Networks

Abstract

The rapid proliferation of streaming media applications has driven the need for multipath transport on mobile devices. While multipath techniques successfully improve throughput by exploiting multiple network interfaces, our study reveals that path instability leads to excessive end-to-end latency. This paper analyzes the data path of multipath networks and observes that the high latency is always caused by the "last mile" wireless link, instead of the core network. Additionally, unlike traditional scenarios, both reliable and unreliable data are transmitted across these paths. However, existing multipath schedulers did not fully account for the reliability characteristics in the design. To address this gap, this paper proposes STORM, a novel multipath scheduler that aims to ensure low latency under unstable mobile networks. We integrate STORM with the mobile device's wireless modules (e.g., WiFi and 5G). STORM differentiates between reliable and unreliable traffic. This approach prevents retransmissions from hindering critical data flows. Our evaluation on real devices shows that STORM reduces tail packet delay by 98.2% and improves the frame rate of streaming media by 1.95x under unstable networks, compared to the state-of-the-art.

1 Introduction

Recent years have witnessed the popular trend of streaming-media-based applications, such as real-time footage of unmanned aerial vehicles (UAVs) [45], 360° panoramic videos of virtual/mixed reality (VR/MR) headsets [30], ultra-high definition (UHD) videos [4], and cloud gaming [44]. With their increased demand for high-quality content, multipath transport is increasingly important for mobile devices. By making use of multiple network interfaces (e.g., WiFi, cellular network, and satellite communication) on mobile devices, the throughput of streaming-media transport can be enhanced as the data is split over various sub-flows and transmitted in parallel.

*Changlong Li is the corresponding author, email: clli@cs.ecnu.edu.cn.

TCP-based multipath transport (MPTCP [31]) is the most famous protocol, establishing a subflow over each TCP path. MPTCP is naturally unsuitable for streaming media data transmission for its strict reliability and retransmission mechanism [29]. Differently, QUIC supports unreliable transport as it is developed based on UDP, which is more friendly for transmitting streaming media data. Hence, the industry has been moving toward QUIC in many emerging scenarios, and as its extension, multipath QUIC (abbreviated as MPQUIC) has been widely studied recently [21, 22, 26, 49, 51].

However, most bandwidth-hungry applications are also latency-sensitive. For example, the latency of VR visuals should be less than 130 ms, or people may feel dizzy during usage [27]. Even though MPQUIC enhances throughput, this paper shows that the end-to-end latency is unexpectedly high if the signal of one path becomes unstable. Our evaluations in a moving vehicle illustrate that the tail latency is up to 4.59s when enabling MPQUIC, which is 6.38x higher than the original system, even though the average throughput is effectively enhanced. Unfortunately, with the increasing mobility, such as high-speed railways [25], vehicles [16, 26], and the Electric Vertical Takeoff and Landing (eVTOL [1]) in the near future, the instability of wireless networks is an increasingly common phenomenon. Enhanced mobility introduces more frequent and abrupt cellular network handovers and WiFi roaming et al. Therefore, ensuring quick streaming media transport on multipath when the network becomes unstable, instead of the normal stable case, is crucial in practice.

As the core element of MPQUIC, the scheduler determines when and how to distribute packets to each sub-flow. This paper shows that existing schedulers cannot address the latency issue of MPQUIC from neither '*when*' nor '*how*' aspects.

First, existing schedulers' response speed on network path deterioration is slow, which cannot meet the low-latency demand of streaming media services. Indeed, the mobility-induced instability problem has been considered in recent studies [5, 22, 49]. However, existing solutions estimate the path status based on the congestion status on a path within a certain period or the already appeared user experience phe-

nomena. Such a design philosophy tends to lag, especially for wireless links that experience unexpected outages accompanied by high burst loss. We find that the scheduler does nothing at the moment that the signal of one path already becomes weak, and start to reduce the data transmission proportion on a certain path while the signal of this path is already recoverd. In this paper, we make an interesting observation that the transmission latency bottleneck lies in the "last mile wireless link" (e.g., link from end devices to the base station or access point) rather than the core network. By co-designing with the end device's WiFi and 4G/5G module, the scheduler has the potential to be aware of unstable wireless link conditions and do scheduling instantly.

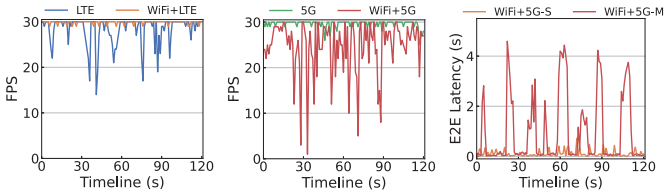
Second, reliable and unreliable packets are allowed to be transported on QUIC paths simultaneously [28]. Existing schedulers did not take the packet reliability into account. When one path faces burst loss, our evaluation in Section 2 will show that the retransmission of reliable packets blocks the unreliable ones, and the unreliable packets further block many reliable packets. Specifically, the scheduler consistently prioritizes retransmitted reliable packets over normal packets in MPQUIC. During severe burst loss, a substantial volume of reliable packets requiring retransmission monopolizes bandwidth resources, leading to a backlog of unreliable packets. Since the existing scheduler treats reliable and unreliable packets without differentiation, the subsequent reliable packets have to wait for all accumulated unreliable packets to be sent.

Inspired by the observations, this paper proposes STORM, a **M**ultipath QUIC **S**cheduler for quick st**r**eaming-media **T**ransport under m**o**bile networks. STORM aims to ensure low latency of streaming media applications when the multipath suffers "network storm". To achieve this goal, two novel schemes are further proposed: a signal-watermark mechanism (**SWM**) and a Reliability-aware scheduling (**RAS**) strategy. The SWM implementation relies on tightly coupling the MPQUIC software stack with the wireless network modules on the end device. Like the memory-watermark mechanism in the Linux kernel [17], SWM maintains a signal-watermark to estimate the path state. Compared to existing solutions, the lightweight SWM can be aware of the network storm more timely and accurately. Based on that, RAS realizes reliability differentiated scheduling by managing them as blocks and streams separately.

We have developed STORM based on the MPQUIC protocol and implemented it on real devices. Mobile systems can use STORM without rooting the device or recompiling the kernel. Experimental results show that the tail packet delay decreases by 98.2% when enabling STORM, and the average retransmission ratio is reduced by 12.8%. With STORM, the user experience is effectively improved. Specifically, the frame rate of streaming media data is improved by 1.95x when under unstable networks, compared to the state-of-the-art [21, 51].

The contributions of this paper are summarized as follows:

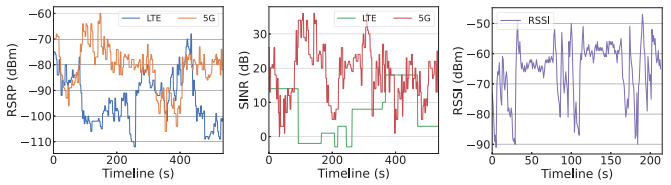
- STORM is the first effort to address the latency issue of MPQUIC under unstable mobile networks. By making use of the characteristics of QUIC protocol and streaming media data, this paper demonstrates that the transport latency with MPQUIC has the potential to be further reduced.
- We breakdown the data path of multipath networks and observe that the bottleneck is located at the "last mile" wireless link, instead of the core network. Inspired by this observation, this paper shows that the multipath scheduler can be designed in a lightweight but more practical approach.
- This paper is the first to propose a scheduler that distinguishes reliable and unreliable data on multipath. In this approach, the streaming media data on emerging scenarios can be transported with minimized retransmission, which is critical to reducing the end-to-end latency.
- We have implemented STORM on real-life mobile devices. Experimental results show that tail packet delay with STORM can be reduced by 98.2% and the frame rate of streaming media data is improved by 1.95x when under unstable networks, compared to the state-of-the-art solutions.



2 Background and Motivation

2.1 Trends in Mobile Applications

The development of STORM is motivated by a series of trends in mobile application scenarios.



Emerging Scenarios and Demands. There are diversified streaming media-based usage scenarios (e.g., video conferencing [5], AR/VR [7], teleoperated driving [6], and cloud gaming [44]) nowadays that significantly change people's lives. For example, using Apple Vision Pro [11], the data from a neighbor Macbook can be presented on an MR headset in a 3D approach. More people prefer to have conferences and buy online, which spawns a wave of Internet celebrity economy [19]. The COVID-19 pandemic is further accelerating such transitions in consumers' habits. In addition, modern operation systems (e.g., Fuchsia [12] and Harmony [13]) are trying to connect various mobile devices as a unit. They expect to let consumers use remote devices as if in local [3, 18, 40]. These emerging scenarios need high network bandwidth support. It motivates the development of multipath transport techniques. However, it imposes more stringent user experience requirements because viewers are less tolerant of slow response speed [39]. Besides improving throughput, the transport latency should also be considered in the scheduler design.

Enhanced Mobility. Different from traditional computers, mobile devices always move. People may use their phones

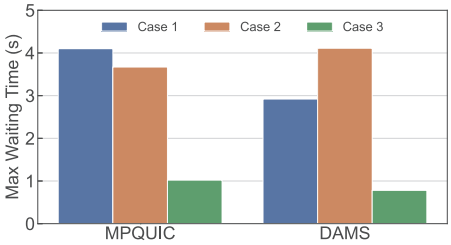

Figure 5: Maximum waiting time of critical data in different cases.

when walking or on the high-speed railway. Video streaming from vehicles unlocks a host of novel applications, like in-vehicle entertainment and gaming [9]. The mobility can lead to sudden signal changes on the end device side, caused by cellular network handover or weak WiFi signal et al. With the development of the next-generation cellular network, mobile devices will suffer more handover in the future because the coverage area of a single 5G/6G base station is smaller than that of the 4G LTE base station [24]. The enhanced mobility introduces more frequent and sudden signal fluctuates.

Reliability Differentiated Transmission. The importance of transmitted data is different. For example, video streams have I-frames and P-frames [48]. I-frames are independent and serve as the start of a GOP (Group of Pictures), while P-frames depend on the previous frame. The loss of an I-frame renders all dependent data useless, but existing systems (e.g., SVC extensions [36]) allow skipping P-frames without affecting the decoding of subsequent frames. Transporting all the data reliably prolongs the latency. MPQUIC supports reliability differentiated transmission: critical data is transmitted reliably while uncritical data is not.

2.2 Effect of MPQUIC on QoE

To explore the effect of modern MPQUIC on the Quality of Experience (QoE), this paper conducts a series of evaluations on a Xiaomi 12S Pro with LTE, 5G, and WiFi network interfaces. We ported the open-source Ringmaster [33, 34] video conference platform to Android, enabling two conference endpoints to communicate via MPQUIC. We adopt frame rate as the metric to quantify the smooth experience and collect the FPS (frame-per-second). Furthermore, the per-frame end-to-end latency is measured.

2.2.1 Effect on FPS

We first evaluate the FPS of UHD video conferences under LTE. Fig. 1(a) shows that single-path transport results in frame rate fluctuations. Specifically, the worst frame rate is only 14fps. Since LTE bandwidth is insufficient to support UHD video conferences, the delivery interval between frames becomes prolonged, causing a decrease in frame rate. Also in this position, enabling multipath (LTE+WiFi) effectively enhances FPS, with all rates exceeding 29fps. This shows that the multipath technique improves bandwidth-hungry apps.

When moving on campus, the signal strength changes. For multipath transport, the frame rate significantly degrades if one path's signal is poor. FPS is even worse than in single-path transport. As shown in Fig. 1(b), average FPS with 5G is 29.6fps, while reduced by 18.4% with 5G+WiFi. In the worst case, single-path 5G has a frame rate of 25fps when moving, while multipath drops to 10fps. That is, even though multipath transport is necessary for streaming media-based applications, its effect is negative instead of positive in some cases.

2.2.2 Per-frame E2E Latency

This paper further explores the end-to-end (E2E) latency of each frame. For a high user experience, the latency should be minimized. As shown in Fig. 1(c), 92.3% of the latency for multipath transmission is less than 100ms. However, when moving, the tail latency reaches 4.59 seconds, which is 5.37x of the stationary case. Such high latency makes real-time communication for video conference attendees impossible, causing frequent frame drops and video artifacts on the screen.

2.3 Root Cause Analysis

2.3.1 Mobility-induced Signal Changes

To explore the reasons, the signal strength during evaluation is analyzed. We collect three types of signal strength indicators at the physical layer through the OS's API: Received Signal Received Power (RSRP), Signal to Interference plus Noise Ratio (SINR), and Received Signal Strength Indicator (RSSI) [15, 32, 47]. At the transport layer, the packet loss rate is recorded. Fig. 2 shows that the wireless signal strength changes dramatically when the device moves around campus. In some areas, the WiFi signal drops, while the cellular network signal drops suddenly in other places. For example, we find that public WiFi signals are stronger in office buildings, while cellular network signals tend to be weaker indoors compared to outdoors.

We further explore the effect of such signal fluctuations on the transmission. Fig. 3 shows the relationship between RSSI (lower dBm values mean worse signal) and loss rate. In the figure, each point represents an RSSI-loss measurement, with darker red shades indicating higher point concentration. Specifically, we can see all measured loss rates remain under 10% at -70dBm. As the RSSI drops to -80dBm, a significant cluster emerges between 60% and 80% loss, and in some cases reaches 100%. When the value of RSSI is reduced, the loss rate tends to be higher. This phenomenon is widely observed in the evaluation. As loss rates rise, more retransmissions occur, consuming bandwidth that could serve subsequent data.

The results demonstrate that the scheduler cannot respond to these rapid signal changes. This is due to the "visibility gap" and unawareness of link outages. Our log analysis indicates that the scheduler selects and schedules according to the path bandwidth and RTT obtained by the congestion control mechanism. As a result, severe burst loss can last several seconds. Due to dependencies between packets on the two paths, overall performance is reduced. The delay in data arrival prevents rendering the next frame, causing video stutter and video artifacts.

2.3.2 Scheduling without Reliability Differentiation

Keyframes (e.g., I-frames) are crucial for video smoothness, as non-keyframes depend on them for decoding [50]. Without keyframes, non-keyframes are useless. MPQUIC provides reliable transmission for these critical data, while other data are transmitted unreliably. Theoretically, this scheme can effectively reduce the additional delay due to lost retransmissions. However, the practice performance is not as expected. Fig. 4 shows that MPQUIC's median and third quartile packet delays improve by 26.6% and 67.55% compared to MPQUIC-R. However, MPQUIC has a higher maximum packet delay outlier (rhombic scatter) than MPQUIC-R, reaching up to 1.65x.

We further explore the cause of this phenomenon by calculating the waiting time of keyframes in the video conference. In our study, waiting time refers to the delay from when the application hands data to MPQUIC until MPQUIC has finished transmitting the data. We compare the default MPQUIC scheduler (minRTT [21]) with the state-of-the-art deadline-aware scheduler (DAMS [51]). The deadline is set to 300ms[1].

We evaluate the scheduler in three cases. (1) Both critical and uncritical data are treated as reliable and scheduled without differentiation. (2) Critical data are treated as reliable, and uncritical data as unreliable, flagged in QUIC as `STREAM` and `DATAGRAM` frames [28], respectively. (3) Similar to Case-2, with modified scheduling: unreliable data waits if any reliable data are in the sending queue.

Fig. 5 shows the critical data, maximum waiting time in three cases when moving around the campus. In Case-1, the maximum waiting time is 4.1s for MPQUIC and 2.92s for DAMS. When distinguishing unreliable packets, the maximum waiting time for MPQUIC was only reduced by 11.79%. Unexpectedly, the maximum waiting time for DAMS increased by 39.93%. Comparing Case-2 and Case-3, we observe a significant reduction in maximum waiting time.

Burst loss from poor signals triggers extensive retransmissions of reliable data, which are prioritized over all normal traffic. Consequently, unreliable data remains queued until retransmissions are complete. Afterward, queued unreliable data floods the network, delaying subsequent reliable data. This mutual blockage increases latency, resulting in worse tail packet delay for MPQUIC than for MPQUIC-R. Ideally, reliable data should not be so heavily affected by unreliable data. Case-3 shows that prioritizing reliable data does help. A scheduler that better coordinates both data types is needed.

3 Design

3.1 STORM Overview

This paper proposes STORM, an MPQUIC scheduler for quick streaming media transport under mobile networks. STORM aims to ensure low latency when the multipath suffers unstable networks.

3.1.1 Key Components

See Fig. 6, to achieve STORM, two core components are maintained: a signal-watermark mechanism (SWM) and a reliability-aware scheduling (RAS) strategy.

Signal-watermark mechanism. As analyzed, link outages during device movement and the sender scheduler's unawareness result in a vicious cycle of packet loss and retransmissions. This phenomenon motivates us to propose a memory-watermark-like mechanism for the mobile devices' MPQUIC.

[1]We set the deadline as 300ms by default since delivering latency over this value will cause significant delays and disruptions [20].

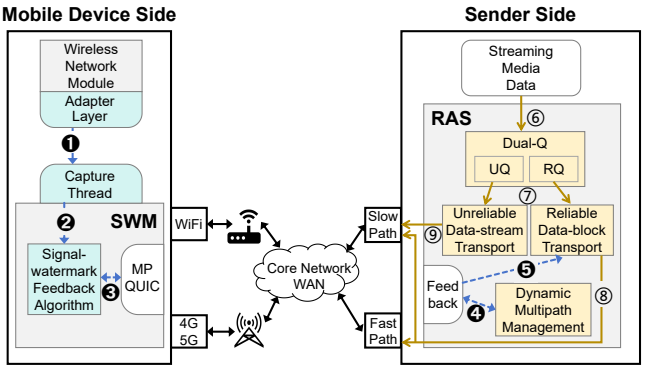

Figure 6: Architecture overview.

The basic idea is to quantify the path's signal strength, compare it with a predefined watermark, and then send differentiated feedback based on the comparison. There are many challenges to tackle in SWM design, for example, how to quantify multiple signal strength indicators into a signal quality index, and how to ensure the flexibility and applicability of the watermark. We will discuss this in detail in Section 3.2.

Reliability-aware scheduling. Based on SWM, this paper further proposes an RAS strategy on the sender side. RAS treats reliable and unreliable data differently. Specifically, reliable data is organized as blocks and unreliable data is organized as streams. The details and advantages of such an approach will be discussed in Section 3.3.

3.1.2 Workflow

Also see Fig. 6, STORM's workflow consists of a feedback flow and a scheduling flow, forming a scheduling system that strings together the two components. Specifically, the blue arrows in the figure are feedback flows (❶ - ❺), while the brown arrows are scheduling flows (⑥ - ⑨).

Feedback flow begins at the adapter layer encapsulated in the wireless network module of the mobile device. (1) A dedicated thread collects signal strength indicators from this adapter layer. (2) These indicators are input to the Signal-Watermark feedback algorithm. (3) The algorithm sends feedback to the sender via MPQUIC and adjusts the watermark based on subsequent results. (4) Upon receiving the feedback, the sender notifies the Dynamic Multipath Management module in the RAS component to decide whether to activate or deactivate a path. (5) The Reliable Data-block Transport module also uses this feedback to adjust its path allocation ratio. After these steps, the feedback flow completes, and scheduling can proceed using the updated signal conditions. (6) The scheduling flow starts once streaming media data arrives at the RAS component, which places the data into Dual-Q based on reliability requirements. (7) Dual-Q maintains separate queues for different reliability classes, each governed by its own scheduling strategy. (8) The Reliable Data-block Transport module distributes reliable data across two paths to maximize aggregate bandwidth, reducing allocations on any path identified (via SWM feedback) as having poor signal. (9) The Unreliable Data-stream Transport module then injects data into idle times on the slower path after each reliable data send.

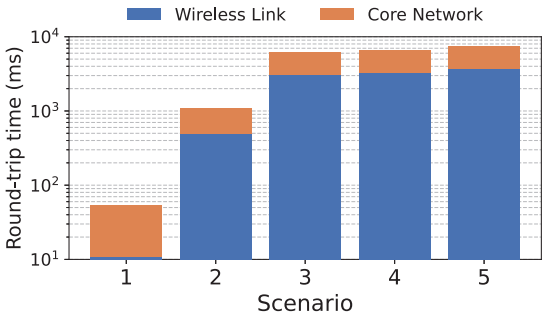

Figure 7: Breakdown of End-to-End RTT: Wireless Link vs. Core Network RTT (Scenario 1: strong signal location for stationary; Scenario 2: underground mall; Scenario 3: subway; Scenario 4: hotel room; Scenario 5: high-speed railroad).

3.2 Signal-watermark Mechanism

3.2.1 Data Path Breakdown

Extensive research has examined whether wireless links (so called the "last mile") act as a bottleneck for network throughput [2, 37]. However, the latency bottleneck on the data path has not been thoroughly analyzed. In this paper, we breakdown the data path to understand where the latency bottleneck locates on the network path.

To accurately obtain the round trip time (RTT) between the base station and the device, we innovatively utilize the first hop IP address after entering the core network from the base station. Specifically, we employ a traceroute-like function to identify this first-hop IP address. Since the latency between the base station and its first hop is typically under 5ms, measuring the RTT of this address effectively represents the wireless link's latency.

Fig. 7 shows results from various scenarios, including poor RSRP (low coverage) and poor SINR (high interference). We observe that poor RSRP (Scenario 2 and 4) leads to more frequent failed handovers compared to poor SINR (Scenario 3). The severity of packet loss and wireless link latency due to handover failure intensifies whenever either RSRP or SINR deteriorates. In the worst case, the E2E RTT reaches 3,781 ms, with the wireless link RTT at 3,750 ms. This trend is consistent across all mobile scenarios, indicating that despite advancements in wireless technology claiming low latency, the wireless link remains the latency bottleneck in mobile environments. Therefore, designing SWM to monitor signal conditions and provide feedback is essential for quickly reducing latency.

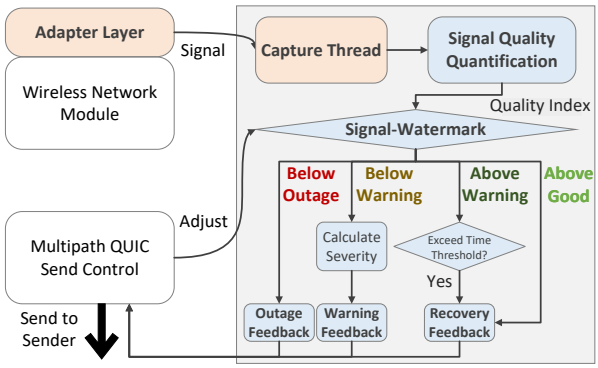

Figure 8: The workflow of SWM. The gray box works on the MPQUIC protocol stack.

3.2.2 Co-Design with the Wireless Network Module

As shown in Fig. 8, to enable SWM's signal-awareness, we co-designed MPQUIC with the wireless network module. Our goals were to provide a unified way to retrieve signal strength across different platforms and to maintain MPQUIC's performance by avoiding blocking operations.

Originally, the mobile device's wireless module ran independently of MPQUIC. To allow seamless access to signal strength indicators, we extended it with an adapter layer that standardizes retrieval across platforms (see the orange box on the left in the figure). MPQUIC then obtains signal strength through a single, unified API.

MPQUIC uses a non-blocking I/O event loop for multipath transfers. Directly polling signal strength in this loop could block it, degrading performance. To avoid this, we delegate signal-strength capture to a dedicated thread (see the orange box on the right in the figure). This thread periodically calls the adapter layer's API and updates atomic variables in SWM. By employing lock-free programming, we minimize overhead on MPQUIC's main event loop.

3.2.3 Signal-watermark Feedback Algorithm

Upon receiving signal strength indicators from the capture thread, the Signal-Watermark feedback algorithm begins execution. Its workflow is shown in the blue box of Fig. 8.

Signal Quality Quantification. Signal strength indicators such as SINR and RSRP vary in scales and units, influencing signal quality from distinct dimensions—coverage and interference. To coherently quantify their combined impact, we normalize these indicators into a unified interval for direct comparison. Since SINR and RSRP inherently exhibit multiplicative and proportional characteristics, we adopt a weighted geometric mean rather than a linear combination. The weights tune the relative influence of each indicator, recognizing that SINR and RSRP affect signal quality to different extents (see Section 3.2.1). As shown in Eq. 1, the base quality Q_{base} is defined as:

$$Q_{\text{base}} = \left((SINR_{norm})^{w_{sinr}} \times (RSRP_{norm})^{w_{rsrp}}\right)^{\frac{1}{w_{sinr}+w_{rsrp}}} \quad (1)$$

where w_{rsrp} and w_{sinr} are adjustable weights in [0,1]. Requiring the sum of weights to exceed 1 imposes a compressive effect, preventing large jumps in Q_{base} from minor improvements and pulling Q_{base} toward moderate values when indicators are extremely low, maintaining stability and avoiding excessive dispersion. Note that for WiFi, which only uses RSSI, Q_{base} equals $RSSI_{norm}$.

To further refine this measure, we introduce a modulation factor that reacts to packet loss trends. The packet loss rate is a critical indicator of whether current feedback decisions are effective: a persistent rise in loss ($\Delta loss > 0$) shows that the signal-degrading path is still over-utilised. Accordingly, the modulation factor amplifies the negative adjustment, aggressively reducing that path's utilization and achieving the desired effect more quickly. Conversely, when $\Delta loss \leq 0$, the factor does not raise the quality score, because temporary loss reductions do not yet signal genuine recovery. The modulation factor $H(\Delta loss)$ is defined as:

$$H(\Delta loss) = \begin{cases} 1, & \Delta loss \leq 0 \\ \exp(-\gamma \cdot \Delta loss), & \Delta loss > 0 \end{cases} \quad (2)$$

Here, $\gamma \in [0,1)$ controls sensitivity to increasing loss: a larger γ sharply reduces quality when loss rises, while a smaller γ allows for subtle adjustments. This keeps the base quality as the primary determinant, with $\Delta loss$ as a secondary cue.

The final quality index $Q \in [0,1]$ is:

$$Q = Q_{\text{base}} \times H(\Delta loss) \quad (3)$$

As shown in the blue box at the top right of Fig. 8, the final quality index will be passed to the Signal-watermark for comparison.

Adaptive Signal-watermark Feedback. After obtaining the quality index, it is compared against three watermarks: *Good*, *Warning*, and *Outage*. If the index falls below the *Warning* watermark, a `warning` feedback is generated, indicating the gap between the current index and the *Warning* watermark, to help adjust path allocation ratios. Dropping below the *Outage* watermark triggers high-priority `outage` feedback, instructing the sender to stop scheduling on that path. When the index exceeds the *Warning* watermark, SWM will consider generating `recovery` feedback.

To prevent frequent feedback caused by the unstable quality index, a timing threshold mechanism with Fast Suppression/Slow Recovery is implemented. Feedback is promptly generated when the index falls below *Warning* or *Outage*. However, `recovery` feedback is only immediately issued when the index recovers from below *Outage* to above *Good*. If the index rises to between *Outage* and *Warning*, no action is taken. When the index surpasses *Warning*, a timer starts, and `recovery` feedback is generated only if the index remains above *Warning* for a threshold time T_{rec}; otherwise, the timer resets. This approach ensures that signal improvements are sustained.

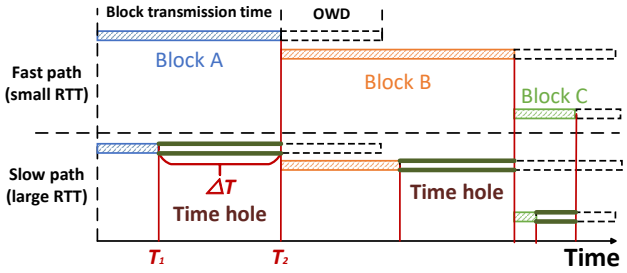

Figure 9: Slow path time hole.

However, rapid fluctuations in the quality index can lead to a worst-case scenario where the corresponding path remains inactive for an extended period. Specifically, if the index continuously and quickly oscillates across multiple watermarks, it may never stabilize above the *Warning* watermark for the entire recovery feedback period (T_{rec}), thus failing to generate any `recovery` feedback. Even if it briefly exceeds the *Good* watermark, it will be deactivated again upon falling below the *Outage* watermark. In fact, utilizing paths with severe quality fluctuations offers no performance advantage and considerably impairs user experience. Hence, sustained deactivation of such unstable paths is beneficial.

The default watermark settings were based on extensive experiments (see Fig. 3), but device-specific conditions, network technologies, and environments can affect effectiveness. To accommodate this variability, watermarks are adaptive. Specifically, the SWM evaluates the effects of previous feedback through MPQUIC send control. If the *Outage* watermark fails to prevent high burst loss, it is increased until the loss is curtailed. Similarly, if the burst loss exceeds 10% when below the *Warning* watermark, it is raised by a smaller step for finer granularity. To prevent aggressive path deactivation and bandwidth waste, the *Outage* watermark decreases if burst loss above 50% does not occur, ensuring alignment with actual link outages. These adaptive adjustments keep the watermarks calibrated to real-world link conditions.

3.3 Reliability-aware Scheduling

To enable the sender to fully utilize SWM feedback, a new scheduling scheme must be devised. Merely adjusting multipath scheduling allocation ratios and deactivating link outages path may improve performance to some extent, but does not address the root cause. Although SWM can mitigate high burst loss, it cannot achieve a loss-free environment in real wireless networks. As analyzed in Section 2.3.2, loss cause reliable and unreliable data to block one another, making coordinated scheduling of both essential for further improving latency.

Dual-Q for Reliable and Unreliable Data. To coordinate the scheduling of data with different reliability requirements, we manage them using two separate queues. Specifically, we revise the MPQUIC protocol to adopt a Dual-Q architecture, consisting of an RQ for reliable data blocks and a UQ for unreliable data streams. In the RQ, reliable data are handled as individual blocks, each with its own priority and deadline set by the application. The scheduler establishes a subflow for each path and distributes these blocks accordingly. Meanwhile, in the UQ, unreliable data are sorted by their deadlines. if a loss occurs, RAS discards the affected data and proceeds to the next.

Maintaining two distinct data types, including blocks for reliable data and streams for unreliable data, offers two key advantages. First, by representing reliable data as discrete blocks, each block is fully delivered as a unit, meeting the requirement for complete, in-order delivery. Second, treating unreliable data as streams enables more flexible use of idle bandwidth without the constraints imposed by fixed block sizes. We now introduce the scheduling strategy in detail.

Reliable Data-block Transport. For reliable data blocks, RAS aims to deliver as many as possible before the deadline. Aligning arrival rather than sending times maximizes the faster path's potential [8]. To ensure packets belonging to one block can arrive at a similar time, the data size allocated on the paths ($Size_1$ and $Size_2$) follows the constraint:

$$\frac{Size_1 \times bw_{agg}}{bw_1 \times F_1} + OWD_1 = \frac{Size_2 \times bw_{agg}}{bw_2 \times F_2} + OWD_2 \quad (4)$$

Here, bw_i represents the current path bandwidth, and OWD_i refers to the one-way delay on the corresponding paths. Path bandwidth is estimated based on the congestion control algorithm employed by the MPQUIC. To prevent the division result from approaching zero, we normalize with the aggregated bandwidth bw_{agg} (the sum of the two paths' bandwidths). F_i is determined by the mobile device side SWM's feedback: more severe `warning` feedback lower the F_i value, indicating a higher potential loss rate. Fewer data allocations are made to paths with lower F_i values to avoid burst loss. Upon receiving a `recovery` feedback, the F_i value is restored to one.

RAS calculates the residual time to send at that moment for each subflow. For subflow on path i, its residual time is:

$$Trsd_i = deadline_i - Tpsd_i - OWD_i \quad (5)$$

Here, $Tpsd_i$ represents the time already passed before processing. If less than 0, the data is proven to be expired. RAS cancels the sending operation and evicts it from RQ.

The urgency of the deadline depends on both residual time and block size. A large block with a distant deadline can still be urgent. Based on Eq. 5, we calculate the gap between the current bandwidth (Cbw) and the minimal required bandwidth (Mbw), as shown in Eq. 6. Mbw corresponds to $\frac{Size_i}{Trsd_i}$. If not processed immediately, the required bandwidth increases as the block nears its deadline.

Blocks with smaller Gbw values are more urgent. If the gap is less than zero, the data cannot be delivered within the remaining time under current conditions. In this case, RAS

delays processing this block to prioritize others.

$$Gbw = \min_{i \in \{1,2\}} \left(Cbw_i - \frac{Size_i}{Trsd_i} \right) \quad (6)$$

Ultimately, RAS determines weights based on the bandwidth gap and block priority. Blocks with lower weight are more likely to be scheduled.

We normalize the bandwidth gap and block priority to calculate the final weights. The gap is divided by bw_{agg}, and the priority is divided by the current maximum priority value (P_{max}). Parameter α adjusts the importance of each in the weight calculation. To avoid unfairness to smaller blocks, we multiply the gap by parameter R, representing the unsent data ratio in a block. This adjustment ensures blocks that have already sent most of their data receive a lower weight (higher priority).

$$weight = \alpha \times \frac{Gbw}{bw_{agg}} \times R + (1-\alpha) \times \frac{priority}{P_{max}} \quad (7)$$

Unreliable Data-stream Transport. After achieving efficient scheduling for reliable data blocks, we must consider how to handle unreliable streaming data. If we simply allocate them across two paths in the same manner as reliable data, the loss affecting reliable data will continue to cause mutual blockage. Furthermore, as shown in Fig. 9, block A finishes on two paths at T_1 and T_2. The idle period ΔT $(T_2 - T_1)$ on the slow path creates a *time hole*. This *time hole* reduces throughput, and when combined with mutual blockage, it becomes nearly impossible for both data types to meet their deadlines.

RAS manages unreliable data on UQ as a stream arranged by deadlines, with their weight set higher than P_{max} for differentiation. During ΔT, RAS schedules UQ data to the slow path. Because unreliable data is injected only during time hole, any blockage lasts only for a single retransmission. Once that retransmission completes, the next reliable block creates another time hole, allowing the scheduling of unreliable data in this new hole. This approach effectively alleviates mutual blockage and further improves overall delivery speed.

Dynamic Multipath Management. Another challenge is sudden link outages. Upon receiving `outage` feedback from the mobile device, the affected path is quickly deactivated to minimize the impact of burst loss. With only a single path remaining, Eq. 4 is no longer applicable. Instead, RAS employs subsequent equations to calculate each block's weight based on the full allocation to the remaining path. Due to bandwidth constraints, the unreliable stream is scheduled by the deadline only after all reliable blocks have been transmitted and there is available congestion window capacity. When `recovery` feedback is received, the path is immediately reactivated to maximize bandwidth utilization.

Even though subsequent data will not be scheduled to the deactivated path, prior scheduling decisions cannot be undone. If not processed, these data may be delivered late. To solve this, RAS employs deadline-aware reinjection. RAS calculates if unacknowledged data can meet the deadline with the current available path's bandwidth. If feasible, it reinjects the data; otherwise discarding them. Reinjection occurs after the scheduling round to avoid delaying normally scheduled data. Unreliable data are discarded without reinjection.

4 Implement STORM with MPQUIC

STORM is implemented based on the QUIC protocol. Specifically, we developed STORM based on Alibaba's XQUIC [10]. Features of QUIC, like the unreliable QUIC-Datagram based on RFC9221 [28] and multipath functionality incorporated into the IETF WG Draft [21], are used by STORM. Based on that, we modify QUIC with 1,342 lines of C language code, excluding the libraries.

Wireless Network Module Adapter Layer. MPQUIC uses abstract paths to adapt to various mobile network interfaces, preventing direct access to signal strength indicators. We introduce an adapter layer to the wireless network module. On Android, we implemented Java logic to monitor wireless network signal changes. These indicators are stored as atomic variables and accessed by SWM via Java Native Interface (JNI) calls every 100 milliseconds.

The adapter layer implementation introduces minimal modifications to user equipment. Unlike previous approaches that required hardware adjustments or system-level root privileges, our adapter-based method efficiently retrieves cellular signal strength indicators by utilizing standard Android classes (e.g., WifiManager [42] and TelephonyManager [41]). Specifically, the adapter achieves this with only 102 lines of Java code, significantly simplifying developers' workload and seamlessly integrating into existing systems.

Reliable Data-block Transport. MPQUIC supports various frame types to handle different data reliability requirements. Specifically, `STREAM` frames carry reliable data, while `DATAGRAM` frames carry unreliable data [14, 28]. STORM extends this capability by mapping different reliability data to different frame types.

MPQUIC packetizes data into a doubly linked list for write streams, complicating fine-grained scheduling. To minimize overhead, STORM schedules data based on block metadata and caches reliable blocks in a vector.

Unreliable Data-stream Transport. MPQUIC's stream management supports unreliable data streams but faces synchronization challenges: data must be packetized pre-injection into the slow path, complicating alignment between unreliable data on the slow path and reliable data on the fast path. Fixed packet sizes worsen timing mismatches, leading to inconsistent finishes of unreliable transmissions relative to reliable blocks under varying bandwidth conditions.

To solve these issues, STORM introduces a novel scheme. Unreliable data is placed in a doubly linked send queue organized by deadlines, where each node holds an entire data

segment rather than individual packets. This approach defers packetization until injecting data into the slow path, thereby reducing scheduling overhead and improving synchronization with reliable data.

Dynamic Multipath Management. MPQUIC manages multipath usage by sending `PATH_STANDBY` and `PATH_AVAILABLE` frames to notify peers of path states. A STANDBY path does not schedule packets unless the AVAILABLE path is unavailable [21]. However, this mechanism is inadequate for signal-aware path management due to two issues: (1) In-flight packets on a STANDBY path remain until lost, while buffered data continues to transmit, increasing latency and packet loss. (2) If the AVAILABLE path's congestion window is exhausted, new packets are sent through the STANDBY path. These behaviors conflict with the deactivation of paths experiencing link outages, highlighting a limitation in MPQUIC's scheduling.

STORM introduces a new frame type, `PATH_ALERT`, containing feedback from the SWM. Upon receiving a `PATH_ALERT` frame, the sender manages multipath according to RAS's design.

Abstraction and API. STORM encapsulates the process and offers an API to the upper layer. Applications just need to call the *STORM_send* and provide parameters like deadline and priority. Specifically, STORM categorizes application data into Reliable Transport Blocks and Unreliable Transport Streams, executing their logic.

STORM does not use a proxy [25, 26] in its implementation. While proxies reduce application modifications, they only intercept the payload, losing important metadata. This limits QUIC's cross-layer benefits, complicating fine-grained scheduling. Instead, data can be sent directly through the API provided by STORM, reducing code changes.

5 Evaluation

5.1 Experiment Setup

This section provides the evaluation from two aspects:

- **Control Network Environment.** We test STORM in a controlled lab environment. The evaluation focuses on three main aspects: microbenchmarks, the performance effects of individual designs, and the performance effects of parameter settings.
- **Applications in the Wild.** Furthermore, we developed three apps for typical scenarios: video conferencing, low-latency live streaming, and 360° video. These applications were evaluated in real-world mobile Internet environments, and the QoE was analyzed.

Parameter Configurations. The parameters in the evaluation are listed in Table 2. The default signal-watermark was set empirically. w_{rsrp} and w_{sinr} are set to 0.8 and 0.6, respectively, because poor RSRP values are usually more strongly associated with failure of handover. Set γ to 0.01 to avoid overly penalizing the common random losses (under 10%) typical of wireless links, while still enabling a rapid score reduction once $\Delta loss$ exceeds 50. T_{rec} is set to 400 ms. α is set to 0.5.

Symbols	Semantics	Setting
Good	High-watermark that represent strong signal	0.45
Warning	Medium-watermark that represent weak signal	0.32
Outage	Low-watermark that represent link outage	0.21
w_{rsrp}	RSRP weight coefficient	0.8
w_{sinr}	SINR weight coefficient	0.6
γ	Modulation factor sensitivity parameter	0.01
T_{rec}	Time threshold for recovery feedback	400 ms
α	Weight coefficient for reliable data transport	0.5

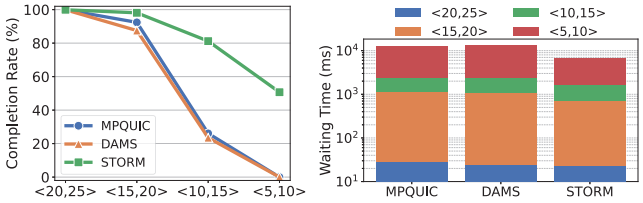

Table 2: Summary of parameters used by STORM.

5.2 Microbenchmark

We developed a toolkit to evaluate STORM's microbenchmark performance under various network conditions. The tool sends six blocks of varying priorities and sizes every 100ms at 30Mbps, each with a 300ms deadline. This setup emulates transmitting a Group of Pictures (GOP) in streaming applications at 60 fps. Specifically, the highest-priority block represents an I frame, three lower-priority blocks represent P frames, and two lowest-priority blocks (transmitted unreliably) represent B frames. Note that STORM supports deadline setting well below 300 ms, discussed in Appendix A.1. Two PCs (see Table 1) are connected to an OpenWrt router with traffic control (*tc*). Ethernet simulates WiFi and cellular networks, avoiding interference. We tested the completion rate and waiting time of high-priority blocks. DAMS [51] and MPQUIC were compared with STORM. Since Ethernet does not reflect wireless link conditions, we only examined STORM performance under a strong signal.

5.2.1 Bandwidth Variation

We evaluated STORM's performance under bandwidth fluctuations using various combinations, denoted in Mbps. Although more combinations were tested and exhibited similar trends, this paper only presents four representative cases: <20, 25> (adequate bandwidth), <15, 20> (nearly adequate), <10, 15> (slightly inadequate), and <5, 10> (severely inadequate). These combinations clearly illustrate STORM's per-

(a) Completion Rate (b) Waiting Time Distribution

Figure 13: Ablation study of STORM's design.

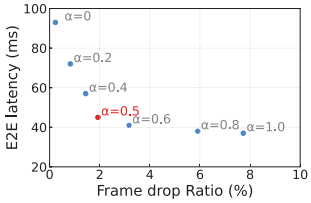

Figure 14: Weight parameter α.

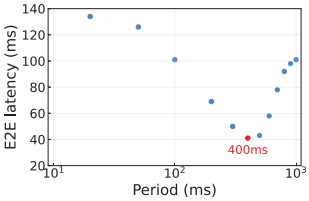

Figure 15: Recovery feedback period T_{rec}.

formance under bandwidth conditions ranging from sufficient to severely insufficient. The RTT for the two paths was set to 30ms and 50ms, with a loss rate of 0.01%.

Completion Rate. Fig. 10(a) shows that with <10, 15> bandwidth combinations, the completion rate[2] of MPQUIC drops from 99.9% to 26.1%. The completion rate of DAMS is reduced by 76.4% compared to the sufficient-bandwidth case. With a bandwidth combination of <5, 10>, both DAMS and MPQUIC nearly reach zero completion rates, unable to deliver on time with only half the required bandwidth. In contrast, STORM's completion rate only decreases by an average of 49.3%.

As Table 3 shows, STORM schedules 66.5% of reliable data to the fast path, while unreliable data is all scheduled on the slow path. In MPQUIC, all data competes equally for the fast path. DAMS, however, utilizes both paths for reliable data and defaults to MPQUIC's approach for unreliable data. As a result, unreliable data consumes 17.4% more bandwidth on the fast path than in MPQUIC. STORM fully utilizes the fast path without wasting the slow path, significantly increasing the completion rate of reliable blocks.

	Reliable data		Unreliable data	
	fast path	slow path	fast path	slow path
MPQUIC	75.1%	24.9%	71.7%	28.3%
DAMS	54.8%	45.2%	89.1%	10.9%
RAS	66.5%	33.5%	0%	100%

Table 3: The ratio of (un)reliable data on the two paths.

Efficiency to Transport High-priority Data. We further verify the advantages of scheduling reliable data more on the fast path. Fig. 10(b) shows the waiting time distribution for high-priority data. The top of each color bar represents the maximum waiting time for that bandwidth combination. As bandwidth decreases, the maximum waiting time for MPQUIC and DAMS increases significantly (by 44.3x and 54.5x, respectively). In the worst case, the time reaches 11 seconds. In contrast, STORM performs better. For example, with the <5,10> bandwidth combination, STORM's maximum waiting time is 49.6% of MPQUIC's and 45.3% of DAMS's.

[2]The completion rate is the ratio of packets successfully delivered before the deadline to the total number of packets.

5.2.2 RTT Variation

We further explore the effect of RTT variation. In the evaluation, one path's RTT is fixed at 30ms, while the other varies from 30ms to 180ms. The bandwidths of the two paths are set to 20Mbps and 14Mbps. As shown in Fig. 11, two phenomena are observed: First, STORM consistently outperforms DAMS and MPQUIC in the completion rate across various RTT combinations. With the <30,120> RTT combination, STORM's completion rate increased by 37.3% and 37.6% over MPQUIC and DAMS, respectively. Second, we observed DAMS's completion rate rising to 64.4% with the RTT combination <30, 150>. Due to excessive RTT differences, DAMS can hardly use the slow path to accelerate delivery, scheduling more data to the fast path. The fast path's 20Mbps bandwidth is sufficient for this higher completion rate. MPQUIC, however, allocates data to the slow path when the fast path's congestion window is exhausted, increasing missed deadlines.

5.3 STORM Deep Dive

In this section, we replay user walking network traces to investigate how each design affects STORM's performance. We modified saturatr [46] to trace when the mobile device detects a signal strength change, providing these records to SWM for simulating signal strength capture. We set up a mpshell [23]

testbed with a sender application and a virtual low-latency live streaming player. The player focuses on network transmission without actual decoding or rendering.

Signal State Sync Bias. Studies show that reporting signal strength to user space can be delayed by up to 200 ms [25], causing synchronization bias between signal change and feedback receipt. Fig. 12 shows that the 'captured vs. actual' signal strength differs minimally: about 1.14% on average and 0.95% at the median. With a capture-to-feedback delay of at most 300 ms, large spatial shifts are unlikely. Even at high speeds, STORM quickly reacts to signal degradation, then waits for stabilization before readjusting.

Ablation Study. We conducted an ablation study to investigate the impact of the Signal-Watermark Mechanism (SWM) and Reliability-Aware Scheduling (RAS) components. Fig. 13 shows that the complete design (SWM+RAS) is crucial for STORM to optimize user experience during signal fluctuations. Disabling SWM reduces goodput by 26.6% and increases rebuffering time by 6.8x. Disabling RAS reduces goodput by 15.7% and increases rebuffering time by 2.9x.

Computational Overhead. STORM is a lightweight multipath scheduler integrated into MPQUIC with negligible computational overhead. RAS's average processing time for data in Dual-Q is 5.03 ms, only 7.4% of the total transmission time (68.1 ms). The feedback algorithms in SWM have $O(1)$ complexity, incurring only μs-level overhead. With our implementation, the number of Java Native Interface (JNI) calls is minimized to further reduce overhead. Specifically, the most time-consuming JNI call introduces an average overhead of 78 μs per invocation. Given that this call occurs once every 100 ms, it results in merely 780 μs of additional CPU time per second, leading to negligible extra CPU usage.

5.4 Sensitive Study

We in this part test the sensitivity of STORM performance to different parameter settings.

Parameter α Tuning. A larger value of α in Eq. 7 leads to STORM scheduling the more urgent packets first, which decreases its consideration of their priority. We evaluate STORM with α values from 0 to 1, shown in Fig. 14. As α increases, E2E latency decreases as the scheduler favors urgent packets for timely delivery, but this raises the frame drop ratio. If critical decoding data is delayed by urgent packets, the player favors received data, compromising smoothness and quality despite lower latency. Thus, a suitable STORM balance is $\alpha = 0.5$.

Recovery Feedback Period. To find the optimal period T_{rec} for SWM to generate recovery feedback, we test a range of values in [20, 50, 100, 200, 300, 400, 500, 600, 700, 800, 900, 1000]ms. Fig. 15 shows the E2E latency for these period settings. Periods under 100ms produce overly frequent recovery feedback. This excessive frequency can disrupt transmission and cause traffic fluctuations. Periods over 800ms waste bandwidth and increase end-to-end latency. We select 400ms as the period for STORM. Note that as mobility increases, this period should be extended to ensure the signal stabilizes.

5.5 Real-world Applications Evaluation

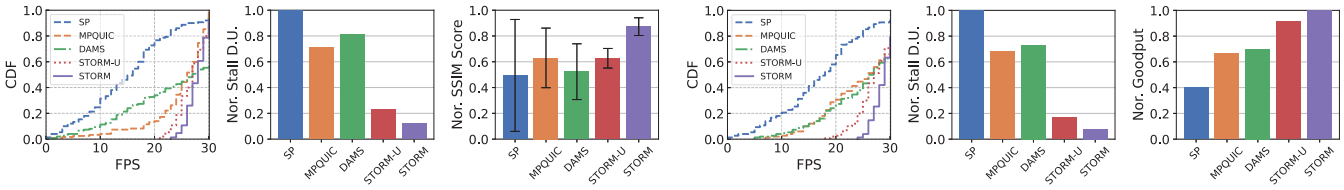
We further explore STORM's effect on user QoE in the real-world mobile network. Three typical streaming media applications were tested on a Xiaomi 12S Pro phone, communicating with Tencent Cloud servers located in Asia (see Table 1).

Video Conference. We prepared three video streams to transport from the server to the client. The server encodes them into VP9 format frames using ffmpeg and libvpx. One stream is a real-time conference, serving as the mainstream. The other two streams are workloads. Mainstream keyframes have the highest priority. The non-keyframes of the other streams are set to unreliable data. Resolution is 1280x720, with a bitrate of 30 Mbps and a frame rate of 30 fps.

Low-latency Live Streaming. We simulate a live pull stream. We encoded a 1080p video at 30Mbps using ffmpeg. I and P frames are high and medium-priority blocks, respectively. And B frames are an unreliable stream. The video plays continuously for two minutes at 30 fps.

360° Video. We developed a 360° video application. The video is delivered as tiles, with tiles near the center of the user's viewport given higher priority. Unreliable masking streams prevent tile skipping. Due to the complexity of implementing 360° video on an Android phone, the client was implemented on a laptop with two wireless cards.

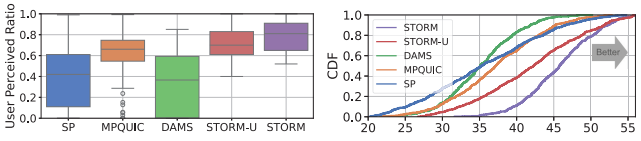
5.5.1 Benefit on QoE



Our evaluation includes different QoE metrics. The following metrics were used:

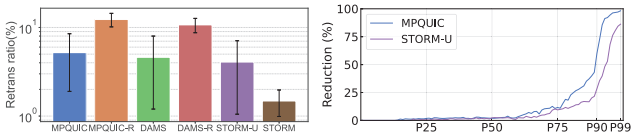
- **Video Conference:** Frame rate distribution, normalized stall duration, and normalized SSIM score.
- **Low-latency Live Streaming:** Frame rate distribution, normalized stall duration, and normalized video goodput.
- **360° Video:** Peak Signal-to-Noise Ratio (PSNR) and User Perceived Ratio (the ratio of actual bitrate received by the user to the video bitrate).

To explore the real-world performance impact of SWM, we implemented a variant of STORM, STORM-U, using RAS without SWM feedback. Single path (SP) performance is also considered.



We conducted field tests at five real-world locations, such as the parking lot and the library. These locations are covered by WiFi and cellular networks, with the phone connected to both. To examine mobility's effect on multipath transmission performance, we divided the tests into two scenarios.

In Changing Signal Strength. In this case the user runs three applications while walking within a given area and



(a) Video conference's QoE (b) Low-latency live streaming's QoE

Figure 16: The video conference and low-latency live streaming's QoE.

(a) User perceived ratio (b) PSNR (dB) distribution

Figure 17: The 360° video's QoE

(a) Retransmission ratio (b) Packet delay reduction

Figure 18: Transport improvement.

experiences sudden link outages both indoors and outdoors. We measured how these rapid signal fluctuations affect each solution.

Fig. 16 shows DAMS's performance declines significantly with signal fluctuations, more so than MPQUIC. In contrast, STORM maintains good performance. A frame rate of 24 fps is generally considered the minimum for motion to appear natural to the human eye. Lower rates produce perceptibly unsmooth motion. For video conference, STORM's unsmooth FPS (below 24 fps) ratio improved by 95.1% compared to MPQUIC and 96.8% compared to DAMS. STORM also excels in stall duration, outperforming MPQUIC by 83.0% and DAMS by 85.2%. SP struggled with tests due to link outages, causing performance fluctuations. Lower FPS and longer stalls lead to more video stutters, while STORM effectively reduces both during signal fluctuations, enhancing user experience.

STORM quickly deactivates the path during link outages, minimizing loss and latency. STORM-U, however, cannot sense sudden changes. Delayed data leads to decoding failures, which in turn produce video artifacts and degrade video quality. For 360° video, STORM's median user-perceived ratio and PSNR are 0.81dB and 46.1dB (see Fig. 17), improving by 11.1% and 7.7% over STORM-U, resulting in the best video quality.

In Stable Signal Strength. In this case, the user runs three applications while staying in a position with a good signal. We begin by showing the QoE in the video conference. Table 4 shows that STORM performed the best. With sufficient bandwidth and low latency in stationary conditions, the performance differences among individual solutions are minimal. Similar results are observed in low-latency live streaming and 360° video.

5.5.2 Transport Improvement

We finally explored how STORM can improve transport performance in real-world applications. MPQUIC-R and DAMS-R are included for comparison.

APP	Metrics	MPQUIC	DAMS	STORM-U	STORM
1	**FPS**	29.2	29.4	29.4	29.6
	Stall Dur.	1	0.97	0.96	0.96
	SSIM	0.99	0.99	0.99	0.99
2	**FPS**	29.1	29.2	29.3	29.5
	Stall Dur.	1	0.97	0.97	0.96
	Goodput	0.84	0.90	0.93	1
3	**UPR**	0.92	0.95	0.94	0.98
	Median PSNR	47.2dB	47.4dB	47.8dB	47.9dB

Table 4: The QoE of (1) video conference, (2) low latency live streaming, and (3) 360° video applications under a stable signal strength.

Fig. 18(a) shows that STORM achieves the lowest retransmission ratio. MPQUIC-R and DAMS-R suffer severe retransmissions during sudden link outages. In contrast, DAMS and MPQUIC perform better in retransmission ratio by delivering non-critical data over unreliable transmissions. Despite its efficient scheduling, STORM-U still encounters an average retransmission ratio of 4.1% due to its inability to sense the wireless link. By quickly deactivating the broken path, STORM reduces the average retransmission ratio to 1.5%. Fig. 18(b) shows the packet delay reduction of STORM compared to other solutions at different percentiles. We selected the optimal MPQUIC and STORM-U solutions for comparison. The results show a 98.2% decrease in packet delay at the 99th percentile with MPQUIC, demonstrating its strong advantage in improving tail packet delay. Although STORM-U outperforms MPQUIC in other aspects, its delayed response to signal changes still results in high tail delays.

6 Related Works

Multipath Transport for Streaming Media. The growing demand for high-throughput and low-latency video streaming has led to much work on multipath transport. MPTCP [31] introduced the concept of establishing subflows across multiple TCP connections to use interfaces such as Wi-Fi and

cellular, but its strict reliability can degrade real-time streaming [29]. Even works designed to mitigate HOL blocking [8, 35, 38, 43] often remain suboptimal when mobility causes rapid link fluctuations. By contrast, QUIC, operating over UDP, is better suited for real-time data since it supports both reliable and unreliable modes [28]. Based on this, MPQUIC [21,22,26,49,51] aggregates throughput across multiple paths but, as our experiments show, still suffers high latency when one path's signal drop suddenly. STORM overcomes this issue by making use of the characteristics of QUIC protocol and streaming media data.

MPQUIC Scheduling. A key element of MPQUIC is the scheduler, which allocates packets across subflows. Existing mechanisms, such as minRTT [21], or QoE-based feedback [22, 49], rely on historical metrics that fail to react quickly to sudden signal drops. Although these approaches boost throughput, they often overlook stringent latency requirements demanded by real-time streaming (e.g., VR or cloud gaming). Consequently, severe tail latencies persist under unstable networks. STORM addresses this gap by offering fast signal-awareness and scheduling decisions that reduce latency without sacrificing throughput.

7 Conclusion

This paper proposed STORM, an MPQUIC scheduler for quick streaming media transport under mobile networks. Based on the signal-watermark mechanism and reliability-aware scheduling strategy, STORM ensure low latency of streaming media applications when the multipath suffers "network storm". We have implemented STORM on real-life devices. Our evaluation shows that STORM reduces tail packet delay by 98.2% and improves the frame rate of streaming media by 1.95x under unstable networks when enabling STORM, compared to the state-of-the-art.

A Appendix

A.1 Deadline Setting Based on Application Real-Time Requirements

The microbenchmark experiments in Section 5.2 use a 300 ms end-to-end deadline. This value does not restrict STORM to traffic that must meet precisely 300ms. It simply reflects the minimum latency budget frequently cited for interactive video conferencing [20], as already noted in the footnote of Section 2.3.2. In practice, every unit of data that an application hands to STORM carries its own deadline in the metadata. The API function *STORM_send* exported by STORM therefore includes an explicit field, `deadline_us`, whose value is filled in by the application on a per-message basis and expressed in microseconds. Because the STORM reads this field directly, developers can tighten or relax the requirement for each video frame, audio chunk, or control message at run time without recompiling or reconfiguring the STORM.

Section 5.5 demonstrates this flexibility by evaluating three representative applications, each configured with a deadline that matches its real-time requirements. The video-conference prototype operates under a strict 150ms budget. The low-latency live-streaming scenario employs a 500ms budget, reflecting industry practice for end-to-end latency. The immersive 360° video workload targets an 80ms motion-to-photon limit. Whether a batch of packets meets the deadline in practice depends on the bandwidth and one-way delay of the active paths. STORM optimizes scheduling based on the current path conditions and operates within each path's inherent upper limits.

STORM is therefore deadline-agnostic. The 300ms setting in the microbenchmark experiments serves only as a conservative experimental baseline. When an application supplies a tighter or looser deadline, the same scheduling strategy remains valid and optimises scheduling under the newly specified deadline.

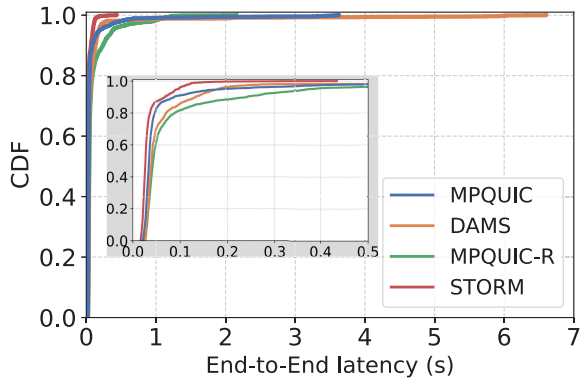

Figure 19: End-to-End latency distribution

A.2 Absolute End-to-End Latency Distribution

Section 5.5.2 evaluates the packet delay reduction achieved by STORM at selected percentile points. To obtain a more detailed view, we also collected absolute end-to-end latency samples under the same testbed configuration and plotted their cumulative distribution functions (CDFs). For clarity the figure retains only four representative solutions: STORM, MPQUIC, MPQUIC-R, and DAMS. Curves for the remaining solutions overlap and are therefore omitted.

Figure 19 indicates that 90% of STORM's latency measurements fall below 68.2ms and 99% remain under 129.8ms. MPQUIC, the best of the other solutions, records 90% of latencies under 89.8ms and 99% under 758.6ms. Hence, STORM significantly reduces both median and tail end-to-end latency and yields a much tighter distribution, which benefits real-time media streams.

Figure 19 also reveals a contrasting outcome for MPQUIC-R. Among the four evaluated solutions, MPQUIC-R exhibits the highest median end-to-end latency, clearly highlighting the latency cost introduced by its fully reliable delivery strategy. However, its tail end-to-end latency stops at 2.15s, well below the 3.62s of MPQUIC and the 6.60s of DAMS. This observation confirms that mutual blockage between data with different reliability requirements imposes a severe performance penalty, a problem that STORM mitigates through its RAS component.

Internet Connection Splitting: What's Old is New Again

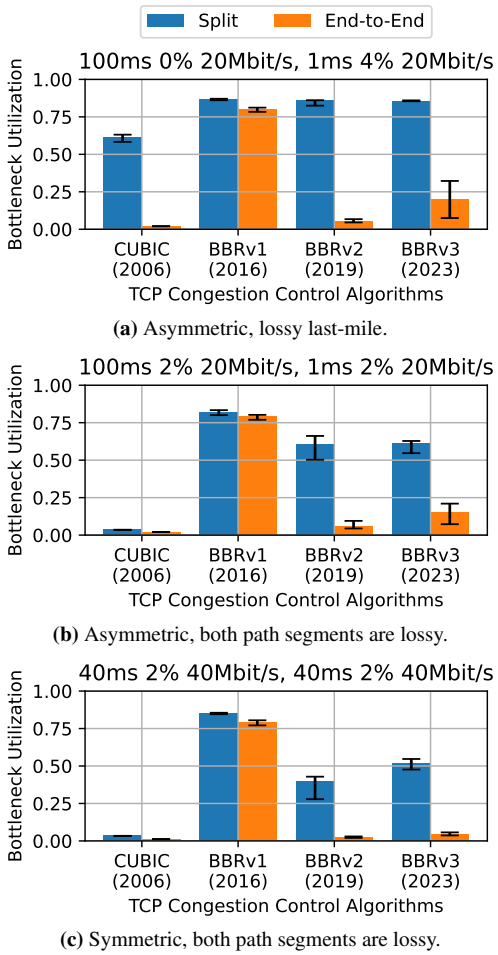
Abstract



In the 1990s, many networks deployed performance-enhancing proxies (PEPs) that transparently split TCP connections to aid performance, especially over lossy, long-delay paths. Two recent developments have cast doubts on their relevance: the BBR congestion-control algorithm, which de-emphasizes loss as a congestion signal, and the QUIC transport protocol, which prevents transparent connection-splitting yet empirically matches or exceeds TCP's performance in wide deployment, using the same congestion control.

In light of this, are PEPs obsolete? This paper presents a range of emulation measurements indicating: "probably not." While BBR's original 2016 version didn't benefit markedly from connection-splitting, more recent versions of BBR *do* and, in some cases, even *more* so than earlier "loss-based" congestion-control algorithms. We also find that QUIC implementations of the "same" congestion-control algorithms vary dramatically and further differ from those of Linux TCP—frustrating head-to-head comparisons. Notwithstanding their controversial nature, our results suggest that PEPs remain relevant to Internet performance for the foreseeable future.

1 Introduction

A stylized history of connection-splitting over the Internet could go roughly as follows: In the 1970s, TCP was designed as a host-to-host transport for flow-controlled reliable byte streams. In the late 1980s, TCP implementations added congestion control [24] to respond to network-path limitations and contention, with indications of packet loss as the primary congestion signals. As Internet use exploded in the 1990s, it became apparent that contemporary TCP implementations performed poorly over long paths with packet loss. By the late 1990s, many network operators deployed commercial "TCP accelerators," also known as "performance-enhancing proxies" [17, 21], to improve customers' TCP throughput. These proxies transparently split a TCP connection in two, providing an intermediate point of acknowledgment and retransmission and transforming an end-to-end TCP connection into two independent connections.

PEPs were marketed as improving users' throughput, especially where a PEP splits a high-delay, lossy path into two segments, each with less delay or less loss. Past surveys found connection-splitting PEPs deployed on large numbers of wireless and satellite networks [17, 21]. But for almost as long as these PEPs have existed, purists have criticized their alleged benefits as exaggerated or unfair, sensitive to the details of an endpoint's congestion-control scheme, contrary to end-to-end arguments [42], and likely to lead to ossification [13, 38].

(a) Asymmetric, lossy last-mile.

(b) Asymmetric, both path segments are lossy.

(c) Symmetric, both path segments are lossy.

Figure 1: Three classes of network settings in which the throughput of a long-lived data transfer using BBRv3 benefits significantly from connection-splitting. While the throughput of TCP using BBRv1 may not have benefitted from a PEP, as the BBR algorithm has evolved over time, it has also made splitting pertinent again. In two of these classes, split BBRv3 even achieves high bottleneck link rate utilization where split CUBIC does not. IQR of $n = 20$.

Two more-recent developments have put PEPs on the back foot. The QUIC transport protocol, standardized in 2021 [23], is encrypted end-to-end and, unlike TCP, its connections can't be split by a transparent proxy—but its wide deployment

by major traffic sources (particularly Google) in the 2010s didn't produce a measured reduction in performance, compared with TCP connections that do benefit from PEPs in the field [31]. If PEPs had really been aiding TCP connections all this time, QUIC could have been expected to experience lower sustained throughput over such paths (compared with TCP connections between the same endpoints, using the same congestion-control schemes).

Furthermore, the BBR congestion-control scheme [8], first released in 2016, now controls a large percentage of Internet traffic (both TCP and QUIC) [51] and puts less emphasis on packet loss as a congestion signal than older schemes in wide deployment, such as CUBIC. Because much of PEPs' benefit comes from splitting up long, lossy paths for the benefit of "loss-based" schemes, it has been suggested that BBR has led to a sharp decline in the use of PEPs [25].

Do BBR and QUIC make connection-splitting obsolete? In this paper, we present findings that suggest that neither of these developments should be regarded as reliable; Connection-splitting may yet play a performance-enhancing role on the Internet, despite its controversial nature.

We conduct a measurement study in emulation to investigate what kinds of congestion control schemes, network scenarios, and transport protocols may still experience increased sustained throughput from connection-splitting. We aid our analysis with a *split throughput heuristic* for predicting the throughput of a split connection, based on the measured end-to-end throughput of each segment on the split path. We aim to (1) explore a wide parameter space of network settings and congestion control schemes and (2) reason about encrypted transport protocols (QUIC) that we cannot directly measure.

We present three major findings:

Finding 1: Splitting has become significantly more beneficial to TCP BBR since it was initially released in 2016. We confirm that BBR's initial "v1" release does not benefit markedly from splitting, unlike earlier congestion-control schemes. But as the BBR algorithm has evolved into BBRv2 in 2019 and now BBRv3 in 2023, it has also evolved to behave more conventionally in the sense that it benefits from being split—just like more traditional, loss-based congestion control schemes such as CUBIC (Fig. 1).

The regression in split throughput follows directly from the regression in end-to-end throughput, via the heuristic. While BBRv1 nearly always achieves full utilization, BBRv3 sees lower utilization in lossy settings, leaving more to gain from splitting. The end-to-end regression is because BBRv3 has increased its loss sensitivity to coexist fairly with "loss-based" schemes such as Reno and CUBIC [6, 50, 54]. Thus, we find that BBR and its split behavior continue to evolve, and that the model-based BBR algorithm has *not* made the performance enhancements of connection-splitting obsolete.

Finding 2: There exist classes of network paths where TCP BBR would significantly benefit from splitting but TCP CUBIC would not. Splitting not only benefits BBRv3 in all the same scenarios as CUBIC (in terms of long-lived throughput), it also benefits BBRv3 in *new* scenarios. In particular, there exist classes of network settings where the CCA achieves a very low bottleneck link rate utilization *without* a PEP, but a high bottleneck link rate utilization *with* a PEP.

More specifically, in addition to edge deployments with a lossy last-mile (Fig. 1a), BBRv3 can also benefit from splitting in scenarios where there is loss on both path segments (Fig. 1b), and when the connection-splitter is located farther from the edge (Fig. 1c). This suggests that in these network classes, simple split BBRv3 can replace the proprietary protocols that have traditionally been used to address middle-mile loss, particularly in satellite and wireless ad-hoc networks [2, 17, 39]. We should continue to evaluate the behavior of split CCAs in new types of networks, especially in space.

Finding 3: Implementations of the "same" congestion-control schemes in QUIC vary significantly, and further differ those of Linux TCP—frustrating attempts to directly compare performance between QUIC and TCP. In an initial study of three QUIC implementations, we find that the end-to-end behaviors of the same congestion control schemes vary significantly by implementation. The implementations vary in both baseline performance and sensitivity to loss and delay. By applying the split throughput heuristic, we find that some CUBIC implementations can actually benefit in the same classes of network paths as TCP BBRv3. We also find that BBR is challenging to implement, with various BBRv3 implementations exhibiting non-uniform end-to-end behavior and thus no clear trend in split behavior. We argue that the benefits of in-network assistance should be considered along with not just a CCA, but their specific implementations.

Our initial evaluation suggests that the performance improvements of connection-splitting remain relevant in the context of today's model-based congestion control algorithms, encrypted transport protocols, and satellite and wireless ad-hoc network settings. As congestion-control schemes continue to evolve, we urge researchers to refer to them by algorithm/implementation/version, not just "BBR" or even "QUIC BBRv1". We urge the community to create a performance test suite for an implementation to be able to claim that it conforms to a particular congestion-control standard. Finally, we hope that this work motivates the community to pursue protocol-agnostic PEPs that achieve the performance benefits of in-network assistance without the ossification downsides.

2 Background

In this section, we provide additional context on some concepts that we refer to throughout the text.

Performance-enhancing proxies. The idea of in-network assistance has long brought pain to the hearts of Internet researchers, protocol designers, and network operators. In

particular, the word "middleboxes" is often associated with NATs, firewalls, and other policy enforcers that modify or inspect data in ways that break end-to-end behavior. A substantial percentage of Internet paths are affected by feature or protocol-breaking policies of middleboxes [13].

In contrast, we refer specifically to the type of assistance provided by performance-enhancing "proxies", or PEPs, that transparently split a TCP connection in two [17]. While PEPs still interfere with end-to-end transport mechanisms, their goal is to enhance the user experience by maximizing performance, as opposed to enforce security or routing policies.

Connection-splitting PEPs can enhance performance in several ways. By providing an intermediate point of acknowledgment and retransmission, PEPs reduce the length of the feedback loop for signals of loss and congestion. The PEP also allows each side of the split connection to better optimize congestion control and flow control for network conditions local to the path segment. We can expect PEPs to impact a variety of performance metrics, including startup time, packet jitter, retransmission overheads, and more. In this paper, we focus only on the impact of connection-splitting on the *sustained throughput* of long-lived data transfers.

Congestion control. Congestion control was originally deployed in the 1980s to manage the explosive growth of the Internet [24]. Foundational algorithms such as slow start and fast retransmit eventually became part of the Tahoe congestion control scheme. Variants such as NewReno and CUBIC emerged over time to improve performance with fairness [18]. CUBIC is the default congestion control module for TCP in the Linux kernel, and widely deployed. It is the primary "loss-based" congestion control scheme that we evaluate.

The word "TCP" is sometimes used synonomously with the congestion control algorithms that it implements. In reality, the two are distinct, though deeply intertwined. For example, the QUIC transport protocol implements many of the same algorithms as TCP to manage network traffic, even though it runs over UDP [23]. In this paper, we refer to "TCP" and "QUIC" as the transport protocols, "Linux TCP" as the implementation of TCP in the Linux kernel, and congestion control schemes as the particular manifestations of a congestion control algorithm in a transport protocol implementation.

BBR. Today, the focus on congestion control has shifted towards BBR. BBR is sometimes referred to as a "model-based" congestion control scheme because it relies on a fundamentally different approach of modeling network bandwidth and round-trip time. It does not use packet loss as the primary signal for congestion. Google initially presented BBR in 2016 as addressing the problems of CUBIC in high-speed networks [7].

Over time, BBR encountered controversy for its unfairness towards loss-based schemes [4, 40, 50]. In response, "v1" of BBR has now evolved into BBRv2 in 2019 and BBRv3 in 2023, driven by efforts at Google. Today, Google recommends that BBRv1 and BBRv2 be deprecated in favor of BBRv3 [6].

BBR is also widely deployed [15, 51]. Google has contributed BBR implementations to the Linux kernel, and Amazon, Akamai, Meta, and Cloudflare CDNs all use BBRv1 for TCP. At Google, BBRv3 is used in all google.com and YouTube public Internet traffic with TCP, and is currently being A/B tested against BBRv1 in Google QUIC traffic [6]. It is estimated that 40% of traffic used BBR in 2019 [37].

Since 2017, there have been ongoing efforts to standardize BBR in the IETF [9]. However, progress has been slow. The Internet draft goes years or months at a time without an update at the mercy of Google contributors. While companies have been quick to adopt BBR in Linux TCP, adoption in QUIC has been slower. Anecdotally, some have resorted to reverse engineering the Linux implementation, and some such as Cloudflare, Meta, and Cisco are actively experimenting with variants of BBRv2+ in their QUIC stacks [15].

QUIC. The QUIC transport protocol was originally developed by Google in 2012 to improve performance for HTTPS traffic and to enable the rapid evolution of transport mechanisms. QUIC is implemented over UDP, and moves congestion control development from kernel space to user space.

As of 2021, QUIC is now a standards-track RFC [23] with widespread deployment and interoperability testing [46]. It is estimated that 8.4% of global websites support QUIC [49], many of them major traffic sources such as Cloudflare. Still, many high-speed flows remain on TCP due to better TCP hardware capabilities and "per-origin" caching, which complicates multi-CDN deployments that mix protocols.

Evaluations of QUIC at the Internet scale generally show improved performance compared to TCP, except in satellite networks. Features like zero-RTT connection establishment and stream multiplexing enable measured improvements in search latency, rebuffer rate, and other video playback metrics at Google [31]. Satellite network operators, on the other hand, experience strife when it comes to QUIC. Several studies have measured the negative impact of encryption on performance in split satellite environments [2, 26, 30, 32].

3 The Split Throughput Heuristic

When initially considering which network scenarios to evaluate in our emulation study, we discovered it to be non-trivial to pick scenarios that would lead to a general understanding of the throughput of a congestion control scheme in a split setting. It is challenging to select which network settings and combinations of path segments to evaluate, as the parameter space for combinations of path segments can be quite large. Also, not all CCA implementations can be trivially split.

For this paper, we refer to *throughput* as the throughput of a long-lived data transfer in an emulated network, using a single flow. We do not evaluate other metrics such as startup time, retransmission overheads, or short-lived data transfers, which have been of interest to PEPs and could also be impacted by connection-splitting. When discussing throughput, we refer

to *end-to-end throughput* as the throughput of an end-to-end connection, and *split throughput* as the throughput of the same connection when there is a connection-splitting PEP.

We realized that while split throughput is not necessarily well understood for any combination of CCA, transport protocol, and network setting, the end-to-end throughput often *is*. We make the following insight based on an ideal setting:

> **Split Throughput Heuristic:** We can estimate the long-lived "split throughput" of a connection by measuring the long-lived "end-to-end throughput" on each segment of the split path and taking the minimum.

Figure 2: A heuristic for evaluating split behavior from end-to-end behavior in an emulated network.

Thus if we know the throughput of the much smaller parameter space of end-to-end connections, we can easily derive:

1. The split throughput of a CCA on a network path composed of two path segments,
2. The end-to-end throughput on the network path,
3. The expected throughput benefit of using a connection-splitting PEP on the network path.

Furthermore, it is impossible to quantitatively evaluate the split throughput of encrypted transport protocols without creating a custom and explicit connection-splitting PEP. As a result, it is challenging to establish a baseline for the throughput that is potentially achievable by QUIC with in-network assistance, leaving many studies to compare QUIC only to split TCP [2, 48, 52]. The split throughput heuristic allows us to estimate the throughput of encrypted transport protocols using knowledge about its end-to-end throughput, without actually splitting the connection.

In §6, we discuss potential sources of error in the heuristic, including the lack of consideration of the queue configuration on the proxy or the placement of the bottleneck link relative to the data sender. However, we believe there is a design tradeoff in accuracy versus simplicity.

In the rest of this section, we first describe how to use this heuristic to analyze the split throughput benefit in a single network setting, without having to run an emulation with a connection splitter. Then we describe how we cache emulation results for an end-to-end parameter space to enable a more open-ended analysis of CCAs over a variety of networks. Finally, we discuss the limitations of our methodology using the heuristic, and propose possible extensions.

3.1 Analyzing Split Throughput Benefit in a Single Network Setting

Given a network model of the two path segments that compose an end-to-end network path, we would like to be able to estimate the expected throughput benefit of using a connection-splitting PEP between the two segments. In our emulation study, our simplified network model consists of three parameters: delay, bandwidth, and loss.

```
class NetworkModel:
    def __init__(self, delay, bw, loss):
        self.delay = delay
        self.bw = bw
        self.loss = loss

def compose(s1: NetworkModel,
            s2: NetworkModel) -> NetworkModel:
    delay = s1.delay + s2.delay
    bw = min(s1.bw, s2.bw)
    loss = s1.loss * (1-s1.loss)*s2.loss
    return NetworkModel(delay, bw, loss)

def throughput(s: NetworkModel) -> float:
    return run_emulation(s)
```

Listing 1: An interface for modeling a network path and estimating throughput. The `compose()` function models an end-to-end network path from two path segments. The `throughput()` function obtains a throughput measurement for a path segment.

```
def pred_split_throughput(s1: NetworkModel,
                          s2: NetworkModel) -> float:
    return min(throughput(s1), throughput(s2))

def pred_e2e_throughput(s1: NetworkModel,
                        s2: NetworkModel) -> float:
    s = compose(s1, s2)
    return throughput(s)
```

Listing 2: Functions that apply our simplified network model and the split throughput heuristic (Fig. 2) to predict split and end-to-end throughput, using the interface in Listing 1.

We explicitly define the interface we use to query split and end-to-end throughput in Listings 1 and 2. In addition to the network model, we implement functions to `compose()` a model of an end-to-end network path from two path segments and to query the end-to-end `throughput()` of a segment.

The `compose()` function. Since our network model consists of three parameters, we describe how to compose each of these parameters to model the end-to-end network path. Bandwidth is the minimum of the two bandwidths, which is the bottleneck. (We may also refer to "bandwidth" as "link rate.") Delay is just additive. If we think of loss as independent random loss, then the composition of the two is $loss = loss1 + (1 - loss1) \cdot loss2 = loss1 + loss2 - loss1 \cdot loss2$.

Note that many combinations of path segments can compose to the same end-to-end network path. This makes sense because regardless of where on the network path loss occurs or which path segment has the bottleneck bandwidth, from an end-to-end perspective, the network properties look the same.

Parameter	Values	Unit
Bandwidth	[10, 20, 30, 40, 50]	Mbit/s
Delay	[1, 20, 40, 60, 80, 100]	ms
Loss	[0, 1, 2, 3, 4]	%

Table 1: Network parameter space for the $5 \cdot 6 \cdot 5 = 150$ combinations of network settings that we analyze in §5. These values attempt to realistically reflect network settings in which we'd see a PEP.

The `throughput()` function. This is the throughput of a long-running HTTPS connection in a `mininet` emulation. The emulated network is parameterized by the network model of a single path segment, and the HTTPS implementation uses the congestion control scheme of interest. We describe additional details about the emulation in §4.

Calculating the split improvement. Listing 2 demonstrates how we can estimate the split throughput benefit using the interface in Listing 1. We `pred_split_throughput()` by taking the minimum measured throughput on each network path segment, and `pred_e2e_throughput()` by composing the path segments into an end-to-end network path and using the measured throughput of that network path. The split throughput benefit is just how much the split throughput has improved (if it has) relative to the end-to-end throughput.

3.2 Caching Measurements for Analysis

While we can now predict split throughput for congestion control schemes which are not easily splittable, evaluating split throughput on a variety of network settings still requires running emulations for each query. In order to speed up our analysis, we select a parameter space of delay, bandwidth, and loss within our network model and cache the end-to-end emulation results for this parameter space. We describe our choice of parameter space and other modifications as follows:

Selecting a parameter space. We select a range of values we thought would realistically reflect network settings in which we'd see a PEP (Table 1). We select propagation delays from 1 ms for a Wi-Fi last hop to 100 ms to reflect the longer RTTs of a satellite connection. Bottleneck bandwidths range from 10 to 50 Mbit/s for a single connection, and are within the CPU constraints of emulation. Random loss rates range from 0% for a stable connection to 4% for random loss caused by e.g., wireless interference and extraterrestrial weather.

Modifying the `compose()` function. We make some subtle changes to the compose function to keep composed network models within our parameter space. In some sense, each parameter e.g., delay, can be thought of as an algebraic group where the operator function is defined in `compose()`.

For path segments with small delays (1 ms), we consider the composed path segment to just have the delay of the longer segment, so we can have segments with 1 ms delay. For loss, note that when loss rates are small, $loss1 \cdot loss2$ is negligibly small. In our case, the loss is always below 4%, so we omit the term in the composition and loss becomes additive.

Collecting data efficiently. For some CCAs, we expect a large number of network settings in the parameter space to have extremely low throughput. Thus we set a utilization threshold of 5% of the link rate below which we are not interested in the exact throughput of that network setting.

To more efficiently build the cache, we run a search algorithm on the parameter space to explore faster network settings first. The initial network setting we evaluate has the lowest delay, bandwidth, and loss. We explore adjacent data points if and only if the current data point has not timed out.

3.3 Limitations

Although our methodology is more efficient for evaluating many network settings and enables the exploration of theoretical scenarios, caching measurements in emulation still takes non-negligible time. A much faster method to estimate sustained throughput would be to use a theoretical model, such as the TCP macroscopic model for AIMD schemes [36]. However, this method does not reflect the nuances of implementation, and as Mathis states himself, new models are needed for BBR and modern paradigms [34, 35].

Another limitation is our simplified network model and emulation testbed. One could incorporate more parameters into the network model, such as the fluctuating bandwidths of cellular networks [20], or how BBR incorporates ACK aggregation [5]. Another idea is to generate end-to-end measurements from real testbeds instead of emulation. We believe these challenges are not limited to emulation studies on split performance, and hope to use the much more well-understood space of end-to-end behavior to extrapolate split behavior.

We acknowledge that we only test connections in a single-flow environment. This limits what we can say about inter-flow fairness, but we can still infer some aspects from how congestion-control schemes respond to loss and delay in isolation, a classical concept known as "TCP friendliness" [19]. While split connections reduce retransmissions by buffering on the path, their high throughput may also make them unfair. There may also be different fairness implications when combining split with end-to-end connections. If every connection is split, then we refer to other studies for understanding fairness at scale for each side of the concatenation [40].

We also acknowledge that TCP is not limited to bulk data transfers, and that it would be valuable to study other metrics that could be impacted by connection-splitting, such as startup time, packet jitter, and retransmission overheads.

Finally, our heuristic makes the simplified assumption that we can identify the bottleneck path segment based on the minimum measured throughput. In reality, the ability of a data sender to sustain that throughput depends on its ability to saturate the send buffer. This is particularly true for data senders farther along the network path, as their behavior will depend on the queue configuration and the burstiness of previous

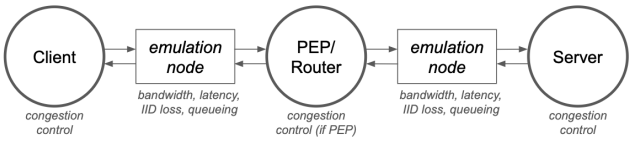


Figure 3: Two-segment network topology in `mininet`. The middle node splits the path into two segments with different properties.

senders. We explore this more in §6.

4 Measurement Methodology

We want to evaluate different congestion control schemes in a variety of network settings. To do this, we run emulation experiments in `mininet` with simple HTTPS clients and servers to measure the throughputs of long-lived data transfers. In this section, we describe our emulated network configurations, HTTPS endpoints and PEP, and other specifications.

Network configuration. We used two linear network topologies: a one-segment topology for caching end-to-end measurements and a two-segment topology for evaluation with a connection-splitting PEP (Fig. 3). Both have a client and server node at each end. The two-segment topology additionally has a router node in between. Each path segment has a bridging node to emulate network properties on the link.

We parameterize each path segment in three dimensions: delay, bandwidth, and a random loss rate. We configure the network properties on the bridging nodes' egress interfaces, using `tc-netem` to set delay and random loss, and `tc-htb` to set bandwidth. Additionally, we use `tc-qdisc` to configure the queues to use RED[1], which is the source of congestive loss. Each link is symmetric in the uplink and downlink directions. For some versions of BBR, we set an `fq` qdisc on the host nodes' egress interfaces for pacing.

[1]We apply RED and not droptail because it gives more continuous feedback about loss for congestion control, and is commonly used in core routers. We also do not need the multi-flow and low-delay properties of other queue disciplines. We use RED in `adaptive harddrop` mode with a maximum queuing delay of ≈ 1 BDP. Exact parameters are available in the code.

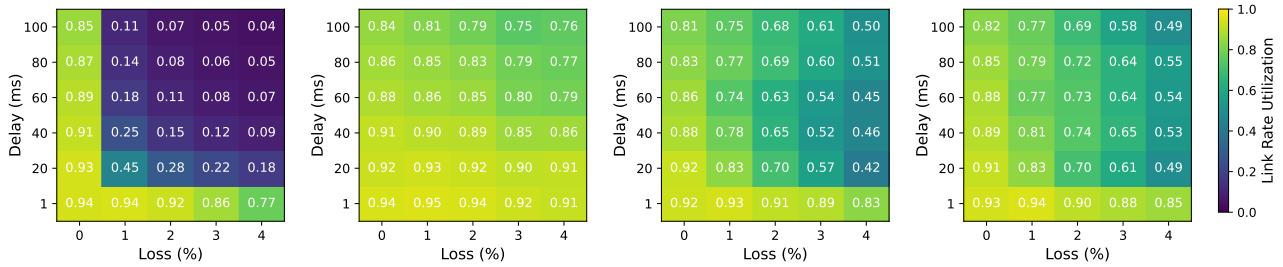
Host configuration. We create simple HTTPS wrappers around each transport protocol implementation to evaluate the congestion control schemes in Table 2. The TCP endpoints use the Python `http` module. For the QUIC implementations, we modify comparable client/server applications from each repository. With the exception of enabling TCP pacing where required by BBR, we use "default values" for tunable parameters, considering these to be part of each implementation.

In TCP, we set the CCA by using a specific Linux kernel version and loading the congestion control module. We use the default kernel's implementations of CUBIC and BBRv1, and Google's kernel fork for BBRv2 and BBRv3 (Table 2).

In QUIC, we simply select the CCA as a command-line argument to the user space implementation. We evaluate Google `quiche` [16], Cloudflare `quiche` [10], and `picoquic` [22]. Google and Cloudflare `quiche` are their production implementations of the same name, and `picoquic` is a minimalist implementation based on the IETF spec. All three include CUBIC and BBRv1 implementations, as well as some form of BBRv2 or BBRv3, which is still undergoing standardization.

For the transparent, connection-splitting TCP PEP, we use PEPsal [3]. PEPsal intercepts the SYN packet during the three-way handshake and forms separate TCP connections with each endpoint, copying data between the two sockets. Note that discussions of split QUIC are based only on the split throughput heuristic and do not use an actual splitter.

Experiment specification. In each experiment, the HTTPS client requests a specific number of bytes to be transferred from the server in the HTTPS payload. This number corresponds to the amount of data that can be transmitted through the bottleneck link over a 10-second period. We have found this to be sufficiently large to reflect sustained throughput.



In practice, we report the "single-stream goodput" calculated as the number of application-layer bytes received (excluding HTTPS headers) divided by request completion time (from when the client sends a request to when it receives a complete response). Due to header overhead and request latency, this metric will never equal the link rate.

Machine specification. All experiments use CloudLab [12] x86_64 rs630 nodes in the Massachusetts cluster running Ubuntu 22.04.2. The nodes use the default Linux kernel v5.15.0-122-generic, except for TCP BBRv2 and BBRv3.

5 Results

In our emulation measurement study, we aim to answer three questions to gain a more comprehensive understanding of the relevance of connection-splitting with modern networks:

1. Has the model-based BBR algorithm made the throughput enhancements of connection-splitting obsolete?
2. Are there classes of network settings where BBR benefits significantly from splitting but CUBIC does not?
3. How does CCA implementation impact end-to-end behavior, and therefore split behavior?

(a) TCP CUBIC. **(b)** TCP BBRv1. **(c)** TCP BBRv2. **(d)** TCP BBRv3.

Figure 4: The link rate utilization calculated as the ratio of achieved goodput to link rate for various TCP CCAs in an emulated network path, at various loss rates and one-way delays, at 10 Mbit/s. CUBIC is the most sensitive to loss and delay, while BBRv1 is the most aggressive and achieves the highest utilizations; BBRv2 and BBRv3 are more sensitive to loss than BBRv1 and utilization starts to suffer (left to right). CCAs tend to achieve lower utilizations, though higher absolute goodputs, as the link rate increases (Appendix A). Median of $n = 20$ trials.

To recap our measurement methodology, we have a method for measuring the throughput of TCP connections in emulation both with and without a transparent PEP. We also have the ability to estimate throughput both with and without a generic connection splitter, for both TCP and QUIC, based on knowledge of the network model of each path segment, and the measured end-to-end throughput on each segment.

For our analysis, we cache measurements for the end-to-end network parameters in Table 1 and the congestion control schemes in Table 2. We also run experiments in the two-segment network topology to validate some of these predictions. Raw data for the end-to-end behavior of each CCA implementation are available in Appendix A. Our emulation benchmarks are also publicly available on GitHub: https://github.com/StanfordSNR/connection-splitting.

5.1 Finding: Splitting has become significantly more beneficial to TCP BBR since it was initially released in 2016.

Has the model-based BBR algorithm made the throughput enhancements of connection-splitting obsolete? We find this line of thought has some truth with the initial release of TCP BBRv1 in 2016. But as the BBR algorithm has evolved into BBRv2 in 2019 and now BBRv3 in 2023, it has also evolved to behave more conventionally in the sense that it benefits from being split—just like more traditional, loss-based congestion control schemes such as CUBIC.

Fig. 1 shows three different network settings in which BBRv2 and BBRv3 show significant throughput gains from connection-splitting. When BBRv1 was released, its throughput both with and without the connection-splitter were roughly the same, and nearly achieved the bottleneck link rate. With BBRv2 and BBRv3, the end-to-end throughput drastically deteriorated, behaving more like CUBIC than BBRv1. However, the split throughput remained relatively high, suggesting that BBRv3 today would still benefit from connection-splitting.

Analysis. To explore why CUBIC and BBRv3 benefit from splitting but BBRv1 does not, we analyze end-to-end throughputs of each CCA and apply the split throughput heuristic (Fig. 2). As described in §3, this methodology allows us to study split settings by measuring the much smaller parameter space of end-to-end connections. We find that connection-splitting is likely to improve throughput on lossy paths for CUBIC, BBRv2, and BBRv3 connections, but not for BBRv1.

Fig. 4 visualizes our cached end-to-end measurements as link rate utilization heatmaps of loss vs. delay. Here is an example for how to interpret these graphs using Fig. 4d. The top-left cell represents a 100 ms 0% segment with 0.82 utilization of the 10 Mbit/s link rate, and the bottom-right cell represents a 1 ms 4% segment with 0.85 utilization of the 10 Mbit/s link rate. The predicted split utilization of a network path composed of these two segments is just 0.82, the minimum. The two cells compose to the top-right cell, which represents a 100 ms 4% 10 Mbit/s segment with an end-to-end utilization of 0.49. Since $0.82 > 0.49$, we say that splitting has improved the throughput of this network path.

BBRv1 achieves high link rate utilization in all settings (Fig. 4b), showing it has little to gain from splitting. In fact, previous studies have shown that BBRv1 achieves ≈85% link utilization regardless of loss (same as our findings) before it reaches a cliff point at around 20% loss [4, 8]. This may be why it appears that splitting in lossy settings is now obsolete with BBR. However, one should note that BBRv1's high throughput has long been attributed to its aggressiveness and unfairness to legacy algorithms [4, 50], which is what led to the changes in BBRv2 and BBRv3.

While BBRv2 is a large departure from BBRv1, BBRv3 has been described as BBRv2 with bugfixes and performance tuning [6], which supports why the two are so similar. We focus on BBRv3 since Google hopes to now deprecate BBRv2 [6].

BBRv3 is more sensitive to loss than its previous versions (Fig. 4d), and more similar to CUBIC (Fig. 4a) in that there exist scenarios where end-to-end throughput suffers. These reflect existing findings of lower utilization in BBRv2 and BBRv3 [11, 47, 54]. Based on the heuristic, it is clear that in some lossy networks such as the ones empirically evaluated

in Fig. 1, connection-splitting can significantly increase the throughput of BBRv3 connections. It is possible that the BBR algorithm continues to evolve in this direction given that BBR's unfairness remains contentious today [11, 54].

Summary. While BBR may not have benefited from splitting with the release of "v1" in 2016, BBRv2 and now BBRv3 have evolved to behave more conventionally—similar to traditional, loss-based CCAs such as CUBIC—in the sense that they *do*. Even so-called "model-based" congestion control algorithms seem to now react to loss as a congestion signal, as the BBR algorithm continues to evolve.

5.2 Finding: There exist classes of network paths where TCP BBRv3 would significantly benefit from splitting but TCP CUBIC would not.

Are there new classes of network settings where BBR benefits significantly from splitting but CUBIC does not? We want to understand the network settings in which a congestion control scheme is not able to achieve practical bottleneck link rate utilizations end-to-end, but is with a connection-splitter.

We find that while splitting benefits BBRv3 in all the same scenarios as CUBIC, it also has the potential to benefit BBRv3 in many *new* scenarios. In addition to edge deployments with a lossy last-mile, BBRv3 also benefits from splitting in scenarios where there is loss on both path segments, and when the connection-splitter is located farther from the edge. We partition these scenarios into three classes of network settings:

I. Paths with asymmetric delay and a lossy last-mile,
II. Lossy paths with asymmetric delay,
III. Lossy paths with more symmetric delay.

Figs. 1a to 1c represent network settings in each class, respectively. "Asymmetric" refers to the delays on the two path segments. These emulations empirically demonstrate that CUBIC only benefits in the first class, while BBRv3 benefits in all three. BBRv1 does not need splitting in any context.

Analysis. To identify which network paths benefit from connection-splitting and where along the paths PEPs should be deployed, we apply the heuristic (Fig. 2). For each CCA, we conduct an exhaustive search of the $15 \cdot 21 \cdot 25 = 7875$ combinations of settings within our parameter space (Table 1), and efficiently predict the split and end-to-end throughputs.

We filter on the predicted throughputs for network settings where splitting improves end-to-end throughput by at least $3\times$, and where the split connection utilizes at least half the bottleneck link rate (Table 3). BBRv1 does not meet these criteria is any scenarios, and the theoretical connection-splitter is unable to improve the throughput of BBRv1 by even 50%. CUBIC and BBRv3 meet these criteria in 942 and 188 scenarios, respectively. CUBIC benefits from splitting in more scenarios because its end-to-end utilization is more frequently low, so it more frequently has a large split improvement.

Filter	BBRv1	CUBIC	BBRv3
Initial	7875	7875	7875
Split imprvmnt. $> 3\times$	0	2231	234
Split utilization > 0.5	0	942	188
Asymmetric, last-mile	0	942	38
Asymmetric, lossy	0	0	72
Symmetric, lossy	0	0	78

Table 3: An exhaustive search of network paths and their PEP locations that benefit from splitting for each CCA, and the number of filtered settings that belong to each class.

Since the distribution of network paths in our parameter space does not reflect any meaningful real world distribution, we are more interested in the *classes* of network settings that benefit from splitting. We realized that *all* of the relevant network settings for CUBIC can be clustered into Class I, as network paths where one path segment has 1 ms delay and non-zero loss, and the other has > 1 ms delay and 0% loss. However, Class I only accounts for 21% of the relevant network settings for BBRv3. We identify Class II, which is the same as I, except both path segments have non-zero loss. Class III is the same as II, except both path segments have > 1 ms delay. We used the results to select three representative network settings to empirically evaluate in Fig. 1.

Intuitively, we can understand why BBRv3 benefits more from splitting in lossy scenarios than CUBIC based on how it reacts to loss and delay (Fig. 4d). BBRv3's sensitivity to loss and delay is more gradual than abrupt, so it is more likely to benefit when splitting a lossy, high-delay network path in any way. In comparison, CUBIC's throughput falls off a cliff for many of these segmentations.

Discussion. Do these results reflect where PEP deployments have been useful in the real world? Connection-splitters have traditionally been found in satellite, cellular, and Wi-Fi networks with a wireless link or rate policer [13, 21]. This resembles Class I, where the network path consists of a lossy last-mile, and a reliable Internet path segment. It makes sense then for PEPs to be traditionally located at the edge to address the issues of loss-based schemes [14, 17, 39]. We expect these PEPs to similarly benefit BBRv3 in the same locations.

In Classes I and II, asymmetric delay can be severe in low-resource networks in addition to wireless last-mile links; Consider, for example, regions with no IXPs in which a significant proportion of Internet traffic travels internationally.

For Classes II and III, satellite (and also wireless ad-hoc) networks are known for having lossy "middle-miles" [2, 30, 39, 41]. This can be due to bad weather, fast-moving satellites, and long-distance radio waves, etc. Since CUBIC does not trivially benefit from splitting in these scenarios, the traditional solution has been to split the connection at multiple points and to use an FEC-based or other proprietary protocol in the satellite backhaul [2, 17, 39]. Our results suggest such

an invasive solution may not be necessary for BBRv3.

How could this inform the deployment of connection-splitting PEPs? With the caveat that futher exploration is required to understand how the heuristic extrapolates to the real world, one idea is to determine where to deploy PEPs along an existing network path for maximum benefit especially as congestion-control schemes evolve. Another idea is given the location of a PEP, determine which connections going through the PEP would most benefit based on knowledge of each connection's network path. We leave network operators to decide how best to model their networks and apply the heuristic to evaluate potential PEP deployments.

Summary. While TCP CUBIC only benefits from connection-splitting when the PEP is located at the lossy last-mile, TCP BBRv3 can also benefit when there is loss on both sides of the PEP and when there are longer propagation delays. This suggests that TCP connections using BBRv3 should benefit from splitters at the same locations as for CUBIC, and also that traditional methods used to address loss in the middle-mile could use simple connection-splitting instead. We believe this method of analyzing useful network paths and PEP placements for connection-splitting can be extended to model new types of networks, especially in space.

5.3 Finding: QUIC implementations of the same congestion control schemes vary significantly, and further differ from Linux's TCP implementations.

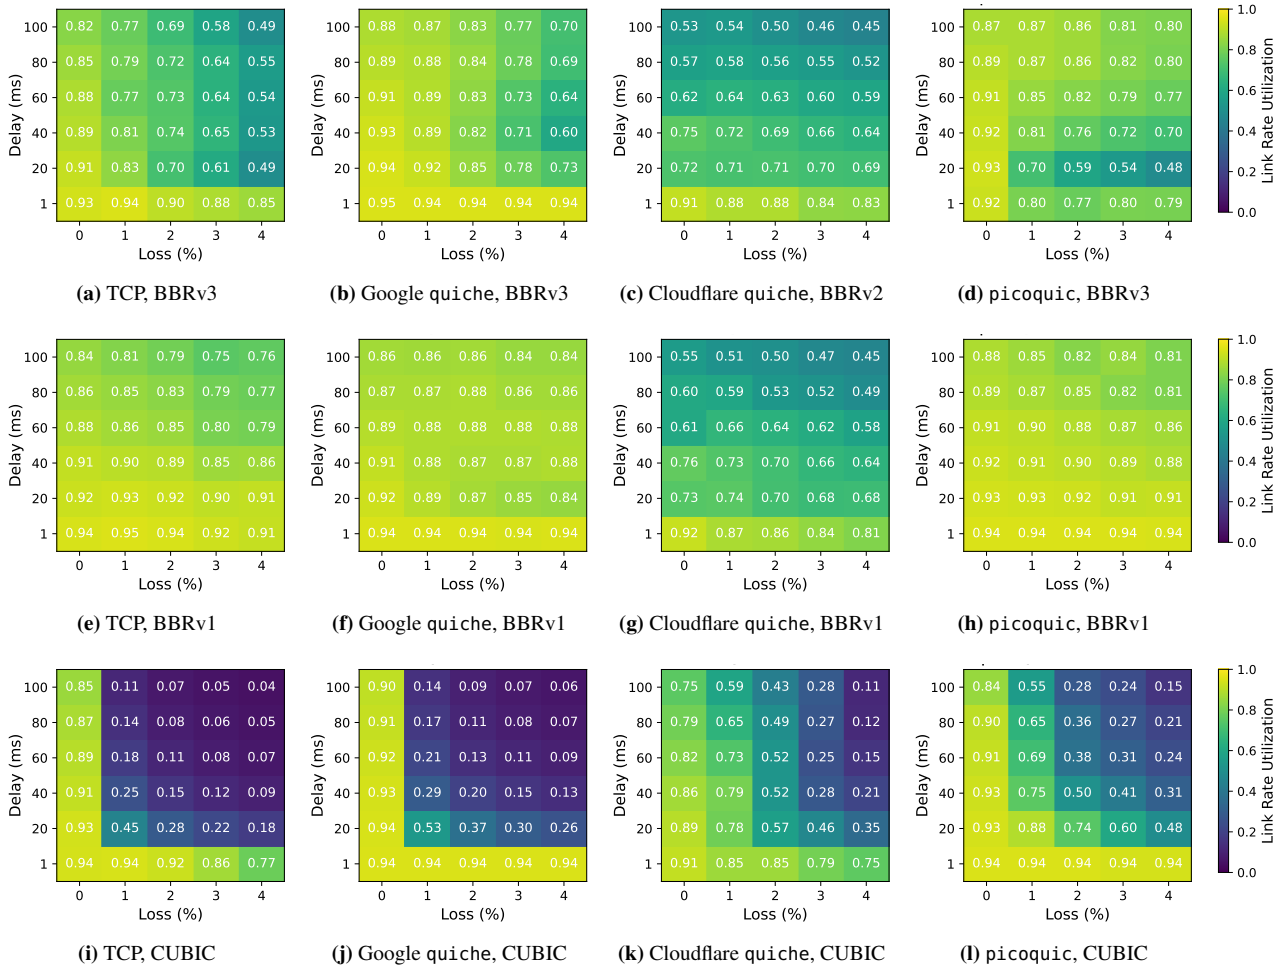
How does CCA implementation impact end-to-end behavior, and therefore split behavior? Might claims about "split throughput" depend not just on the CCA, but also the *implementation* and/or the transport protocol on top of it?

For our initial study, we compared end-to-end throughput for four open-source implementations each of CUBIC, BBRv1, and BBRv2/3; one using TCP and three using QUIC. We find that the end-to-end behavior of each CCA varies by implementation in both baseline throughput and sensitivity to loss and delay. To evaluate the split behavior of QUIC, instead of creating a custom and explicit connection-splitting PEP for each QUIC implementation, we apply the split throughput heuristic and argue that these implementations will likewise respond differently to connection-splitting PEPs.

Fig. 5 visualizes the end-to-end behavior of these schemes. We highlight that the Cloudflare and `picoquic` CUBIC implementations are less sensitive to loss than Google or TCP; the former may benefit from splitting in more classes of network settings than the latter. Additionally, their BBR implementations exhibit non-uniform behavior, suggesting a non-uniform response to connection-splitting. These variations indicate that the benefits of in-network assistance should be considered along with not just the CCA but its specific implementations.

Analysis. The Google QUIC (Figs. 5b, 5f and 5j) and TCP (Figs. 5a, 5e and 5i) implementations are most similar to each other for each CCA. This is reasonable if we take the community-based CUBIC implementation in Linux to be the standard, and considering that Google contributed to the Linux BBR implementations. In general, Google QUIC achieves slightly higher utilization than Linux TCP.

The Cloudflare QUIC BBR implementations (Figs. 5c and 5g) exhibit profoundly different behavior from Linux TCP in baseline performance. Note that Cloudflare uses BBRv1 for TCP but their use of BBR in QUIC is experimental. Anecdotally, a Cloudflare employee has expressed difficulty making their BBR implementation performant, having to reverse engineer the Linux kernel [15]. Given the wide adoption of BBRv1 for TCP at many CDNs [51], we expect it to be desirable yet challenging for these same companies to correctly incorporate BBRv3 into their QUIC stacks in the coming years.



The `picoquic` BBR implementations (Figs. 5d and 5h) are more similar to Linux TCP, although its BBRv3 implementation seems to have a contradicting reaction to delay. We note that `picoquic` is intended for experimental use in the IETF [22]. It is important then to understand its congestion control behavior if it is to be used to evaluate IETF proposals. We believe its differences from Linux TCP warrant further exploration, but perhaps also that the ongoing standardization efforts of BBR in the IETF [9] indicate that there is no monolith yet of "the BBR algorithm."

The Cloudflare QUIC and `picoquic` implementations of CUBIC (Figs. 5k and 5l) interestingly both exhibit a more gradual degradation in response to loss and delay than Linux TCP (Fig. 5i). We find this harder to explain, given that TCP CUBIC has been around since 2006, and perhaps can be attributed to transport protocol mechanisms in QUIC. Nevertheless, this indicates that it is important to understand the behavior of a CCA in the context of its entire implementation.

Fig. 6 applies the heuristic to show how split behavior can vary for CCA implementations with different end-to-end behaviors. Some QUIC CUBIC implementations benefit in new network settings where TCP CUBIC does not, while the various QUIC BBRv3 implementations exhibit non-uniform end-to-end behavior and thus no clear trend in split behavior.

Discussion. Why do we believe we can extrapolate split behavior from the end-to-end behavior of QUIC? Previous studies explore the effects of QUIC's transport protocol mechanisms in such a case [26, 48]. They find that the effects of zero-RTT connection establishment with regards to long-lived throughput to be minimal, and stream multiplexing to be mutually beneficial in both scenarios. Further studies can clarify the interactions between CCAs and transport mechanisms.

How do we know that the difference in behavior is due to the congestion control implementation and not other transport protocol mechanisms? Well, we don't, and there is known to be significant variance in the features supported by different QUIC implementations [33]. However, we find it intuitive that congestion control would be a major factor in the measured sustained goodput of a bulk file transfer.

(a) TCP, BBRv3 **(b)** Google `quiche`, BBRv3 **(c)** Cloudflare `quiche`, BBRv2 **(d)** `picoquic`, BBRv3

(e) TCP, BBRv1 **(f)** Google `quiche`, BBRv1 **(g)** Cloudflare `quiche`, BBRv1 **(h)** `picoquic`, BBRv1

(i) TCP, CUBIC **(j)** Google `quiche`, CUBIC **(k)** Cloudflare `quiche`, CUBIC **(l)** `picoquic`, CUBIC

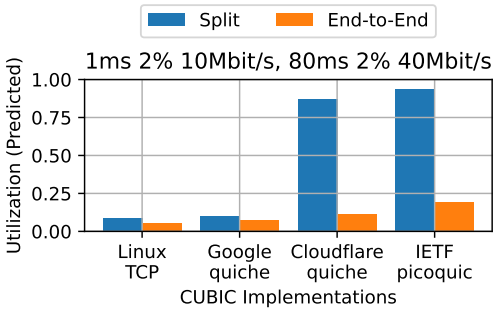


Figure 5: Heatmaps for three QUIC implementations of BBRv3 (or BBRv2), BBRv1, and CUBIC showing link rate utilization calculated as the ratio of achieved goodput to link rate, compared to Linux TCP. The heatmaps are shown at various loss rates and one-way delays with a fixed link rate of 10 Mbit/s. User-space QUIC is not CPU-limited, achieving high utilizations at 1 ms delay and 0% loss. The QUIC implementations are Google `quiche`, Cloudflare `quiche`, and a minimalist implementation based on the IETF spec called `picoquic`. Median of $n = 20$ trials.

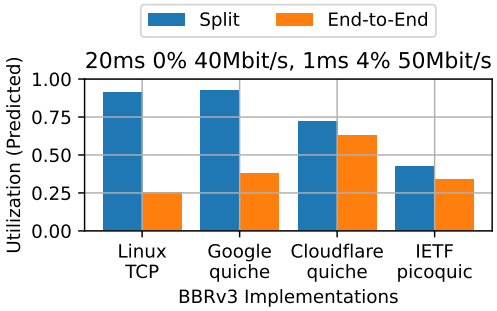
The divergence in QUIC implementations is not so dissimilar from that of TCP at a similar state of evolution [1], but there are still some fundamental differences. With QUIC implementations in userspace, there is a larger diversity of implementations that are easier to tune for a specific application metric, as opposed to correctness or fairness from a congestion-control point of view. These algorithms are also highly parameterized, with no standard nor test suite, so it's not surprising that the implementations differ.



If there is reason to believe that QUIC is losing out on throughput by not connection-splitting, then there will continue to be research on how to achieve the same benefits without ossification [28, 29, 52, 53]. The heuristic helps us understand the theoretical achievable throughput with a simple connection-splitter, or even by combining multiple end-to-end congestion control schemes. In addition to research, this could motivate privacy-minded proposals in the Internet standards community to also view themselves as potential deployment opportunities for private PEPs [27, 43–45].

Another application of analyzing CCA implementations is to analyze the Linux TCP implementations of BBR *within* a major version over time. We did this analysis with BBRv1 on 13 Linux kernels between 2016 and 2024, but found no significant variance. However, given the dynamic nature of BBR and the Linux networking stack, it is possible there will still be changes to the split behavior of TCP in the future.

Summary. We believe it is important to understand the end-to-end behavior of a congestion control scheme in the context of its entire implementation. Our results suggest that BBR is challenging to implement, and that even CUBIC implementations can vary based on context. Whether the prevailing wisdom is that a specific CCA or transport protocol has made in-network assistance undesirable, these results suggest that it is valuable to consistently re-evaluate these claims.

(a) Some QUIC CUBIC implementations can benefit in new network classes where TCP CUBIC could not.

(b) The various BBRv3 implementations have non-uniform end-to-end behavior and no clear resulting split behavior.

Figure 6: Predicted bottleneck link rate utilizations calculated from the predicted end-to-end and split throughputs of the TCP and QUIC implementations, on two different network path segments. End-to-end behavior of each CCA varies significantly by implementation.

6 Accuracy Analysis

Our analysis of connection-splitting for TCP and its extensions to QUIC rely on the accuracy of the split throughput heuristic. In this section, we are primarily concerned with how accurate our predictions, which are based on measurements from a one-segment topology, are for measurements from a two-segment topology in emulation, without and with a connection-splitting TCP PEP:

- Does the `compose` function accurately represent the combined network path in the end-to-end throughput?
- Does the split throughput heuristic accurately predict split throughput?

Most importantly, we find the heuristic to be able to usefully predict *trends*. In terms of absolute predictions, we find the `pred_e2e_throughput()` and `pred_split_throughput()` functions to be correct within a reasonable tolerance, with a slight tendency to overestimate.

Orthogonally, we do not evaluate the accuracy to which emulation studies reflect the real world with multi-flow settings and more complex network properties, nor how the accuracy would extrapolate to QUIC connections with custom connection splitters. It may be interesting to explore how to incorporate such factors into the network model and heuristic.

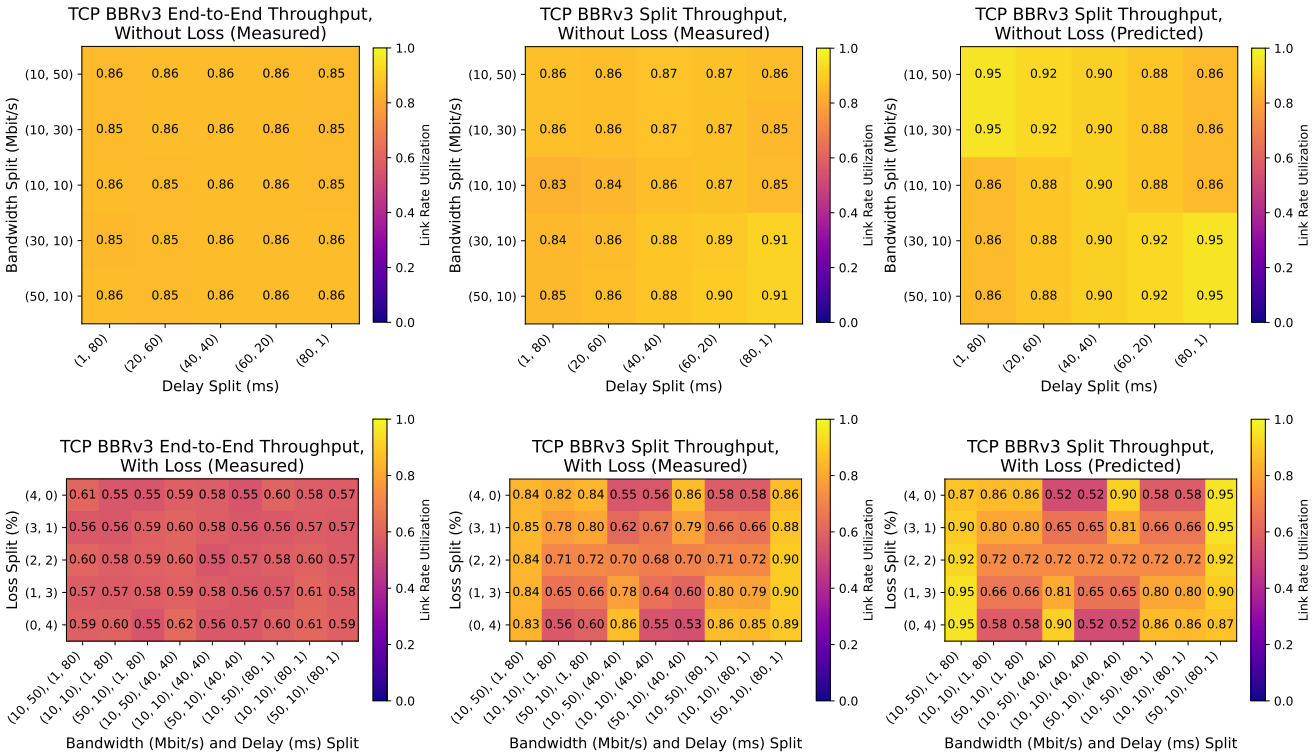
Methodology. Recall that for a given network path composed of two path segments, we can obtain both the predicted end-to-end and split throughputs, and the ground truth throughputs in an emulated network with and without a TCP PEP. Then for a network setting, we can compute the accuracy as the percent error in predicted vs. measured throughput.

We perform an empirical accuracy analysis of BBRv3 for two end-to-end network paths with identical bandwidth and delay, both without (0%) and with (4%) loss. We test various splits for the bandwidth, delay, and loss and analyze the accuracy trends. In particular, we select delay splits such that the end-to-end delay is 80 ms, bandwidth splits such that the bottleneck bandwidth is 10 Mbit/s, and loss splits such that the total loss is either 0% or 4%. We parameterize the network path segments to use the cached measurements from Table 1.

6.1 End-to-End Throughput Accuracy

Each of our splits composes to the same end-to-end network path, so we predict the same end-to-end throughput for each. Our experimental results in Fig. 7a show that the measured end-to-end throughputs are also roughly uniform, especially without loss, indicating that our method of composing network path segments in emulation represents the same end-to-end network path.

6.2 Split Throughput Accuracy



The split throughput predictions accurately reflect trends in loss, delay, and bandwidth (Fig. 7b). For example, split throughput is generally higher when the high-bandwidth link is paired with high delay (the yellow-est cells). It is also lower when the lossy link is paired with high delay (columns 1 and 2) or low bandwidth (columns 3-5).

The split throughput predictions tend to slightly overestimate, but we think the level of error is small enough to be helpful for informing real PEP deployment. The maximum error is $\pm 14\%$, and on average $\pm 4\%$. This dwarfs the measured gains in some situations, and rules out a large gain in others.

One factor that may lead to overestimation of split throughput is the queue behavior and the burstiness of the sender. With small queues and bursty sending, we would expect the far path segment from the data sender to sometimes be limited by the send buffer. This could subsequently affect how the far connection probes for and utilizes available link rate capacity.

Another factor is the proximity of the bottleneck link to the sender. While our heuristic does not account for this, the real split throughputs for symmetric pairs of network paths (e.g., the left three and right three columns in Fig. 7b), show that we slightly overestimate when the low-bandwidth bottleneck link is far from the sender. Based on our reasoning about queues, this would suggest that the far path segment, already the bottleneck, is even further under-saturated.

Overall, we find our end-to-end and split throughput predictions to usefully reflect relative trends and absolute throughput within a reasonable tolerance. They are not intended to

(a) End-to-end throughput accuracy.

(b) Split throughput accuracy.

Figure 7: Heatmaps of the measured and predicted BBRv3 throughputs for various splits of delay, bandwidth, and loss, both without (top) and with (bottom) loss. The *end-to-end throughput* predictions (not pictured) are the same for all cells at 0.86 utilization without loss and 0.58 utilization with loss, because they represent the same network path, so end-to-end prediction errors are roughly uniform. The *split throughput* predictions err slightly on the side of overestimation, but they accurately reflect trends in higher or lower throughputs for measurements on different splits of the same network path. Median of $n = 40$ trials.

make claims about exact achievable throughputs nor about the immediate utility of PEPs in the real world, but simply to reason about how connection-splitting may impact long-lived throughput in a simplified network model.

7 Conclusion

We performed an emulation measurement study on the impact of connection-splitting PEPs on sustained throughput in the context of recent developments such as BBR and QUIC. We found that TCP BBR benefits more from splitting today than when it was first released, and its current version benefits in settings where TCP CUBIC does not. QUIC congestion-control implementations exhibit substantial variability both within QUIC and with Linux TCP.

In the short term, we urge researchers to refer to congestion-control schemes by algorithm/implementation/version, not just "BBR" or even "QUIC BBRv1". We urge the community to create regression and acceptance tests—possibly including our heatmaps with "permissible zones"—for a scheme to call itself an implementation of the XYZv1 algorithm.

For connection-splitting to truly be relevant again, there must be clear scenarios where PEPs offer significant benefits but end-to-end solutions fall short. This paper is a first step, but real-world studies are needed. Next, even though the problem is old, the solution need not be to "just do the same things." We hope this paper motivates the community to pursue protocol-agnostic approaches to in-network assistance and destigmatize the controversial nature of PEPs.

Acknowledgments

Abstract

GPU communication plays a pivotal role in collaborative computation across multiple devices. Despite advancements in inter-device communication fabrics and architectures, synchronization still remains a significant challenge due to the manual coordination required between producers and consumers at the application level. In this work, we first reveal that traditional synchronization is a primary bottleneck in GPU communication, where consumers frequently poll for producer data availability. Specifically, early-started polling leads to the unnecessary occupation of computational resources. To address this issue, we propose Warp-level Interrupt-based Communication (WIC), a novel synchronization framework for GPU communication that introduces a fine-grained interruption mechanism at the warp level to replace repetitive polling. WIC preemptively stalls warps engaged in frequent polling and releases computational resources for other warps, thereby effectively overlapping producer-consumer synchronization with ongoing computations. Comprehensive experiments demonstrate that WIC significantly outperforms conventional polling methods by 1.13× on average across various applications with diverse communication patterns.

1 Introduction

GPU communication plays a pivotal role in collaborative computation between CPUs and GPUs [23], especially as the complexity [22, 25, 47] and the scale of parallel computing tasks [13, 44] outpace the capabilities of single-GPU setups [48]. Despite advancements in communication architectures such as *GPUDirect P2P* [32] and *RDMA* [33], and architectures like *NVLinks* [34], synchronization challenges persist prominently within GPU communication [49]. Specifically, programmers must manually synchronize the timing of producer production and consumer consumption [17], typically involving repetitive polling for the availability of producer data before transfer [20, 35, 41, 43], which introduces considerable overhead and complexity into system operations [1, 36].

Traditionally, GPU cross-device communication research focuses on inter-kernel coordination, strategically scheduling computing kernels (k_0-k_n) to overlap synchronization overheads and boost throughput [12, 21], as shown in Figure 1(a). In-kernel optimizations enable asynchronous data transfers without kernel terminations to fine-tune producer-consumer models. Predominantly, these studies emphasize optimizations on the producer side, including scheduling additional transfer threads [31] or employing page placements [9, 30] to dispatch data asynchronously. For the consumer side, a typical approach is GPS [29], which proactively transfers data to the consumer assuming data availability before consumer demand, as shown in Figure 1(b).

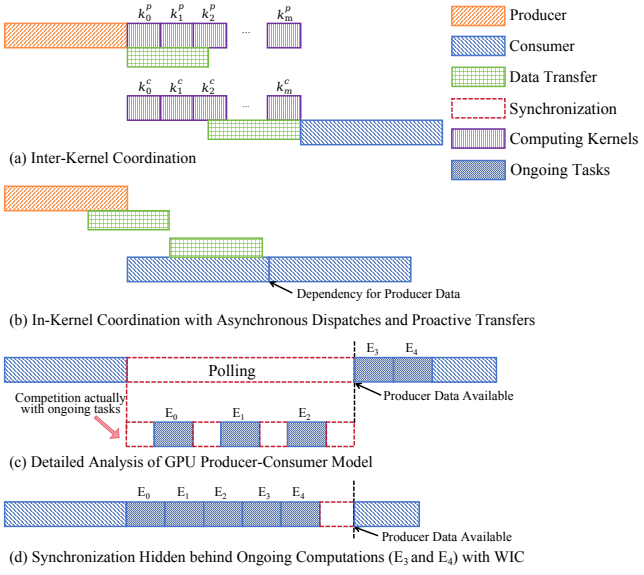

Figure 1: Different Communication Paradigms

However, our experimental results from practical GPU com-

*Corresponding author: Fangyu Wu (fangyu.wu02@xjtlu.edu.cn)

munication applications reveal significant synchronization overhead on the consumer side, primarily due to consumers waiting for the producer's data and repeatedly polling for its availability across devices, as detailed in Section 4. While existing research has contributed valuable insights, it has not fully captured this issue, leading to limited improvements in real-world application performance. To effectively hide the synchronization overhead, this paper proposes a novel GPU communication framework, **W**arp-level **I**nterrupt-based **C**ommunication (WIC), that introduces a fine-grained interruption mechanism at the warp level to replace repetitive polling for producer data availability.

In this work, we first pinpoint the nuances of the GPU producer-consumer model. From a traditional producer-consumer perspective, executable tasks before polling have usually completed, leaving no computational tasks to overlap with synchronization, which makes the effects of polling and interruption seem similar. However, in GPU environments, the situation is markedly different. Consumer kernels are executed across multiple threads with varying completion times. Further exploration at the thread level reveals that early-started polling is a primary cause of synchronization overhead. Specifically, substantial threads remain incomplete when polling begins, causing unnecessary polling to squander computational resources and compete with ongoing tasks (E_0-E_2), as illustrated in Figure 1(c). Furthermore, by the end of polling, many threads remain unfinished, indicating that their unfinished execution (E_3 and E_4) could have overlapped with the synchronization latency.

To mitigate these inefficiencies, WIC preempts warps engaged in frequent polling, thereby releasing their computational resources for other warps. This approach allows unfinished tasks delayed by polling to take precedence, effectively hiding synchronization behind ongoing computations and improving overall GPU communication efficiency, as shown in Figure 1(d). WIC incorporates three key components: the **Interrupter** module, detecting warp requests for producer data and triggers interruptions to swap other executable warps; the **Monitor** module, tracking the availability of the producer data; and the **Activator** module, resuming the stalled warps once the required data becomes available. To manage warp interruptions efficiently, WIC is integrated within the Unified Virtual Memory (UVM) context, employing UVM page placements to transfer communication messages and track data availability. All of these changes are implemented through modifications to the UVM host kernels, allowing programmers to request producer data functioning in a manner akin to a system call, thereby bypassing the need for manual orchestration of synchronization with polling, ensuring full transparency to programmers.

Our contributions can be summarized as follows:

- We present an in-depth analysis of the synchronization overhead within GPU communications, highlighting that early-started polling monopolizes computational resources, the crucial bottleneck in GPU communications.
- We introduce WIC, a novel GPU communication framework that incorporates a finer-grained interruption mechanism at the warp level to replace repetitive polling, aiming to hide the synchronization latency behind the computation.
- We propose a novel classification perspective that shifts from traditional memory access patterns to a focus on communication patterns. Comprehensive experimental results across 10 applications with diverse communication patterns demonstrate significant performance enhancements with WIC, achieving an average speedup of 1.13× compared to conventional methods.

2 Background

2.1 Producer-Consumer Model

The producer-consumer model is a concurrency design pattern that coordinates communication between processes sharing common resources [7]. In this model, the producer generates data and populates a buffer, while the consumer retrieves that data from the buffer, allowing both to operate simultaneously and thus boosting operational efficiency through continuous data flow [18]. However, the model necessitates robust synchronization mechanisms to ensure data integrity, preventing the producer from overwriting unread data and the consumer from retrieving uninitialized data [28]. Effective synchronization is typically achieved using semaphores or monitors [14]. Semaphores include two primary types: counting semaphores, which manage how many slots are occupied or available, and mutexes, which provide mutual exclusion when multiple processes access the buffer. Monitors offer an alternative approach by encapsulating the buffer operations within a single construct that coordinates producer and consumer interactions.

2.2 GPU Cross-Device Communications

Cross-device communications in GPU environments involve multiple GPUs cooperating to share data, a critical process in large-scale applications such as deep learning training, scientific simulations, and graphics rendering [38, 46]. Different from traditional host-side producer-consumer models [5], the simultaneous execution of massive threads in GPU environments necessitates advanced synchronization strategies to manage fine-grained interactions [37]. However, due to the absence of native cross-device semaphores in GPU APIs, programmers must manually coordinate synchronization through CUDA streams, events, or synchronization flags. Typically, producers indicate data readiness via flags, while consumers must actively poll or wait on these signals to maintain data

consistency and avoid race conditions [20, 35, 43]. Our work specifically addresses the polling phase, which incurs substantial overhead on the consumer side.

3 Analysis Methodology

In this section, we introduce a novel classification for communication applications. Based on the classification, we detail the specific applications with various communication patterns selected for analysis and describe the system specifications.

3.1 Communication Patterns

The reliance on traditional memory access patterns for GPU communication analysis [4, 9, 29–31, 42] can be misleading, as these patterns generally provide a macroscopic view of program behavior rather than reflecting the specific dynamics of device interactions. For example, the *Bitonic Sort* algorithm utilizes a random memory access pattern. However, its inter-device communication, essential for the global merging phase, primarily exhibits a gather-scatter pattern, where GPUs fetch pre-sorted data (gather) and then write back the results following comparison and swapping (scatter). Moreover, the communication model is also a critical factor in classifying applications, through its impact on synchronization methods and data flow across communication iterations.

To conduct a more comprehensive analysis of GPU communications, we propose a dual-dimensional classification, *communication patterns*, including communication access patterns and communication models. Communication access patterns are categorized into four types—streaming, adjacent, scatter-gather, and random—each representing different access behaviors during device interactions. Additionally, communication models are defined by the nature of data transfer during communication iterations, as detailed in Table 1.

Table 1: Communication Models

Unidirectional Communication $(D_0 \rightarrow D_1)^N$ This model represents one-way communication between two devices ($D_{0,1}$). D_0 consistently acts as the producer, while D_1 always functions as the consumer. N represents the number of communication iterations.	**Alternating Communication** $(D_0 \rightarrow D_1, \quad D_1 \rightarrow D_0)^N$ Within a single communication iteration, D_0 starts as the producer, sending messages to D_1. After processing these messages, D_1 then acts as the producer, sending the resultant data back to D_0. Both devices alternate roles between producer and consumer throughout a communication iteration.
Multiple Communication $((D_0 \rightarrow D_1)^{n_0}, \quad (D_1 \rightarrow D_0)^{n_1})^N$ This model involves multiple transmissions between devices within a single communication iteration. D_0, acting as the producer, transfers messages to D_1 multiple times (n_0), and after processing, D_1 transfers messages back to D_0 n_1 times.	**Probabilistic Communication** $((D_0 \rightarrow D_1)^{\epsilon_i^0 \cdot n_0}, \quad D_1 \rightarrow D_0)^{\epsilon_i^1 \cdot n_1})^N$ This model characterizes the communication between devices where the mode and frequency of transfers within each communication cycle are probabilistic.

3.2 Applications

To encompass a comprehensive spectrum of UVM scenarios, we select ten applications from FAIR1M [40], Mantevo [26], Comb [6], Polybench [39], Rodinia [8], and Savina [16] benchmark suites as listed in Table 2. This benchmark selection, based on a classification of different patterns, has been demonstrated to avoid *benchmarking crimes* [45] and is widely adopted in GPU communication evaluations [4, 9, 11]. In our study, we further refine this classification to focus more sharply on communication access patterns and incorporate synchronization dynamics into our selection process. The chosen applications fully cover the complete dual-dimensional classification defined in Section 3.1, encompassing four communication access patterns: streaming, adjacent, scatter-gather, and random patterns, as well as four communication models: unidirectional, alternating, multiple, and probabilistic models. Specifically, C_SRS and G_KMN require only unidirectional, streaming patterns, where data is transferred back to a single device. C_CG, C_FE, and G_C2D engage in an Alternating communication model, where two devices exchange information with Random and Streaming access patterns. Multiple transfers during each iteration are necessary for C_H3D, G_BS, G_STN, and G_GEM. For instance, G_STN repeatedly sends boundary data of its subdomain to an adjacent GPU. These applications exhibit Adjacent and Scatter-Gather access patterns. G_BFS, with its unpredictable access manner, fits into a Random and Probabilistic model. Additionally, the inclusion of the communication-intensive application, C_H3D, enriches our evaluation with diverse GPU communication behaviors.

The applications include both CPU-GPU communications (the first four applications listed in Table 2) and inter-GPU communications (the last six applications listed in Table 2).

Table 2: List of Applications

Abbr.	Applications	Benchmark Suite	Comm. Model	Access Pattern
C_SRS	Satellite Remote Sensing Image Processing and Distribution	FAIR1M	streaming	Unidirectional
C_CG	High Performance Computing Conjugate Gradients	Mantevo	Random	Alternating
C_FE	Finite Element Mini-Application	Mantevo	Random	Alternating
C_H3D	Halo 3D Cube	Comb	Adjacent	Multiple
G_BFS	Breadth-first Search	Rodinia	Random	Probabilistic
G_BS	Bitonic Sort	Savina	Scatter-Gather	Multiple
G_C2D	Convolution 2D	Polybench	Adjacent	Alternating
G_STN	Stencil	Polybench	Adjacent	Multiple
G_GEM	General Matrix Multiplication	Polybench	streaming	Multiple
G_KMN	Kmeans	Rodinia	streaming	Unidirectional

3.3 Naive Communication Applications

In GPU cross-device tasks, programmers must manually coordinate fine-grained synchronization to ensure data integrity during producer-consumer communications. To analyze the communication inefficiency, our work adopts a representative GPU producer-consumer paradigm, as detailed in Algorithm 1. Communication resources are divided into subdomains associated with consumer thread block requests, each marked by a *syncFlag*, indicating producer data availability. Both communication data and flags are maintained within UVM, allowing uniform access by producers and consumers.

Algorithm 1 Naive Communications

```
1:  procedure CONSUMERSYNC
2:      Independent Processing (C1);
3:      __syncthreads();
4:      if tid == 0 then
5:          while atomicAdd(&(producer[bid]) -> syncFlag), 0) != 1 do
6:          end while
7:          Access the producer's data through UVM;
8:      end if
9:      __syncthreads();
10: end procedure
11: procedure PRODUCER
12:     Compute producer's data (P1);
13:     __syncthreads();
14:     if tid == 0 then atomicAdd(&(producer[bid]) -> syncFlag), 1);
15:     end if
16:     __syncthreads();
17: end procedure
```

On the consumer side, threads complete preliminary processing ($C1$), synchronizing via *__syncthreads*. Subsequently, the lead thread ($tid = 0$) continuously polls syncFlag in a loop (Line 5). Once the flag indicates data availability, an atomic operation secures the syncFlag from producer-side updates, enabling the lead thread to safely access the corresponding data (Line 7). Remaining threads wait via *__syncthreads* until the lead thread completes this communication step. On the producer side, once data production completes, the corresponding syncFlag is set to 1. This communication model involves three distinct UVM page faults: the consumer polling an unavailable syncFlag, updating syncFlag upon data readiness, and transferring producer data.

3.4 System Specifications

CPU-GPU Communication Setup consists of an NVIDIA RTX 4090 GPU with 24GB of DRAM, coupled with a high-performance CPU, the 14900KF, featuring 24 cores.
Inter-GPU Communication Setup consists of four NVIDIA $A800$ GPUs, each with 80GB of DRAM, coupled with two high-performance CPUs, Xeon 6138, each featuring 20 cores.

4 Motivation

In the motivation section, we first establish that consumer-side overhead significantly impedes efficiency in producer-consumer communications. We then identify that repetitive polling is the predominant source of this overhead. Moreover, a detailed examination of the polling phase at the thread level reveals that polling initiated too early causes considerable resource contention, which further indicates that these resources could have been better utilized by overlapping with synchronization latency, allowing other executable tasks to proceed without delay. Our experimental setup for collecting data is discussed in Section 3.

4.1 Critical Focus on the Consumer Side

Observation 1: The consumer side exhibits significantly higher latencies compared to the producer side. Figure 2 shows the proportion of communication latency for each application on both the consumer and producer sides. For the producer side, latencies are consistently low, generally staying within 10% across various applications, and the differences in latency proportions among these applications are relatively minor. In contrast, the consumer side displays markedly higher latency proportions, typically ranging from 20∼ 50%. This discrepancy is most pronounced in the C_H3D application, where its communication-intensive nature results in a consumer-side latency peaking at 81.97%.

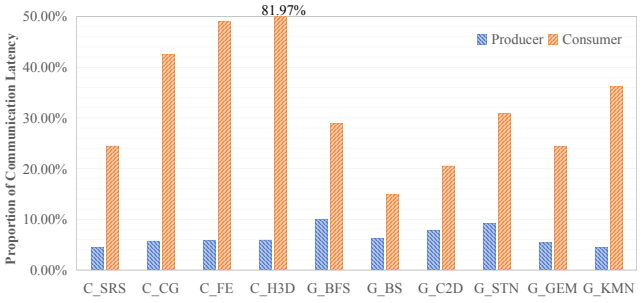

Figure 2: Proportion of Communication Latency on both Consumer and Producer Sides across Different Applications

The higher latency on the consumer side primarily stems from additional synchronization requirements. On the producer side, Direct Memory Access (DMA) enables asynchronous operations that permit data transfers without halting ongoing computational tasks, effectively minimizing communication latency. However, the situation on the consumer side presents more complexities. The consumer kernel verifies the

physical presence of producer data on the local device prior to processing, inherently introducing additional latency.

This asymmetry highlights a pivotal direction for communication optimizations: the consumer side, as the primary contributor to communication latency, demands targeted efforts. While existing research largely focuses on optimizing the producer side [9, 30, 31], addressing the latency issues more prevalent on the consumer side holds significant potential to boost the overall efficiency of GPU communications.

4.2 A Deeper Investigation into the Consumer-Side Latency

The consumer-side communication can be analyzed by categorizing it into two distinct scenarios based on the availability of producer's data. Firstly, we divide the consumer kernel into two parts: C_1 and C_2. The C_1 portion operates independently of the producer's data and is typically used for auxiliary tasks or computations from previous communication iterations. C_2, however, depends on data generated by the producer in the current iteration. The completion time of C_1 is denoted as T_c, and the producer's data generation is denoted as T_p. Two scenarios are distinguished based on the relationship between T_c and T_p, specifically assessing whether the consumer must wait for the producer's data to become available.

Scenario 1: T_p occurs before T_c, as shown in Figure 3(a). In this scenario, the producer's data is pre-available, allowing the consumer to directly copy the data without availability checks. Transfer time (W_t) can be overlapped with the C_1, by predicting the data dependency and proactively transferring the data to the consumer in advance.

Scenario 2: T_c occurs before T_p, as shown in Figure 3(b). In this scenario, the producer's data is not available when the consumer needs it, requiring the consumer to repeatedly check its status (*polling*). The total waiting time includes both the polling (W_p) and data transferring time (W_t).

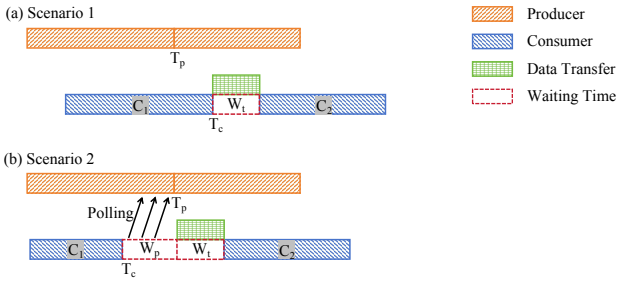

Figure 3: Two Scenarios based on the Availability of Producer's Data

To investigate consumer communication scenarios across real-world applications, we analyze the average time differences between T_p and T_c along with their standard deviations, where positive values indicate T_c occurring before T_p, while negative values indicate the reverse. Given substantial variability in these time differences, we normalize them to the communication task duration to provide a clear impact of these delays, as shown in Figure 4.

Observation 2: In most applications, consumers face substantial waiting times for producer data, with significant variability across and within applications.

Specifically, all applications except G_BS exhibit positive values, indicating that in most cases, the consumer's T_c occurs before the producer's T_p. Moreover, except for the G_BFS application, the time difference for the other applications exceeds 20%, suggesting that consumers typically face considerable waiting time until producers finish generating data. The large standard deviations for C_CG, C_FE, and G_BFS highlight significant variability in waiting times in the same applications. For C_CG and C_FE, the variation is primarily due to the alternating computation tasks between the CPU and GPU. Meanwhile, G_BFS's high variability is due to its unpredictable access manner, leading to more random data availability timings.

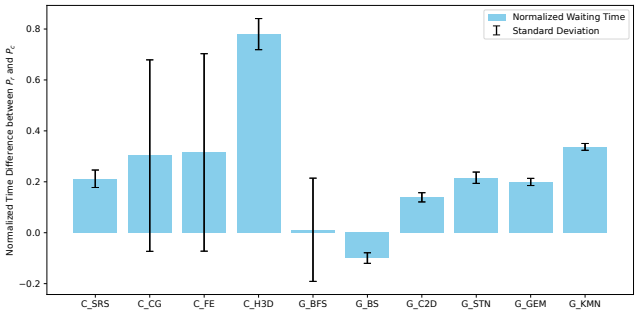

Figure 4: Normalized Time Difference between Production (T_p) and Consumption (T_c)

Based on the observation, we conclude that *Scenario* 2, where the consumer is required to wait for the producer's data, is more common. Furthermore, due to the uncertainty and potential variability of data generation on the producer side, the polling mechanism employed in *Scenario* 2 is crucial for ensuring stable and correct program execution.

Observation 3: Consumer-side polling, where consumers repeatedly check the availability of the producer's data, constitutes a significant portion of the consumer communication overhead in *Scenario* 2. Figure 5 illustrates both the proportion of polling within the overall consumer communication overhead and the average number of checks required per communication. Except for G_BFS, polling accounts for over 60% of the consumer communication overhead, with applications, C_H3D and G_KMN, exceeding 90%. Additionally, the number of checks per communication is extremely high, typically in the range of millions to tens of millions. This

extensive polling overhead arises from necessary inter-device communication.

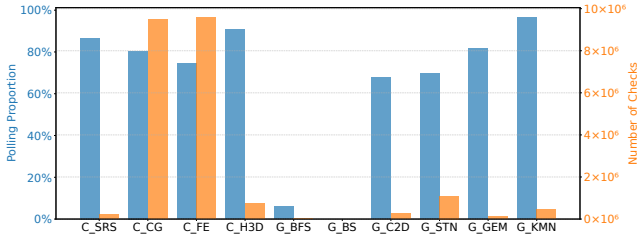

Figure 5: The Polling Proportion within Consumer Communication Overhead and the Average Number of Checks Required per Communication

Summary of Consumer-Side Latency: The high latency on the consumer side is primarily due to consumers waiting for the producer's data and repeatedly checking its availability with cross-device communication.

4.3 A Finer-Grained Analysis on Polling

The producer-consumer model in GPU architectures significantly diverges from traditional CPU-based setups. In CPU systems, a producer or consumer task tends to be assigned to a single process. Therefore, when reaching the T_c in *Scenario* 2, there are no additional tasks within the consumer that can be pipelined to fill the waiting time gap. Consequently, the overhead associated with polling cannot be optimized further. However, in GPU architectures, the consumer kernel is executed by a multitude of parallel threads. The non-uniform completion progress of these threads, orchestrated by the GPU's *warp scheduler*, often means that not all threads reach the T_c simultaneously during the polling phase. Moreover, some *independent threads* may not depend on the producer's data and thus do not need to repeatedly check for its availability.

To deepen our understanding at the thread level, we analyze the proportion of threads that have not reached the T_c and the proportion of independent threads remaining incomplete as polling progresses for four applications, C_SRS, C_CG, G_BFS, and G_STN, with different communication types.

Observation 3.1: Consumer's polling significantly impacts the completion of computational tasks before reaching the T_c. This observation can be inferred from the results shown in Figure 6, supported by three key insights as follows:

- At the onset of polling, substantial threads still completing their C_1 tasks have not reached T_c, causing them to compete for computational resources with polling.
- The curve features several nearly horizontal segments, signifying substantial preemption of computational resources for these threads. This preemption results in stagnation, as polling dominates the limited resource within the device.
- Even after the completion of polling, a large number of threads still have not reached T_c.

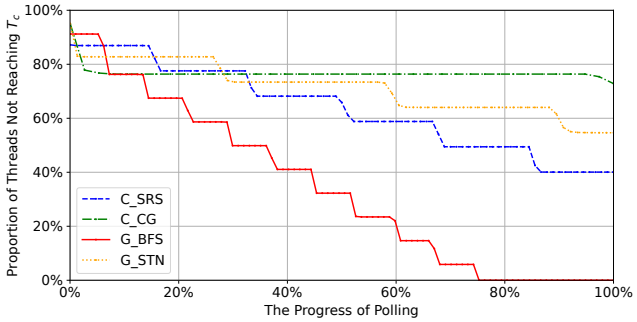

Figure 6: The Proportion of Threads not Reaching T_c as the Polling Progress

Observation 3.2: Consumer's polling significantly disrupts the computational tasks of independent threads. Despite these threads comprising a smaller proportion of the overall program, they suffer prolonged stagnation due to resource preemption by polling activities, particularly in applications like G_BFS and G_STN, as shown in Figure 7. Furthermore, these independent threads still fail to complete their tasks promptly even after polling ends.

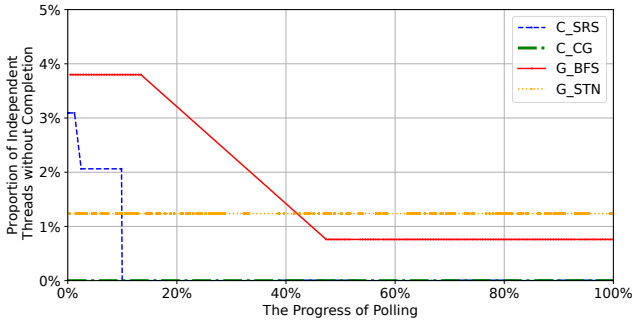

Figure 7: The Proportion of Independent Threads without Completion as the Polling Progress

The analysis of consumer-side polling reveals significant inefficiencies in resource utilization, with early-started polling significantly tying up GPU computational resources and delaying tasks. These include tasks from threads completing C_1 operations and those from threads that operate independently of polling demands, suggesting that synchronization overhead could be effectively overlapped with these ongoing tasks.

5 Design of WIC

5.1 Interrupt-based Mechanism at Warp Level

Based on the analysis in Motivation, it is advised to delay polling to overlap synchronization delays with other executable tasks. However, directly intervening in GPU runtime kernels to reschedule computational resources is impractical for three main reasons:

- Determining an optimal execution sequence is challenging due to the difficulty in accurately predicting thread dependencies at runtime.
- Rescheduling the execution order of parallel threads can disrupt the inherent parallelism of the program.
- GPU APIs typically do not provide direct access for rescheduling resources.

We propose an interrupt-based synchronization framework, WIC, at the warp level to optimize computational resources by prioritizing executable tasks. Specifically, WIC preemptively stalls warps engaged in a blockage due to unavailability of data, switching to another warp that is ready to execute. This mechanism hides the synchronization latency and enhances GPU resource utilization by ensuring that all executable tasks are processed before waiting, minimizing idle times.

WIC incorporates three key components: Interrupter, Monitor, and Activator, as illustrated in Figure 8. The **Interrupter** prevents warps from being blocked by triggering interruptions when they request producer data and switching to other warps. The **Monitor** tracks data availability and notifies the Activator when the data is ready. The **Activator** then facilitates data transfer to the consumer side, and resumes the stalled warps.

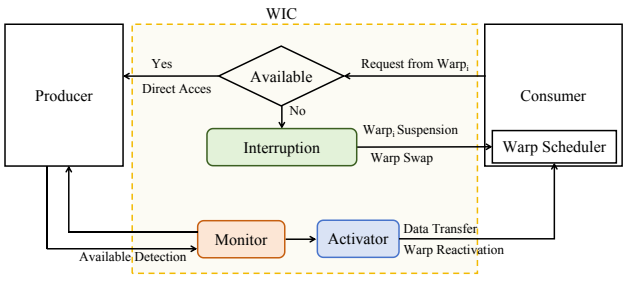

Figure 8: The Overall Workflow of Warp-Level Interrupt-Based Communication (WIC)

5.2 Integration with UVM

To efficiently manage interruptions, we propose integrating WIC within the UVM context, employing UVM page placements to preempt blocked warps by modifying open-source UVM kernel drivers, without the need for additional GPU hardware intervention.

The UVM system uniquely offers explicit control over the *stalling* and *replaying* of warps in UVM kernel drivers: **On the GPU side**, when warps attempt to access UVM pages that are not present on the local device, the UVM system stalls these warps and schedules other warps for processing. **On the host side**, UVM drivers can send replay signals to the GPU to reactivate the stalled warps.

By artificially inducing UVM page faults, WIC can interrupt warps waiting for producer data. By pushing a replay signal to the consumer kernel, WIC can dynamically reactivate these stalled warps upon data available. Additionally, by transferring producer data directly onto the faulting pages, WIC enables efficient producer-consumer communication without requiring extra transfers.

Figure 9 illustrates the integration of the WIC within the UVM system in detail. WIC defines a specific memory space within UVM, which comprises two key components: the Producer-Consumer Communication Medium (PCM) and Producer Availability Tags (PAT).

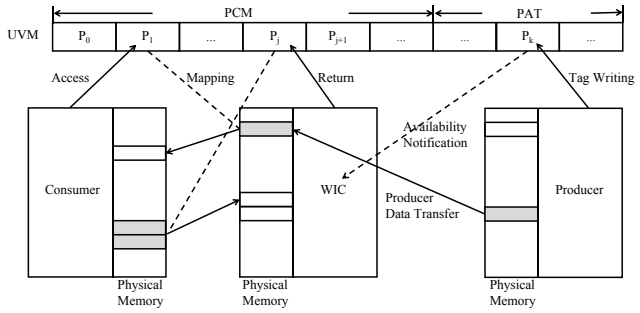

Figure 9: Integration with UVM

PCM is essential for transfer management between producers and consumers and interruption supports for blocked warps. Memory in PCM is allocated on a per-page basis, with free PCM pages residing on the host side to ensure they are available for triggering page faults in consumer-side warps. When warps request producer data, WIC directs them to access PCM pages, triggering a page fault that stalls the warps. These faults are processed on the host side further, where the WIC writes the producer data into the corresponding pages. Once the transfer is complete, WIC signals the consumer kernel to resume stalled warps. After consumption, the pages are returned to the host for future use in WIC communications.

PAT is employed to notify WIC when the producer's data is ready for transfer in inter-GPU communications. Rather than repeatedly polling the PAT, WIC relies on page placement to determine data availability. Specifically, data tags are stored as individual pages on the host side. When the producer completes data preparation, it modifies the tag, trig-

gering a page fault. The host-side UVM driver then captures the tag's address, allowing the identification of the corresponding producer-available data. After the data is consumed, the tags are recycled by the host for future use.

Prefetching options for PCM and PAT within UVM memory are disabled to prevent other memories from proactively migrating to devices, which would otherwise hinder the triggering of necessary faulting.

5.3 Interrupter

The Interrupter module manages PCM page allocations for communication and provides interruption support for warps. To optimize transfer utilization, the Interrupter batches 16 warps at a time, allocating the contiguous PCM pages based on $\lceil totalSize/pageSize \rceil$. After allocation, it registers the page information, including the starting address and length, along with the requested data details, with the WIC. The Interrupter then directs the warps to access the starting address of these pages, triggering a page fault and stalling the warps.

To efficiently locate continuous free pages within PCM, the Interrupter incorporates a *segment tree*. Typically, PCM encompasses $16K$ pages, capable of handling up to $256M$ of communication data. The availability of these pages is tracked using a boolean array, where a '0' indicates an allocated page and a '1' denotes a free page. A $64K$ tree array is used to build the segment tree, where each node represents the state of a segment of pages, including the total number of free blocks (*sum*), the length of the longest contiguous block of free pages (*maxLen*), the length of contiguous free pages from the left boundary (*leftLen*), and from the right boundary (*rightLen*). When querying for k consecutive free pages, if the root node's *maxLen* is less than the required length, it indicates a lack of available space. Otherwise, the search proceeds recursively from the top down, checking *maxLen* of left and right child nodes, as well as the potential contiguous length across the boundary of the two segments (*leftNode.rightLen* + *rightNode.leftLen*). The traversal for each search descends one level down the tree hierarchy, making the query time complexity $O(\log n)$. Similarly, updating the status of a page also starts from the root and proceeds recursively down to the leaf node, maintaining the same time complexity of $O(\log n)$.

5.4 Monitor

The Monitor module, deployed within the host driver, oversees the fault entries retrieved from the GPU fault buffer, specifically capturing PCM and PAT faults. It utilizes PCM faults to manage producer-consumer communication processing and leverages PAT faults to notify the availability of data from the producer.

The Monitor module maintains two key data structures: the Data Availability Bitmap (DAB) and the Pending Faults Queue (PFQ), as shown in Figure 10. Each bit in the DAB corresponds to an availability tag for the producer data. The PFQ holds pending faults due to unavailable data, with each entry containing the fault address and the associated data tags indicating unavailability.

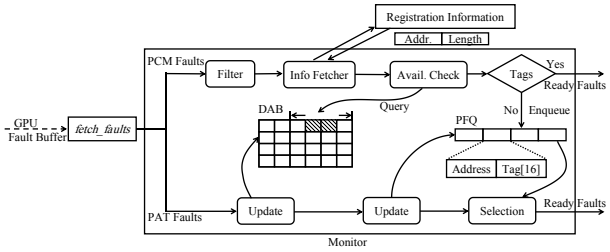

Figure 10: The Monitor Module in WIC

The Monitor detects PCM and PAT faults by checking if the fault address falls within the registered memory block ranges, which are stored in the WIC when these blocks are defined. Upon capturing a PCM fault, the Monitor assigns an independent thread to manage the communication task, ensuring that overall process flow is not disrupted. It first filters out duplicate faults, then reads the required producer data addresses from the Registration Information and checks the corresponding availability tags in DAB. If any tags are false, the fault and corresponding tag IDs are enqueued in the PFQ, suspending the faulting process. If all tags are true, the Monitor notifies the Activator module to proceed.

Monitoring the availability of producer data occurs in two scenarios. For CPU-GPU communications, where the producer is a user process on the host, it updates the DAB directly after data production, prompting the Monitor to update the unavailable tags in the PFQ and verify if fault processing can proceed (i.e., ensuring no unavailable tags remain). Once ready, the Monitor resumes fault processing. Alternatively, for inter-GPU communications, where the producer kernel resides on another GPU, the Monitor detects producer data availability through PAT faults. After the producer finalizes data, it modifies tags in the PAT on the host side. Upon capturing a PAT fault, the Monitor updates the DAB and PFQ with the new available data indicated by the fault address. If a fault process in PFQ is ready, the Monitor activates it and notifies the Activator module to proceed with the next steps.

5.5 Activator

The Activator module fulfills two functions: activation and recycling. Its activation role entails reactivating pending fault processing and reactivating stalled consumer-side warps following the fault processing. The recycling function reclaims PCM pages from the consumer and returns them to the host, ensuring their availability for future communications.

Activation: Upon receiving a signal from the Monitor that

a pending fault is ready, the Activator resumes fault processing and transfers the producer data onto designated PCM pages. If the producer kernel resides on another GPU, the data is transferred via DMA once the physical GPU address is verified. After all data has been written, the Activator services the fault and sends a replay signal to the consumer device, which reactivates the stalled warps. These warps then access the locally available PCM pages to retrieve the producer data, thus completing a cycle of producer-consumer communication.

Recycling: At the end of a communication cycle, PCM pages holding producer data often remain on the consumer side. To ensure proper triggering of page faults by the Interrupter module in subsequent requests, it is essential to recycle these pages back to the host. The Activator addresses this by sending an invalidation signal from the host to notify the consumer device that these pages have been updated. However, the timing of this signal is not precisely controlled to fit between the completion of data retrieval by consumer warps and the subsequent request from the Interrupter module. To address this, each PCM page P is paired with a companion page P', serving alternately in communication cycles to ensure effective and accurate invalidation. Specifically, when the Activator issues a replay signal for P, it concurrently sends an invalidation signal for P'. Once the consumer-side warps have successfully retrieved data from P, P' becomes invalidated. In the subsequent cycle, the Interrupter allocates P' to trigger interruptions, and the Activator prepares P for the next cycle by pushing its invalidation signal, maintaining continuous communication flow.

5.6 Putting All Together

Figure 11 provides an overview of the entire process of WIC. It begins when consumer warps request producer data via the Interrupter module, which then allocates free PCM pages based on the data size (i) and guides warps to access these pages, thereby triggering a page fault and stalling the warps (ii). On the host side, the Monitor module captures these PCM faults and checks for the availability of the required producer data (iii). If the data is unavailable, fault processing is suspended, and the faults are queued in the PFQ to await data availability. Conversely, if the data is available, the faults progress to the Activator for processing. Simultaneously, the Monitor tracks producer data availability by monitoring PAT faults, updating the local DAB, and scanning the PFQ for any ready faults (iv). These ready faults are then reactivated and forwarded to the Activator module for processing. The Activator writes the producer data into the designated PCM pages (v) and subsequently issues replay signals to reactivate the stalled consumer warps, while also recycling these pages for future communications (vi).

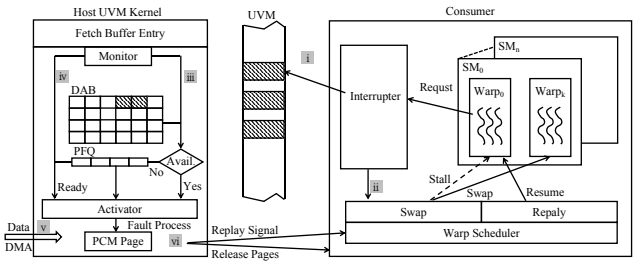

Figure 11: Overview of WIC

5.7 Adaptability of WIC

The WIC's core principle of preemptive scheduling, although primarily implemented within the host-side UVM context, is adaptable to other GPU communication architectures, such as NVLink and Direct P2P. By orchestrating warp interruptions through the communication control path, WIC introduces a fine-grained, non-blocking synchronization mechanism that significantly alleviates the synchronization overhead inherent to traditional polling methods. This design is independent of the specific control path used; thus, if the communication path is optimized beyond the host-side UVM kernel, WIC's interruption management can similarly be integrated into alternative mechanisms, such as capturing the interrupted faults in the PCI-e bus protocol for Direct P2P communication.

6 Evaluation

In this section, we first evaluate the overall performance of WIC against traditional cross-device communications. To delve deeper into its detailed effectiveness, we focus on whether WIC allows more executable tasks to overlap with synchronization time, a concern highlighted in Section 4. Furthermore, we examine the overhead associated with WIC and evaluate its scalability across different numbers of parallel threads. Finally, we compare WIC with state-of-the-art (SOTA) systems for cross-device communication. Our evaluations employ ten applications with diverse communication patterns, conducted on both CPU-GPU and inter-GPU platforms, as detailed in Section 3.

6.1 Overall Performance

We evaluate the effectiveness of our WIC method against traditional cross-device communications. Figure 12 presents the performance enhancements achieved with WIC, as well as shifts in communication overhead proportions. From these results, we derive three key observations.

Firstly, WIC significantly enhances the overall communication performance. As depicted in Figure 12(a), except for G_BFS and G_BS, most applications exhibit about 10% im-

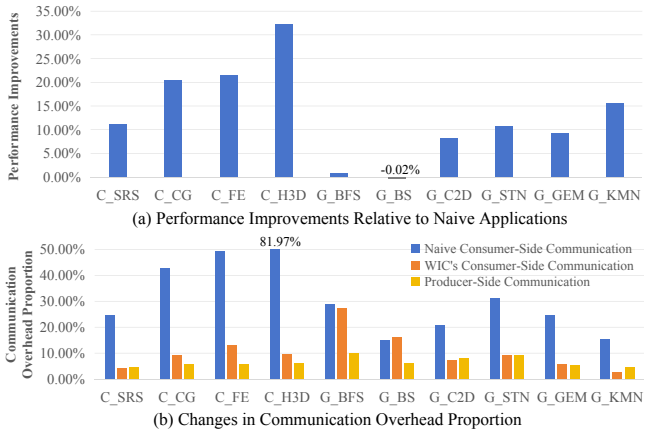

Figure 12: Performance Improvements and Communication Overhead Proportion

provements. The effect is especially significant in CPU-GPU communications, where applications such as C_CG, C_FE, and C_H3D experience enhancements exceeding 20%. For the communication-intensive application, C_H3D, optimization of communication through WIC can lead to substantial performance gains, with increases surpassing 30%.

Secondly, WIC is compatible with both communication scenarios described in Section 4.2. It is ideally suited for *Scenario* 2, where consumers await producer results, but it also supports G_BFS and G_BS applications correctly. G_BS operates entirely under *Scenario* 1 with pre-generated data, and G_BFS involves both scenarios during runtime. This versatility benefits from the Monitor module of WIC, which promptly checks for data availability and activates the Activator for immediate fault processing. However, for G_BS, WIC does not enhance performance, showing a slight decline, primarily because it only maintains a copy of producer availability on the host side without pre-fetching data to the device. Additionally, the overhead with WIC slightly detracts from performance compared to naive communication applications.

Thirdly, WIC significantly decreases consumer-side communication overhead, thereby enhancing program performance. Specifically, compared to naive implementations in Figure 12(b), WIC reduces the consumer-side overhead by about 20%, nearly equalizing the proportion of overhead with the producer-side. Notably, applications with communication access patterns characterized as streaming, such as C_SRS and G_KMN, exhibit minimal communication overhead with WIC. This efficiency is attributed to WIC's Interrupter module capability to batch PCM pages based on their regular access patterns. Conversely, applications with probabilistic communication models and random access patterns generally show a larger proportion of overhead.

6.2 Detailed Analysis

We validate the detailed effectiveness of our method by evaluating its ability to complete more executable tasks on the consumer side before initiating unnecessary waiting, thus overlapping synchronization time. Our analysis concentrates on two aspects: the completion status of threads before waiting and the synchronization time overlapped with computations.

In the WIC framework, we redefine unnecessary waiting times as periods when no active tasks are executed on the consumer end. We track the completion of executable threads from the moment they first request data from the producer until they commence waiting. As GPUs do not provide direct statistics on completion times for all threads, we use *Nsight System* to approximate executable task completion times by tracking when the threads trigger WIC's PCM faults. Figure 13 illustrates the completion status of PCM faulting threads as they wait for producer data availability, covering four applications with diverse communication patterns as detailed in Section 4.3. The results demonstrate that WIC allows the majority of tasks to be completed before the waiting time, with the curves showing that the tasks are completed in advance of waiting periods. Furthermore, the absence of prolonged flat segments in the completion curves under WIC indicates that there are no significant stalling states, thus confirming minimal unnecessary waiting times.

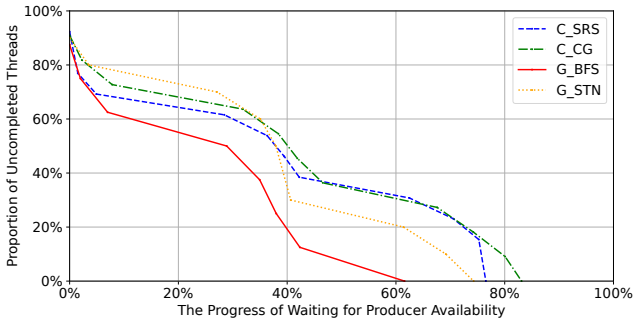

Figure 13: Uncompleted PCM Faulting Threads as Waiting for Producer Data Availability

The results in Figure 14 demonstrate that WIC significantly enhances the communication efficiency by the significant proportion of synchronization hidden behind computation. Different from naive applications, which typically achieve only about 10% overlapping efficiency, most applications equipped with WIC achieve an average overlapping efficiency exceeding 80%. Notably, C_H3D and C_FE exhibit the largest gains at approximately 85%, while even the less significant improvements in applications like G_STN and G_KMN are around 70%. This boost in overlapping efficiency demonstrates WIC's capability to pipeline more computational tasks effectively. Specifically, this improvement is achieved by re-

placing traditional polling with interruptions and its granular scheduling at the warp level. Furthermore, WIC is particularly adept at handling CPU-GPU communication tasks, where the proportion of hidden synchronization reaches up to 90%, compared to 80% in inter-GPU communications. This advantage is largely attributed to WIC's integration with the host-side UVM kernel, enabling more flexible task scheduling and overlapping, and its Monitor module's efficient checking of producer data availability, allowing producer data to be more readily accessible. These benefits depend on the current WIC implementation, and performance might vary if WIC's communication control path were based on other architectures like NVLink or PCI-e bus protocols.

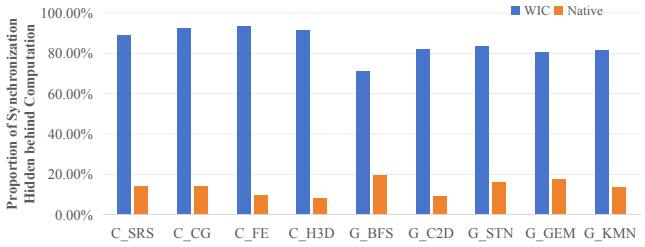

Figure 14: Synchronization Overlapped with Computations

6.3 Overheads

WIC's overhead is primarily divided between the consumer and host sides. On the consumer side, the main overheads originate from the Interrupter module's allocation of PCM pages. On the host side, the overheads are mainly attributed to the Monitor module's role in suspending and awakening page fault processing, as well as checking and updating the DAB for producer availability. We evaluate these specific overheads, along with the total overhead associated with WIC, as illustrated in Figure 15.

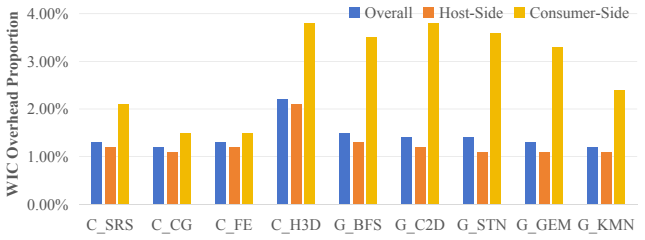

Figure 15: Overhead Associated with WIC

The overall overhead associated with WIC is relatively minor and maintains remarkable stability across different applications. Apart from C_H3D, where overhead is slightly higher, the overheads for other applications consistently hover around 1.4%, with deviations not exceeding 0.2%. Despite relatively higher overheads on the host side, the total overhead is minimally impacted thanks to WIC's interruption mechanism, which schedules other executable warps to overlap with host processing time.

Consumer-side overhead closely mirrors the total overhead and consistently remains stable across various applications, regardless of their differing communication patterns. This stability is supported by the Interrupter module's utilization of a *segment tree* for PCM page management, ensuring efficient and consistent identification of free pages with a time complexity of $O(\log n)$.

Host-side overhead is relatively higher, averaging around 3%, and demonstrates variability according to different communication patterns of applications. Inter-GPU communications often incur about 1-2% higher overhead than CPU-GPU communications due to the complexities involved in transferring producer data and monitoring availability across devices. Applications characterized by multiple communication models, such as G_STN and G_GEM, show the highest overheads, reaching up to 3.6% and 3.4% respectively, due to frequent demands for data availability checks required by multiple transfers. Conversely, applications like G_KMN, exhibit lower overheads at 2.4%, benefiting from relatively regular access behaviors.

WIC introduces no additional overheads for page faulting compared to naive applications. In naive setups, page faulting occurs three times per communication cycle: reading the availability tag for producer data, copying the tags after updates, and transferring the producer data. In contrast, WIC simplifies this process to just one PCM fault on the consumer side. If the producer kernel is on another GPU, an additional PAT fault should be required. Beyond this, WIC leverages UVM's direct copy for all other cross-device data transfers, treating the data in a read-only fashion at the receiving end. WIC ensures these transfers maintain transactional integrity, thus eliminating the need for faulting to safeguard transmission.

6.4 Scaling Performance

In the scaling experiment, we evaluate the performance of WIC as the number of threads is escalated from 64 to 1 million across four applications with distinct communication patterns. The results, as illustrated in Figure 16, demonstrate that WIC consistently boosts performance even under extensive thread scaling. Specifically, performance speedups in applications with thread counts from $1K$ to 1 million threads remain near peak values. However, despite this overall stability, there is a slight performance decline as thread counts increase. For instance, C_CG exhibits approximately a 5% decrease from its peak performance. This performance limitation is attributed to the UVM's capacity to handle only 256 faults at a time. When WIC allocates more than 256 PCM faults for consumer warps, any surplus faults must queue,

creating a bottleneck. Although the Interrupter module attempts to mitigate this issue by batching warps' requests to minimize the number of faults, blockages may still occur as producer-consumer communication escalates. However, applications like G_STN, benefit from quick producer responses to PCM faults, mitigating some scaling issues. In smaller-scale scenarios, particularly from 64 to 512 threads, WIC shows little benefit due to insufficient executable warps to effectively overlap synchronization overhead.

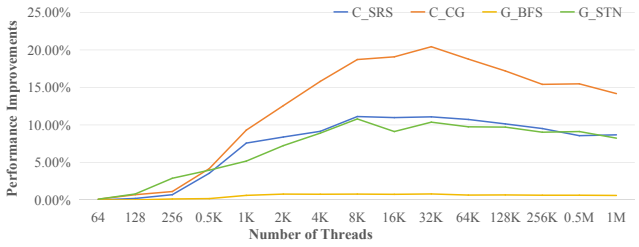

Figure 16: Performance for Scaling Experiment

6.5 Compared to State-of-the-art

In GPU communication research, SOTA systems are primarily categorized into CPU-GPU and inter-GPU communications. For comparison, several well-regarded systems that support in-kernel communications serve as baselines. For CPU-GPU communications, systems like NBlocking [10] and DemandCpy [19] are considered, whereas EffShare [31], GPS [29], and FinePack [30] are evaluated for inter-GPU communications. Notably, systems like DemandCpy, GPS, and FinePack, which involve hardware modifications, are not feasible in actual GPU environments and are therefore reimplemented at the application level for this analysis.

Figure 17 presents a performance comparison between WIC and various SOTA systems, normalized to naive setups. The results indicate that WIC outperforms most SOTA systems in various applications, with the exceptions of G_BS and G_BFS, where it slightly lags behind EffShare and GPS. Specifically, in CPU-GPU communication applications, WIC outperforms NBlocking by an average of 20% and DemandCpy by 15%. This superior performance is attributed to WIC's use of an interruption-based mechanism to overlap synchronization times between the host and device, contrasting with the simple busy-wait synchronization used by other systems. Furthermore, WIC focuses on enhancing producer-communication across various communication patterns, which contributes to its strong performance across different applications. Conversely, NBlocking's strategy of utilizing kernel fusion shows limited success in applications with multiple communication models, such as C_SRS and C_CG. DemandCpy, tailored for unidirectional transfers by replacing in-kernel demand page requests with direct *memcpy*, struggles with bi-directional communication models.

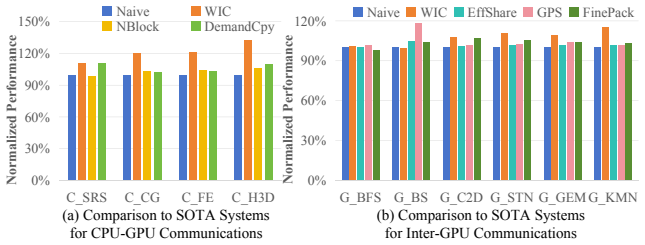

Figure 17: Comparison to State-of-the-art Systems

For inter-GPU communications, WIC demonstrates a 15% performance lead on average, with the exceptions of G_BS and G_BFS. In G_BS, EffShare and GPS perform better due to their strategies of pre-copying producer-generated data to the consumer side, effectively reducing consumer waiting times. FinePack, which proposes packing small and frequent transfers, shows adequate performance in scenarios with regular communication access patterns like streaming or adjacent. However, these systems still depend on cross-device polling when waiting for producer data, which incurs significant overheads, making their overall performance inferior to WIC.

7 Related Work

Optimizations in cross-device communication are predominantly classified into two categories: inter-kernel and in-kernel coordination.

7.1 Inter-Kernel Coordination

StarPU [2] first highlighted the significant impact of synchronization overheads, like data transfers, on CPU-GPU computational performance and introduced strategies such as Greedy to manage parallel tasks effectively. Building on this, Lustig et al. [27] further developed schemes by striking the balance between data transfer and computation, effectively minimizing idle times. Shifting away from static predictions, GPUSync [11] adopted a priority scheduling system that dynamically adjusted based on real-time monitoring of execution budgets. To analyze the intricate dependencies of tasks more precisely, Taskflow [15] employed an expressive task graph programming model incorporating in-graph control flow to facilitate task management. Furthermore, Bak et al. [3] expanded on this model by integrating gang-scheduling with work-stealing techniques, aiming for a more effective balance of workloads across tasks.

Despite the throughput improvements by overlapping more discrete kernels, inter-kernel strategies do not inherently enhance the performance of individual producer or consumer

kernels. Furthermore, the process of launching and terminating kernels imposes additional overheads, further complicating efficient execution within inter-kernel strategies.

7.2 In-Kernel Coordination

Koukos et al. [24] pioneered a fine-grained CPU-GPU collaborative architecture leveraging the UVM framework to lower cross-device communication costs. However, DemandCpy [19] criticized the substantial overhead associated with UVM's page placements, and proposed a novel CPU-GPU transfer method that combined traditional blocking *memcpy* with asynchronous page transfers, although it struggles with bidirectional read-write operations. Alternatively, NBlocking [10] explored an in-kernel communication strategy by merging kernels and employing UVM's zero-copy feature for asynchronous data transmission to GPUs. FinePack [1] tackled the underutilization of UVM's transfers by suggesting that transfer messages be accumulated in a buffer and batched. However, these approaches generally overlooked synchronization issues between producers and consumers.

EffShare [31] assigned dedicated *transfer threads* to manage producer-consumer data transfers, enabling producers to write results directly into global memory and continue with other computational tasks, promoting asynchronous data dispatch. However, the synchronization required to activate these transfer threads still introduces significant overhead. On the consumer side, GPS [29] pioneered a proactive data transfer approach assuming pre-generated producer data, designed to overlap the loading time with communication.

Despite these innovations, the prevalent and costly issue of consumers waiting for producer data in practical applications has not been fully explored. Our method, WIC, addresses this by introducing a fine-grained interruption mechanism that effectively overlaps the synchronization latency with ongoing computations when consumers wait for producer data, significantly enhancing the efficiency of GPU communications.

8 Conclusion

This paper proposes WIC, a warp-level, interrupt-based synchronization framework designed to optimize GPU communication by overlapping synchronization delays with computations. We first pinpoint traditional synchronization, characterized by consumers repetitively polling for producer data, as a primary bottleneck in GPU communication. Detailed thread-level analysis within the GPU producer-consumer model reveals that early-started polling squanders significant computational resources and competes with ongoing tasks. To tackle this inefficiency, WIC employs a fine-grained interruption mechanism that preempts warps waiting for data, freeing up resources for active warps. Specifically, WIC integrates three core components: the Interrupter to trigger interruptions to swap other executable warps, the Monitor to track the availability of the producer data, and the Activator to resume the stalled warps when data is ready. Built on unified memory copying, WIC supports over 20 types of cross-platform data communications. Experimental results show that our proposed WIC achieves an average of 13% performance improvements compared to traditional cross-device communications.

Abstract

The scale of deep learning recommendation models (DLRM) continues to grow, demanding increasingly vast computing and storage resources. In production environments, improving training efficiency and effectiveness has become the primary goal to meet the needs of numerous model training jobs under resource limitations. We introduce Primus, a unified training system that unifies the training resources, data, and paradigms to support high-performance DLRM training at ByteDance. Specifically, ① Primus provides a unified abstraction of resources and interoperates with multiple scheduling systems, achieving a consistent training experience with horizontal and vertical dynamic scaling strategies across resource pools. ② Primus offers a unified three-tier data definition and employs a data task graph generation approach to support data orchestration of multi-source training samples composed of batch and stream data. ③ Primus devises a new hybrid training paradigm for DLRMs that ensures high model timeliness by controlling parameter updates and applying fine-grained prioritization of mixed batch and stream data.

Primus has demonstrated its efficiency and effectiveness in handling large-scale, enterprise-grade DLRM training over five years of deployment at ByteDance. Evaluations show Primus's optimizations of resources, data, and paradigms. Firstly, dynamic scaling reduces training cost by 17.1% at the cluster level and increases CPU utilization from 50% to 80% per job. Secondly, data orchestration accelerates task generation by 23× and achieves higher training throughput. Lastly, after applying the hybrid training paradigm with 4 different DLRMs, advertising revenue increases by 0.4%-2.4%.

1 Introduction

Deep learning has significantly impacted the internet industry, particularly in applications such as search [63], advertising [14], and recommendations [16, 54]. As the user base and data volume continue to grow, the complexity and computational demands of deep learning recommendation models (DLRM) [60] have increased substantially [11, 22].

As shown in Fig. 1, ByteDance's internal DLRM daily training jobs have grown tenfold in five years, with daily training data per model increasing from 20 TB to 160 TB, and daily CPU virtual core usage rising from 1.5 million to 9 million. As of 2025, ByteDance has employed more than 10 million CPU virtual cores, tens of thousands of GPUs, and 7 EB of total training data for DLRM training. The total training volume for a single model can exceed 20 PB of data and involve more than 1 billion neural network parameters.

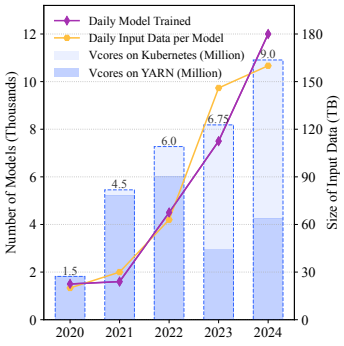

Figure 1: Our DLRM Trends

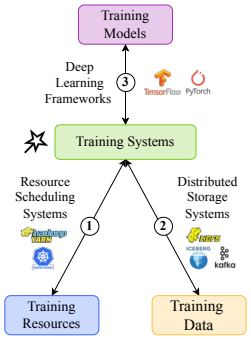

Figure 2: Training Systems

To support such large-scale training, efficient coordination of training resources, data, and models is essential. As illustrated in Fig. 2, developers submit models via deep learning frameworks, after which the training system requests necessary training resources from resource scheduling systems and concurrently loads relevant training data from distributed storage systems. Training large-scale DLRMs requires substantial GPU resources for model parameter updates and CPU resources for data preprocessing [26, 39]. The underlying training system directly affects resource utilization, convergence speed, and model quality [2, 27, 29, 38].

At ByteDance, DLRMs power core services, including Douyin, Xigua, and Toutiao. Meeting the demands of high-

frequency, large-scale training requires an efficient solution capable of coordinating training resources, orchestrating data processing, and supporting training paradigms. Therefore, establishing a unified training system is imperative [18, 21, 56] to meet ByteDance's needs for enhanced training efficiency and effectiveness.

Challenges & Limitations. Although some existing studies [3,25,32,45,64] have addressed one or more aspects of unified training systems, the limitations of current solutions still fail to fully resolve the following production-scale challenges.

① *Complex and diverse environments, with resources hosted in multiple scheduling systems.* Modern large-scale deployments typically span heterogeneous resource pools managed by different scheduling systems. However, current machine learning scheduling frameworks typically only support a single scheduling system, such as YARN [12, 19, 28] or Kubernetes [27, 31]. Elastic training strategies lack the capability to operate across different scheduling systems, like [13, 26, 57, 65, 68] are restricted to GPU elastic training within Kubernetes. Others lack support for heterogeneous resources, for example, only adapting to GPU adjustment [18, 26, 32, 55, 57] or being limited to CPU scheduling [62]. Even systems [50, 64] consider multiple sources but overlook the horizontal and vertical scaling mechanisms.

② *Large-scale multi-source data, including stream and batch processing data.* DLRM training increasingly involves reading samples from multiple data sources, stored across a variety of systems and formats. The lack of a unified data description complicates orchestration, transformation, and integration. Moreover, the growing complexity of feature engineering pipelines [26, 60] imposes substantial preprocessing demands on CPUs, resulting in a bottleneck in data reading and processing during training [50, 66]. Existing training systems [47, 52, 66] rarely offer native support for orchestrating data from both stream and batch data sources. In particular, integrating emerging storage systems and data formats, like Feature Store [43], require intrusive modifications to training frameworks like TensorFlow [1] and PyTorch [44].

③ *Further online model effectiveness improvement, constrained by catastrophic forgetting.* Maintaining the timeliness of DLRMs is critical for ensuring inference effectiveness [36], given the continual evolution of user behaviors and preferences over time. Timely training updates empower DLRMs to reflect current trends more accurately. While online training approaches [28, 33, 35] directly train with stream data to enhance model timeliness, relying solely on stream data poses the forgetting problem. Specifically, data distribution shifts [59], leading to inadequate utilization of historical sample space. Besides, online learning also does not solve the problem of delayed feedback [30]. Even with the use of both offline and online training modes [10], the lack of unified training support in systems hinders high-frequency updates due to the need for model dumping and loading.

Our Solution. To address the above challenges, we have designed and developed Primus, a unified and production-ready training system tailored for large-scale DLRM workloads. As shown in Fig. 3, Primus is a layered yet centralized architecture that provides unified resource scheduling, unified data orchestration, and a unified training paradigm to integrate with multiple resource scheduling systems and distributed storage systems. Primus coordinates resources, data, and models in a cohesive solution, achieving DLRM training efficiency and effectiveness at the industrial scale.

Contributions. Using Primus, thousands of DLRM training jobs across millions of CPU cores, and tens of thousands of GPUs have been trained efficiently and effectively. We

summarize the following four key contributions:

- We introduce a unified resource abstraction technique, which leverages multi-cluster resources and achieves multi-strategy dynamic scaling. We standardize DLRM training jobs and heterogeneous resources through custom resource definitions (CRDs), providing a unified API across scheduling systems. It enables seamless resource scaling, reduces the overhead of restarting training jobs, and improves cluster resource utilization. (Sec. 3)
- We propose a unified three-tier data definition, comprising dataset, data stream, and data source layers, to manage DLRM's training dataset effectively. With this definition, we further optimize the data task graph generation for data orchestration, enhancing the efficiency of processing batch and stream data from multiple sources, and adapting to the diverse data needs of training jobs. (Sec. 4)
- We present a unified offline-online mixture training paradigm that meets the demands for both robustness and timeliness in DLRMs. It leverages both batch and stream data to continuously improve model performance. Primus optimizes the logic for model parameter updates and enhances the integration of batch and stream data for DLRMs at the system level. (Sec. 5)
- Primus has been actively supporting DLRM training within ByteDance for five years. Through empirical evaluations on production models and datasets, we showcase Primus' capabilities in large-scale resource scheduling and data orchestration. Notably, mixture training with Primus yields up to a 2.43% increase in advertising revenue. (Sec. 6)

Open-Source. The open-source version of Primus is available at https://github.com/bytedance/primus.

2 Primus Overview

The architecture of Primus is presented in Fig. 3. Primus is designed as a centralized, layered architecture that addresses the complexity and inefficiencies in large-scale DLRM training. Primus consists of three logical planes: unified resource scheduling, unified data orchestration, and unified training paradigm. We will briefly introduce the end-to-end training workflow and core system components.

2.1 Workflow for DLRM Training

DLRM training typically consists of two phases: offline training and online training [41]. In the offline phase, training jobs' data executors load batch data from offline storage systems like HDFS and Feature Store. After decoding and transformations, the data is used in deep learning frameworks such as TensorFlow or PyTorch to calculate model weights. Subsequently, online training is employed to improve model performance [35] continuously. In the online phase, training jobs use online data samples from stream sources instead of batch sources to update model weights. These model weights are synchronized to inference servers at regular intervals for online service [48]. Due to the presence of high-dimensional sparse features and large embedding tables, DLRM training systems must sustain high data throughput while maintaining training stability across distributed executors.

Developing, training, and deploying DLRMs involves coordinating multiple complex systems [66]. Figure 3 illustrates the DLRM training process within Primus. In the unified training paradigm plane, deep learning developers submit a DLRM training job, defining the training mode as offline, online, or offline-online. The configuration of the training job is stored in the API-Server as JobCRD and DataCRD. In the unified training resource plane, the Primus master initiates first, then it monitors the status of JobCRDs, DataCRDs, and MetricCRDs in the API-Server in real-time, and requests resources from the scheduling system based on JobCRD to build the training topology. Typically, a training topology comprises several data executors for data loading and training executors for training. In the unified training data plane, the task planner in the master constructs DataCRD into data tasks, which are then dispatched to the executors via remote procedure calls (RPC). The data executors read samples from HDFS, Kafka, and Feature Store through the corresponding task runners. These samples are then converted into minibatches and saved to the data server. The training executors pull the minibatches remotely and process them in the neural network to complete model training. The intermediate states and results of the model training are stored in HDFS or parameter servers (PS).

2.2 Component Design and Functionality

Following the concept of tri-unified training resources, data, and paradigms, Primus implements three core components: Primus APIs, Primus Master, and Primus Executors, which collaborate to optimize training efficiency and effectiveness.

- Primus APIs: DLRM information is submitted to the API-Server by deep learning developers via an API-Client. The API-Server stores and records job and data details, that describe each model's requirements and configuration.
- Primus Master: Acting as the central unit for training, the master is responsible for scheduling computational tasks and managing training data. It requests resources from various scheduling systems through the unified resource controller. During execution, the dynamic scaling manager adjusts resources. The task planner translates the DataCRD into actionable tasks while the state/checkpoint manager records the status of tasks. As a centralized design, Primus adopts frequent checkpoints, resource reservation and stable constraints for fault tolerance and high availability.
- Primus Executors: Executors are responsible for executing training tasks. Data executors handle data management,

Table 1: Primus Component Design and Module Functionalities

Component	Module	Functionality
Primus APIs	API-Server	- Stores JobCRDs, DataCRDs, and MetricCRDs, provides API-Client to read/update/watch CRDs.
Primus Master: Training Master	Data Task Planner	- Compiles DataCRDs into dataset logical plans and optimizes them. - Compiles dataset logical plans into dataset physical plans for batch/stream data task generations.
	Unified Resource Controller	- Unifies different resources belonging to various resource scheduling systems. - Monitors JobCRDs, following the change requirements by request, release, and update resources.
	Dynamic Scaling Manager	- Monitors and loads training metrics through the API-Client, generating scaling strategies. - Selects the optimal horizontal and vertical scaling strategies, changing JobCRDs accordingly.
	State/Checkpoint Manager	- Receives heartbeats from executors and records the status of batch tasks (running, finished) into persistent storage.
Primus Data Executor: CPU	Task Runner	- Fetches tasks from the task planner output queue of the master. - Parses and loads tasks as training samples according to their configurations.
	Data Worker	- Extracts, filters, and converts data into standard training samples, saving them locally.
	Dataset Server	- Collects local outputs from different upstream task runners. - Provides an RPC service endpoint for remote data reading by downstream training executors.
Primus Training Executor: GPU/CPU	Training Worker	- Loads models into deep learning frameworks, reads sample tensors, performs forward and backward propagation, and then applies optimization to get final model parameters.
	Dataset Remote Reader	- Remotely reads data from data executors, and aggregates results from different upstream sources, and constructs training minibatches.

while training executors perform complex model computations. Each data executor includes task runners reading different format data from various storage systems, data workers performing sample conversion, and the dataset server aggregating the converted samples. The training executors retrieve data from the data executors via the dataset remote reader and perform further training computations.

Table. 1 outlines the modules within each component, detailing their associated entities and respective functionalities.

3 Unified Resource Scheduling

To fully utilize existing resources to meet the increasing demands of large-scale DLRM training at ByteDance, Primus integrates resources through the unified resource controller and dynamic scaling manager, as shown in Fig. 4. Specifically, the unified resource controller standardizes the semantics of different resource scheduling systems with JobCRD. Additionally, the dynamic scaling manager enhances the capability for elastic training through collaborative vertical and horizontal scaling. Primus significantly improves training efficiency through multi-cluster resource scheduling and multi-strategy dynamic scaling capabilities.

3.1 Multi-Cluster Resource Scheduling

We design the unified resource controller to adapt to the two most widely used resource scheduling systems, YARN [6], and Kubernetes [9]. This allows developers to define a training job topology independent of the underlying resource scheduling systems using the standard JobCRD, ensuring a unified user experience and reducing development costs.

The unified resource controller converts the JobCRD into resource requests specific to each scheduling system, providing a container manager for each job on YARN or an operator as a resource controller for each cluster on Kubernetes. When running on YARN, an API-Server is started for each job to provide read/write services for CRDs, whereas, on Kubernetes, the cluster's API-Server is used directly. Primus can automatically select resources from multiple YARN and Kubernetes clusters for scheduling based on their idle status. It leverages resources from underutilized clusters while releasing resources when cluster resource utilization is high, thus increasing overall resource efficiency.

Besides, the unified resource controller monitors JobCRD changes and schedules resources accordingly without requiring active user intervention. The dynamic scaling manager modifies JobCRDs determined on optimal scaling strategies using MetricCRDs. The unified resource controller facilitates seamless implementation of horizontal and vertical scaling across different scheduling systems. It addresses the issue of insufficient resources on low-performance executors while enhancing the cost-effectiveness of clusters.

3.2 Multi-Strategy Dynamic Scaling

The dynamic scaling manager combines multiple scaling strategies to support distributed training within large-scale, heterogeneous clusters. Motivated by production experience, key metrics like CPU, memory, network, GPU, and dataset pool size are monitored and aggregated into MetricCRDs. Based on these metrics, the following scaling strategies are automatically selected to increase training throughput and improve resource utilization. For stability, only one scaling

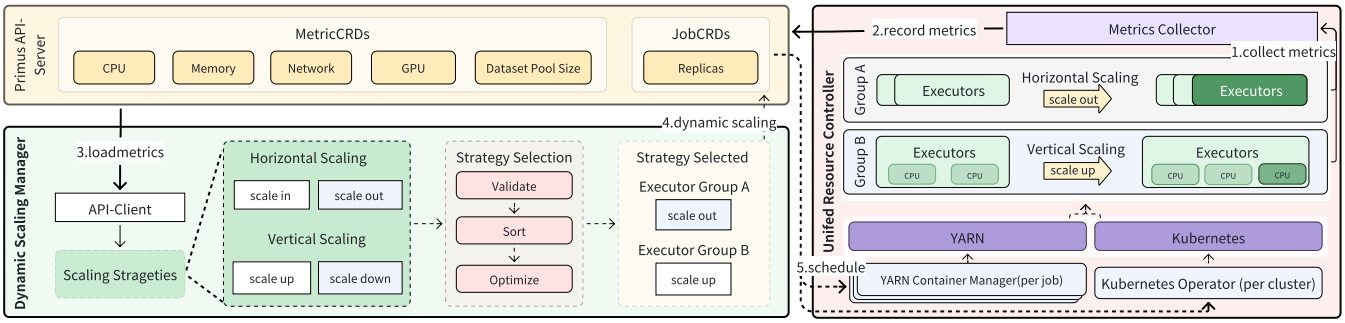

Figure 4: Unified Resource Scheduling

strategy is executed at a time, while it is still a minute-level dynamic scheduling decision. The selection involves validating, sorting, and optimizing steps using previous scaling strategies, resource type, adjustment range, etc.

Dynamic Horizontal Scaling: Primus' horizontal scaling capabilities are well-suited for large-scale cluster scenarios, achieving dynamic parallelism. In CPU and GPU collaborative training scenarios, tuning the ratio of data executors and training executors is allowed.

- Efficient scaling of executors within large clusters: Gradually increasing the number of training executors has been shown to improve AUC (area under the receiver operating characteristic curve) performance [17]. However, scheduling latency is challenging in large-scale scheduling systems with over 1 million cores. Primus reduces scheduling latency by deploying sharded operators for larger clusters and assigning different training jobs to different operators using hashed job names.
- Auto-tuning in collaborative CPU and GPU training: Predetermining the optimal ratio of data to training executors for various jobs is challenging. Primus employs horizontal scaling to dynamically adjust the ratio of data executors to training executors based on a load value L_u calculated using metrics from data executors. Let $\mathbf{u} = [u_b, u_c, u_m]$ represent the total buffer pool, CPU, and memory utilization of data executors, respectively. Users can assign customized weight vector $\mathbf{w} = [w_1, w_2, w_3]$ for each utilization metric based on their training job's requirements. Primus offers an intuitive interface and recommended weights.

$$L_u = \mathbf{w} \cdot \mathbf{u} \tag{1}$$

A load threshold L_θ is predefined based on historical job data and performance metrics. When $L_u < L_\theta$, indicating a higher training executor capacity than data executor capacity, Primus increases the number of data executors. Conversely, when $L_u > L_\theta$, Primus reduces the number of data executors. This automatic adjustment improves training throughput and efficiency without resource waste.

Dynamic Vertical Scaling: Primus uses real-time metrics to dynamically adjust CPU and memory resources on individual executors. Each executor has a metrics collector that regularly gathers data on CPU and memory utilization, I/O throughput, and network bandwidth. These metrics are collected from each executor and made accessible through the API-Server. The dynamic scaling manager calculates future resource requirements based on these metrics and updates the JobCRD accordingly. The unified resource controller then adjusts the resource allocation as needed.

We gather N_R historical resource metrics denoted by R, and utilize function $D(N_R)$ to forecast resource changes in the subsequent period, as expressed in Eq. (2). Recognizing the temporal relevance of these metrics, we assign weights $w_i = \frac{1}{N_R - i + 1}$, emphasizing a stronger influence from more recent metrics. To determine the adjustment range R_x, we analyze resource changes over the past x minutes, maintaining a small interval—typically 10 minutes—to enhance utilization while ensuring stability. That is, $R_x = D(x)$.

$$D(N_R) = \sum_{i \in [1, N_R]} \frac{w(i) \cdot (R_i - R_{i-1})}{N_R}, w(i) = \frac{1}{N_R - i + 1} \tag{2}$$

We use R_{alloc} to represent the currently allocated resources for each executor, while R_{use} denotes the maximum resource used over the past x minutes. To ensure stability, a predefined resource safety margin R_s guarantees resource redundancy, preventing individual executors from encountering out-of-memory (OOM) errors due to overly sensitive adjustments. The sign of R_x determines the direction of resource adjustment. We employ Eq. (3) to compute the updated resource allocation R'_{alloc}. Additionally, a minimum adjustment threshold R_θ is set. Adjustments where $|R'_{alloc} - R_{alloc}| \leq R_\theta$ are not implemented to avoid frequent minor adjustments.

$$R'_{alloc} = R_{used} + R_x + R_s \tag{3}$$

4 Unified Data Orchestration

At ByteDance, data sources are typically organized by business units and stored across various storage systems, such as

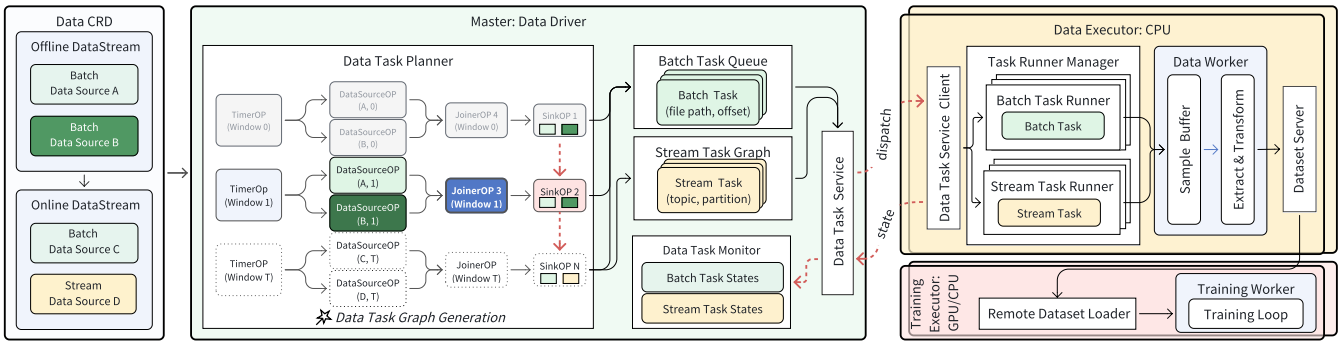

Figure 5: Unified Data Orchestration

HDFS, Kafka, and Feature Store. Additionally, utilizing data samples from multiple data sources can help DLRMs capture more complete information. While existing data orchestration solutions [7, 64] and modern ML frameworks [1, 44] support diverse data types, challenges remain in efficiently managing chronological data across multiple sources, particularly for stream data in online training environments at production scale. In pursuit of efficient data management for DLRMs, we propose an integrated data component that abstracts both data definition and acquisition logic, serving data to training jobs in the desired order through streamlined APIs. This solution optimizes data orchestration, improving both performance and stability in DLRM training.

4.1 Three-Tier Data Definition

To facilitate training jobs for DLRM in our production environments, there are three unique data orchestration requirements for optimizing model effectiveness: 1) scheduling training data among data workers with a sliding window over data generation time, 2) supporting stream data sources to minimize the time required for online training data to enter a training topology, and 3) providing mixed training data from stream and batch data sources for more sophisticated models. Therefore, to fulfill these requirements, Primus stratifies the definition of training data into three tiers: Primus dataset, Primus data stream, and Primus data source:

- Primus Dataset: A Primus dataset represents an unbounded stateful data input for a training job. It manages the lifecycle of one or multiple Primus data streams, which can be served sequentially or simultaneously according to the requirements of training models.
- Primus Data Stream: A Primus data stream is composed of one or multiple Primus data sources. It serves data to its designated data workers by mixing and scheduling the Primus data sources with a sliding window in either hourly or daily granularity.
- Primus Data Source: A Primus data source represents the data of a given period persisted in a particular storage system. This period could be either bounded or unbounded for continuous online training. Additionally, Primus data sources are responsible for converting data to the format specified by training models to eliminate discrepancies in data formats across different storage systems.

4.2 Data Task Graph Generation (DTGG)

Primus embraces data parallelism to harvest the performance improvement from distributed training. Although existing solutions are able to efficiently orchestrate data at scale [52], they lack the support for mixing multiple data sources and serving them chronologically. To address these needs, Primus analyses the assigned Primus data streams and generates data tasks, which are subsequently dispatched to the data executor according to their generation order, where a data task specifies the data from a Primus data source in a time window.

However, data task generation has become a bottleneck due to the increasing data volume since naive implementations may leave training workers pending for data and ultimately lead to underutilized computational resources. Therefore, we introduce data task graph generation (DTGG), a technique designed to improve the performance of data task generation. A DTGG comprises four types of operations (OPs) to serve a Primus data stream, as shown in Fig. 5.

- Timer OPs: The timer OPs are populated for every time window that can be derived from a Primus data stream, and thus, timer OPs are populated indefinitely for unbounded Primus data streams.
- Data Source OPs: The data source OPs are derived from their corresponding Primus data sources and are responsible for generating data tasks based on the time window propagated from their depending timer OPs. For instance, a Feature Store data source OP queries the designated Feature Store table with the propagated time window to locate the relevant data files on storage, which are later built into individual data tasks.
- Joiner OPs: The joiner OPs collect all the data tasks generated from their depending data source OPs. The completion

of a joiner OP marks the successful generation of data tasks for its designated time window.

- Sink OPs: The sink OPs are responsible for pushing the generated data tasks into a buffer for future assignments to data executors. Importantly, sink OPs always depend on their predecessor to ensure the correct chronological order in data task executions.

In addition to parallelization, DTGG can further accelerate data task generation at runtime by caching data tasks for repeated usages and fusing data source OPs derived from the same Primus data sources to amortize the cost of interacting with storage systems.

4.3 Data Component Architecture

To ensure stability, especially for online models, each training job is assigned to a dedicated data component. As shown in Fig. 5, the data driver generates data tasks for the configured Primus data streams and orchestrates their execution among data executors at the center. Meanwhile, the surrounding data executors process the dispatched data tasks and serve the acquired data to their corresponding data workers. Benefiting from the centralized architecture [7], the data component can load balance across data workers via dynamic sharding and provides fault tolerance mechanisms.

4.3.1 Data Driver

In order to well orchestrate data tasks among data executors, the data driver has to generate data tasks efficiently, distribute them to data executors, monitor their status, and provide fault tolerance mechanisms. Therefore, to fulfill these responsibilities, the data driver is composed of five modules.

- Data Task Planner: The data task planner obtains the configured Primus data stream for the training job from API-Server and generates corresponding data tasks using DTGG. The generated tasks from batch data sources and stream data sources are then forwarded to the batch task queue and stream task graph, respectively, for subsequent assignments to data executors.
- Batch Data Task Queue: The batch task queue manages the lifecycles of generated batch tasks, which are tracked through four states: pending, running, succeeded, and failed. Meanwhile, the batch task queue persists batch tasks on remote storage to prevent batch task reconstructions in cases of errors.
- Stream Task Graph: Similarly to the batch task queue, the stream task graph manages the lifecycles of stream tasks. However, since stream tasks run infinitely by binding a data executor to a message queue topic and partition, there are only two states for stream tasks: assigned and unassigned, where the stream data loaded offsets are directly committed to the message queue.
- Data Task Service: The data task service is RPC-based that orchestrates data tasks among data executors by assigning data tasks to them and tracking their status. Importantly, to ensure alignment between batch and stream data serving time windows, the data task service may throttle task assignments when necessary.
- Data Task Monitor: The data task monitor tracks the status of assigned data tasks as reported by data executors. It also periodically or on-demand creates checkpoints for fault tolerance to accurately align with model checkpoints.

4.3.2 Data Executor

Data executors are initiated by the data driver to serve orchestrated data. Through the data task service, data executors obtain data tasks and report both their own status and that of the assigned tasks. Upon data task assignments, data executors launch a new data task runner to execute the assigned data task and push the pre-processed data into an in-memory sample buffer, which is finally served to its hosting training worker in a standardized format such as Apache Arrow [4]. As shown in Fig. 5, multiple data task runners are employed in parallel on each data executor to fully utilize the allocated computational resources.

- Batch Task Runner: For every assigned batch task, the data executor launches a new batch task runner, which executes the batch task and terminates upon completion. Meanwhile, the data executor periodically reports the status of the assigned batch tasks to the data driver.
- Stream Task Runner: Streaming task runners are launched for assigned stream tasks. Nevertheless, pursuing better stability in loading stream data sources, stream task runners instead keep running without termination.

However, the static relationships between data executors and the underlying topic and partition of message queues make data component vulnerable to skewed data, which could significantly impact the effectiveness of online models due to the delays in learning stream data. Therefore, data component supports a shuffle mechanism. By allowing data executors to obtain data from each other, data component can well handle skewed data with overheads on memory footprint and network bandwidth in exchange for better overall stability in preparing samples from stream data sources. To support various training scenarios, Primus provides two different stream data loading modes of data executors as listed in Tab. 2:

5 Unified Training Paradigm

To effectively combine online stream data with offline batch data, leveraging the strengths of both online and offline training, we propose a unified training paradigm. Utilizing unified

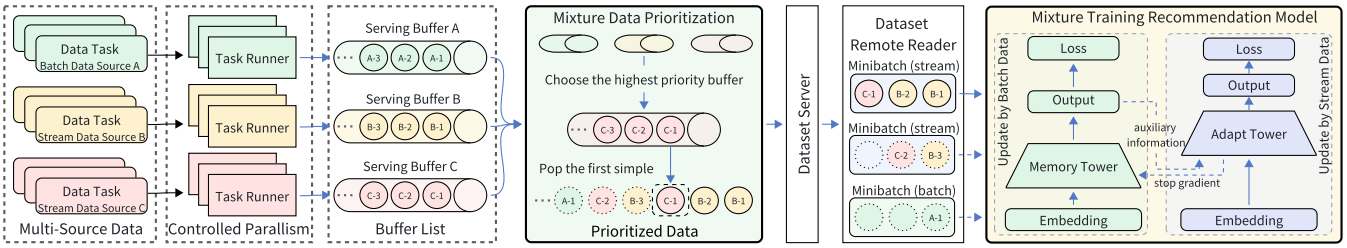

Figure 6: Unified Training Paradigm

Table 2: Stream Data Loading Modes of Data Executors

Mode	Description
Forward	Fetch and pre-process data only from assigned topics and partitions.
Rebalance	Re-deliver fetched data to others for pre-processing.

resources and data, we delegate the complex resource scheduling and data orchestration to Primus. This allows deep learning developers to focus primarily on model structure updating, thereby facilitating model design. As shown in Fig. 6, we design a mixture training recommendation model (MTRM) that controls the learning sequence of batch and stream data through different computational graphs for training. Additionally, we introduce a mixture data prioritization mechanism, which optimizes the logic for multi-source data retrieval and provides row-level priority control. MTRM is one of the training paradigms supported by Primus, which also provides pure batch, pure stream, and sequential batch-then-stream training.

5.1 Mixture Training Recommendation Model

Through statistical analysis and hypothesis testing, we identify two critical observations: 1) The non-MTRM suffers from catastrophic forgetting, where the model prioritizes memorizing the "current distribution". This leads to two primary issues: first, it fails to retain samples over time, underutilizing historical knowledge; and second, it becomes more susceptible to bias and delays in feedback, which results in instability. 2) Different batch data sources exhibit varying output delays due to output strategies, such as label splicing goals (e.g., next-day retention, 7-day retention, etc.). Therefore, MTRM requires controlling the sequence of multi-source data and aligning batch data with stream data.

We propose the universal recommendation model framework MTRM for mixture training, as shown in Fig. 6 (right). The model comprises two key components: the memory tower and the adapt tower. The memory tower focuses on long-term parameter storage, processing historical data from batch data sources to prevent catastrophic forgetting. The adapt tower adapts to recent data from stream data sources, ensuring the model remains updated with the latest trends. Typically, the memory tower has a smaller network structure, minimizing computational overhead. MTRM offers flexibility, allowing the memory and adapt towers to be extended to various neural network structures, supporting model innovation.

Algorithm 1: MTRM Training Process

Input: Continuous minibatches $\mathbf{X}$ from D_{pri}
Output: Updated MTRM with θ_M^{new} and θ_A^{new}

Initialize or load model parameters: memory tower θ_M, adapt tower θ_A;
Set learning rates α and loss functions $\mathcal{L}_M$, $\mathcal{L}_A$;
while *Not all minibatches* $\mathbf{X}$ *are processed* **do**
  if $\mathbf{X}$ *is* $\mathbf{X}_{batch}$ **then**
    $\mathbf{e}_{\text{batch}} \leftarrow \text{Embedding}(\mathbf{X}_{\text{batch}})$;
    $\mathbf{h}_M \leftarrow \text{MemoryTowerForward}(\mathbf{e}_{\text{batch}}, \theta_M)$;
    $\mathcal{L}_M \leftarrow \text{ComputeLoss}(\mathbf{X}_{\text{batch}}, \mathbf{h}_M, \theta_M)$;
    $\theta_M^{\text{new}} \leftarrow \theta_M - \alpha \nabla_\theta \mathcal{L}_M$;
  else if $\mathbf{X}$ *is* $\mathbf{X}_{stream}$ **then**
    $\mathbf{e}_{\text{stream}} \leftarrow \text{Embedding}(\mathbf{X}_{\text{stream}})$;
    $\mathbf{h}_{\text{aux}} \leftarrow \text{MemoryTowerForward}(\mathbf{e}_{\text{stream}}, \theta_M)$;
    $\mathbf{h}_A \leftarrow \text{AdaptTowerForward}(\mathbf{e}_{\text{stream}} \oplus \mathbf{h}_{\text{aux}}, \theta_A)$;
    $\mathcal{L}_A \leftarrow \text{ComputeLoss}(\mathbf{X}_{\text{stream}}, \mathbf{h}_A, \theta_A)$;
    $\theta_A^{\text{new}} \leftarrow \theta_A - \alpha \nabla_\theta \mathcal{L}_A$;
return θ_M^{new} or θ_A^{new}

During training, the dataset remote reader maintains two separate queues for batch and stream samples pushed by the dataset service. The accumulation speed is dynamically determined by the mixture data prioritization mechanism in Sec. 5.2. Whenever samples in either queue reach the size of a minibatch, the training worker executes a training loop as outlined in Algorithm 1. The updated model parameters are synchronized periodically between training workers. For convenience, we denote a minibatch $\mathbf{X}$ of batch or stream data samples as $\mathbf{X}_{\text{batch}}$ or $\mathbf{X}_{\text{stream}}$, respectively.

Each data sample from batch or stream sources is utilized only once during training to avoid overfitting to the latest data and to leverage long-term trends. We design the neural network parameter update control logic as follows:

- Embedding Calculation: The input minibatch $\mathbf{X}$ passes

through the embedding layers, generating the corresponding feature embeddings $\mathbf{e}_{\text{batch}}$ or $\mathbf{e}_{\text{stream}}$.

- Forward Propagation with Memory or Adapt Towers: 1) The memory tower processes $\mathbf{e}_{\text{batch}}$ or $\mathbf{e}_{\text{stream}}$, generating $\mathbf{h}_M = f_{\theta_M}(\mathbf{e}_{\text{batch}})$ or $\mathbf{h}_{\text{aux}} = f_{\theta_M}(\mathbf{e}_{\text{stream}})$, with θ_M as its parameters. 2) The adapt tower combines $\mathbf{e}_{\text{stream}}$ with $\mathbf{h}_{\text{aux}}$ to generate $\mathbf{h}_A = f_{\theta_A}(\mathbf{e}_{\text{batch}} \oplus \mathbf{h}_{\text{aux}})$, using θ_A as its parameters.
- Loss Calculation and Parameter Updates: During backpropagation, the memory (or adapt) tower's output $\mathbf{h}_M$ (or $\mathbf{h}_A$) are used to compute the loss $\mathcal{L}_M$ (or $\mathcal{L}_A$). Its gradients iteratively update the corresponding tower's parameters.

Since batch data samples are processed several hours or days after the corresponding stream data, the memory tower has not yet encountered samples from the most recent time period. Besides, $\mathbf{h}_{\text{aux}}$ is not used in the backpropagation of the memory tower. This temporal and tower parameter separation minimizes the risk of information leakage when $\mathbf{h}_{\text{aux}}$ is used as auxiliary information for the adapt tower.

By leveraging this parameter update control logic, we aim to balance overfitting concerns with the efficient handling of delayed feedback, thus enhancing the robustness and effectiveness of recommendation models.

5.2 Mixture Data Prioritization

Essentially, MTRMs are trained on data generated at different times with constant offsets; therefore, the ability to effectively orchestrate and integrate data from multiple sources is essential. By creating the prioritized data constructed from stream and batch data sources configured with different offsets, the required mixture data is served to model training. This design is inspired by empirical observations of performance degradation caused by stream data lag in production environments.

Due to the nature of production services, MTRMs are occasionally struck by sudden surges in stream data, particularly during peak hours or hot events. This can cause delays in loading stream data and subsequently affect model effectiveness. In such cases, merely scaling out data workers is not ideal, as computing resources are limited and surge durations are unpredictable. Therefore, an adaptive and resource-aware prioritization strategy is essential.

To retain MTRMs' effectiveness under high load conditions, Primus enables data workers to prioritize data from different data sources based on their importance and current load. Algorithm 2 shows the detailed process of how data are prioritized and served to the training workers. Data tasks from multi-sources are executed by data workers with controlled parallelism and pushed into their respective serving buffers. When the dataset remote reader requests data, the dataset server fetches data from the serving buffer with the highest priority calculated by Eq. (4):

$$\arg \max_{i \in 1,2,\ldots,n} p_i = w_i \cdot \frac{1}{1+e^{-q_i}} \tag{4}$$

Algorithm 2: Prioritized Data from Serving Buffers

Input: Serving buffers $D = \{D_1, D_2, \ldots, D_n\}$, buffer weight $W = \{w_1, w_2, \ldots, w_n\}$, and buffer queued data length $Q = \{q_1, q_2, \ldots, q_n\}$
Output: Continuous prioritized data queue D_{pri}

```
while Serving buffers D ≠ ∅ do
    maxIndex ← −1, maxPri ← −∞;
    for i ← 0 to bufferList.size − 1 do
        p_i ← w_i · sigmoid(q_i) ;
        if p_i > maxPri then
            maxIndex ← i, maxPri ← p_i ;
    sample ← D_maxIndex.pop();
    D_pri.append(sample);
return D_pri;
```

where n is the number of severing buffer, p_i is the priority for the i-th buffer, w_i is the weight assigned to the i-th buffer indicating its importance, and q_i is the length of the queued data in the i-th buffer. The sigmoid function ensures that buffer length contributes non-linearly to the priority score, allowing Primus to flexibly balance data timeliness, buffer backpressure, and source importance.

In production, the weights of stream data sources are much higher than their batch counterparts due to their impacts on model effectiveness. This flexible mixed data prioritization can dynamically adjust the processing order of different data sources to reduce data latency during high load periods.

6 Evalutions

We validate Primus' capabilities within a large-scale distributed environment. The key highlights are as follows:

- Horizontal scaling saves over 17.1% of resources while vertical scaling improves utilization from 50% to 80%.
- Generating around 4 million data tasks speeds up 23× in 1 thread and can be completed in 42s with 4 threads.
- Model effectiveness in advertising is significantly improved by 0.03%-0.07% in AUC and 0.4%-2.4% in revenue.

As a large-scale, enterprise-grade DLRM training system within ByteDance, we provide detailed information about workloads currently undertaken by Primus in Tab. 3.

6.1 Unified Resource Evaluation

We assess Primus' horizontal and vertical dynamic scaling capabilities in different training scenarios. The evaluation measures training throughput (minibatches/s), CPU/memory utilization, and model effectiveness (AUC).

Dynamic Horizontal Scaling: To evaluate the performance of large-scale dynamic parallelism, a baseline setup running

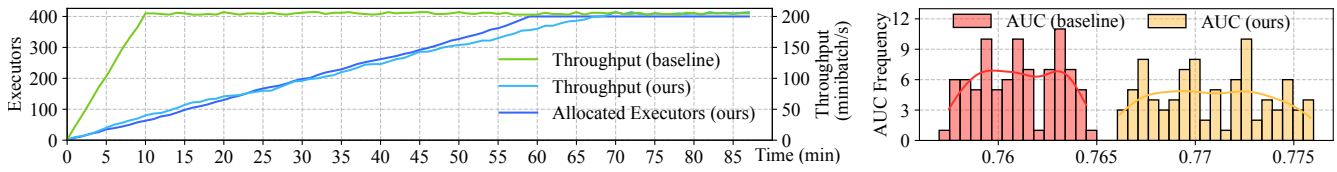

Figure 7: Dynamic Horizontal Scaling

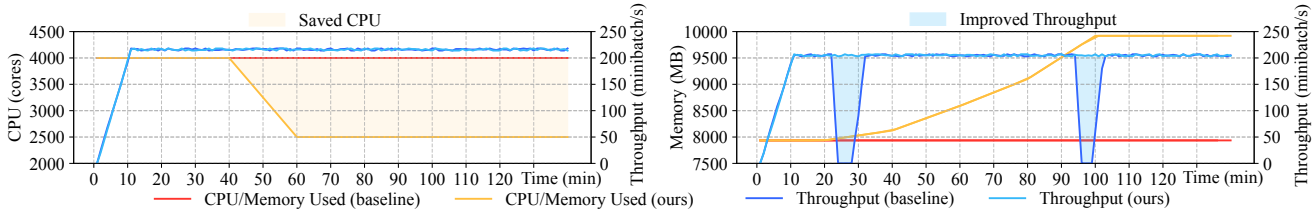

Figure 8: Dynamic Vertical Scaling Improves Resource Efficiency

a fixed number of 400 data executors is compared with our setup, where data executors are gradually scaled from 0 to 400 every 10 seconds. As shown in Fig. 7, Primus's training throughput is gradually increased to 210 minibatch/s, similar to the baseline setup's throughput of 205 minibatch/s, while AUC is approximately 0.4% higher than the baseline, improving training effectiveness with the scaling strategy.

To evaluate the impact of tuning the ratio of training executors and data executors, a baseline setup using 900 8-core data executors and 8 training executors throughout the training process is compared with our setup initially using 450 8-core data executors and also 8 training executors. As shown in Tab. 4, the total training time and the training AUC of our setup are comparable to the baseline. However, our setup eventually uses 690 data executors, resulting in a 23.33% saving in CPU cores compared to the baseline. The tuning improves resource utilization without negatively affecting training performance or speed. When the feature is enabled for a production cluster, training throughput per core (ROI) gradually increases from 30.26 to 35.44, representing a 17.1% improvement.

Dynamic Vertical Scaling: We assess Primus' vertical scaling with two typical training scenarios. The first scenario simulates an excessive CPU resource allocation to workers, causing resource wastage. Both jobs are started with 400 10-core data executors, with Primus' vertical scaling expected to adjust the CPU core allocation of the executors. As shown in Fig. 8 (left), the baseline utilizes a fixed number of CPU cores, while ours scales down by 1600 CPU cores, representing an adjustment per executor from 10 to 6 cores. The effect is an increase of CPU utilization from 50% to 80% and no impact on both training throughput and AUC.

The other scenario simulates insufficient memory allocation for PS executors, leading to OOM errors, which cause failovers and disrupt training progress. Both the baseline and ours are initiated with 496 PS executors with 16 GB of memory each. Primus' vertical scaling is expected to dynamically adjust the memory of PS executors for our task to avoid OOM errors. As shown in Fig. 8 (right), the baseline frequently encounters PS executor OOM errors, resulting in periods with low training throughput. Ours adjusts the allocated memory to a total of 9920 GB from 7936 GB compared to the baseline, which prevents the OOM issues. The effect is an increase in throughput from 275 minibatch/s to 496 minibatch/s, and an AUC increase from 0.62 to 0.78.

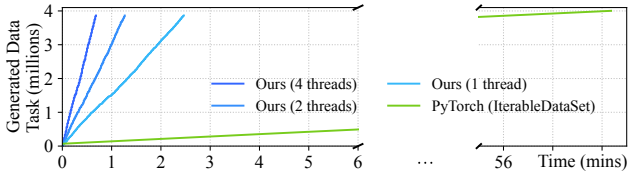

Figure 9: Data Task Generation Speed

6.2 Unified Data Evaluation

We evaluate the performance of Primus data component, which analyses the designated data sources and subsequently serves the data to training workers. Therefore, the overall performance is a collective result of the two major responsibilities: data task generation and data loading.

Data Task Generation Evaluation: We evaluate the efficiency of Primus's data component in generating data tasks from large-scale production data. The experiment is performed on a single data driver with 8 CPU cores and 25 GB memory to eliminate the impact of memory pressure. The input workload consists of 20-day production data from two Feature Store tables, comprising over 56 million underlying files and yielding approximately 4 million generated data tasks. As shown in Fig. 9, DTGG achieves significantly faster task generation compared to a naive single-threaded baseline implemented with PyTorch. By fusing multiple scan requests

Table 3: Characteristics of DLRM Training Workloads on Primus

Categories	Types	Details
Resource	General Data Workers	800 CPU data workers, each with 5 cores and 50 GB memory
	General Training Workers	4 GPU training workers, each with 8 GPUs
Data	Data Tasks	Ranging from 0 to 80 million tasks (∼ 180–540 days' data)
	Data Sources	Spanning 2 to 18 sources, each with 10–20 PB data
	Training Throughput	Ranging from 200,000 to 600,000 samples per second
Model	Model Size	Varying from 500 GB to 1 TB
	Sample Features	The 75th percentile of the number of features is ∼3200

Table 4: Dynamic Horizontal Scaling Comparision

Method	CPU Used (cores)	AUC	Training Time (days)	Cluster ROI
Baseline	7200	0.9385	1.86	30.26
Ours	5520	0.9382	1.90	35.44+17.12%

Table 5: Model and Resource Settings

No.	Model Basis*	Model Size (GB)	Executors Number	Executors CPU (cores)	Executors Memory (GB)
1	DSSM [24], LHUC [49]	600	60	13	45
2	FM [46], Transformer [51]	1200	40	6	30
3	FM, DIN [67], Transformer	800	50	12	35
4	EMSNet [20], LHUC	3700	50	8	30

*Production DLRMs absorb and integrate the various model structures listed.

to the underlying HDFS storage, the 1-thread DTGG reduces the generation time from 58 minutes to 149 seconds (23×) and further improves to 42 seconds with the 4-thread DTGG. These results demonstrate DTGG's efficiency in handling multiple data sources and time windows.

Data Loading Evaluation: Compared to batch data sources, stream data sources are widely adapted by online training jobs which have higher performance requirements, especially in production environments. Figure 10 shows the performance comparison of serving stream data sources between Primus and Flink [5] (a widely used online model training framework). This experiment is performed on 40 executors on machines equipped with 2 CPU cores and 4 GB memory each, where 10 of them are configured extremely slower than others to simulate anomalies such as hardware degradation in production environments. Both Primus and Frink enable shuffle mechanisms to balance load across executors dynamically. Primus data component achieves 3.97 GB/s, which is 1.25× to 3.17 GB/s with Flink. Since shuffling data with Flink incorporates two layers of task managers for generalized usages, Flink is more fragile to defective machines, as the back pressure induced by the latter layer could lead to resource underutilization in the former layer. On the contrary, Primus data executors are equal and thus will not impede the performance of others. Therefore, though the resource utilization of slow executors is similar, Primus's shuffle mechanism design allows for better overall utilization across all executors. This leads to higher effective throughput under unstable environments or skewed data.

6.3 Unified Training Evaluation

To evaluate the performance of the unified training paradigm, we use production data to conduct the effectiveness of MTRM and mixture data prioritization.

MTRM Evaluation: We select four representative production models for Conversion Rate (CVR) and Click-Through Rate (CTR) estimation models to thoroughly assess the effectiveness of MTRM in various scenarios. Each model's structural information and resource specifications are detailed in Tab. 5. Without MTRM (w/o), these baseline models can be viewed as single-tower-like models that process both batch and stream data without separation. When utilizing MTRM (w/), these four models all employ a memory tower to learn from 24-hour delayed batch data, while an adapt tower remains the same structure as baselines but only updated by stream data. Both the models with and without MTRM are pre-trained on one year of historical data. Both the models with and without MTRM are pre-trained on one year of historical data. Since both models utilize the same stream data, they share relatively comparable AUC values. AUC quantifies the model's ability to rank positive instances (e.g., clicks or conversions) ahead of negative ones, and serves as a reliable proxy for model quality prior to online deployment. As shown in Tab. 6, the implementation of MTRM results in increased AUC uniformity across the four production models, with an average improvement of 0.03% to 0.07%. Additionally, we conduct A/B testing, with the number of samples diverted by each model presented in Tab. 6. After applying MTRM, the advertising revenue increases by 1.045%, 0.806%, 2.438%, and 0.397%, respectively. These results demonstrate that using MTRM can effectively enhance the performance and revenue of recommendation models.

Mixture Data Prioritization: For evaluating serving mixture data under traffic pressure, we conduct an experiment with 60

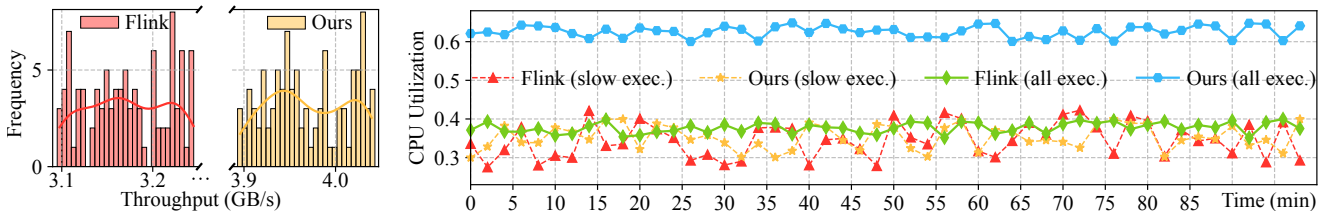

Figure 10: Primus Online Training VS. Flink Online Training with 25% Slow Executors

Table 6: Comparison of AUC and Revenue Performance for Various Models without (w/o) and with (w/) MTRM

Model		Evaluation (AUC) Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Avg.	A/B Testing Samples	Revenue
1	w/o	0.92411	0.91992	0.92538	0.92737	0.92187	0.92554	0.92642	0.92437	2,252,037	-

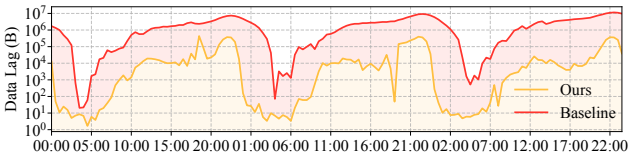

Figure 11: Data Prioritization Reduces Loading Lag

data executors equipped with 11 CPU cores and 40 GB memory loading 1-day data of a production Kafka topic of 1,024 partitions with average traffic of 600 MB/s and its corresponding historical copy persisted on Feature Store. As shown in Fig. 11, the baseline result without mixture data prioritization suffers badly from data loading lags during peak hours, which eventually renders negative impacts on the model effectiveness. On the contrary, with mixture data prioritization, the loading lags are hugely reduced, and thus, the model effectiveness is better protected, which verifies that Primus is able to control the proportion of loaded data from different data sources in a fine-grained manner, especially during peak hours with limited computation resources.

7 Lessons

In this section, we share our experiences and lessons learned during the design and implementation of Primus.

Road Towards Unified Resource Scheduling: In the early stages of Primus, Kubernetes lacked sufficient pod scheduling throughput and did not support gang scheduling semantics. Consequently, training resources were primarily managed by YARN, through a hybrid deployment of YARN NodeManager and Kubelet. As Kubernetes' scheduling capabilities improved, along with its support for gang scheduling semantics, a greater portion of training jobs was migrated to Kubernetes. During this migration, ensuring consistency in user experience became critical, as system changes could not impact users. To address this, Primus services as an intermediary layer, insulating users from the differences between scheduling systems by the unified resource scheduling design. Over time, Primus evolves to support more comprehensive dynamic horizontal and vertical scaling capabilities.

Optimizing Data Access for Various Formats: The vast quantities of sample data are stored in diverse formats (e.g., TFRecord, Protobuff, and 4mz) and compressed with multiple algorithms (e.g., Snappy, ZSTD, and GZIP). Initially, a separate Java process (using InputFormat) was used to read files and pipe them to training executors which faced overhead in cross-process communication and data format conversions. To address this, Primus re-engineers the data access layer using Arrow for cross-language efficiency and NativeClient for optimized stream data handling, reducing CPU usage by 40%. Additionally, Primus master employs ClassLoader and other isolation techniques to allow seamless integration of diverse data lakes like Iceberg and Hudi, balancing data management complexity with high retrieval efficiency.

Necessity of Mixture Data Prioritization: Initially, Primus employed two distinct groups of executors to process batch and stream data separately. However, we observed that batch data processing occurred more rapidly, resulting in resource wastage. Then, Primus was updated to handle both batch and stream data within the same executors. While this approach

increased resource efficiency, we found that the large volume and fast arrival rate of batch data often consumed excessive resources, delaying the processing of stream data, particularly during peak hours. To address this, we design the continuous prioritized data queue that ensures stream data is processed first. It helps prevent MTRM performance degradation by ensuring timely learning of stream data.

8 Related Work

Deep Learning Scheduler. Deep learning training optimization with various resource schedulers has received attention in recent years in recent years [34, 42]. Studies indicate that YARN and Kubernetes are the mainstream training frameworks at present [23]. Current optimization strategies like dynamic resource allocation [15] , face portability issues when applied across heterogeneous environments. Systems like Oobleck [26] and DynamoML [13] concentrate on elastic GPU training but remain tightly coupled to Kubernetes, limiting their applicability to more diverse production infrastructures.. GoldMiner [64] proposes a novel resource allocation paradigm on Kubernetes, separating CPU and GPU and allocating both resources automatically to improve the efficiency of the cluster. However, GoldMiner is only adapted to Kubernetes, which cannot be extended to other schedulers. While ElasticFlow [18] elegantly supports dynamic GPU reallocation, it is not designed to accommodate heterogeneous executor configurations. Moreover, while horizontal pod autoscaling leverages workload predictions to reduce unnecessary resource allocation, discussions on machine learning-based vertical pod autoscaling remain relatively scarce [61]. Primus enables dynamic scaling and precise resource control for both CPU and GPU workers, supporting collaboration with multiple scheduling systems.

Deep Learning Data Loading. Along with the increase of data amount, data reading and preprocessing become complicated and critical [60]. tf.data [40] proposes a machine learning preprocessing framework, which mainly concentrates on throughput optimization during sample reading. However, massive metadata training is not considered, and data fragmentation is not supported in elastic training scenarios. tf.data service [7] maximizes GPU utilization to save training time and implements sample concurrent preprocessing with CPU data preprocessing. However, there is an additional loss in RPC data transmission. Meanwhile, current training systems such as Horovod [47], DLRover [52], and others [58] usually only have a single data source, which fails to have built-in support for multiple data sources with various storage systems and formats. Primus seamlessly integrates various data sources, encompassing both stream and batch data stored in HDFS, Kafka, and Feature Store.

DLRM Online Training. DLRMs are widely employed by internet companies for various tasks such as ad CTR prediction [41]. Due to the rapid increase in data scale, the training of DLRM models in distributed memory and computing systems faces challenges [53]. cDLRM [8] implements training large DLRM model with single GPU and pure data parallel training by unique caching strategy. Monolith [35] and Persia [33] focus primarily on innovations in model structures, such as sparse-dense parameter separation and large model efficient distributed updates. They are tightly coupled with specific model structures and directly train online DLRM with only stream data in homogeneous GPU-based training environments. General stream processing systems, such as Flink [5] and Ray [37], require a lot of user code modifications to use batch data. Primus provides strong model-agnostic support for DLRM training, providing features such as error handling, dynamic scaling, and data orchestration.

9 Conclusion

We present Primus, a tri-unified training framework for DLRM that encompasses three primary innovations. First, Primus provides a unified resource scheduling abstraction across multiple resource scheduling systems. To the best of our knowledge, Primus is the first to offer a multi-strategy dynamic scaling mechanism utilizing a standardized API server that interoperates seamlessly with both YARN and Kubernetes clusters. Second, Primus introduces a three-tier data definition that facilitates efficient offline and online training within a single framework. It implements DTGG to enable parallel task generation for orchestrating training data at scale. Third, Primus features an offline-online mixture training paradigm, allowing for continuous ingestion of historical offline batch data during online model training, resulting in a significant increase in advertising revenue. Since 2019, Primus has been utilized for all ByteDance production DLRM training, leveraging a resource scale exceeding 10 million CPU cores and tens of thousands of GPUs. We continue to enhance Primus to achieve better efficiency and effectiveness in DLRM training.

Acknowledgments

We would like to thank all those who contributed to the design and development of Primus, including Han Qian, Dongyan Zhou, Hanqing Zhao, Irshad Kandy, Kai Xie, Chi Zhang, Di Wu, and Hoang Le. We are also grateful to our business partners across the search, advertising, and recommendation teams for their valuable support and collaboration. This work was supported by the National Key R&D Program of China (2024YFF0617700), the National Natural Science Foundation of China (U23A20309, 62272302, 62372296), "Pioneer" and "Leading Goose" R&D Program of Zhejiang (2024C01167), and the ByteDance Research Project (CT20250218122839). Xiuqi Huang completed the majority of her contributions during her Ph.D. studies at Shanghai Jiao Tong University and her research internship at ByteDance.

Chitu: Avoiding Unnecessary Fallback in Byzantine Consensus

Abstract

Most Byzantine-Fault Tolerant (BFT) consensus protocols either pre-select a single leader with the help of additional timing assumptions (i.e., partially synchronous ones) or resort to random coins to achieve only probabilistic termination (i.e., asynchronous ones). The single leader may become a performance bottleneck and/or lead to availability problems, while probabilistic termination increases latency.

We re-consider the consensus problem from its first principles, where neither synchrony assumption or any designated role, nor randomization is intrinsic to consensus. We thus formally study a framework for designing robust BFT protocols with low latency: nodes first try to achieve consensus merely based on message exchange, but only resort to a fallback mechanism like random coin or leader election if correct nodes have divergent opinions on a proposal. We further present Chitu, an asynchronous DAG-based protocols following this framework. Chitu in the best case commits proposals in four message delays, even in the presence of faulty nodes and/or under asynchrony. In the worst case, Chitu still ensures predictable performance with $O(1)$ time complexity in expectation. Experimental results on Amazon EC2 show that Chitu achieves a significant reduction in latency compared to two representative DAG-based protocols that always put a leader or randomization on the execution path.

1 Introduction

Blockchains [8,69], or Byzantine-Fault Tolerance (BFT) state-machine replication (SMR) protocols [27, 44, 45, 80] are a promising approach to providing robust services for decentralized applications. Boosting the performance of BFT protocols is thus becoming a hot topic in recent years [16, 71, 77, 79]. At the core of SMR protocols is a consensus algorithm that reaches agreement among a group of replicas or *nodes*. Byzantine consensus protocols [58] further assume faulty nodes can exhibit arbitrary or malicious behaviors. Consensus protocols are roughly categorized into three types according to their timing assumptions: synchronous [34, 58, 67], partially synchronous [22, 27, 37, 80] and asynchronous [21, 32, 62, 66]. Synchronous or partially synchronous protocols rely on network synchrony to ensure safety or liveness property, while asynchronous variants resort to randomization to achieve only probabilistic termination due to FLP impossibility [40].

Many existing BFT protocols [22, 27, 44, 48, 56, 80] are leader-based and designed assuming the partial synchrony model, in which a single leader is elected by the help of network synchrony assumption. The leader is responsible for making a proposal and coordinating consensus process. If the leader (and the network) is stable, non-faulty nodes can reach consensus within *a fixed number of communication phases*, achieving promising performance. However, partially synchronous protocols rely on a complicated view synchronization mechanism [28, 70] to keep every correct node in sync with one another, and a predefined maximum network delay Δ to help trigger the replacement of a problematic leader (a.k.a., view change). During view change (which lasts at least Δ time), no available service can be provided. Even worse, if network synchrony assumption does not hold, partially synchronous protocols may be involved in consecutive view changes, forfeiting liveness property. Network problems can occur more often than not in Wide-Area-Network (WAN) [38], which is the typical setting for blockchain systems [48].

Asynchronous protocols, in contrast, have no synchrony assumptions and do not pre-select a leader [21, 25, 26, 32, 36, 47, 66]. Asynchronous protocols require every node to make a proposal in each consensus instance, and participate in several phases of message exchange. Finally, a coin-flipping phase is used to help non-faulty nodes converge and reach a final agreement. With probability one, every non-faulty node outputs the same set of committed proposals. Recently-proposed asynchronous protocols typically select a leader a posteriori in order to achieve $O(1)$ time complexity in expectation [32, 47, 53].

*These authors contributed equally and are listed in alphabetical order
#Corresponding author: shengyun.liu@sjtu.edu.cn

Although asynchronous protocols are becoming prevalent, they often incur more rounds of communications compared to their partially synchronous counterparts [46, 63]. We argue that the problem mainly comes from the coin-flipping phase when it is located on the critical path. The appeal of partially synchronous protocols is in their simplicity when the network is stable most of the time, with predictable latency between correct nodes, and when protocol execution path *skips* costly timeout event and view change mechanism, achieving *fast termination*.

Applying a fast path (often with optimistic assumptions) to normal-case operations is a widely-used approach for boosting system performance, and also has profound influence on consensus protocols [30, 56, 57, 62]. Actually, several up-to-date asynchronous protocols [63] adopt a fast path that mimics the normal case operations of partially synchronous protocols and a slow path that still provides liveness even under asynchrony. We can view them as combining assumptions and essential steps of both worlds. Therefore, the fast path of these protocols still relies on some special role (e.g., the single leader) and synchrony assumptions to move forward. In other words, their fast path possesses both advantages and disadvantages of partially synchronous protocols.

Meanwhile, we also found two recent works that enable fast termination in a pretty different way: Red Belly [30] (using DBFT [29]) under partial synchrony and MyTumbler [62] under asynchrony. Red Belly requires every node to make a proposal in each consensus instance. Unlike other partially synchronous counterparts, Red Belly uses a binary agreement (BA) protocol to determine the decision of each proposal (either committed or aborted). By doing so, Red Belly resorts to a lightweight coordinator in BA to break ties *only if* correct nodes are divergent on some proposal[1]. In a similar vein, MyTumbler (under asynchrony) skips random coins in its BA protocol if most correct nodes are consistent on a proposal.

If we consider both leader (coordinator) election and coin flipping a fallback mechanism that sidesteps FLP impossibility [40], Red Belly and MyTumbler can entirely skip the fallback via their fast paths. This departs from other fast path design in the *absence* of any special role. Although the above two mentioned protocols have such an appealing feature, Red Belly still puts timers on its fast path, and both of them use binary agreement (BA), meaning that they have to explicitly resolve ambiguity of at most n BA instances.

Inspired by Red Belly and MyTumbler, we first formally study a framework for designing robust BFT protocols with low latency: correct nodes first try to reach agreement merely based on message exchange (which we call the *fast path*), but only resort to a fallback mechanism like random coins or leader election when correct nodes have divergent opinions on some proposal. Figure 1 depicts different frameworks. Partially synchronous protocols (except Red Belly) pre-select a special role (such as the leader) with the help of additional timing assumptions, while asynchronous BFT protocols (except MyTumbler) either put randomization on the critical path or re-introduce synchrony assumptions and some special role in their fast path. In contrast, the framework we study has the following unique features:

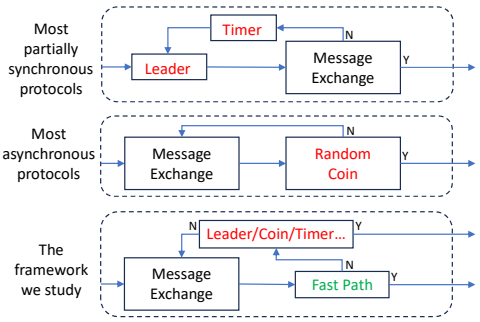

Figure 1: Frameworks for consensus protocols.

- In the fast path there is no special role (such as the leader) used or elected, and thus *no* synchrony assumption is re-introduced; and,
- there is no switch between fast and normal paths, as both can proceed concurrently and in a unified manner.

From a different viewpoint, the model of the fast path being studied in this paper could be considered a variant of fair schedulers [21]. Fair scheduler was proposed four decades ago, but was somehow overlooked from engineering perspectives. The main drawback of fair scheduler is that if the adversary controls message scheduling at will, the protocols no longer provide liveness. Hence, a *fallback* mechanism such as leader election and/or randomization is essential for mitigating such attacks targeting the fast path.

We name the framework we study Fair-Fallback. Following this framework, we further present Chitu, an asynchronous BFT protocol designed on top of a well-structured Directed Acyclic Graph (DAG). Each proposal in a DAG is represented as a vertex. DAG-based BFT protocols are becoming prevalent in permissionless blockchains [11, 32, 53, 60, 76]. They embed the consensus process in the dynamic construction of a DAG structure without involving additional messages, simplifying protocol design and implementation. Chitu is largely inspired by Tusk [32] and DAG-Rider [53], two recently proposed DAG-based protocols. Besides possessing the same $O(1)$ time complexity in expectation in the worst case, Chitu further bypasses the fallback mechanism (i.e., the single leader vertex in DAG) provided that most nodes have observed the same set of vertices in a round (i.e., a consensus instance), thus achieving fast termination.

Guided by the Fair-Fallback, the next challenge for Chitu is to find a way to commit as many proposals as possible through the fast path, which we found is a non-trivial task. After several attempts at devising and evaluating different commit rules and also according to the design of prior work [30, 62], we

[1] E.g., some nodes input 1 into a BA instance, while others input 0.

located a useful rule of thumb: *a node should wait as long as possible for a proposal to enter the fast path, provided that this wait does not introduce significant costs or violate liveness properties.* To this end, we further propose an adaptive wait mechanism that helps Chitu dramatically increase the chance of achieving fast termination.

Finally, we evaluate Chitu, Tusk and BullShark [76] on Amazon EC2 platform. BullShark is another DAG protocol designed under partial synchrony. The experimental result shows that in fault-free case, Chitu can reduces end-to-end latency, achieving up to 82.5% reduction compared to Tusk. Under crash faults, Chitu can still go through the fast path, while the performance of BullShark is significantly affected by the faulty node. We also mimic an adversarial situation under Byzantine attack, where each round is prolonged with extra waiting and the fast path is disabled. Even if all the proposals go through random coins in this case, the performance of Chitu degrades gracefully.

2 Background

2.1 Model

We focus on the Blockchain or state-machine replication (SMR) problem [73], a solution to which is a robust distributed system that coordinates a group of processes or nodes, in order to mask a bounded number of failures. SMR protocols order requests issued by clients, such that:

- (Safety) If two requests $req1$ and $req2$ are committed in the same position (or with the same block height in blockchain contexts), then $req1 = req2$;
- (Liveness) Eventually every request req issued by a correct client can be committed.

We target Byzantine faults, which may exhibit arbitrary behaviors even collusion attacks. For simplicity, we assume there are a group Π of $n = 3f + 1$ nodes [37], in which at most f nodes may be faulty. Thus, a Byzantine quorum consists of $\lceil \frac{n+f+1}{2} \rceil = n - f = 2f + 1$ nodes. We assume reliable and authenticated channels between each pair of correct nodes, meaning that any message sent by a correct node will be eventually delivered by every correct receiver. Asynchronous protocols must rely on reliable channels to provide liveness, so does the fast path of Chitu.

2.2 Fast termination and the leader's bottleneck in partially synchronous protocols

Partially synchronous protocols are commonly separated into two sub-routines: the normal-case operations that allow a single leader (e.g., the primary in PBFT [27] or the leader in HotStuff [80]) to coordinate consensus and make its proposal (i.e., a batch of requests or transactions) committed, and the view-change operations that elect a new leader when, e.g., the previous one has crashed. The safety property of partially synchronous protocols is ensured by quorum-based techniques [78]. The liveness property, however, is ensured by further introducing network synchrony between the single leader and others. Such timing assumptions also help trigger the view-change operations. When the leader is correct and the network is stable, partially synchronous protocols can reach consensus within a fixed number of message exchange, achieving deterministic and *fast termination*. In summary,

- partially synchronous protocols have normal-case operations that rely on a single leader to reach consensus without involving time-related steps;
- the leader and other $2f$ correct nodes must remain in the same view for a sufficiently long period of time, such that consensus can be achieved before timeout.

Note that the second reason is critical in ensuring liveness and providing good performance. Otherwise, partially synchronous protocols may be involved in consecutive view changes.

When the leader is slow or has crashed, partially synchronous protocols incur more communication phases and additional timeout events for electing a new leader. We argue that the problem mainly stems from the existence of some special role, which is always on the critical path regardless of the system state.

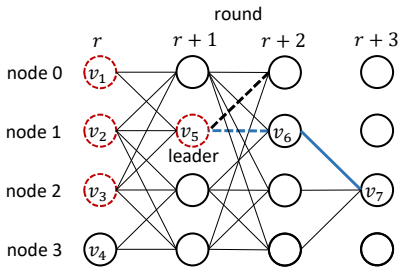

Figure 2: Example of commit rules in DAG-based protocols like Tusk [32] when $n = 4$ and $f = 1$. Each circle represents a vertex in the DAG. Dotted circles represent vertices committed by the leader (v_5), while dotted lines represent edges making the leader valid.

2.3 Randomization in asynchronous protocols

Asynchronous protocols [13, 32, 36, 47, 53, 66, 72] work in a somewhat leaderless manner, in the sense that no special role (such as the leader) is pre-selected by the help of timing assumptions. Asynchronous protocols are commonly round-based, where in each round every node is required to suggest a value and participate in several communication phases. The value a node suggests in a round is influenced by message exchange of previous rounds. To determine which value(s) can be committed, asynchronous protocols introduce a coin-flipping phase, which breaks ties and helps correct nodes converge.

Figure 2 depicts how Tusk [32], a recently proposed DAG-based asynchronous protocol, proceeds round by round. Each round corresponds to a new consensus instance. Since consecutive rounds are connected by edges, the execution of consecutive consensus instances is pipelined, similarly to the way HotStuff [80] chains consecutive proposals.

In each round r, a node i makes a proposal, i.e., a vertex in the DAG. Node i then propagates the vertex to others via a Byzantine Reliable Broadcast (BRB) protocol [21, 24]. BRB ensures that the delivered message (vertex) is the same for all correct nodes despite f Byzantine faults. BRB in Tusk takes three phases of message exchange. Each vertex of round $r+1$ has exactly $n-f$ edges connecting to vertices of round r. For example, vertex v_5 in Figure 2 connects to v_1, v_2 and v_3 (but not v_4). DAG is merely a partially ordered set, in which vertices are *not* totally ordered. To this end, Tusk generates a random coin in each odd round (e.g., round $r+1$ in Figure 2), by which correct nodes collectively select a leader vertex (e.g., v_5). Random coins can be instantiated using a deterministic threshold signature scheme [19]. If the leader vertex is *valid*, i.e., is connected by at least $f+1$ vertices of the subsequent round (e.g., v_5), it recursively commits all the ancestors in the DAG in a deterministic manner. Such a validity check is used to ensure there is a path (in the DAG) between a valid leader vertex and any subsequent leader vertex. For instance, if v_7 in Figure 2 is selected as the leader vertex of round $r+3$, there must be a path connecting v_7 and v_5 because v_5 is connected by $f+1$ vertices of round $r+2$ and v_7 must connect to $n-f$ vertices of round $r+2$. By ensuring this property, no one may miss or skip any valid leader vertex but commit them in the same order.

The random coin of round $r+1$ is generated when $n-f$ nodes have entered round $r+3$,[2] as the leader information should not be revealed in advance. This is to ensure with non-zero probability the selected leader vertex is valid. Otherwise, if an adversary that controls message delivery knows the coin in advance, it may always keep the corresponding leader vertex connected by less than $f+1$ vertices, forfeiting liveness properties. As the protocol proceeds round by round, with probability 1 some new leader vertex and its ancestors can be committed.

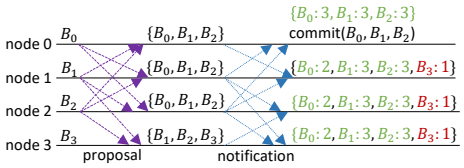
As we can observe, (1) compared to partially synchronous counterparts like PBFT, Tusk involves more rounds of message exchange, even in the absence of node/network failures; and, (2) random coins are always located on the execution path, thus making termination probabilistic. If the selected leader vertex is not valid, at least another two rounds are involved. In practice, such a delayed commit can happen when, e.g., the proposer of the leader vertex is slow or has crashed.

The design choices of Tusk (and most asynchronous protocols) are solely based on a pessimistic assumption: an adversarial scheduler can always control message scheduling at will. Hence, Tusk has only one path for committing proposals, i.e., by selecting a leader vertex with the help of random coins. In practice, such an omnipotent adversary does not (always) exist and the network performance is predictable most of the time [43, 61].

[2] At the time when most edges between rounds $r+1$ and $r+2$ are confirmed.

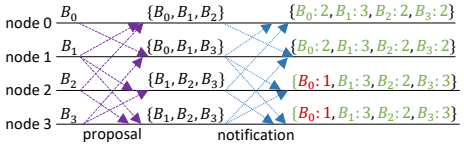
3 The Fair-Fallback Framework

3.1 Motivation and first principles of consensus



We simplify the discussion by focusing on one-shot consensus. Any solution to the multivalued consensus problem requires each *proposer* i to make a proposal B_i. After several phases of message exchange, correct nodes eventually *decide* on a single proposal or a subset of all proposals [65].

Generally, we can also consider any consensus protocol running m Binary Agreement (BA) instances (implicitly or explicitly), each of which determines the result of a given proposal. Eventually, each proposal is either committed (output 1) or aborted (output 0). Following the concept and terminology used in the seminal FLP impossibility [40], once a decision can be made, we say each proposal B_i becomes *univalent*, i.e., either *1-valent* or *0-valent*. Initially, every proposal is *bivalent*. For leader-based protocols, only a single proposal becomes 1-valent, and it is also the final decision. Other proposals are 0-valent. For leaderless variants such as asynchronous protocols, multiple proposals may become 1-valent and be included in the final decision.



We observe that the general pattern discussed above neither introduces a leader or any special role, nor does it rely on random coins to break ties. In other words, *neither any special role (or the maximum network delay Δ) nor randomization is intrinsic to the consensus problem*. If correct nodes can reach agreement of each proposal merely based on message exchange, no additional assumptions or mechanisms should be put on the execution path. If we target the more practical multi-instance consensus problem (or SMR), where a series of consensus instances are sequentially ordered, either we can consider this order obtained out-of-band (e.g., pre-defined sequence numbers), or for DAG protocols the edges in DAG natively represent the partial order between proposals. In both cases, no special role exists in consensus.

3.2 A strawman protocol

We present a simple strawman protocol to better illustrate the fast path of our approach. To simplify our discussion, we further assume (1) each node acts both as a proposer and as a validator, and (2) there is no equivocation and every node is benign (i.e., correct or crashed), though we still have $n = 3f+1$ nodes. In §4 we give full-fledged Chitu which also tolerates Byzantine faults.

(a) Node 0 decides on B_0, B_1 and B_2, while every node selects B_0, B_1 and B_2 as the candidates.

(b) Nodes 0 and 1 select B_0, B_1, B_2 and B_3 as the candidates, while nodes 2 and 3 exclude B_0.

Figure 3: Example for the strawman protocol ($n = 4$).

First, ① each (correct) node i makes a proposal B_i and propagates B_i to others. As at most f nodes may be faulty, ② after receiving $n-f$ proposals, node i casts a vote on each proposal by notifying others of all the proposals received. Finally, ③ after receiving $n-f$ such notifications (again, the other f nodes may be faulty), node i selects the proposals that have each obtained $f+1$ votes as the *candidates* for final decisions.

For each proposal B, there are three cases, where the first two are univalent:

- (**1-valent**) If at least $n-f$ nodes have notified of B, we say B is 1-valent;
- (**0-valent**) If at least $n-f$ nodes have *not* notified of B (if B exists), we say B is 0-valent; and,
- (**bivalent**) If neither of the above conditions is met, we say B is bivalent.

Fast path. If for each proposal B, B is either 1-valent or 0-valent, we can safely commit all the 1-valent proposals and abort 0-valent ones. This works because every node in step ③ will select the same candidates (i.e., only 1-valent ones). Even with further communication and/or any additional mechanism, correct nodes will eventually commit the same set of proposals. For instance, in Figure 3a, node 0 immediately commits B_0, B_1 and B_2 upon observing they are 1-valent (as included in $n-f$ notifications) and B_3 is 0-valent (as not included in $n-f$ notifications). Other nodes will only select B_0, B_1 and B_2 (but not B_3) as the candidates for further negotiations.

On the contrary, if any proposal B is bivalent, more communication and/or additional mechanism is needed in order to determine the final result of each bivalent proposal. For instance, in Figure 3b, B_1, B_2 and B_3 are 1-valent, but B_0 is bivalent. Actually, the main challenge for any (multi-instance) consensus protocol is to obtain a total order on committed proposals. Thus, the fast path of our protocol may fail due to a possible discrepancy in the final order. That is why a fallback mechanism (like leader election or random coin) is needed.

3.3 The framework

There are several ways to reach final agreement on bivalent proposals. We can repeat the notification step described in §3.2 (i.e., step ②), where each node only notifies of the selected candidates. If with *non-zero* probability each repeat results in a univalent status, the protocol can itself achieve probabilistic termination. Such a model, a.k.a., fair scheduler, was formally described in the seminal work of Bracha and Toueg [21].

However, if Byzantine nodes precisely control the delivery speed of their own messages, they may always keep their own proposals bivalent (e.g., node 0 and proposal B_0 in Figure 3b), thus breaking liveness properties. To mitigate this problem, we must rely on a fallback mechanism to break ties. We first integrated a light-weight leader into the fast path. In contrast to partially synchronous protocols, we do not rely on synchrony assumptions (or any timer) but only leverage a pre-selected leader to resolve ambiguity, which provides probabilistic termination if Byzantine nodes only manipulate the delivery speed of their own messages but not that of correct nodes.

In the worst case, if the adversary also controls message scheduling of correct nodes, some proposal may forever be bivalent and the pre-selected leader may not work. To defend against such a powerful adversary, existing asynchronous protocols explicitly introduce random coins to make correct nodes converge. Similarly, we further integrate random coins into the fast path and obtain Chitu (in a similar vein as Tusk, see §2.3), if the problem needs to be dealt with.

Maybe more interestingly, if we assume the adversary can control message scheduling but cannot (always) break synchrony assumptions, we can instead integrate Δ (the maximum network delay) into the fast path and obtain a partially synchronous protocol. Thanks to the simplicity of DAG structure, we can readily apply the fast path to Bullshark [76] by pre-selecting a leader in a round-robin fashion and waiting Δ time for each leader vertex. We may even remove timeouts (but keep leaders) and obtain an asynchronous protocol under fair schedulers [21], which refrains from using a burdensome random number generation protocol (e.g., threshold signature). Since they share very similar features with Chitu, in this paper we only focus on Chitu. Note that in all above-mentioned protocols a fallback mechanism (i.e., random coins or pre-selected leaders) is needed *only if* some proposals are bivalent. The framework we use is depicted in Figure 4.

Generalization of the fast path. There can be different ways to instantiate the fast path. In §3.2 (and §4) we only give one concrete solution. Generally, assume the conditions for the fast path to commit a proposal are denoted as $\mathcal{CON}_{\mathcal{C}}$ (e.g., 1-valent ones in §3.2), while the conditions for the fast path to abort a proposal are $\mathcal{CON}_{\mathcal{A}}$ (e.g., 0-valent ones in §3.2). Further assume the conditions for the fallback to commit a proposal are $\mathcal{CON}_{\mathcal{F}}$. Then, the following two invariants must

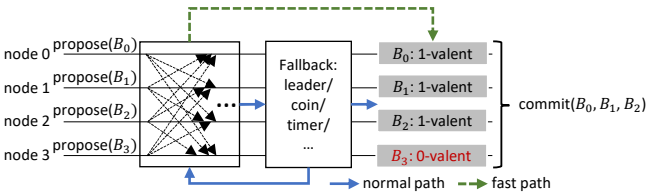


Figure 4: The Fair-Fallback framework.

hold:

- If any proposal B satisfies $\mathcal{CON}_{\mathcal{C}}$, then B must also satisfy $\mathcal{CON}_{\mathcal{F}}$; and,
- If any proposal B satisfies $\mathcal{CON}_{\mathcal{A}}$, then B must *not* satisfy $\mathcal{CON}_{\mathcal{F}}$.

These two variants guarantee that even if some nodes go through the fast path, while others proceed by the fallback, they still obtain the same result for each proposal.

There are two remaining questions: (1) how to ensure safety properties under Byzantine faults; and, (2) how to efficiently integrate the fast path into a fallback mechanism, such that there is no switch between two paths and each path commits the same set of proposals. For the first question, every message in our strawman protocol (i.e., proposal and notification) is disseminated through a Byzantine Reliable Broadcast (BRB) protocol, such that a Byzantine sender cannot make correct nodes deliver distinct messages. For the second question, our full-fledged solution (see §4) is inspired by recently-proposed DAG protocols [32, 53, 76]. The fallback mechanism (i.e., the selected leader vertices) is embedded into the dynamic construction of DAG, enabling consensus to be achieved without sending extra messages, so is the fast path. With the same DAG and the same leader selected by random coins, no matter whether nodes proceed through the fast path or the fallback, they commit the same set of (1-valent) proposals.

4 The Chitu Protocol

Chitu is inspired by Tusk [32] and DAG-Rider [53], both of which adopt DAG as the underlying structure. Chitu differs from Tusk and DAG-Rider in that it is further enhanced by a fast path relying on no special role. In the best case, Chitu takes only four communication phases to commit a proposal. In the following, we first discuss the main idea of Chitu in §4.1. We then describe the detail of Chitu in §4.2-§4.5 and sketch its proof in §4.6. We postpone its pseudocode and correctness proof to Appendices A and B due to space limit.

4.1 Main idea

Chitu dynamically constructs a DAG in a round-by-round manner. In each round, every (correct) node proposes a vertex in the DAG and propagates it to others via a Byzantine Reliable Broadcast (BRB) protocol (see §4.2 for details). BRB guarantees that the sender can make at most one vertex delivered in a round. Hence, each round has at most $n = 3f+1$ and at least $n-f = 2f+1$ vertices delivered via BRB. A vertex v in round r has at least $n-f$ edges connecting to vertices associated with round $r-1$. For ease of explanation, we first give the following definition:

Definition 4.1 (Observe)**.** *We say vertex v in round r observes vertex u in round $r' < r$, if there is a path (in the DAG) from v to u.*

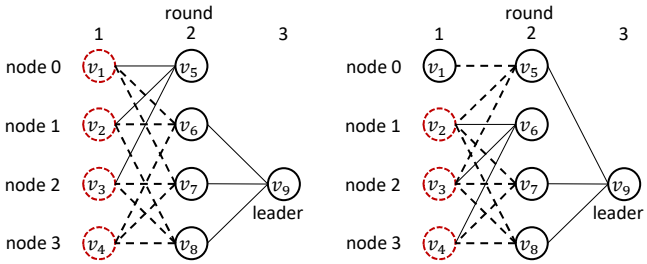
The first challenge for Chitu is to embed the message pattern of our strawman approach (§3.2) into a DAG structure, as consensus instances in DAG are naturally pipelined. To this end, a vertex v in round r simultaneously represents a proposal (of round r) and a notification of the proposals (of round $r-1$) observed by v. Besides, as discussed in §2.3, the selected leader vertices in DAG solely determine the set of committed (or 1-valent) proposals, which are ancestors of leaders. When the fast path is enabled, each leader must be able to distinguish between 1-valent and 0-valent vertices and commits only 1-valent ones.

Assume vertices u and u' are in round r and vertex v is in round $r+2$. We note that when u is observed by $n-f$ vertices of round $r+1$ (denoted as group $\mathcal{G}$), at least $f+1$ of those are observed by v. This is because every vertex in round $r+2$ (e.g., v) observes $n-f = 2f+1$ vertices, among which at least $f+1$ are in $\mathcal{G}$. On the contrary, if at least $n-f$ vertices of round $r+1$ have not observed u', there exist *no* $f+1$ vertices (of round $r+1$) observing u'. The above-mentioned properties provide us a way to distinguish between 1-valent and 0-valent vertices.

We say a node i *decides* a round r, if every proposal of round r has been decided univalent from i's perspective. Round r can be decided in either of the following two ways:

1. (fast path) when vertices of round $r+1$ help decide round r; and,
2. (normal path) when a selected leader of round $r' > r+1$ helps decide round r.

To ensure the safety property, the following invariant must hold:



Invariant 4.1. *For any round r, if a group of vertices $\mathcal{V}$ is decided 1-valent by node i via the fast path, while a group of vertices $\mathcal{V}'$ is decided 1-valent by node j via the normal path, then $\mathcal{V} = \mathcal{V}'$.*

We then give the following definition.

Definition 4.2 (Strongly observe)**.** *We say vertex v in round $r' \geq r+2$ strongly observes vertex u in round r, if there are (at least) $f+1$ vertices of round $r+1$ connecting v and u.*

Correspondingly, we have the following important invariants:

Invariant 4.2. *if vertex u in round r is observed by $2f+1$ vertices of round $r+1$, then every vertex of round $r' \geq r+2$ strongly observes u.*

(a) Case I: all 1-valent (b) Case II: some 0-valent (v_1)

Figure 5: Example for Chitu fast path ($n = 4$). Dotted circles denote 1-valent vertices, while dotted lines denote edges enabling the leader vertex to commit the same set of vertices.

Invariant 4.3. *if vertex u' in round r is observed by less than $f+1$ vertices of round $r+1$, then no vertex of round $r' \geq r+2$ strongly observes u'.*

Invariants 4.2 and 4.3 play crucial roles in designing Chitu. For each vertex u in round r, if *either* u is observed by at least $2f+1$ vertices of round $r+1$, *or* u cannot be observed by $f+1$ vertices of round $r+1$, round r can be decided. In this case, if node i decides round r but node j (temporarily) skips round r and decides $r+2$, any vertex in round $r+2$ can distinguish between those that are strongly observed and those not, and *only decide strongly observed ones in round r*. Generally, the leader of round $r' = r+2k$ ($k \in \mathbb{N}^+$) can help decide round r in an indirect way. Figure 5 gives an example.

4.2 DAG construction

Each vertex v represents a proposal broadcast by a single node. It contains basic information such as a round number r, a source which identifies the node who created v, a block of transactions, and, most importantly, a set of edges which refer to vertices of the last round. Each node maintains a local copy of the DAG according to messages it receives. A vertex v is added into the DAG if v is delivered by BRB. A node i enters round $r+1$ and makes a new proposal if node i has delivered $n-f$ vertices of round r.

Reliable Broadcast (BRB). In Chitu reliable broadcast protocol, a vertex goes through two communication phases. We denote two types of messages by VAL and PREPARE. Each node i first broadcasts a VAL message when starting a new round r, containing a new vertex v proposed by i. Upon receiving VAL message or $f+1$ PREPARE messages for the same vertex v, node i checks the validity and broadcasts a signed PREPARE message. As an optimization, $f+1$ PREPARE messages guarantee that the corresponding VAL message is received by at least one correct node and hence can be received by i eventually. Upon receiving $n-f$ PREPARE messages for the same vertex v, v can be delivered, i.e. added into the local DAG. Note that if node i receives v from node j but has not delivered some vertex v' connected by v, it can ask j for v' that must be in j's local DAG. After each of $n-f$ vertices in round r collects $n-f$ PREPARE messages, node i can advance to the next round (§4.4 presents an optimization that delays the advancement).

Weak edges. As $n-f$ nodes may quickly move forward, vertices proposed by other slow nodes may be constantly ignored. To solve this problem, Chitu can also leverage *weak edges* proposed in DAG-rider [53], enabling vertex v in round r to weakly connect to vertex v' in round $r' < r-1$. Then, v' can be committed if v is committed. Since vertices proposed by a single node are chained and totally ordered, each vertex only needs to connect to at most $n = 3f+1$ vertices in previous rounds, each of which is from a different node.

4.3 Commit rules

Each node decides vertices round by round merely based on its local view of the DAG. For a vertex v in round r, it connects at least $n-f$ vertices of round $r-1$, which can be considered the proposer of v votes for vertices connected by v but vetoes others not.

Fast path. Through the fast path, round $r+1$ helps decide round r when node i delivers $n-f$ or more vertices of round $r+1$. We denote three statuses for a vertex v in round r:

- *1-valent*: v is 1-valent if at least $n-f$ vertices of round $r+1$ observe v.
- *0-valent*: v is 0-valent if at least $n-f$ vertices of round $r+1$ do not observe v.
- *bivalent*: v is bivalent if it is possible that more than f but less than $n-f$ vertices of round $r+1$ observe v.

Both 1-valent and 0-valent are univalent, while bivalent indicates that v is temporarily unsettled and may need to wait for decisions of subsequent rounds. The local DAG of node i changes dynamically, so the status of each vertex may also change as i keeps delivering new vertices. However, 1-valent and 0-valent are incompatible, meaning that if some correct node decides vertex v 1-valent, no correct node may ever decides v 0-valent (but v can be bivalent temporarily). *If every vertex v in round r is decided univalent*, node i can *decide* round r with all the 1-valent vertices (due to Invariants 4.2 and 4.3 in §4.1).

Normal path. Chitu selects leaders by random coins (like Tusk) to survive malicious schedulers that can totally control message delivery. Leader vertices are used to (recursively) decide preceding rounds, if the fast path does not work.

In the same vein as DAG-Rider and Tusk, we say a leader vertex v in round r is *valid*, if (1) v is observed by at least $f+1$ vertices of round $r+1$, or (2) v is observed by the next valid leader vertex in round $r' = r+2k$ ($k \in \mathbb{N}^+$). Note that in Chitu leader vertices in odd (even) rounds only decide vertices in odd (even) rounds, i.e., odd and even rounds are separated. This is because two leader vertices in consecutive rounds, e.g., round r and $r+1$, may not have a path in the DAG. With a

valid leader vertex v in even (odd) round r, a node decides all the previous even (odd) rounds that have not be decided. Like Tusk, these rounds are decided recursively. Each round is decided either by v, or by v' that is made valid by v (i.e., observed by v). In each round, every vertex strongly observed by v (or v') is decided 1-valent while the others are decided 0-valent. Such a rule ensures that *every round is decided either by the fast path or by the same leader vertex*.

Finally, node i commits round r if (1) all the preceding rounds are committed; and (2) round r is decided. That is to say, each node must commit rounds sequentially, though odd and even rounds are decided independently. Once round r is committed, all the ancestors of the 1-valent vertices of round r are also committed indirectly, thanks to DAG structure.

Leader selection. When $n-f$ vertices in round $r+1$ are delivered, node i broadcasts its signature share (for threshold signatures) and later determines the leader vertex of round r. With the help of the leader vertex, node i tries to decide round $r-2$ and all the preceding odd (or even) rounds recursively. Finally, if round r and every preceding round $r' < r$ are decided, node i commits rounds sequentially till round r. Figure 6 depicts an example for Chitu commit rules.

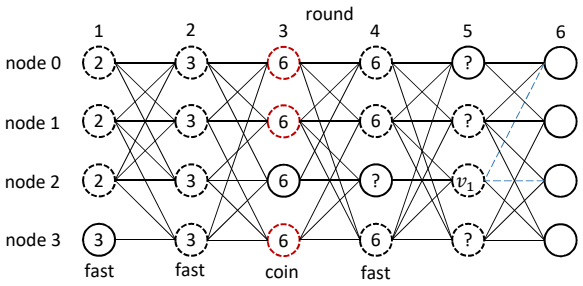


Figure 6: An example for commit rules of Chitu. Dotted circles denote strongly observed vertices in each round. The number in each circle denotes the round after which the corresponding vertex is committed. Rounds 1 and 2 are decided through the fast path, and thus their strongly observed vertices are committed immediately. In round 1, the vertex proposed by node 3 is committed indirectly by round 2, as it is observed by the strongly observed vertices of round 2. Since round 3 is decided through random coins, even if round 4 is decided through the fast path, it cannot be committed until the leader vertex v_1 of round 5 is selected, which decides round 3. In round 3, the vertex proposed by node 2 can also be committed because it is observed by a strongly observed vertex (node 0) in round 4.

4.4 Adaptive wait

Motivation. Consider the DAG construction stated in §4.2, each vertex is, on average, connected by $n-f$ vertices of the next round, which is exactly the 1-valent condition via the fast path. However, due to discrepancy in latency between nodes, some vertices may be connected by more than $n-f$ edges while others are not. Those connected by more than f but less than $n-f$ edges cannot be decided via the fast path. To mitigate this problem, intuitively more edges are needed to help those vertices become 1-valent, *by nodes trying to wait for more than $n-f$ vertices delivered to advance to the next round*. It is irrational to simply (re-)introduce a timeout mechanism (i.e. waiting Δ time) here, for a deterministic timeout is always an inevitable barricade on the fast path. It is also difficult to quantify Δ in unstable asynchronous networks. Besides, we must guarantee that such a wait will not prevent correct nodes from proceeding.

Adaptive mechanism. We observe that any vertex v received by $f+1$ nodes can be propagated to every correct node eventually (even with f faults). We say this kind of vertices are *pre-accepted*. In our adaptive wait mechanism, a node i keeps waiting for every pre-accepted vertex v to be delivered (through BRB), *so long as* the sender of v does not broadcast two distinct vertices in a round. Such an adaptive mechanism creates a gap between when a node i delivers $n-f$ vertices of round r and when i enters round $r+1$, effectively increasing the chance of connecting more vertices in round r. Besides, since i keeps receiving new messages while waiting, i may notice more pre-accepted vertices to wait for.

To guarantee that every pre-accepted vertex v can be delivered or an equivocation can be detected, node i needs to forward the VAL and $f+1$ PREPARE messages for v to all the other nodes while waiting. This forwarding scheme enables other (correct) nodes to vote for v or detect the malicious behavior of the sender of v. In the first case, all correct nodes eventually collect $n-f$ PREPARE messages for v; in the second case, all correct nodes stop waiting for v and enter the next round if no other pre-accepted vertex exists.

4.5 Performance analysis

We first analyze the performance of Chitu and Tusk (see Table 1). Chitu has a fast path that can quickly commit all vertices in 2 rounds. Specifically, when f nodes crash, Chitu always goes through the fast path. Through random coins, the probability to select a valid leader vertex is at least $\frac{f+1}{3f+1} > \frac{1}{3}$. Thus, in expectation, there exists a valid leader vertex in every three odd (even) rounds. Chitu can commit a round r only if both odd and even rounds after r select a valid leader vertex. Therefore, Chitu commits a round in every six rounds through random coins. Tusk has the same expected time complexity (through random coins), though it selects a leader vertex in every odd round. Chitu introduces an all-to-all message pattern in its Byzantine Reliable Broadcast (BRB), and thus has $O(n^2)$ message complexity and 2 message delays per round. As for communication complexity, each vertex v in round $r+1$ must connect to at least $2f+1$ vertices in round r, each of which contains $2f+1$ signatures. The complexity of each VAL messages is $O(n^2)$. Every node is allowed to propose

a new vertex in each round, thus the total communication complexity is $O(n^4)$ as the expected time complexity is $O(1)$. Tusk has the same communication complexity due to the same reason.

Table 1: Performance analysis of Chitu and Tusk. Note that the worst case indicates time complexity (message delays) in expectation.

	Best case	Normal case	Worst case	Message complexity	Communication complexity
Chitu	4	9	15	$O(n^3)$	$O(n^4)$
Tusk	14.5	14.5	25	$O(n^2)$	$O(n^4)$

Furthermore, Table 2 compares Chitu, MyTumbler and Red-Belly regarding their time complexities (message delays), as they all adopt the Fair-Fallback Framework.

Table 2: Performance analysis of the protocols following the Fair-Fallback framework.

	Best case	Worst case	Timing model
Chitu	4	$O(1)$	asynchrony
MyTumbler	4	$O(\log_2 n)$	asynchrony
Red Belly	4	-	partial synchrony

MyTumbler uses SuperMA, a multi-valued agreement protocol to commit proposals in three message delays in the best case, and another one message delay to pass timestamps for execution. If an adversary totally controls message scheduling, however, MyTumbler explicitly runs n asynchronous binary agreement instances, each within a SuperMA instance and has $O(1)$ time complexity in expectation, resulting in at least $O(\log_2 n)$ time complexity in total. Red Belly also commits proposals in four message delays in the best case, i.e., Propose, Echo, Ready and Decide. Red Belly further uses DBFT, a partially synchronous binary agreement protocol, to resolve ambiguity. DBFT selects a weak coordinator to suggest a value. It is not straightforward or fair to compare the worst-case performance between partially synchronous (Red Belly) and asynchronous (Chitu and MyTumbler) protocols as they target different timing models. In summary, the key advantages of Chitu over MyTumbler are the worst-case performance and simplicity (thanks to DAG). Unlike Red Belly, Chitu provides liveness under asynchrony and has no timers on the execution path.

4.6 Sketch of proof

Safety. First, BRB guarantees that any node can make at most one vertex delivered in a round and correct nodes will not deliver different vertices proposed by the same node. Then, since Chitu commits vertices round by round, we prove that in each round the same set of vertices are decided 1-valent, no matter via the normal path or the fast path. Assume nodes i and j decide $\mathcal{V}$ and $\mathcal{V}'$ in round r, respectively.

Case I: Both i and j decide round r via the normal path. W.l.o.g, assume i decides $\mathcal{V}$ by the leader vertex v_1 in round $r_1 \geq r+2$, while j decides $\mathcal{V}'$ by the leader vertex v_2 in round $r_2 \geq r_1+2$. v_1 is observed by $f+1$ vertices of round r_1+1, and v_2 observes at least $2f+1$ vertices in round r_1+1. Since $(f+1)+(2f+1) > 3f+1$, v_1 is observed by v_2. Recursively, j must decide round r by the leader vertex v_1 but not v_2.

Case II: i decides round r via the normal path, while j decides round r via the fast path. Assume i decides $\mathcal{V}$ by the leader vertex v_l in round $r' \geq r+2$, which observes at least $2f+1$ vertices in round $r+1$. For any $v \in \mathcal{V}'$, v is observed by at least $2f+1$ vertices in round $r+1$. Since these two groups of $2f+1$ vertices intersect at $f+1$ vertices, by Definition 4.2 v is strongly observed by v_l, i.e., $v \in \mathcal{V}$. In contrast, for any $v' \notin \mathcal{V}'$, v' is obeserved by less than $f+1$ vertices in round $r+1$, and thus v' cannot be strongly observed by v_l, i.e., $v' \notin \mathcal{V}$. Therefore, $\mathcal{V} = \mathcal{V}'$.

Case III: Both i and j decide round r via the fast path. Assume there exists a vertex $v \in \mathcal{V}$ but $v \notin \mathcal{V}'$. In i's view v is observed by at least $2f+1$ vertices in round $r+1$, while in j's view v is not observed by at least $2f+1$ vertices in round $r+1$. Since these two groups of $2f+1$ vertices intersect at $f+1$ vertices, at least one correct node proposes two different vertices in round $r+1$. A contradiction. For each vertex, any two correct nodes must decide it with the same univalent status, and thus all 1-valent vertices and their causal histories are committed in the same order.

Liveness. We first argue that for every round r, there are at least $f+1$ vertices strongly observed by the next valid leader vertex v_l in round $r+2k$ ($k \in \mathbb{N}^+$). At least $2f+1$ vertices in round $r+1$ are observed by v_l, denoted by $\mathcal{G}$. The total number of edges $\mathcal{G}$ provides to round r is at least $(2f+1)|\mathcal{G}|$. By Definition 4.2, a vertex in round r is strongly observed by v_l if observed by at least $f+1$ vertices in $\mathcal{G}$. In round r, if only f vertices are strongly observed by v_l and observed by all vertices in $\mathcal{G}$ using the most edges, and the rest $2f+1$ vertices are observed by only f vertices in $\mathcal{G}$, the total number of edges is $f|\mathcal{G}|+(2f+1)f \leq f|\mathcal{G}|+|\mathcal{G}|f = 2f|\mathcal{G}| < (2f+1)|\mathcal{G}|$. Thus, there are at least $f+1$ vertices strongly observed by v_l, i.e., satisfying the rule of valid leaders. Since the adversary cannot know the leader of round r until $2f+1$ vertices of round $r+1$ are delivered, it is impossible to control their edges to impede it becoming valid. Thus, the probability to select a valid leader is at least $\frac{f+1}{3f+1} > \frac{1}{3}$. As the protocol runs round by round, with probability 1 the leader of some round r is valid, and then all rounds $r-2k$ ($k \in \mathbb{N}^+$) are decided.

5 Performance Evaluation

We implement Chitu in Golang, using noise [7] for asynchronous networking. We use SHA256 to compute hash values and Ed25519 to sign and verify sig-

natures, implemented by Golang crypto library. Boneh-Lynn-Shacham (BLS) threshold signatures are used to construct random coins, computed by bls-eth-go-binary [2]. GoGo Protobuf [5] library is used for serialization. The code is available at https://github.com/Decentralized-Computing-Lab/ChituBFT.

We compare Chitu to Tusk [32] and BullShark [76], two representative DAG-based BFT protocols, with open-source implementations [3, 6]. Tusk and BullShark have the same structured DAG provided by Narwhal [32] but with different consensus protocols. Narwhal introduces additional worker nodes to disseminate blocks separately, leaving the primary nodes only running consensus protocol.

We run experiments on AWS EC2, with t3.2xlarge instances with 8 vCPUs, 32 GiB RAM and 5 Gbps Network burst bandwidth, running Ubuntu 22.04.4 LTS. Nodes and clients are deployed over 5 different regions across the globe: Ohio, Singapore, Tokyo, Canada (Central) and Frankfurt. The average RTT among 5 regions is 135 ms. For each node, there is a client running in the same region and sending a given number of requests to it per 50 ms (i.e. client rate). Each node gathers requests into blocks and proposes them when a new vertex is generated. We measure end-to-end latency as the time elapsed from when the client sends its request till when the client receives the confirmation from the same node. In all experiments, we set request size to 1000 B, which represents the trend towards larger transactions for Blockchain applications such as Bitcoin [1] and Ethereum [4].

5.1 Fault-free performance

We first compare the performance of Chitu, Tusk and BullShark when there is no fault. We gradually increase the rate that clients send requests until the system is saturated. We run experiments at different scales ($n = 4$, $n = 10$ and $n = 100$). When $n = 4$, nodes and clients are deployed in Ohio, Singapore, Tokyo and Frankfurt.

Figures 7 to 9 show the results. The end-to-end latency of Chitu is around 500 ms when the system is not saturated. Compared to Tusk, Chitu achieves up to 82.5% (440 ms versus 2519 ms) and 82.2% (485 ms versus 2729 ms) reduction in latency when each client sends 100 requests for every 50 ms, when $n = 4$ and $n = 10$ respectively. This is due to three reasons. First, most vertices in Chitu are committed via the fast path at small scales, where in the best case only four communication phases (i.e. two DAG rounds) are taken and random coins are bypassed. Second, in the normal path, the probability to select a valid leader is higher in Chitu than in Tusk and BullShark, for more edges are connected between rounds thanks to the wait mechanism. Third, Chitu trades off message complexity for less communication phases per round. With the moderately large number of nodes, the latency of Chitu is still much lower than that of Tusk and BullShark, with around 50% vertices committed via the fast path when $n = 100$.

Limitation. The percentage of fast-path commits becomes lower as the scale grows. Assume the evolvement of each vertex is an independent event, and the probability of a vertex being connected by more than $2f$ or less than $f+1$ vertices (i.e., 1-valent or 0-valent) is p. As the number of nodes grows, the probability that a round goes through the fast path is thus p^n, impeding larger-scale deployments. A possible solution to mitigate this problem is to select a subset of nodes as proposers while leaving others as validators, a typical way permissionless blockchains adopt to achieve scalability [42, 49]. We however leave this direction to future work.

BullShark has lower latency than Tusk since BullShark preselects a leader in each odd round and can commit vertices within 3.5 DAG rounds, while Tusk has to go through random coins and selects a valid leader every six rounds in expectation. Chitu has the advantage over BullShark not only in taking fewer rounds to commit vertices via the fast path, but also the leaderless feature and the way of advancing rounds. Nodes in BullShark additionally wait for a predefined leader to become valid (or at most Δ time), which may take longer time when the proposer of such a vertex is slow.

Wait mechanism. To further analyze the effects of the wait mechanism, we compare the average and 95%ile latency, and the percentage of fast-path commits, of Chitu with and without the wait mechanism. Figure 10 shows the result when $n = 4$ at four request rates corresponding to the points highlighted in Figure 7. With the wait mechanism, almost all vertices are committed through the fast path when the system is not saturated, achieving 99.5% when the request rate is 100 requests per 50 ms. In contrast, without the wait mechanism, only 12% vertices are committed through the fast path at the same request rate, with 1.75x latency (772 ms vs. 440 ms). This is mainly because the normal path takes eight communication phases to commit vertices. As the request rate grows, each vertex contains more requests and takes more time to propagate, which directly increases latency. Without the wait mechanism, it becomes more difficult to propagate vertices proposed by slow nodes, and hence they can be decided 0-valent via the fast path more easily. Thus, the percentage of fast-path commits becomes higher under slightly heavier workloads, but still much lower than that with the wait mechanism.

The wait mechanism helps a node observe as many vertices as possible, except those propagated by very slow nodes. These vertices may be observed by other $f+1$ but less than $n-f$ nodes also due to the wait mechanism, leading to the failure of the fast path. Thus, with the wait mechanism, the percentage of fast-path commits becomes a little lower under the heavier workload (but still around 92.5%). Moreover, as the scale grows, the probability of achieving fast termination without the wait mechanism declines rapidly. When $n = 10$, almost no round goes through the fast path without the wait mechanism, even as the request rate increases, due to the similar limitation discussed above. Therefore, the wait mechanism

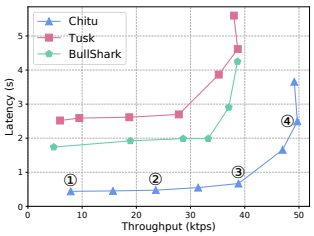

Figure 7: $n = 4$, fault-free.

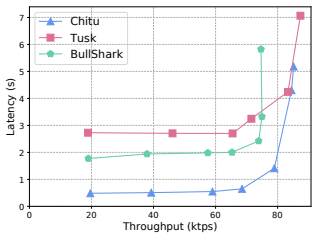

Figure 8: $n = 10$, fault-free.

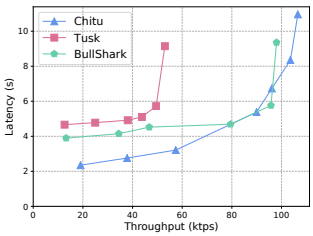

Figure 9: $n = 100$, fault-free.

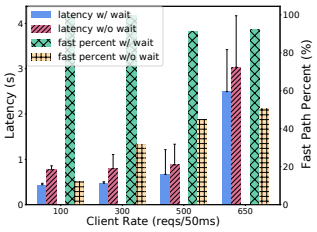

Figure 10: Performance with and without wait mechanism.

is critical for enabling the fast path.

5.2 Performance under crash faults

We then measure the performance of Chitu, Tusk and BullShark when disabling f nodes in advance, as there is no separation between normal case and view change in these protocols, i.e., Tusk, BullShark and Chitu have no failover to execute. The faulty nodes may crash or purposely keep silent. We run the experiments at different scales ($n = 4$, $n = 10$ and $n = 100$).

Figure 11 to 13 depict the results. Chitu has lower latency and higher peak throughput in this scenario. When f nodes crash, each vertex can observe only $n - f$ vertices of the last round. This implies that each vertex are observed by exactly $n - f$ vertices of the next round, and hence Chitu can completely skip random coins and terminate deterministically in this particular scenario, as no vertex is bivalent. The fast path takes four communication phases to determine that the rest f vertices (if exist) cannot be observed by more than f vertices, i.e., they must be 0-valent. However, in this scenario, each node needs to deliver vertices from all the others to advance to the next round, which may not be the fastest $n - f$ nodes in the fault-free scenario. Therefore, the latency of Chitu under the light workload slightly increases to around 550 ms at small scales. The peak throughput of all the protocols degrades in this case, as f faulty nodes cannot make proposals anymore. Nonetheless, it is noteworthy that the peak throughput of Chitu decreases by the least and is higher than the other two. This is because the wait mechanism cannot be triggered when there are only $n - f$ vertices in each round, and there is no need to forward the votes for pre-accepted vertices.

Compared to Chitu, Tusk and BullShark suffer a larger increase in latency under crash faults. Tusk always relies on random coins to terminate. With f faults, the selected leader is less likely to be valid, for with probability $\frac{1}{3}$ it is faulty. As for BullShark, such a high-latency problem even gets worse. BullShark requires each node to additionally wait Δ time, during which the pre-selected leader can be delivered. However, if the proposer is faulty (with probability $\frac{1}{3}$), such a timeout is located on the critical path. The default value of Δ is set to 5 sec in BullShark's open-source implementation. The average latency of BullShark increases to more than 5 sec at all scales. By this experiment we show the benefit of offloading the fallback mechanism when correct nodes can reach agreement leaderlessly.

5.3 Performance under Byzantine faults

Byzantine nodes may badly affect the performance of Chitu, especially by purposely disabling the fast path. Since it is difficult to manipulate message scheduling in practice, we evaluate Chitu in a typical scenario: (1) the fast path is disabled; (2) the wait mechanism is maliciously exploited by the adversary, so that each node has to deliver n vertices to advance to the next round; and, (3) Byzantine nodes disseminate their proposals with no payload and do not participate in message exchange of any proposal.

We run the experiment with $n = 10$, where one node in Canada Central and two nodes in Frankfurt are Byzantine faulty. Figure 15 depicts the results. When the system is not saturated (Figure 15a), the average latency under Byzantine faults is about 2x more than that under crash faults. This is mainly because the normal path takes 2x more communication phases than the fast path. The peak throughput (Figure 15b) moderately degrades under Byzantine faults compared to the one with f crash nodes. This is because it takes more bandwidth overhead for correct nodes to deliver the vertices proposed by Byzantine nodes, i.e. more PREPARE messages broadcast and forwarded. However, the wait mechanism also plays a role in synchronization, making slow nodes catch up with the pace of fast nodes. Therefore, the measured degradation of the peak throughput is acceptable, decreased by 5.78% (from 65.7 ktps to 61.9 ktps).

Note that one Byzantine node is sufficient to disable the fast path if the node can make its proposal bivalent (i.e., observed by more than f but less than $n - f$ vertices of the next round). In reality, initiating such an attack is a bit tricky because the Byzantine node must send its proposal at an appropriate time. Consider the all-to-all pattern of the Chitu broadcast, its adaptive wait mechanism, and even gossip-like communication in large-scale blockchains, the attack is feasible but not trivial. Nonetheless, even if the fast path is turned off, Chitu still has the fallback that provides acceptable performance.

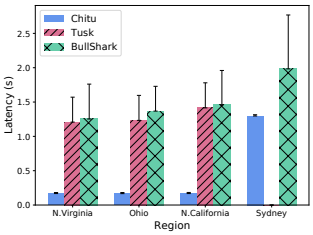

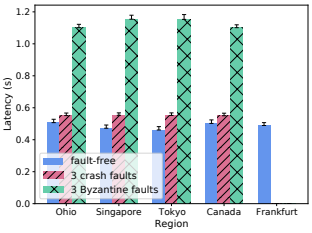

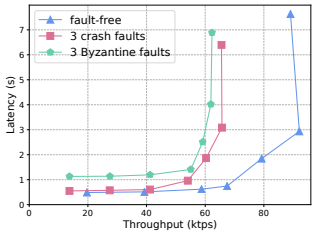

Figure 14: Performance with skewed distribution.

(a) latency on different regions

(b) latency vs. throughput

Figure 15: Performance under Byzantine faults ($n = 10$).

5.4 Performance with skewed distribution

Finally, we measure the performance of Chitu, Tusk and BullShark with more skewed node distribution. We run the experiment with $n = 4$ nodes in N.Virginia, Ohio, N.California and Sydney respectively. Three of them are in the US, with lower round-trip latency among one another, while Sydney is far away from them. We set the request rate to 50 requests per 50 ms (not saturated) and measure the average and 95%ile latency of each region.

The results are presented in Figure 14. In this particular setting, three nodes in the US are capable of pushing forward DAG construction, while the node in Sydney fails to keep pace with others. Even if Chitu has the wait mechanism, almost no vertices from Sydney are observed by those in the US, as the physical distance brings too much delay. Similarly, Tusk can move on with only three nodes in the US and hence has no data in Sydney. In contrast, BullShark and Chitu further leverage weak edges, which can connect to "outdated" vertices of previous rounds, though with a significantly increased latency.

The latency of Chitu is still lower than that of Tusk and BullShark in all regions. The reason is similar to the case when f nodes crash, where the fast path is enabled in Chitu, but proposals from the node in Sydney are committed with the help of weak edges. Tusk also outperforms BullShark in N. Virginia, Ohio and N. California. This is because BullShark periodically selects the node in Sydney as a leader, which delays the progress of the whole system. This result further demonstrates the effectiveness of the fast path in Chitu, as it relies on no special role.

6 Related Work

Partially synchronous protocols. A big family of BFT protocols are designed under partial asynchrony, where additional timing assumptions are used for electing a special role [17, 22, 27, 44, 56, 76, 80]. We argue that they prematurely rely on leader election and timing assumptions to resolve potential divergences among nodes, which are not necessary when correct nodes can quickly reach consensus in a leaderless manner. Our framework can also be applied to partially synchronous protocols, e.g., integrating the fast path with Bullshark [76] and treating leader election as a fallback mechanism.

Classical asynchronous protocols. Asynchronous protocols ensure safety and liveness properties despite network asynchrony. Asynchronous protocols can be traced back to the 1980s, when the seminal works of Rabin [72] and Ben-Or [13] were proposed. HoneyBadgerBFT [66] is considered the first practical solution, which makes use of a reliable broadcast protocol [20] and a randomized binary agreement protocol [68] to construct a common subset among all correct nodes. Since then, numerous variants [36, 46, 47, 79] are proposed, which greatly improve the performance of asynchronous protocols. However, they still put randomization on execution paths, and thus only achieve probabilistic termination. One exception is Bolt [63], a mechanism that explicitly switches between a fast pah (i.e., Fastlane in the original paper) and a pessimistic path. Bolt however reintroduces timer to trigger switching to pessimistic path. A similar idea of fast termination in Chitu can be applied to classical asynchronous protocols, which we leave for future work.

Certified DAGs. In contrast to classical protocols, DAG-based variants [11, 32, 53, 76] embed consensus into DAG construction, which not only reduces the number of messages needed, but greatly simplifies the design and implementation. Chitu, by leveraging the similar structure, also possesses the simplicity feature. In contrast to DAG-Rider [53] and Tusk [32], Chitu has the fast path that can bypass random coins. Autobahn [43] is a recently proposed DAG protocol

that incorporates a partially synchronous consensus mechanism into an asynchronous DAG construction layer, such that Autobahn can both reduce latency (compared to existing DAG protocols) and maintain the seamlessness feature of DAG protocols. Autobahn still relies on a correct leader to quickly reach consensus, while Chitu goes through the fast path in a pure leaderless manner. Shoal [75] and Shoal++ [9] leverage a reputation mechanism to select fast and stable nodes as anchors (leaders), in order to eliminate timeouts in most cases. Shoal++ further introduces a fast commit rule to quickly commit anchors. Sailfish [74] allows to select leader vertices in every round (rather than once every two or more rounds), thus reducing end-to-end latency.

Uncertified DAGs. Best Effort Broadcast (or uncertified DAG) helps reduce the number of message exchanges per round compared to certified DAG, but complicates fault handling logic as malicious nodes may send distinct proposals to different nodes. BBCA-CHAIN [64] leverages a variant of Byzantine Consistent Broadcast (BCB) named BBCA to broadcast only leader blocks, while non-leader blocks can be propagated by Best Effort Broadcast. Mahi-Mahi [51] manually configures the number of leader slots for each round and selects leaders using a global coin (randomization). Mysticeti [10] is a partially synchronous protocol that achieves three message delays in the best case. Mysticeti and Chitu share similarities in distinguishing between proposals that are observed or supported by $2f+1$ subsequent proposals and that are not observed by $2f+1$ proposals, but Mysticeti still waits timeout for a primary block of each round in order to provide liveness. In contrast to uncertified DAGs, Chitu follows the paradigm of certified DAG (like Tusk and Bullshark) and has no special role in its fast path but treats every proposal equally. We envision that by integrating the idea of Chitu into an uncertified DAG, we may further reduce commit delays for both paths.

Fast path. In recent years, numerous BFT variants [10, 18, 31, 74, 75] are proposed with a fast path. Most of them rely on a leader or some special role to coordinate consensus. Their fast path inevitably assumes the correctness of the single leader and puts Δ on the critical path, thus incurring additional waiting time if such a role crashes or be partitioned. Besides, more message delays may be introduced if they resort to a new leader to take over and move forward. The framework we study in this paper, in contrast, can quickly skip faulty or slow nodes in a responsive manner. There are three exceptions, which together motivate our study: Red Belly [30] under partial synchrony model, and HashGraph [11] and MyTumbler [62] under asynchrony model. Hashgraph uses a gossip protocol to disseminate proposals and derives consensus results from a DAG of degree two. Although the general idea of the fast path of Chitu shares similarities with Hashgraph, it may incur exponential latency [32] when some nodes are Byzantine. Therefore, integrating a fallback mechanism is critical to mitigating adverse effects on performance during an attack. Red Belly still puts timers on the fast path for aborted proposals, while Chitu can quickly terminates even if some proposals are 0-valent. MyTumbler sequences proposals based on physical timestamps and bypasses random coins when correct nodes input the same value into a binary agreement protocol. Our idea also shares similarity with MyTumbler in skipping random coins if correct nodes are convergent on a proposal, but MyTumbler relies on a binary agreement protocol to reach consensus. In the worst case, however, the time complexity of MyTumbler grows to at least $O(\log n)$ [14, 47]. Dumbo-NG [41] is an asynchronous protocol that concurrently runs transaction dissemination and asynchronous agreement, mitigating the tension between throughput and latency.

Other related work. Some BFT protocols [12, 33, 52, 59] make use of trusted hardware to prevent equivocation, so as to ensure both safety and liveness with only $n = 2f+1$ nodes. Such a model can further simplify the design of Chitu. Although we only gave the solution in permissioned settings, Chitu would be a promising approach also for permissionless blockchains [23, 39, 42, 69] when integrating with a Sybil [35] resistance measure such as Proof-of-Work [50] or Proof-of-Stake [54]. As Chitu resorts to all-to-all communication to disseminate and collect votes (PREPARE messages), its communication complexity can be further reduced by using a gossip protocol [15, 71] or threshold signatures [55].

7 Conclusion

In this paper we discussed a generic framework for reducing latency in BFT consensus protocols. We then presented Chitu, a DAG-based protocol following this framework. Chitu not only retains the simplicity feature of DAG protocols, but can also bypass expensive random coins and achieve consensus efficiently, when most nodes are in consistency about their observations. We implemented Chitu and conducted extensive experiments on Amazon EC2 platform. Through evaluation we showed that Chitu can effectively reduce latency in several typical scenarios, compared to existing DAG protocols. Our framework opens avenues for future work. Other partially synchronous or asynchronous protocols, or protocols under crash fault model, can also adopt a similar idea to achieve fast termination.

A Chitu Pseudocode

A.1 Data Structure and Utilities

The data structures and basic utilities of Chitu are specified in Algorithm 1. Each vertex v represents a proposal broadcast by a single node. It contains basic information such as a round number r, a source which identifies the node who created v, a block of transactions, and, most importantly, a set of edges which refer to vertices of the last round. Each node maintains a local copy of the DAG according to messages it delivers. For each node i, we denote its local view of the DAG as $DAG[*]$. $DAG[r]$ for $r \in \mathbb{N}^+$ stores a set of vertices that nodes generated in round r and delivered by i. $txsToPropose$ is a queue that stores valid transactions from clients.

Function path(u,v) is used to check whether there is a path from vertex u to vertex v in the DAG (Line 1), while Function createVertex(r) is used to create a vertex with basic information (Line 3). Function getLeaderVertex(r) computes the selected leader of round r and returns the vertex if it is delivered (Line 10). Otherwise, it returns $\perp$. The leader of round r is determined by a random coin.

A.2 DAG Construction

In Chitu Reliable Broadcast protocol, a vertex goes through two communication phases. The pseudocode is given in Algorithm 2. We denote two types of messages by VAL and PREPARE. Node i first broadcasts a VAL message when starting a new round r, containing a new vertex v proposed by it (Line 1-3). Upon receiving VAL message or $f+1$ PREPARE messages for the same vertex v, node i checks the validity and broadcasts a signed PREPARE message (Line 4-5). Here, $f+1$ PREPARE messages guarantee that the corresponding VAL message is received by at least one correct node and hence will be received by i definitely. Upon receiving $n-f$ PREPARE messages for the same vertex v, v can be delivered, i.e. added into the local DAG (Line 6-7). Note that if node i receives v from node j but has not delivered some vertex v' connected by v, it can ask j for v' that must be in j's local DAG. Procedure advanceRound(r) is called after each of $n-f$ vertices in round r collects $n-f$ PREPARE messages, i.e., when $|DAG[r]| = n-f$ (Line 8-9).

A.3 Commit Rules

The pseudocode of commit rules for node i is given in Algorithm 3. Every time a new vertex is added in round $r+1$, Procedure tryFastPath(r) is called to check whether round r satisfies the rules for the fast path (Line 1-5). Moreover, i also tries to decide round $r-2$ and its preceding odd (or even) rounds the with the help of the leader vertex in round r(Line 6-9). When there exist $n-f$ vertices in round $r+1$, node i can

broadcast its signature share (for threshold signatures) and later determine the leader vertex of round r (Line 7). Procedure decideLeaderPath(v_l, r_l) recursively decides all the preceding odd (or even) rounds by leaders (Line 10-17). Finally, if round r and all rounds $r' < r$ are decided, node i commits rounds sequentially to round r.

B Chitu Correctness Proof

We formally prove the safety and liveness properties of Chitu.

B.1 Safety

We first give the agreement proof of the normal path in Chitu.

Lemma B.1. *If a leader vertex v in round r is valid, then any valid leader vertex v' in the future round $r+2k$ $(k \in \mathbb{N}^+)$ has a path to v.*

Proof. The leader vertex v is valid only if v is observed by at least $f+1$ vertices in round $r+1$. Since every vertex must connect to at least $2f+1$ vertices in the previous round, there are at least $2f+1$ vertices in round $r+1$ observed by v' in round $r+2$. Considering the vertices in round $r+1$ have an intersection by $(2f+1)+(f+1) > 3f+1$, v' must have a path via at least 1 vertex in round $r+1$ to v. By induction, any valid leader vertex v' in round $r+2k$ $(k \in \mathbb{N}^+)$ must have a path to v. □

Lemma B.2. *Let v_1 and v_2 be the valid leader vertices in round r and $r+2k$ $(k \in \mathbb{N}^+)$, respectively. If a correct node enters the decide phase by v_1 before v_2, then no other correct nodes enter the decide phase by v_1 after v_2.*

Proof. We prove this lemma by contradiction. Since v_1 is selected to decide before v_2, there is no directed path from v_1 to v_2 in the DAG. If some correct node enters the decide phase by v_1 after v_2, then there is no path from v_2 to v_1. However, by Lemma B.1, there must exist a path from one of them to the other. A contradiction. □

Theorem B.1 (Agreement of the normal path)**.** *For each vertex, any two correct nodes decide it to the same univalent status through the normal path.*

Proof. If a correct node enters the decide phase by some valid leader vertex v in round r, by Lemma B.1 all valid leader vertices in round $r-2k$ $(k \in \mathbb{N}^+)$ are learned. Then, with Lemma B.2, any two correct nodes enter the decide phase by all valid leader vertices in the same sequence, for odd rounds and even rounds respectively. Since it can be seen as pipelining to decide odd rounds and even rounds, the decide results on these two are independent. Therefore, any two correct nodes decide each round by the same leader vertex, and hence decide the same univalent status on each vertex in each round. □

Theorem B.1 guarantees the agreement of the normal path in Chitu. Then we prove the agreement of the fast path and the normal path.

Lemma B.3. *If a correct node considers a vertex v in round r 1-valent through the fast path, then no other correct nodes consider v 0-valent through the fast path, and vice versa.*

Proof. We prove this lemma by contradiction. a correct node considers v 1-valent through the fast path only if at least $2f+1$ vertices in round $r+1$ observe v. Assume v is considered 0-valent by some correct node through the fast path, then at least $2f+1$ vertices in round $r+1$ do not observe v. The number of vertices in round $r+1$ is $(2f+1)+(2f+1) > 3f+1$. A contradiction. □

Lemma B.4. *If a vertex v in round r is considered 1-valent through the fast path, then v is strongly observed by the next valid leader vertex v_l in round $r+2k$ $(k \in \mathbb{N}^+)$ through the normal path.*

Proof. We prove this lemma by contradiction. v is considered 1-valent only if at least $2f+1$ vertices in round $r+1$ observe v. Denote by S the set of vertices in round $r+1$ observed by v_l, $|S| \geq 2f+1$. Assuming v is not strongly observed by v_l, by Definition 4.2 there are less than $f+1$ vertices in S that observe v. Thus, at least $f+1$ vertices in S do not observe v. The number of vertices in round $r+1$ is $(2f+1)+(f+1) > 3f+1$. A contradiction. □

Lemma B.5. *If a vertex v in round r is considered 0-valent through the fast path, then v cannot be strongly observed by the next valid leader vertex v_l in round $r+2k$ $(k \in \mathbb{N}^+)$ through the normal path.*

Proof. We prove this lemma by contradiction. v is considered 0-valent only if at least $2f+1$ vertices in round $r+1$ do not observe v. Denote by S the set of $2f+1$ vertices in round $r+1$ observed by v_l. Assuming v is strongly observed by v_l, by Definition 4.2 there are at least $f+1$ vertices in S that observe v. The number of vertices in round $r+1$ is $(2f+1)+(f+1) > 3f+1$. A contradiction. □

We give the total agreement of Chitu through different commit paths:

Theorem B.2 (Agreement of different paths)**.** *For each vertex, any two correct nodes decide it to the same univalent status.*

Proof. Let i and j be two correct nodes. We prove this theorem in three cases.

Case I: Both i and j decide vertex v through the fast path. By Lemma B.3, v is decided to the same status by i and j.

Case II: i decides vertex v through the fast path while j decides v through the normal path. By Lemma B.4 and Lemma B.5, if v is considered 1-valent (0-valent) by i through the fast path, then v can (cannot) be strongly observed by the

next valid leader vertex in j's view. Thus, v can be decided to the same status as i by j through the normal path.

Case III: Both i and j decide vertex v through the normal path. By Theorem B.1, v is decided to the same status by i and j. □

Theorem B.3 (Total order)**.** *Any two correct nodes commit vertices with the same order.*

Proof. Chitu commits vertices round by round consecutively. By Theorem B.2, any two correct nodes have the same decide result on each vertex, and hence can commit all vertices that are decided 1-valent with the same pre-defined order in each round. In the meantime, the causal history of these vertices are also committed with the same order. Therefore, Chitu satisfies total order. □

B.2 Liveness

Lemma B.6. *For every round r, there are at least $f+1$ vertices strongly observed by the next valid leader vertex v_l in round $r+2k$ ($k \in \mathbb{N}^+$).*

Proof. A vertex must connect to at least $2f+1$ vertices in the previous round. Denote by S the set of vertices in round $r+1$ observed by v_l, $|S| \geq 2f+1$. The total number of edges S provide to round r is at least $(2f+1)|S|$. By Definition 4.2, a vertex in round r is strongly observed by v_l if it is observed by at least $f+1$ vertices in S. There are at most $3f+1$ vertices in round r. Therefore, if only f vertices in round r are strongly observed by v_l, which are observed by all vertices in S using the most edges, and the rest $2f+1$ vertices in round r are observed by only f vertices in S, the maximum total number of edges is $f|S|+(2f+1)f \leq f|S|+|S|f = 2f|S| < (2f+1)|S|$. Thus, there are at least $f+1$ vertices strongly observed by v_l. □

Lemma B.6 shows that for every round r there are at least $f+1$ vertices each observed by at least $f+1$ vertices in round $r+1$. This connection feature is the same as the rules of valid leaders, i.e., a leader vertex v_l in round r is valid if v_l is observed by at least $f+1$ vertices in round $r+1$. Then the following lemma is simply derived.

Lemma B.7. *For every round r, there are at least $f+1$ vertices that satisfy the rules of valid leaders.*

Theorem B.4 (Termination of leader selection)**.** *In expectation, Chitu selects a valid leader vertex for odd (even) rounds every 6 rounds in the DAG under an asynchronous adversary.*

Proof. To select a leader vertex in round r, the random coin is generated when $2f+1$ vertices in round $r+1$ are added to the DAG. Only after the DAG of the next round is fixed can the adversary identify the leader of the round before, so that it is impossible to manipulate the edges connected to the leader. Since by Lemma B.7 at least $f+1$ vertices in each round satisfy the rules of valid leaders and the coin is uniformly distributed, the probability to select a valid leader in each selection is at least $\frac{f+1}{3f+1} > \frac{1}{3}$. Thus, in expectation, there exists a valid leader every 3 selections. Since each selection takes 2 rounds, and Chitu selects leaders for odd rounds and even rounds respectively, in expectation, a valid leader for odd (even) rounds is selected every 6 rounds in the DAG. □

Lemma B.8. *If a leader vertex v in round r is valid, then any vertex in round $r-2k$ ($k \in \mathbb{N}^+$) is decided to a univalent status.*

Proof. By Lemma B.1, all valid leaders in round $r-2k$ ($k \in \mathbb{N}^+$) can be learned, and hence all vertices in round $r-2k$ ($k \in \mathbb{N}^+$) are decided to a univalent status. □

Theorem B.5 (Termination)**.** *In networks with random message delays, in expectation, Chitu decides each vertex to a univalent status within less than 5 rounds in the DAG.*

Proof. Let v_l be the leader vertex in round r selected through random coins. Since message delays are distributed uniformly, each vertex in round $r+1$ connects to at least $2f+1$ vertices in round r independently of other vertices in round $r+1$. Therefore, the probability that each vertex in round $r+1$ observes v_l is at least $\frac{2f+1}{3f+1} > \frac{2}{3}$. Considering v_l is valid if it is observed by at least $f+1$ vertices in round $r+1$, the probability that an selected leader can be valid is at least $\sum_{k=f+1}^{2f+1} \binom{2f+1}{k} \left(\frac{2}{3}\right)^k \left(\frac{1}{3}\right)^{2f+1-k}$. Since this probability increases as f grows, we can compute that the minimum probability is $\frac{12}{27} + \frac{8}{27} = 0.74$ when $f=1$. Thus, in expectation, an selected leader is valid every $\frac{1}{0.74} = 1.35$ selections, i.e. $1.35 \times 2 = 2.7$ rounds, at most. Then, by Lemma B.8 each vertex in odd (even) rounds can be decided by the nearest subsequent valid leader in odd (even) rounds. In expectation, each vertex is decided by a valid leader after $\frac{1\times 1+0.35\times 1.35}{1.35} \times 2 = 2.18$ rounds. Combining the above results, in expectation, Chitu decides each vertex to a univalent status within $2.7+2.18 = 4.88 \approx 5$ rounds (or less when $f>1$) in the DAG. Moreover, if the fast path is achieved, each vertex is decided every 2 rounds in the DAG, which reduces the expectation of rounds to decide each vertex further. □

Theorem B.6 (Validity)**.** *In each round, at least one vertex proposed by a correct node is decided 1-valent.*

Proof. By Lemma B.6, for each round, at least one vertex from a correct node can be strongly observed by the subsequent valid leader and decided 1-valent. Therefore, the adversary can not fully occupy the 1-valent vertices. Chitu satisfies validity. □

Fast Distributed Transactions for RDMA-based Disaggregated Memory

Abstract

Memory disaggregation has emerged as a promising datacenter architecture since it improves memory utilization and scalability. However, it is usually costly to process distributed transactions in disaggregated memory systems due to relatively high latency of remote memory accesses. In this paper, we present HDTX, a high-performance distributed transaction system for RDMA-based disaggregated memory. We advocate three novel designs. First, we propose a *fast commit protocol* (FCP) to minimize network round trips by coalescing different phases of distributed transaction processing. Second, we propose an RDMA-enabled offloading mechanism to reduce data transfers across computing and memory nodes by carefully orchestrating different RDMA primitives. Third, we propose decentralized priority-based locking to schedule mission-critical transactions, and thus further reduce the latency of distributed transactions. Experimental results show that HDTX reduces the latency of distributed transactions by up to 88.3% and 72.1%, and improves the throughput by up to 2.08× and 84.7%, compared with RDMA-based distributed transaction systems–FaRM and FORD, respectively.

1 Introduction

Resource disaggregation has emerged as one fundamental shift that we organize and manage different types of resources (e.g. CPU, memory) in datacenters. It has attracted extensive interests in both academia [42, 53, 54] and industry [9, 17] in recent years. Under resource disaggregation, monolithic servers are disaggregated into dedicated computing and memory nodes which are typically connected by high-speed networks such as *Remote Direct Memory Access* (RDMA) or *Compute Express Link* (CXL). The computing nodes run programs using a small local DRAM buffer backed with a large remote memory pool, while the memory nodes are usually equipped with very limited computing units for memory allocations and network initialization/connectivity. By pooling and sharing different resources, this resource disaggregation architecture substantially improves resource utilization, and facilitates resource scaling and failure isolation.

When correlated objects are concurrently accessed in the *disaggregated memory* (DM) pool, the computing nodes have to exploit *distributed transactions* (dtxns) to guarantee data integrity and consistency. However, most previous RDMA-based dtxn systems [28, 48] are designed for conventional monolithic servers in which computing and memory resources are tightly coupled. They are not applicable to DM systems because memory nodes usually have very limited computing resource to process costly operations during dtxn processing, such as buffer polling [12], locking [48], and data copying [28]. Recently, the state-of-the-art FORD [53] has been proposed particularly for processing dtxns in DM systems. However, it still incurs relatively high latency and high network bandwidth consumption. Moreover, dtxn processing systems should offer low latency for mission-critical applications. This low-latency requirement further increases the difficulty of deploying dtxn processing systems in the DM architecture due to the following challenges.

C.1: multiple network round trips (RTT) caused by multi-phase dtxn processing. Traditional dtxn systems usually exploit *optimistic concurrency control* (OCC) [46] to achieve lock-free dtxn processing on read-only data, and adopt the *primary-backup replication* (PBR) mechanism [28, 48] to guarantee high availability. Thus, existing dtxn systems [12, 49] generally process a single dtxn in five phases. Specifically, coordinators execute the dtxn in the *Execution* phase, serialize the dtxn in the *Locking* and *Validation* phases, and finally commit the dtxn in the *Commit Backup* and *Commit Primary* phases. Each phase usually incurs an RTT. FORD [53] has optimized the dtxn protocol particularly for DM systems, but still requires four phases to process a dtxn. These multiple phases often cause high latency of dtxn processing.

C.2: inefficient data synchronization in dtxn commit phases. Most previous dtxn processing systems require two phases to commit backups and primaries sequentially [12,

*Haikun Liu is the corresponding author.

49]. To reduce the latency, previous proposals [29] [34] rely on CPUs of memory nodes to synchronize the latest data within backups and primaries locally. However, these schemes are not applicable to DM systems since memory nodes do not have sufficient CPU resource to perform the costly data synchronization. Thus, they have to send the log and the latest data from computing nodes to all memory nodes in two rounds of data transfers. This causes substantial pressure on the RDMA bandwidth when the network load is high.

C.3: limited CPU resource in DM nodes for scheduling mission-critical dtxns. For mission-critical dtxns, their execution priority usually should be enhanced to guarantee low latency. Conventional dtxn systems [11, 35] exploit priority-based locking [22] to schedule different dtxns globally using CPUs on storage nodes. However, they cannot be directly adopted in DM systems because memory nodes usually do not have sufficient CPU resource for lock management and dtxn scheduling. Thus, it is challenging to schedule dtxns globally by DM nodes.

In this paper, we present HDTX, a high-performance distributed transaction system for the RDMA-based DM architecture. Through an in-depth analysis of the characteristics of dtxns and one-sided RDMA primitives, we propose three novel designs to address the above three challenges, respectively. Specifically, we make the following contributions.

For C.1, we propose a *fast commit protocol* (FCP) to minimize network round trips by coalescing the *Validation* and *Commit* phases of dtxns. To commit a dtxn earlier while still guaranteeing data consistency, FCP adopts the redo log and a visibility control technique [29, 34, 53] to coalesce three phases: *Validation*, *Commit Backup*, and *Commit Primary*. At first, FCP replaces *Commit Backup* and *Commit Primary* phases with one *Commit* phase and one asynchronous *Release* phase. Moreover, since there is no data dependency between the *Validation* phase and the *Commit* phase, FCP also coalesces these two phases to further reduce network round trips. Thus, the computing node only requires one round trip to commit a dtxn after the *Execution* and *Locking* phases.

For C.2, we propose RDMA-enabled data synchronization offloading to reduce RDMA bandwidth consumption. In the *Release* phase of our fast commit protocol, the computing node should write the latest data to the datastore, update the version of data, and release the lock on memory nodes. Since the redo log containing the latest data has been stored in memory nodes during the *Commit* phase, HDTX can offload these operations (i.e., data synchronization) to *RDMA network interface controller* (RNIC) via a series of `RDMA Write` and `RDMA Atomic` primitives. By orchestrating these primitives with special `RDMA Wait` and `RDMA Enable` primitives, the RNICs of memory nodes can perform the *Release* phase autonomously. In this way, HDTX can avoid additional transfers of the latest data across computing and memory nodes, mitigating the bandwidth contention of RDMA networks.

For C.3, we propose decentralized priority-based locking to reduce the latency of mission-critical applications. During the *Locking* phase, each computing node exploits the `RDMA Fetch-and-Add (FAA)` primitive to request write locks for a read-write set. For mission-critical dtxns, the computing node can set a high priority to the lock request so that it has more opportunities to acquire the required locks. In a global view, our decentralized priority-based locking mechanism can schedule latency-sensitive dtxns without involving memory nodes' CPUs.

We implement HDTX [23] and evaluate it with several benchmarks that simulate real-world workloads[1]. Compared with two typical RDMA-enabled dtxn systems–FaRM [12] and FORD [53], experimental results show that HDTX reduces the latency of dtxns by up to 88.3% and 72.1%, reduces the 99th percentile latency by up to 82.7% and 60.9%, and improves the dtxn throughput by up to 2.08× and 84.7% on average, respectively.

2 Background

2.1 High-Performance RDMA

RDMA networks are widely deployed in *high-performance computing* (HPC) environments and data centers because they offer high-throughput and low-latency remote memory accesses via bypassing traditional I/O stacks. Applications can leverage one-sided RDMA operations, such as `Read/Write` primitives, to directly access remote memory, without the involvement of remote CPUs. Also, applications can use two-sided RDMA operations, such as `Send/Recv` primitives, to communicate with remote CPUs for more complex operations. There are also a number of `RDMA Atomic` primitives, such as `RDMA Compare-and-Swap (CAS)` and `RDMA FAA`. The former can atomically modify 8-byte data under specific conditions, and the latter can atomically add 8-byte data to a specific value. To perform RDMA operations, an application must first construct a *completion queue* (CQ) and a *queue pair* (QP) which comprises a send queue and a receive queue. It then appends RDMA operations to the QP and notifies the RNIC for execution. Once the RDMA operation completes, the RNIC generates an acknowledgment message in the CQ to inform the application.

Besides data transmission, the RDMA driver also supports ordering control via `RDMA Fence` flags or `RDMA Wait` primitives, which can maintain the operation order within a send queue and across different QPs, respectively. Specifically, an RDMA operation with an `RDMA Fence` flag is halted on the sender's RNIC till all previous operations within the same send queue are completed. In contrast, the `RDMA Wait` can block its subsequent RDMA operations till a specific RDMA operation is completed. The `RDMA Enable` primitive allows the RNIC to fetch the metadata of pending RDMA operations

[1]The source code and experiments in this paper are available at Github [23].

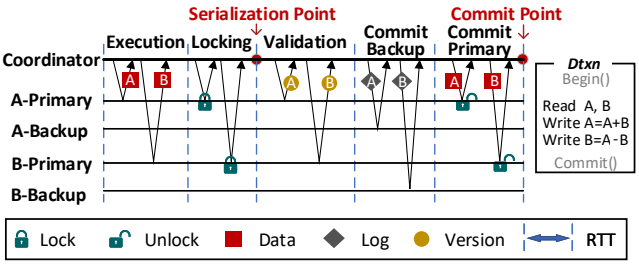

Figure 1: Dtxn processing based on OCC and PBR. Each data (A and B) has two replicas on memory nodes.

in the same work queue, and enables them to be executable. Thus, `RDMA Wait` and `RDMA Enable` can be orchestrated to perform a set of pending RDMA operations autonomously in an event-driven manner [31, 38].

2.2 RDMA-based Distributed Transactions

Distributed transactions are commonly used to ensure data consistency when multiple objects are accessed concurrently. There are two kinds of concurrency control mechanisms for dtxn systems: pessimistic and optimistic. The former locks all objects involved in a transaction to guarantee data consistency in high-contention scenarios, while the latter only locks the write set of a transaction to improve the parallelism of dtxn processing in low-contention scenarios.

Most RDMA-based dtxn systems [13, 28, 48] exploit both OCC and PBR to achieve high performance and high availability, respectively. Figure 1 illustrates a typical dtxn protocol. Upon receiving a dtxn request, the coordinator (i.e., the computing node) fetches the read set from multiple memory nodes and executes the transaction locally. After the *Execution* phase, the coordinator tries to commit the dtxn through four phases. If the read-write data are locked successfully in the *Locking* phase, and the coordinator verifies that the read set has not been modified by other dtxns before the *Validation* phase, it writes the dtxn output to logs on all backups for failure recovery. Once the coordinator receives all acknowledgments (ACKs), it updates and unlocks the data on primary nodes, and finally commits the dtxn. If the validation or any write operation fails, the coordinator should unlock the write set and abort the dtxn. Overall, five RTTs are required to commit a single dtxn in five phases.

3 Motivation

For most online services, dtxn processing systems should offer both high throughput and low latency. However, existing RDMA-based dtxns do not work efficiently in DM systems. By carefully analyzing existing dtxn protocols and ordering constraints of batched RDMA primitives, we find that there are several opportunities for optimizing dtxns in DM systems.

Table 1: Work request operation ordering

First Operation \ Second Operation	Send	Write	Read	Atomic (FAA/CAS)
Send	#	#	#	#
Write	#	#	#	#
Read	F	F	#	F
Atomic (FAA/CAS)	F	F	#	F

*F: Order is maintained only if the second operation has set a Fence flag.
*#: Order is always maintained.

Constraints of RDMA operation ordering. One-sided RDMA supports remote memory accesses without involving remote CPUs. It is applicable to DM systems but poses a number of constraints on dtxn processing. Two RDMA primitives that are batched and delivered from the same send queue should obey multiple operation ordering rules outlined in the *InfiniBand Trade Association* (IBTA) Specification [15,43], as shown in Table 1. Specifically, if the first RDMA operation is an `RDMA Send/Write` and the second RDMA operation can be any type, these two primitives are executed sequentially and thus can be completed within a single RTT. If the first operation is an `RDMA Read/FAA/CAS` and the second operation is not an `RDMA Read`, the sender's RNIC may execute the second operation earlier, causing unpredictable issues. Thus, an `RDMA Fence` flag should be attached to the second RDMA operation to guarantee the ordering but incurs additional network latency. Since RDMA operations for data synchronization among replicas should be ordered to guarantee data consistency, the dtxn processing protocol should be carefully designed to fully exploit different RDMA primitives.

Opportunities for reducing network round trips. Since typical dtxn systems require five RTTs to commit a transaction, as shown in Figure 1, previous studies [48, 53] have proposed several RDMA-based optimizations. The coordinator can combine the *Execution* and *Locking* phases, or the *Locking* and *Validation* phases to reduce network round trips. In addition, the coordinator can also update both primary and backup replicas in a single RTT, at the risk of suffering lower recovery performance upon failures. Despite these optimizations, previous proposals still require three or more RTTs to commit a dtxn. Fortunately, we find that it is possible to further reduce network round trips by carefully orchestrating the logging mechanism and the primary/backup *Commit* phases. By decoupling the data synchronization operation from the primary/backup *Commit* phases, we have an opportunity to coalesce the *Validation* and *Commit* phases, allowing a dtxn to be committed within two RTTs (Section 4.2).

Opportunities for RDMA-enabled data synchronization offloading. Most dtxn systems adopt undo or redo logs to guarantee data consistency in case of failures. In traditional dtxn systems [28,48], data nodes rely on their CPUs to update the data using redo logs, or to generate undo logs using the original data. However, these logging mechanisms are not applicable to DM systems due to lack of CPU resource on

DM nodes. The state-of-the-art dtxn system–FORD [53] uses undo logs for the DM, but its coordinator has to send the log and the latest data to all primaries/backups in two phases of dtxns. Since the coordinator should read the original data from memory nodes and then write it to the undo log, FORD incurs additional network bandwidth consumption due to logging. Although the *multi-version concurrency control* (MVCC) [37, 44] mechanism can avoid the additional data transfer incurred by logging, it requires more computing resource for garbage collection in memory nodes. By revisiting redo logs and `RDMA Wait/Enable` primitives, we find that it is possible to save the RDMA bandwidth by replacing remote memory copying with local memory copying. Since the redo log has been sent to memory nodes, we exploit an `RDMA Wait` and an `RDMA Write` to update the data by copying the redo log locally, avoiding remote memory copying and unnecessary RDMA bandwidth consumption (Section 4.3).

Opportunities for scheduling mission-critical dtxns. Most dtxn systems face a risk of high tail latency due to lock contention and deadlocks. Specifically, some RDMA-based dtxn systems typically acquire locks via `RDMA CAS` primitives with blind retries [12, 53], leading to unpredictable performance and starvation issues. Some proposals [36, 51] schedule tasks in a first-in-first-out manner, and thus also fail to accelerate mission-critical dtxns. Priority-based locking can mitigate these problems by scheduling latency-sensitive dtxns. However, existing priority-based locking mechanisms are inapplicable to the DM architecture because of limited computing resource on memory nodes. Fortunately, since the `RDMA FAA` primitive can perform a read-modify-write operation in a single RTT, it offers an opportunity to design a decentralized locking mechanism for flexible dtxn scheduling. By carefully designing the data structure of priority-based locks and the lock acquisition mechanism, mission-critical dtxns are given a high priority to acquire locks, and thus reduce lock contention with other dtxns. (Section 4.4).

4 Design of HDTX

4.1 Overview

Figure 2 shows the overview of HDTX. The coordinators in the computing pool are responsible for receiving and processing transactions requested by clients. The memory pool stores application data in hash tables. The coordinators (i.e., computing nodes) directly access the remote memory nodes through RDMA networks.

At first, HDTX initializes the datastore and establishes network connections with one CPU thread in the memory pool (①). Meanwhile, the computing pool caches the metadata and the configuration of the datastore for remote data accesses. After HDTX is initialized, coordinators in the computing pool are ready to serve clients' requests (②). Specifically, the coordinator initiates a transaction with `Tx_begin()`. Then, it uses

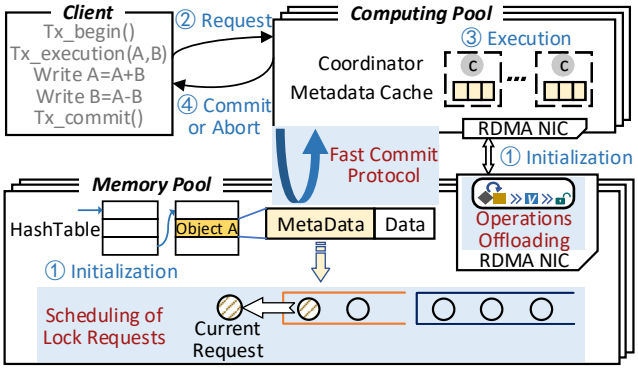

Figure 2: The system overview of HDTX

the `Tx_execution()` to fetch and lock the latest data from the memory pool with priority-based locking (Section 4.4), and executes the transaction locally (③). We note that the coordinator can perform the `Tx_execution()` multiple times to fetch and lock data that is newly-added to the read-write set during the dtxn execution. Once the execution is completed, the coordinator exploits our fast commit protocol (Section 4.2) to commit the transaction using `Tx_commit()`, and returns the transaction output to the client (④).

4.2 Fast Commit Protocol

In this section, we elaborate two key designs that enable fast dtxn commits while still guaranteeing data consistency.

4.2.1 Combining Backup and Primary Commit Phases

When the computing node commits a transaction and responds to the client, the latest data should be persisted in all memory nodes to guarantee consistency. As shown in Figure 1, traditional transaction systems require two RTTs to write the log and data sequentially to backups and primaries, respectively. This ensures fast failure recovery but incurs high latency. In traditional monolithic servers, a straightforward approach for fast dtxn commits can be achieved by combining *Backup Commit* and *Primary Commit* phases within a single RTT. Specifically, the coordinator writes logs to all primaries/backups, and then makes the write set invisible by setting the visibility bit as "0". This visibility control [29, 34, 53] can guarantee data consistency during the combined *Commit* phase. Once receiving ACKs from all primaries/backups, the coordinator can commit the dtxn, and then asynchronously executes a *Release* phase, which is responsible for updating the data and its version, making the write set visible, and releasing locks.

Unfortunately, the above approach incurs additional RTTs when applying to an RDMA-enabled DM architecture due to the ordering rules of RDMA primitives. In the following, we discuss how the primary/backup *Commit* and *Release* phases should be implemented in the DM architecture when using

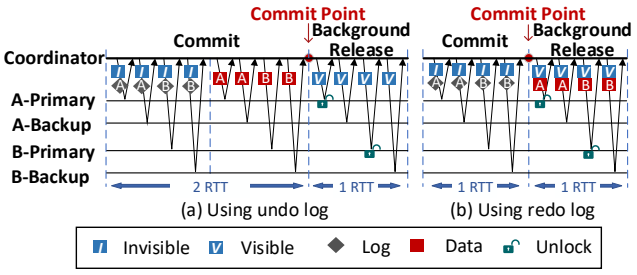

Figure 3: Commit a dtxn using (a) undo log and (b) redo log after the *Validation* phase

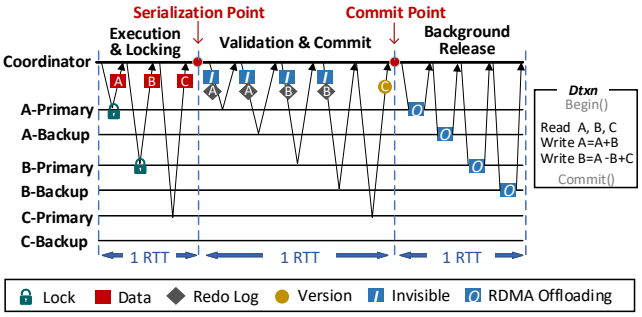

Figure 4: The workflow of dtxn processing in HDTX

undo and redo logs, respectively.

(a) **Using undo log**. The undo log contains the old version of the data and its metadata, and thus the computing node can in-place write the latest data to all memory nodes before committing the dtxn. As illustrated in Figure 3(a), after sending the undo log, the coordinator marks the locked data as invisible via `RDMA Atomic`, and then in-place updates the data via `RDMA Write` to commit the transaction. These two steps should be performed sequentially. Otherwise, other transactions may read the data being updated, causing inconsistent data accesses. However, according to the ordering rules, the coordinator must add `RDMA Fence` flag to the `RDMA Write` to maintain the order. This operation brings an additional RTT to the *Commit* phase. Even though the undo log can be propagated to all primaries/backups during the *Validation* phase, at least two RTTs are required to synchronize the latest data among all memory nodes. **Thus, dtxn systems using undo logs are unable to achieve fast commits in DM systems.**

(b) **Using redo log**: The redo log contains the transaction output (i.e. the latest data) and its metadata. Thus, the computing node can commit the transaction after writing the redo log to all primaries/backups, and then asynchronously updates the data using the redo log. Unlike undo logs, the order of propagating the latest data with redo logs and the visibility control do not affect the read consistency during the *Commit* phase. Thus, the coordinator can simply write the redo log to all primaries/backups via the `RDMA Write`, and then marks the locked data as invisible via the `RDMA Atomic`, as illustrated in Figure 3(b). The locked data can be in-place updated asynchronously in the *Release* phase, which is not on the critical path of dtxns. Since the order of batched `RDMA Write` and `RDMA Atomic` in the *Commit* phase is always maintained, as shown in Table 1, they can be performed sequentially in only one RTT. **Thus, we adopt the redo log and the visibility control mechanism to minimize network round trips during the *Commit* phase.**

4.2.2 Combining Validation and Commit Phases

The *Validation* phase checks whether the read-only set is updated by other dtxns during the *Execution* and *Locking* phases. The *Commit* phase propagates redo logs of the write set to all primaries/backups. Since there is no data dependency between the *Validation* phase and the *Commit* phase, HDTX combines these two phases to further reduce network round trips. In this way, HDTX can shorten the lock duration and enable fast dtxn commits. However, when there are high read-write conflicts, HDTX may rollback the *Commit* phase due to unsuccessful *Validation*. Fortunately, since redo logs can be discarded or overwritten directly, the rollback of the *Commit* phase incurs rather low performance overhead. Thus, this design can significantly accelerate dtxn processing particularly for workloads with low read-write contention.

4.2.3 Dtxn Workflow in HDTX

The *Execution* and *Locking* phases can be also combined to reduce network round trips [7,53]. Putting these optimizations together, Figure 4 illustrates how HDTX processes a dtxn using our fast commit protocol in DM systems. *It mainly includes the following three phases but can commit a dtxn within only two RTTs.*

(1) *Execution* & *Locking* phase. The coordinator issues batched `RDMA FAA(Atomic)` and `RDMA Read` primitives to lock and fetch the read-write set from primaries in one RTT. Since the order of these two primitives is always maintained according to the operation ordering rules, the coordinator can obtain the write lock and the latest data within one network round trip.

(2) *Validation* & *Commit* phase. The coordinator issues an `RDMA Read` to fetch the visibility bit and the version number of read-only data for validation. Meanwhile, it issues batched `RDMA Write` and `RDMA Read` to persistently write the redo log to all replicas, and uses `RDMA FAA(Atomic)` to atomically mark the locked data as invisible. Once the coordinator receives acknowledgments from all replicas and verifies that there is no conflict, it can commit the dtxn. We note that the visibility control can provide a consistent view among replicas when in-place updating the write set. Therefore, other coordinators only need to check the data version and visibility bits rather than the write locks, enabling concurrent accesses to read-only data. If the coordinator detects a missing acknowledgment or a failure before the commit point, it rolls back the dtxn. In this case, it should notify all replicas to reset visibility bits and release write locks.

Table 2: A summary of different dtxn systems

Dtxn Systems	Phases of dtxn protocol	# RTTs to commit
FaRM [12, 39]	*Execution + Locking + Validation + Commit Backup + Commit Primary*	5 RTTs
FaSST [28]	*Execution&Locking + Validation + Log + Commit Backup + Commit Primary*	5 RTTs
DrTM+H [48]	*Execution + Locking&Validation + Commit Backup + Commit Primary*	4 RTTs
FORD [53]	*Execution&Locking (UndoLog) + Validation + Commit + Background Release*	3 RTTs
HDTX	*Execution&Locking + Validation&Commit (RedoLog) + Background Release*	2 RTTs

(3) *Release* phase. The coordinator should update the locked data, increase the version number, make the locked data visible, and release the write lock. The coordinator issues an `RDMA Send` primitive to asynchronously conduct all these operations via RDMA-enabled offloading, as described in Section 4.3. If a failure occurs in this phase, the coordinator handles the failure according to the status of the uncompleted dtxn (Section 4.5).

We summarize previous dtxn protocols in Table 2. FaRM [12, 13] and FaSST [28] both require 5 RTTs to process a dtxn. DrTM+H [48] combines the *Locking* and *Validation* phases, and thus processes a dtxn with 4 RTTs. FORD combines the *Execution* and *Locking* phases, and performs its *Release* phase in the background, and thus can commit a dtxn in 3 RTTs. Our HDTX only requires two phases to commit a dtxn, and then performs the *Background Release* phase asynchronously.

When the validation fails due to read-write conflicts, all dtxn systems abort the current dtxn. In this case, both HDTX and other systems must release all acquired locks via RDMA operations. Since both HDTX and FORD send logs to memory nodes before the Validation phase, they both waste RDMA bandwidth for the log transmission upon a dtxn abort. Thus, the performance overhead of the rollback in HDTX is comparable to that of FORD.

4.3 RDMA-enabled Release Phase Offloading

We next consider how to efficiently execute the *Release* phase of dtxns on DM nodes. As discussed in Section 3, it is costly to send the latest data and the log in two rounds of data transfers in DM systems. We observe that the in-place updating of the write set can be efficiently achieved by RNICs on memory nodes, because it only involves data movement within each memory node when using redo logs. Thus, we leverage `RDMA Wait` and `RDMA Enable` primitives to sequentially offload all operations in the *Release* phase to RNICs of memory nodes.

Figure 5 illustrates how the memory node's RNIC can "copy" the redo log to update the data locally via RDMA-enabled operation offloading. When HDTX is initialized, two work queues are created particularly for RDMA offloading in the memory nodes' RNIC. Specifically, work queue 1 is paired with a work queue in the computing node to receive RDMA

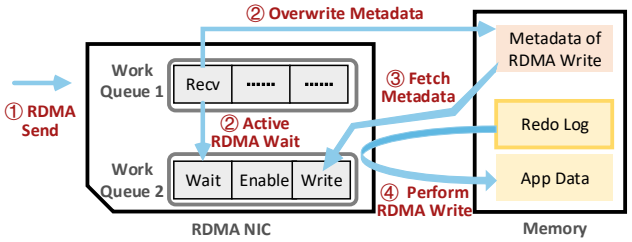

Figure 5: Offloading the data copying operation to the memory node's RNIC via `RDMA Wait/Enable` primitives

offloading messages. The memory node sequentially issues three RDMA primitives, i.e., `RDMA Wait`, `RDMA Enable`, and `RDMA Write` to work queue 2. At this time, the source and destination addresses of the `RDMA Write` are set as NULL in its metadata. Besides the addresses, the metadata of RDMA primitives also contains the type of RDMA operation, access permissions, the data size, and so on. These items can be used by the RNIC on the memory node to perform `RDMA Write` operations. Then, the memory node issues an `RDMA Recv` to work queue 1. The destination address of the `RDMA Recv` is the memory region that stores the metadata of the `RDMA Write`. Since the `RDMA Wait` in work queue 2 is configured to wait for the work completion event of the first position in work queue 1, the RNIC should monitor the completion event of `RDMA Recv`, and then continue the pending RDMA primitives blocked by the `RDMA Wait`.

When the redo log in the memory node should be copied to update the application data locally, the computing node sends the source and destination addresses of the data copying operation to the memory node via an `RDMA Send` (①), which consumes the `RDMA Recv` in work queue 1 and overwrites the metadata of the `RDMA Write` with the content of the `RDMA Send`. Meanwhile, the RNIC generates a work completion event of work queue 1, which activates the pending `RDMA Wait` in work queue 2 (②). Then, the RNIC continues to process the other two pending RDMA primitives in work queue 2. Since the `RDMA Write` is accompanied by an `RDMA Enable`, the RNIC fetches the metadata of the `RDMA Write` from the memory node, enabling it to be executable (③). Finally, the memory node's RNIC performs the `RDMA Write` (④) to copy data from the redo log to the application's data area, without the intervention of the memory node's CPUs.

To offload all operations in the *Release* phase to the RNIC, the memory node has to issue two `RDMA Writes` and one `RDMA FAA` to its RNIC and blocks them via `RDMA Wait/Enable` primitives during the initialization of HDTX. Figure 6 shows all operations in the *Release* phase executed by RNICs on memory nodes. After responding the dtxn output to clients, the coordinator issues an `RDMA Send` to activate all blocked RDMA operations for each memory node. Then, the memory nodes' RNICs overwrite the metadata of blocked RDMA operations according to the content of the `RDMA Send`, including the address of redo logs, the addresses

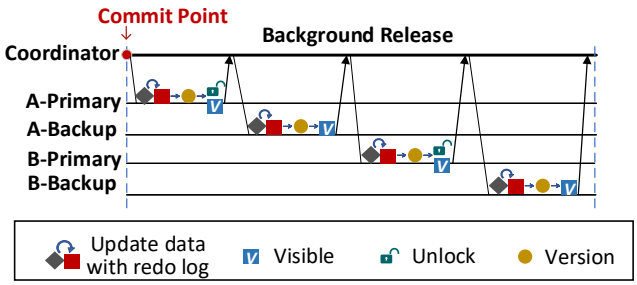

Figure 6: Operations executed by RNICs in the *Release* phase

of the data and its metadata, and the data size. At this time, memory nodes' RNICs are aware of the source and destination addresses of the pending data copying operation, and perform the first blocked `RDMA Write` to update the data with redo logs. Similarly, HDTX leverages the second blocked `RDMA Write` to offload the version updating. The blocked `RDMA FAA` primitive is used to modify visibility bits for all primaries/backups, and to release locks for all primaries. Since the RDMA-enabled offloading in the *Release* phase would consume a set of RDMA primitives in the two work queues, HDTX supplements these RDMA primitives in batches for upcoming dtxns using a background thread. In this way, all operations in the *Release* phase can be offloaded to the RNIC, without any intervention of the memory node's CPUs.

4.4 Decentralized Priority Locking

Most dtxn processing systems are concerned with the latency of individual transactions. To meet users' requirements, HDTX leverages decentralized priority-based locking to support flexible dtxn scheduling, i.e., assigning a high priority to dtxns that are mission-critical or are about to violate their latency requirements soon.

4.4.1 Lock Presentation

To manage and schedule lock requests for dtxns, we construct two queues assigned different priorities for each lock in memory nodes. Specifically, we queue requests with the same priority in a *first-in-first-out* (FIFO) manner using Lamport's Bakery algorithm [32], and rely on coordinators to determine the order of requests in different queues.

The Lamport's Bakery algorithm is applicable to the lock management in a DM architecture since it allows computing nodes to collect the status of locks on memory nodes, without involving memory nodes' CPUs. When a computing node requests a lock, it receives an incremental token from the memory node. The memory node records the number of lock requests and the token of the current computing node that holds the lock. If the token received by the computing node matches the token recorded by the memory node, the computing node acquires the lock. Based on this algorithm, we manage lock requests using two FIFO queues, i.e., a normal

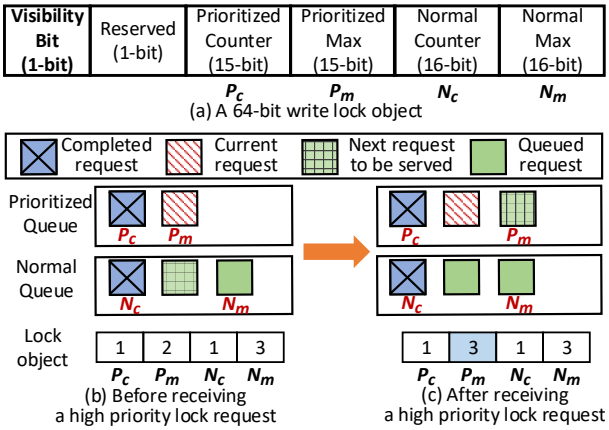

Figure 7: The write lock representation and an illustration of the decentralized priority-based locking

queue and a prioritized queue, to achieve more flexible dtxn scheduling. The former and latter queues are assigned with a low priority and a high priority, respectively.

Figure 7(a) shows the 64-bit representation of a priority-based lock object. For each lock, we construct a normal queue using a pair of $< N_c,\ N_m >$, which denotes the token of the current dtxn holding the lock and the number of dtxns requesting the lock, respectively. We also use a pair of $< P_c, P_m >$ to construct the prioritized queue, which works similarly to the normal queue. Once the current lock is released, the pending requests in the prioritized queue can acquire the lock ahead of requests in the normal queue. If a dtxn fails to acquire a lock for several times, it would retry with a high-priority lock request so that the priority of dtxns can be dynamically adjusted to mitigate the risk of latency requirement violations.

Figure 7(b) and (c) illustrate how the status of the lock object and two queues change when a high-priority lock request is received. As shown in Figure 7(b), there are two lock requests in the prioritized queue (P_m=2). The first request in the prioritized queue is completed (P_c=1), while the second request has acquired the lock. In the normal queue, there are three lock requests (N_m=3), and the first request is completed (N_c=1). If the current request completes, the second request in the normal queue can acquire the lock. When a new lock request with a high priority arrives, as shown in Figure 7(c), the number of requests in the prioritized queue increases from two to three (P_m=3). According to our priority-based locking algorithm, if the current request completes, the third request in the prioritized queue instead of the second request in the normal queue can acquire the lock. In this way, our priority-based locking mechanism can reduce the latency of mission-critical dtxns by assigning them a high priority.

4.4.2 Handling Priority-based Locking

HDTX leverages `RDMA FAA` primitives for locking operations, including lock acquisition and release. The `RDMA CAS` primitive is also used for special cases, such as handling lock over-

Table 3: Key notations and procedures used in HDTX

Function	Description
L(segment)	returns the value of *segment* in the 64-bit lock object L. The *segment* is one of P_c, P_m, N_c, and N_m.
READ(lock)	fetches the value of the *lock* via an RDMA Read.
FAA(lock, segment, value)	atomically adds *value* to a *segment* of *lock* via an RDMA FAA and receives the original value of *lock*.
CAS(lock, value)	compares and swaps the value of *lock* if it equals to the given *value* via an RDMA CAS, and receives the original value of *lock*.
CheckOverflow(L)	checks whether there is an overflow or an error on the lock L, i.e. $L(P_m) > maximum$ or $L(N_m) > maximum$, and returns *True* if an overflow occurs.

flows and deadlocks. Upon receiving a dtxn request, the coordinator performs the *Execution & Locking* phase to fetch and lock the read-write set. The coordinator determines whether it acquires the lock by comparing the returned token with the current value of the lock object. Once the coordinator acquires all locks required by the dtxn, it begins the next phase to validate the version and commit the dtxn. In the *Release* phase, the coordinator releases write locks via the `RDMA FAA`. We elaborate these locking operations in the following.

Algorithm 1: Normal Lock Acquisition

```
   input  : the requested lock object
   output : Success or Failure
1  L_old = FAA(lock, N_m, 1);
2  L = L_old;
3  do
4      if CheckOverflow(L) = True then
5          Repeat CAS(lock, L_old) till it succeeds or the lock
             resets;
6          return Failure;
7      end
8      if L(P_c) = L(P_m) AND L(N_c) = L_old(N_m) then return
         Success;
9      L = READ(lock);
10     Sleep ( L_old(N_m) - L(N_c) + L(P_m) - L(P_c) ) μs;
11 while true;
```

Lock Acquisition: Algorithm 1 and Algorithm 2 show pseudocodes for lock acquisitions in HDTX. All notations and procedures used in these algorithms are listed in Table 3. For **(a) normal requests**, as shown in Algorithm 1, the coordinator adds "1" to N_m and obtains its token from the returned value via `RDMA FAA`. Then, it polls the lock till there are no pending requests in these two queues (lines 3-11 in Algorithm 1). To mitigate the overhead of busy polling, the coordinator waits an interval that is proportional to the number of pending high-priority requests ($L(P_m)$ - $L(P_c)$) and the preceding normal requests ($L_{old}(N_m)$ - $L(N_c)$) before attempting to fetch the lock value again (line 10 in Algorithm 1). For **(b) high-priority requests**, as shown in Algorithm 2, the coordinator adds "1" to P_m and receives the current lock value. According to the number of pending requests, there are three scenarios. (b.1) If both normal and prioritized queues are empty, the coordinator acquires the lock directly (lines 6-7). (b.2) If there are only pending requests in the normal queue, implying that a normal request already acquires the lock, the coordinator waits for the lock till the current request is completed (lines 8-12). (b.3) Otherwise, if there are pending requests in the prioritized queue, the coordinator waits for their completions (lines 14-20).

Algorithm 2: High-Priority Lock Acquisition

```
   input  : the requested lock object
   output : Success or Failure
1  L_old = FAA(lock, P_m, 1);
2  if CheckOverflow(L_old) = True then
3      Repeat CAS(lock, L_old) till it succeeds or the lock resets;
4      return Failure;
5  end
6  if L_old(P_c) = L_old(P_m) then
7      if L_old(N_c) = L_old(N_m) then return Success;
8      do
9          L = READ(lock);
10         CheckOverflow(L);// lines 2-5
11         if L(N_c) = L_old(N_c) + 1 then return Success;
12     while true;
13 else
14     do
15         L = READ(lock);
16         CheckOverflow(L); // lines 2-5
17         if L(P_c) = L_old(P_m) then return Success;
18         Sleep ( L_old(P_m) - L(P_c) ) μs;
19     while true;
20 end
```

Lock Release: After a transaction is committed or aborted, the coordinator asynchronously releases the write lock. This is achieved by adding "1" to N_c or P_c via the `RDMA FAA`. Subsequently, other coordinators waiting for the lock can acquire it according to our lock acquisition algorithm.

Handling Lock Overflows: HDTX stores the 1-bit visibility flag and the 63-bit write lock in an 8-byte value, allowing atomic modifications via `RDMA Atomic` primitives. To detect overflows, the highest bit of each segment is reserved as a canary value [45,51]. Therefore, the maximum of the segment representing the normal queue is 32768. For the prioritized queue, its maximum value is 16384 because the highest bit of the lock is reserved as the visibility bit. When any coordinator finds that its received token is larger than the maximum, it withdraws its request via the `RDMA CAS` (lines 4-7 in Algorithm 1 and lines 2-5 in Algorithm 2). If the current coordinator holding the lock detects an overflow, it releases the lock by resetting all segments to "0" via `RDMA CAS`. Then, the lock overflow is resolved and queued coordinators can retry their lock requests.

4.5 Handling Deadlocks and Failures

HDTX assumes a non-Byzantine failure model in which servers may fail-stop but never exhibit arbitrary faulty behaviors. Like previous systems [25, 47, 51], HDTX extends the lease mechanism [21] to handle various failures. In detail, coordinators calculate an elapsed time locally to monitor the lease expiration for each lock. The coordinator resets the elapsed time to zero once it acquires the lock, or detects an update on N_c or P_c or the visibility bit. The coordinator holding locks can process the dtxn only if all leases are not expired. The coordinator waiting for locks assumes that a failure occurs if the elapsed time of any lock exceeds a threshold. The failure detection relies on an assumption that clocks advance at nearly the same speeds [19, 51]. Fortunately, commercial networks [33] with a clock drift of ± 0.5 ns per microsecond is sufficient for our mechanism.

Deadlocks. In HDTX, deadlocks only occur during the *Execution & Locking* phase. The coordinator assumes a deadlock if the data is readable (i.e., the visibility bit is "1") and the elapsed time is twice greater than the lease expiration time. Similar to DSLR [51], any coordinator detecting a deadlock atomically hands over the lock to its successor via an `RDMA CAS`. Subsequently, it releases all acquired locks and reapplies for high-priority or normal locks later according to the client's latency requirement. Also, the queued requests can retry to acquire the lock. Based on our experimental results, we set the lease expiration time to 1 millisecond by default.

Failures of Computing Nodes. To facilitate failure recovery of computing nodes, the coordinator records the metadata of all objects accessed by a dtxn in the redo log. If a computing node fails (1) during the *Execution & Locking* phase: other coordinators assume a deadlock and atomically hand over the lock. Thus, dtxns executed on the failed coordinator can be safely aborted, and then clients can issue dtxn requests to other coordinators. If a computing node fails (2) after the *Execution & Locking* phase: other coordinators assume a failure of a computing node when the locked data is invisible and the elapsed time is twice greater than the lease expiration time. According to the redo log, another computing node is assigned to check the status of uncompleted dtxns and take over the failed node. (2.1) If any object involved in the dtxn is updated or the client has been acknowledged that the dtxn is committed, the newly-assigned computing node continues the *Release* phase. (2.2) Otherwise, it is safe to abort the dtxn directly. In all cases, when the newly-assigned computing node begins to recover dtxns, the lock lease of coordinators that are suspected to be failed is certain to expire, preventing the suspected coordinator from updating the data.

Failures of Memory Nodes. When any coordinator identifies a failure of a memory node, a computing node is assigned to replicate the replica from other memory nodes. (1) If a memory node fails before the *Release* phase, coordinators can simply terminate their dtxns and release their locks. (2) If a memory node fails during the *Release* phase, coordinators can commit dtxns normally regardless of the failed node, and notify the newly-assigned computing node to recover the replica with the latest version.

Failures of Networks. Network failures result in network partitions, where HDTX allows only the primary partition [6, 20] to serve client requests for strong consistency. When the network connectivity restores, coordinators holding locks yet outside the primary partition cannot continue their dtxns due to the expired lease, thereby guaranteeing data consistency.

4.6 Datastore Implementation

During the cluster initialization, HDTX allocates multiple memory regions on the DM pool to facilitate RDMA operations. Memory nodes use hash tables to store key-value objects in these memory regions. Each hash table entry includes metadata and data of an object. The metadata contains the write lock, the version number, the key, the object size, and the offset in the remote memory region, etc. In HDTX, we set the maximum object size to 1 KB since it satisfies most OLTP workloads. For variable-sized objects, HDTX stores their data and metadata in different areas and accesses the data using pointers. However, a coordinator can still fetch the data and its metadata in a single round trip by issuing two batched `RDMA Read` primitives.

To access an object, the coordinator calculates the address of the hash bucket according to the key and retrieves all entries to locate the object. It then caches the metadata locally, allowing subsequent read requests to directly fetch the object. The coordinator can cache the metadata without a capacity limitation since a GB-scale cache is commonly deployed on computing nodes [41, 53]. Thus, most dtxns can fetch and lock the write set within one RTT if there is no lock contention.

4.7 Discussions

Correctness and Serializability. Similar to traditional dtxn systems using OCC, HDTX locks the read-write set and validates the read-only set to guarantee data consistency. Specifically, the locking mechanism avoids conflicted accesses to the read-write set, while the validation phase can guarantee that the read-only set has not been updated by other dtxns at the serialization point. Unlike existing dtxn systems, HDTX combines *Validation* and *Commit* phases. The coordinator validates the version of the read-only set and transfers the redo logs without modifying the application data. Therefore, a validation failure requires HDTX to roll back the dtxn by releasing the locks and marking data visible. This avoids data inconsistency because the data is unreadable upon validation failures. Since HDTX only commits the dtxn when the version validation and the redo log propagation are completed, the combination of these two phases does not compromise the correctness and serializability of dtxns.

Optimization for Write-Only Dtxns. In HDTX, coordinators acquire locks and read data to perform the transaction logic in the *Execution&Locking* phase. For normal read-modify-write dtxns, coordinators must (1) read data from memory nodes and generate redo logs during the *Execution&Locking* phase, and (2) then send redo log to memory nodes to commit dtxns during the *Validation&Commit* phase. Thus, it requires two phases to commit a read-modify-write dtxn. In contrast, for write-only dtxns, coordinators can directly generate and send redo logs to memory nodes, and meanwhile try to lock the write-set in the first RTT. This process is similar to a write operation in a KV store system. If locks are acquired successfully, the coordinator can commit the dtxn, and then update the data and release the locks asynchronously. In this case, it is possible to commit a write-only dtxn in a single RTT.

Consistency of Reading Lock Objects. HDTX can guarantee data consistency when reading a lock object with an `RDMA Read` primitive. According to Intel's Programming Manual [1], Intel processors can guarantee that the memory operation of reading or writing 8 bytes will always be carried out atomically. The `RDMA Read` operation also relies on CPU's integrated memory controller to access main memory [26, 50]. Thus, like previous work [19, 51], we use the `RDMA Read` to read a lock object atomically.

5 Evaluation

5.1 Experimental Setup

Testbed. We conduct our experiments in an RDMA-capable cluster with 5 servers. All servers are equipped with 128 GB DRAM, 1 TB Intel Optane DCPMM, two-socket Intel Xeon Gold 6230 processors with 20 cores running at 2.10 GHz, and a Mellanox ConnectX-3 40/56 GbE network interface controller. To set up the DM system, we use two servers as memory nodes for 2-way replication, and each node is restricted to use only one CPU core for cluster initialization. All memory nodes use Intel Optane DCPMMs in the *App Direct Mode* to achieve fast durability for the datastore. If not specified otherwise, one server is used as the computing node in which multiple threads are initialized to execute dtxns in parallel. Each computing node communicates with the memory nodes via the RDMA *Reliable Connection* (RC) mode. When the redo logs are written to the disaggregated persistent memory, we exploit the one-sided RDMA Flush [14, 16] (i.e., RDMA read-after-write mechanism) to guarantee the durability of dtxns. Specifically, we use an `RDMA Write` to transfer the log, and an `RDMA Read` to read the last byte of the log for validation. Since the batched `RDMA Write` and `RDMA Read` primitives are strictly ordered, as shown in Table 1, the RDMA read-after-write mechanism can guarantee remote data persistence within one RTT.

Benchmarks. We use three typical OLTP workloads, TPC-C [5], SmallBank [3], and TATP [4], as macro-benchmarks to evaluate the performance of different dtxn systems. **1) TPC-C** simulates a complex ordering system. It consists of 9 tables, with the maximum object size of 672 bytes. There are 92% read-write transactions in this benchmark. We generate 20 warehouses by default. **2) SmallBank** simulates a banking application. It contains 2 tables, and all objects are 16 bytes. There are about 85% read-write transactions in this workload. **3) TATP** is a telecom application. It contains 4 tables, and the maximum object size is 48 bytes. About 80% of its transactions are read-only. Besides the macro-benchmarks, we also develop micro-benchmarks [23] to evaluate the effectiveness of our three individual techniques. In these micro-benchmarks, the hash tables in the memory nodes store one million key-value pairs, where the key size is 8 bytes and the default value size is 40 bytes.

Methodology. In all dtxn systems, the coordinator retries transactions in case of failures and deadlocks [49, 51], and reports a transaction abort to the client only when the transaction becomes time-out ultimately. We set the default timeout as 1 millisecond to guarantee a low transaction abort rate, with a low performance degradation. We measure the throughput by counting the number of committed transactions per second, and measure the latency by recording the interval between two committed transactions. All experimental results are the average of three trials.

Comparisons. We compare HDTX with two OCC-based RDMA-enabled dtxn systems– FORD [53] [18] and FaRM [39] [12]. The state-of-the-art FORD is designed particularly for DM systems, while Microsoft's FaRM is an in-memory distributed computing platform that uses RDMA-based RPCs to process dtxns using memory nodes' CPUs. To evaluate FaRM in a DM environment, we adopt a derivation of FaRM in which the coordinators use one-sided RDMA primitives to access remote data [18]. This DM-compatible FaRM directly accesses data in the persistent memory pool instead of using a circular buffer to receive RDMA messages, and thus saves memory space and avoids the cost of data copying. Thus, we compare HDTX with the DM-compatible FaRM rather than the original FaRM.

For a fair comparison, all systems adopt optimizations in FORD, including coroutines [28], outstanding requests, and doorbell batching [27]. Coroutines are lightweight, user-space functions that manage their own execution flow cooperatively and switch contexts without kernel involvement. We use multiple coroutines in a single thread as coordinators to fully utilize CPU resources when waiting for RDMA ACKs.

5.2 Macro-benchmarks

We use 16 threads, with each thread launching 7 worker coroutines as coordinators. This setup enables all dtxn systems to achieve near-optimal performance using a single computing node. Figure 8 shows the end-to-end performance of each

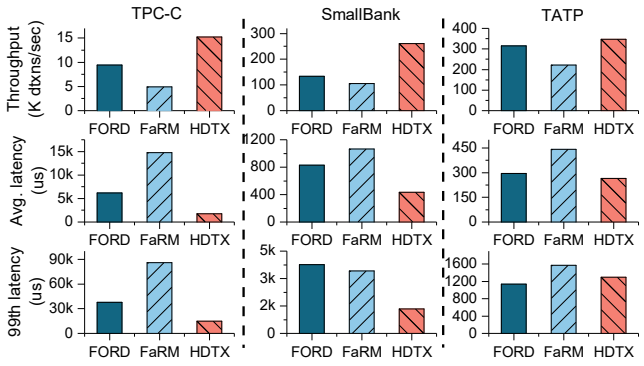

Figure 8: The end-to-end performance of different workloads

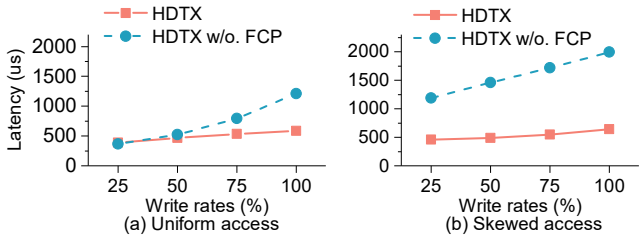

Figure 9: The effectiveness of *fast commit protocol* (FCP)

dtxn system using three OLTP workloads. Compared with FORD and FaRM, HDTX significantly reduces the average latency of TPC-C by 72.1% and 88.3%, improves its throughput by 84.7% and 2.08×, and reduces its 99th percentile latency by 60.9% and 82.7%, respectively. For SmallBank, HDTX also improves the throughput, and reduces the average latency and the tail latency significantly. For TATP, HDTX and FORD show comparable performance because most dtxns in TATP are read-only and they allow all backup memory nodes to serve read requests for high throughput, while coordinators in FaRM can only read data from primary memory nodes.

FORD outperforms FaRM because it exploits the visibility control technique to accelerate the *Commit* phase, and thus reduces network round trips of dtxns. HDTX can further reduce the latency by combining more dtxn processing phases in the proposed fast commit protocol, and can also significantly reduce the latency by scheduling dtxns according to their latency requirements. Thus, HDTX is particularly efficient for dtxns with high read-write conflicts and write-write lock contention, such as TPC-C and SmallBank.

5.3 Micro-benchmarks

In this section, we evaluate the effectiveness and efficiency of the proposed three techniques in HDTX individually.

***Fast Commit Protocol* (FCP).** First, we demonstrate the benefit of FCP using uniform and skewed [8] access distributions. Figure 9 shows the average latency of HDTX with/without FCP at different write rates. We initiate 64 coordinators to serve client requests, with each coordinator accessing two objects per dtxn. HDTX w/o. FCP shows a significant growth of latency when the write rate increases. Particularly, HDTX can reduce the average latency of dtxns by up to 67.7% compared with HDTX w/o. FCP for the skewed access distribution. Although FCP may incur the rollback of the commit phase due to read-write conflicts, FCP still demonstrates its effectiveness for the scenario using skewed access distributions under heavy read-write conflicts, as shown in Figure 9(b). This implies that the benefit of FCP is much higher than the overhead of the rollback. Overall, HDTX exploits the fast commit protocol to minimize the network rounds trips and reduce the average lock duration, and thus can significantly improve the performance of write-intensive workloads.

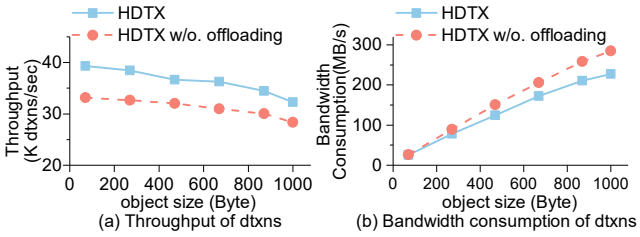

Figure 10: The effectiveness of release phase offloading

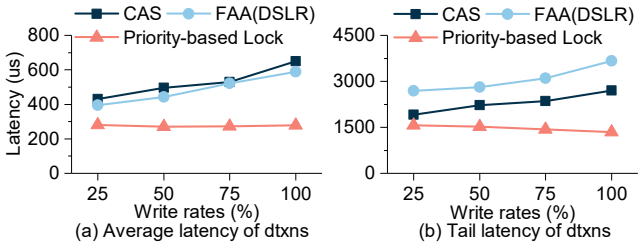

Figure 11: The effectiveness of priority-based locking

RDMA-enabled Release Phase Offloading. Second, to demonstrate the impact of the *Release* phase offloading on RDMA bandwidth consumption, we evaluate this design under high network load by running a background RDMA communication task. Figure 10 shows the throughput and RDMA bandwidth consumption of dtxns when the object size increases from 64 bytes to 1 KB. Each coordinator accesses four objects in a dtxn. Without enabling the offloading mechanism, the coordinator has to send the latest data from coordinators to memory nodes to update the write set during the *Release* phase. Compared with HDTX w/o. offloading, HDTX reduces the RDMA bandwidth consumption by up to 19.1%, and improves the throughput by up to 18.5%. Although `Wait/Enable` primitives may slow down the RNIC pipeline, the net benefit of the RDMA offloading is still considerable because our design can avoid an extra data transfer by offloading the data synchronization operations to memory nodes' RNICs.

Priority-Based Locking for Mission-Critical Dtxns. Third, we demonstrate the effectiveness of the priority-based locking mechanism. We compare it with the `RDMA CAS`-based

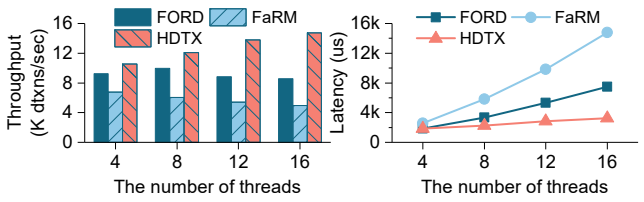

Figure 12: The throughput and the average latency of TPC-C vary with the number of threads

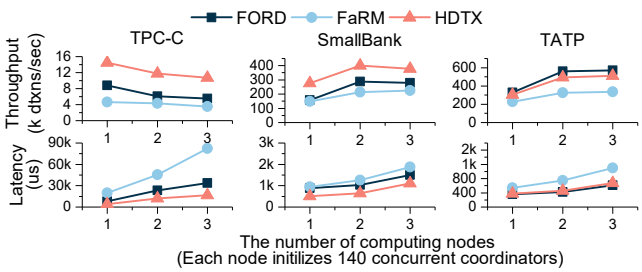

Figure 13: The throughput and the average latency of different applications vary with the number of computing nodes

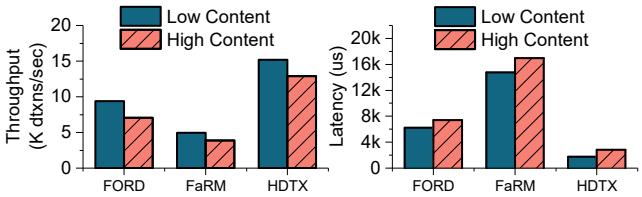

Figure 14: The throughput and average latency in low-contention and high-contention scenarios

locking mechanism adopted by FORD [53] and DrTMR [7], and the `RDMA FAA`-based locking mechanism proposed in DSLR [51]. We randomly select 20% of requests as user-specified mission-critical dtxns with a high priority, and evaluate the average and tail latency of these dtxns under different write rates with a skewed access distribution. As shown in Figure 11, HDTX using priority-based locking reduces the average latency of mission-critical dtxns by 57.1% and 52.8%, and reduces the tail latency by 50.2% and 63.3% compared with `RDMA CAS`-based and `RDMA FAA`-based mechanisms, respectively. For the tail latency, the `RDMA CAS`-based mechanism outperforms the `RDMA FAA`-based mechanism because it aborts and retries dtxns immediately once the coordinator fails to acquire all write locks, while the `RDMA FAA`-based mechanism must wait for a given lease time. Most importantly, these two mechanisms can not schedule user-specified dtxns. In contrast, our priority-based locking mechanism can significantly reduce the latency of read-write dtxns by assigning a high priority, and thus is particularly effective for scheduling mission-critical dtxns.

5.4 Sensitivity Studies

The Number of Threads. Figure 12 shows the throughput and average latency of TPC-C in different dtxn systems when the number of threads in the computing node increases from 4 to 16. Each thread initializes 7 worker coroutines as coordinators. HDTX shows a significant growth of throughput and a slight growth of latency. In contrast, the latency of FaRM increases significantly since FaRM commits a dtxn with five RTTs in a DM architecture. FORD outperforms FaRM because it optimizes the dtxn commits by exploiting the visibility control and undo logs to synchronize the latest data. However, FORD still requires three RTTs to commit a transaction. Since a longer lock duration would increase the potential of lock conflicts, FORD suffers from throughput degradation when the number of threads exceeds 8. When 16 threads are used, HDTX significantly improves the throughput by 72.7% and 1.98×, and reduces the latency by 56.7% and 78.1%, respectively, compared with FORD and FaRM. This implies that HDTX has much better performance scalability when more coordinators are used.

The Scale of Computing Nodes. Figure 13 shows the throughput and average latency of TPC-C, SmallBank, and TATP in different dtxn systems when the number of computing nodes increases. Each computing node initializes 20 threads with 7 worker coroutines per thread. Thus, the three computing nodes can initialize at most 420 concurrent coordinators. Since TPC-C has more read-write conflicts than SmallBank and TATP, the throughput of TPC-C decreases in all dtxn systems when the number of concurrent coordinators is larger than 140 (one computing node). Specifically, when we use 3 computing nodes to initialize a total of 420 concurrent coordinators for TPC-C, HDTX significantly improves the throughput by 81.8% and 2.06×, and reduces the latency by 64.1% and 79.9%, compared with FORD and FaRM, respectively. In this scenario, the high read-write contention causes more validation failures, and thus both FORD and HDTX consume more RDMA bandwidth to write logs. Specifically, FORD writes the undo log before the *Validation* phase, while HDTX writes the redo log during the *Validation* phase. However, since HDTX enables fast transaction commits with fewer execution phases, HDTX shows much higher performance than FORD. Since SmallBank and TATP have fewer read-write conflicts, all dtxn systems can improve the throughput by using more concurrent coordinators, but HDTX offers lower latency than FORD and FaRM. Overall, HDTX shows much better scalability than FORD and FaRM for large-scale concurrent dtxns.

Data Contention. Figure 14 shows the throughput and average latency of TPC-C under low and high contention of data accesses. We can reduce the number of warehouses to increase data contention. In the high-contention scenario, dtxns are more likely to access the same object, resulting in frequent lock contentions and validation failures. However, even when the number of warehouses decreases from 20 to 8,

we find that the failure rate of the *Validation* phase in HDTX only increases from 8.1% to 9.8%. Compared with FORD and FaRM, HDTX reduces the average latency of dtxns by 61.8% and 83.4%, and improves dtxn throughput by 83.2% and 2.3×, respectively, under the high-contention scenario. Since TPC-C has 92% read-write transactions with the maximum object size of 672 bytes, HDTX is particularly effective for handling this application with high contention because our priority-based locking mechanism can significantly reduce lock conflicts between dtxns. Moreover, HDTX can reduce the RDMA bandwidth consumption for large objects by offloading the data synchronization and accelerate the dtxn processing significantly using the fast commit protocol. Thus, HDTX can still achieve high-performance dtxn processing even in high-contention scenarios.

6 Related Work

RDMA-based Distributed Transaction Systems. A number of studies have exploited fast RDMA networks to improve the performance of distributed transactions. Microsoft's FaRM [39] [12] exploits OCC and PBR protocols to support RDMA-based dtxn processing. FaSST [28] adopts RDMA-based RPCs to process complicated messages with remote CPUs, and thus decreases the number of RTTs for dtxn processing. DrTM+H [48] proposes a hybrid approach that exploits one-sided or two-sided RDMA primitives to perform different phases of a transaction. Zeus [30] exploits an ownership protocol to transform dtxns into local ones, and thus can accelerate workloads with high data locality. DINT [55] exploits eBPF technologies to transparently offload some operations of dtxns to the kernel space, without kernel modifications. It eliminates the performance overhead of network stacks while guaranteeing security. However, since these systems are designed for traditional monolithic servers equipped with both computing and memory resources, they cannot be applied to DM systems directly. Xenic [40] offloads some functions of the dtxn protocol to SmartNICs to reduce PCIe operations. FORD [53] exploits one-sided RDMA to achieve fast dtxn processing for DM systems, and guarantees remote persistence with low network overhead. Motor [52] proposes contiguous version tuples to construct a multi-versioning datastore in a DM environment. It eliminates the logging overhead while allowing coordinators to concurrently read data during modification. Inspired by these studies, HDTX further optimizes the performance of dtxn for one-sided RDMA-based DM systems via three novel designs, including the fast commit protocol, RDMA-enabled offloading, and decentralized priority-based locking. By carefully orchestrating these techniques, HDTX can minimize the RTTs for dtxn processing, significantly improve the throughput, and reduce the latency of dtxns.

Management of Distributed Locks. Lock management is a fundamental technique for preventing race conditions and ensuring data consistency in distributed systems. In traditional distributed locking schemes [2, 22, 24], data nodes' CPUs act as a central point to enable flexible scheduling of shared object accesses. To alleviate the CPU load in data nodes, some studies [28, 53] exploit one-sided `RDMA CAS` primitives to request locks in a blind-retry manner. To avoid the starvation problem caused by `RDMA CAS`, a decentralized mutex lock mechanism [10] is proposed to schedule lock requests in a FIFO manner. N-CoSED [36] uses two 32-bit segments of a 64-bit lock object to support shared and exclusive access modes. However, they require additional communications between coordinators to propagate the ownership of the lock along the FIFO queue. DSLR [51] exploits the Lamport's Bakery algorithm to avoid write starvation and to eliminate communication among coordinators, and thus improves the performance of dtxns. We go further to challenge an intuitive understanding that decentralized locks are hard to support priority-based scheduling, and propose decentralized priority-based locking to schedule transactions at each computing node. In this way, HDTX can significantly reduce the latency of mission-critical transactions in DM systems.

7 Conclusion

Distributed transactions usually are processed inefficiently in disaggregated memory systems due to high latency of remote memory accesses. This paper presents HDTX, a high-performance dtxn system that delivers fast dtxn services and supports flexible dtxn scheduling in the DM architecture. We first conduct an in-depth analysis of the characteristics of dtxns and one-sided RDMA primitives. Based on our analysis, we propose a fast commit protocol to commit dtxns within minimum network round trips and significantly reduce the latency of dtxns. We further propose an RDMA-enabled offloading mechanism to reduce data transfers across computing and memory nodes by carefully orchestrating different RDMA primitives. In addition, we propose a decentralized priority-based locking mechanism to schedule mission-critical dtxns, thereby significantly reducing the tail latency of dtxns. Experimental results demonstrate that HDTX provides higher throughput and lower latency than state-of-the-art RDMA-based dtxn systems, such as FaRM and FORD.

Cuckoo for Clients: Disaggregated Cuckoo Hashing

Stewart Grant and Alex C. Snoeren
UC San Diego

Abstract

RCuckoo is a fully disaggregated lock-based key/value store in which clients cooperatively access a passive memory server using exclusively one-sided RDMA operations. RCuckoo employs cuckoo hashing to enable single round-trip reads of small values while updates and deletes require only two. We introduce locality-enhanced dependent hashing that allows us to adjust the expected distance between a key's potential table locations, dramatically improving insert performance compared to prior cuckoo-hashing approaches while limiting I/O amplification and maintaining practical maximum fill factors. We show that not only does RCuckoo outperform all existing state-of-the-art RDMA-based key/value stores when reading small values, but under severe contention RCuckoo delivers up to 7× the throughput of comparison systems across the standard set of YCSB workloads. Moreover, RCuckoo's lease-based locking mechanism enables it to gracefully recover from 100s of client failures per second.

1 Introduction

Disaggregated architectures aim to improve scalability and utilization by pooling network-attached resources [3, 17, 21, 35]. In theory, pooling reduces per-machine fragmentation and stranding by exposing resources over the network. Collectively, disaggregated resources can be provisioned for the sum-of-peak workloads rather than the peak-of-sums [2, 36]. Stagnating DRAM densities are driving interest in primary storage pooling, but performant, general-purpose far-memory tiers remain elusive [1, 4, 5, 11, 18, 24, 35, 42] as even the fastest rack-scale networks have access latencies that are an order-of-magnitude slower than local memory. (e.g., RDMA latency is approximately 1 µs versus DRAM's 50 ns) [40].

As a result, most existing far-memory systems [5, 12, 34, 39, 44] choose to statically partition remote memory to avoid the multiple round trips required to synchronize shared updates. While challenging to achieve, memory sharing is critical to making remote memory pooling practical as it can improve utilization—the entire point of memory disaggregation. To date, the most promising approach to delivering shared access to pooled remote memory is to expose a key/value store (KVS) interface that provides coherent read/write semantics [19, 22, 37, 38, 40, 41, 43]. Yet, most performant KVS systems employ two-sided RDMA operations which rely upon memory-side CPUs to manage locks and execute critical sections [9, 20, 25, 26], reducing their potential savings.

To fully unlock the potential of memory disaggregation, we propose a design where compute and memory are entirely separate. In our fully disaggregated model, a KVS must implement a client-side serialization protocol implemented entirely in one-sided RDMA operations (i.e., read, write, and atomic updates). Maintaining a coherent memory model is the core challenge in designing such systems. Existing KVS's with ordered keys (e.g., BTrees & Radix Trees) rely upon locking schemes [22, 41], while those that provide unordered access favor lock-free techniques [19, 37, 38, 40] to decrease read latency while avoiding the RDMA hardware bottlenecks and complex failure scenarios that can arise with locks. The trade-off, however, is that lock-free approaches perform worse as write intensity increases.

In this work we present RCuckoo, a system that uses lock-based synchronization on commodity RDMA hardware to out-perform existing key/value stores across a wide range of workload mixes. Critically, locks enable the use of cuckoo hashing [32], a well-established, high-performance datastructure for key/value stores. Locks also support in-lining small values in the hash table, delivering significantly higher throughput on common mixed read/write workloads. Further, our fine-grained locks and careful protocol design reduce lock hold times during updates to two round trips in the common case, and we avoid known hardware bottlenecks with RDMA atomic operations by crafting a lock table small enough to be stored entirely on NIC-based memory. Finally, lease-based lock acquisition delivers correct, high-throughput performance even in the face of client failures with held locks.

RCuckoo's efficient locking is made possible by a *dependent hashing* algorithm that makes spatial locality a

tunable parameter. Cuckoo hashing works by deterministically computing two potential hash locations—primary and secondary—for any key; collisions are resolved by relocating the existing entry in a key's primary location to the existing key's secondary location, and so on down what is known as a cuckoo path. Traditionally, a key's two potential locations are drawn independently at random, defeating any locality-based optimizations. By controlling the distance between a key's locations—and therefore the span of a potential cuckoo path—we probabilistically bound the range of memory that must be locked, and, relatedly, the number of locks that a client must acquire.

Combined with aggressive batching of RDMA operations, RCuckoo's spatial locality limits the number of round trips required for all table operations. In the common case, reads execute in one (for small values) or two round trips, uncontested updates and deletes require two round trips, and the median insert operation involves only two round trips—although the expected number increases as the table fills and cuckoo paths grow. On our testbed, RCuckoo delivers comparable or higher performance on small values across the standard set of YCSB benchmarks than all of the existing disaggregated key/value stores we consider. Concretely, with 320 clients RCuckoo delivers up to a 2.5× throughput improvement on read-intensive (YCSB-B) workloads and up to 7.1× their throughput on write-intensive (YCSB-A) workloads. Moreover, RCuckoo's performance remains high despite 100s of clients failing per second.

2 Background

Existing disaggregated key/value stores build upon the extensive literature of RDMA-based key/value stores. In this section we overview that lineage and discuss the algorithmic distinctions between the two. Our hash table design draws on both cuckoo and hopscotch hashing. We provide a brief overview of both approaches and related literature.

2.1 Disaggregated Key/Value Stores

The challenge to adapting existing RDMA-based KVS designs to a fully disaggregated setting is the need to rely exclusively on one-sided operations due to the lack of a server-side CPU. Precursor RDMA KVS systems achieve performance by striking a delicate balance between efficient one-sided RDMA operations and CPU-serialized two-sided operations [8, 15, 25, 26, 28], where the later are used sparingly, but are critical for correctness.

In general, the performance of any KVS on a mixed read/write workload hinges on its serialization performance. Fast consistent writes with one-sided RDMA are hard because RDMA atomic operations operate on small (8-byte) regions of memory and the cost of round trips is high. This constraint has lead to a divide in the design of disaggregated KVS systems between those that support range queries over ordered keys and those that do not. Systems with ordered keys use locks to guard their complex updates, while those with unordered keys employ lock-free optimistic approaches by constraining updates to atomic 8-byte writes. These latter designs typically use hash indexes with 8-byte entries that point to uncontested extent regions where the corresponding values are stored. Commonly the index entries use 48 of the 64 bits as a pointer and the remaining 16 bits for a digest of the key and the size of the value. This approach requires additional round trips to check for a key's presence and limits the size of values that can be stored [38, 45].

On the other hand, KVS systems that support ordered keys use locks to guard the complex operations required to update B-Trees or Radix Trees. In exchange for expensive update operations, locks allow these systems to support inlined values and, thus, faster small-value reads. Performance is gated, however, by lock granularity and hold times. At the time of writing all lock-based KVS systems assume that clients are grouped into co-located servers which can locally coordinate lock accesses and batch their writes [22, 41], an assumption that optimistic KVS systems do not make [37, 38, 40, 45]. We show that it is possible to realize the performance gain of lock-guarded inlined operations without requiring client co-location if locks are sufficiently fine grained and hold times limited.

2.2 RDMA and Network Performance

Historically, network bandwidth has limited KVS throughput more than operation rate. For instance, while a 40-Gbps ConnectX-3 NIC can process 75 million packets per second, line rate restricts it to 5 MOPS when reading 1-KB objects. As commodity datacenter link rates increase from 100 Gbps to 400 Gbps and beyond, however, latency and contention—rather than raw network bandwidth—become the primary scalability bottlenecks. To this end our design choices seek to reduce round trips at the cost of slight bandwidth amplification and we focus our evaluation on workloads with small key/value pairs whose performance is not limited by line rate on our 100-Gbps ConnectX-5 testbed hardware.

Concretely, Figure 1(a) shows the growth in round trip time for RDMA reads of increasing size. On our hardware, the round trip time for a single 1-KB read is lower than the total latency of issuing two dependent reads of

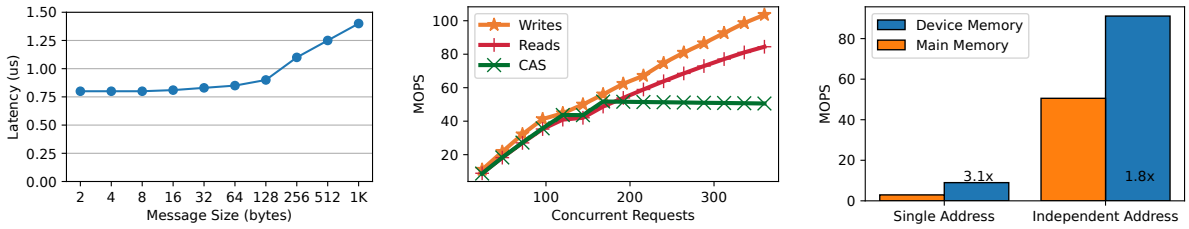

Figure 1: Basic RDMA performance on our testbed. **(a)** Read latency as a function of message size [31]. **(b)** Operation throughput as a function of offered load. **(c)** Atomic compare-and-swap performance on device and main memory.

just a few bytes each. This suggests that performance can be gained if a single large packet can complete the work of two smaller, but dependent messages. Indeed, our evaluation (see Figure 8(d)) shows that even on our 100-Gbps testbed inlining values and servicing lookups with a single large read provides a 4–37% throughput increase compared to an extent-based approach for the same value size.

Prior systems have avoided locks due to the stark performance penalties of RDMA atomics [16]. Figure 1(b) illustrates this bottleneck on ConnectX-5 NICs when atomic operations are issued on remote server memory: reads and writes scale almost linearly while atomics reach a hard limit around 50 MOPS. Using RDMA atomic operations to spin on locks quickly induces these bottlenecks as the cap is even lower (3 MOPS as shown in Figure 1(c)) for atomics that contend with each other (i.e., access the same remote address). Recent ConnectX series NICs sport a small amount (256 KB) of on-NIC memory which avoids a PCIe round trip and raises the cap on atomic operation throughput [30, 41]. Figure 1(c) illustrates the performance improvement for single—i.e., contended—and independent addresses. If a system can arrange to store its locks exclusively in NIC memory it can gain up to a 3× performance improvement on contended workloads.

Others have explored ways to improve RDMA-based lock performance. Citron implements a general purpose, range-based lock table with fairness guarantees [10]. While the current design is ill-suited for our use case (each request solves a knapsack problem, maintains a tree structure, and can introduce false contention), we hope to adapt its fair bakery algorithm to RCuckoo in future work. At present, RCuckoo focuses on raw, common-case performance, supporting concurrent operations across disjoint ranges as described in the following section.

2.3 Cuckoo and Hopscotch Hashing

Both cuckoo and hopscotch hashing have been highly successful as indexes for RDMA KVS [8, 9, 14, 20, 25]. Both algorithms enable clients to locally calculate a key's location (or neighborhood) in the index without consulting the server. This fact enables a critical division of labor for mixed read and write workloads. Reads can be performed asynchronously via one-sided RDMA, while writes require serialization—typically implemented using locks managed by the CPU at the memory server using two-sided RDMA. Both cuckoo and hopscotch hashing algorithms have complex mechanisms for resolving hash collisions which make them difficult to implement entirely with one-sided RDMA. This section describes both algorithms and their associated challenges.

Cuckoo hashing uses independent hash functions to compute a primary and secondary location for each key. Keys are always inserted into their primary location and evict an existing key to their secondary on collision which in turn can cause a chain of evictions (a cuckoo path) shown in Figure 2. Associative locations and BFS search are used to minimize path length [9, 20] which is the largest factor in the cost of insertions. In a fully disaggregated implementation each path step incurs a read to a random index location which requires an RDMA round trip (as the lack of locality makes client-side caching infeasible). The lack of locality similarly frustrates attempts to proactively acquire locks. That said, cuckoo hashing does not require any metadata to be maintained in the index, simplifying collision and error recovery.

Hopscotch hashing, on the other hand, delivers a tunable level of locality for insertions, but at the cost of maintaining index metadata. In hopscotch hashing, all insertions occur in a neighborhood of their original hash location [8, 13]. Evictions are performed by "hopscotching" entries through their neighborhood until an open location is found. Each entry has a bitmask which tracks its collisions. When hopscotching these bitmasks must be updated which requires additional locking. Farm [8] and Reno [14] bound this expense by setting hard limits on chain length but still require a server-side CPU to fix bitmasks when concurrent inserts execute. Hopscotch hashing trades locality for additional metadata, while cuckoo hashing eschews metadata at the cost of random accesses. Our system RCuckoo combines the advantages of both ap-

proaches with a cuckoo hash function with hopscotch-like locality properties in the common case.

3 Design

In this section we describe the design of RCuckoo, a fully disaggregated key/value store implemented as a lock-based cuckoo hash table. RCuckoo's performance stems largely from its extremely compact lock table which is enabled by our dependent hashing algorithm. Before describing the hashing algorithm or lock table, however, we first introduce the datastructures and protocols to read and modify the contents of the key/value store. For simplicity, we describe our design in the context of a single server, but it is straightforward to shard a large table across multiple servers (with a minor tweak, see Section 3.3).

3.1 Datastructures

Figure 2 shows RCuckoo's index and lock table (both maintained at the remote memory server) during an insertion of key K (which requires the cuckooing of key C). The index table (right) is a single region of RDMA-registered main memory divided into rows of fixed-width entries. Each row contains n associative entries (3 in this figure; we use 8 in practice) and terminates with an 8-bit version number and 64-bit CRC (computed over the entire row including version number). Clients access the index table using 1-sided RDMA reads and writes. Clients can safely read one or more rows in a single lock-free RDMA operation as CRCs allow each row's contents to be verified while version numbers enable clients to detect if a row has been modified (used to detect failures; see Section 4.1).

Table entry and key sizes are configuration parameters, but are the same for all rows and must be fixed at table creation. Individual entries, on the other hand, can contain either inlined key/value pairs (bottom left) or a key and 48-bit pointer to an extent to store larger values (bottom right). The least-significant bit of an entry signifies its type; values are inlined by default. Extent entries use 23 bits to encode the value size (which can range from 2^3 to 2^{26} bytes). Extents are located in separate, pre-allocated, per-client, RDMA-registered regions of server memory to avoid contention on inserts. Given the fully-disaggregated context we assume the index table will be initially provisioned at maximum size; we defer resizing to future work.

Locks (stored in a bit vector in NIC memory, shown on the left) each protect a tunable number (here, two; 16 in our experiments) of index rows. Clients perform lock acquisition and release with RDMA compare-and-swap (CAS) operations. Specifically, RCuckoo leverages masked CAS (MCAS) operations [29, 41] to obtain up to 64 locks simultaneously while avoiding false sharing.

3.2 Operations

We detail the operations supported by RCuckoo below; Figure 3 visualizes the corresponding message exchanges.

3.2.1 Reads

RCuckoo is designed to facilitate lock-free, single round-trip reads for small values as they are the dominant operation for key/value stores in many data centers [6, 27]. To read the value associated with a given key clients calculate the potential table locations for the key's entry (using the hash functions described in the next subsection) and issue RDMA reads for both rows simultaneously. Because all operations between a client and a given server travel over a reliable connection, they are intrinsically ordered, but in our description we will only call out when a particular ordering among a batch of messages is required.

Moreover, as suggested by Figure 1(a), if the rows are located sufficiently close together, it can be beneficial for the client to issue a single *covering read* that returns the contents of both rows—as well as any intervening ones—in a single request. In our experiments RCuckoo clients issue a single, large read rather than two small reads if the locations are in adjacent rows. Reads are successful if either row contains an entry with the desired key and a valid CRC. An invalid CRC indicates a torn write or rare failure case, in which case the operation is retried (see Section 4.1). As shown in Figure 3(a) successful inlined reads complete in one round trip, while reads for large values require a second round trip to retrieve the extent.

3.2.2 Updates and deletes

Updates and deletes, like reads, access only two locations in the index table, but require a client to acquire the associated locks. Due to RCuckoo's dependent hashing, it is usually possible to attempt to acquire both locks in a single MCAS operation (Section 3.4.1). If so, the client issues read(s) for the corresponding rows of the index table immediately afterwards but in the same batch of operations.[1] In the rare case that the locks must be acquired independently—necessitating an additional round trip—the reads are batched with the second lock request.

Assuming successful lock acquisition and valid reads, the operation can proceed if the key is present in either location. In a single (ordered) batch of operations, the client first writes the updated/freed entry and recomputed row version and CRC before releasing the locks. When updating values stored in extents, clients store the value to a new extent via an RDMA write that is sent in parallel with lock requests. On lock release clients write the first bit of the old extent to free it. Deletes operate identically save writing a new extent. Clients garbage collect their own extents by occasionally scanning their allocated region for freed extents. Figure 3(b) shows that most uncontested operations complete in two round trips; clients retry acquisitions until they succeed or detect a failed client.

3.2.3 Inserts

Inserts are challenging because concurrent operations might result in cuckoo paths that collide. To avoid the complexity of rolling back partially completed inserts in the event of a collision, RCuckoo clients compute a complete cuckoo path ahead of time and then acquire locks on all the relevant rows to ensure its success. Moreover, to facilitate recovery from client failures, an insert is performed by cuckooing elements one at a time, starting by moving the last entry in the path to the empty location, and then replacing it with the previous entry in the path, and so on until the new entry is inserted in its primary location.

To speed up cuckoo-path searches, RCuckoo clients keep a local, RDMA-registered cache of (relevant portions[2] of) the index table. The cache is populated with the results of any operation, but is used only for inserts. Clients validate—and, if necessary, update—their cache at each step of the insert operation as explained below, so stale entries do not impact correctness, only performance.

At a high level an insert operation proceeds in three (or four) phases. For extent entries, clients first write the value to a free extent—in parallel with the remaining three phases. Clients maintain a local slab allocator that manages their private extent region, so there is no contention. Regardless of whether the entry contains an inlined value or a pointer to an extent, RCuckoo clients start by identifying a potential cuckoo path using only the contents of their local table cache. Clients then simultaneously attempt to acquire the locks for and update their cache of the rows that comprise the candidate path. Using only the contents of their newly updated local cache, clients conduct a second search to confirm that a candidate path—either the initial guess or an alternative that similarly consists only of currently locked rows—exists. If so, the insert is performed; if not, the client releases its locks and retries.

Speculative local search: Each insertion attempt uses a heuristic search to find a *speculative* cuckoo path. An attempt starts by identifying a potential path using the (potentially stale) contents of the client's local table cache. We use breadth-first search (BFS) [20] to identify short paths in an attempt to minimize bandwidth and locking overhead. If the client cache is empty the degenerate path is presumed, i.e., that the key will be inserted into its primary location without the need for any cuckooing. Speculative cuckoo paths are especially useful when client caches are fresh—often due to a failed prior attempt to insert the same key.

Cache synchronization: Armed with a speculative cuckoo path, clients identify the set of locks necessary to protect the relevant rows. Approximately 99% of paths can be locked with a single MCAS operation (Figure 4(c)); longer paths acquire locks in groups (Section 3.4.1). Immediately after, but in the same batch of RDMA operations as each attempt to acquire (a subset of) the locks, clients synchronize their local cache by issuing

[1] Because the lock table is located in NIC memory, RCuckoo clients can employ `SEND_FENCE` on reads batched with lock acquisitions to ensure consistency without incurring a performance penalty.

[2] A small cache suffices; we use 64 KB in our experiments. Caching the entire index yields negligible additional benefit.

reads for all of the rows covered by that set of locks. In general, locks cover multiple rows, so this will be a superset of the rows necessary for the identified path. Note that if lock acquisition is successful, the values returned by the read of the corresponding rows will remain unchanged until the lock is released.

Figure 2 shows an example insert operation where the primary row for K is full and the entry for key C is being evicted to its secondary location. Hence, the client has acquired locks corresponding to the row where it hopes to insert the entry for key K as well as the row into which it plans to cuckoo the existing entry for key C. Rows shaded in gray are synchronized because they are covered by the locks, while the contents of any other rows that happen to be in the client's cache cannot be depended upon without additional validation. Rather, they may increase the likelihood that a subsequent speculative search succeeds.

Second search: If all the lock acquisitions are successful, the client confirms that the speculative path remains valid. Under an insert-heavy workload, however, speculative cuckoo paths are frequently stale. Yet, a valid cuckoo path may still exist within the locked rows. Hence, if the speculative path is no longer viable, clients perform a second search within their cache restricted to only the rows for which they currently hold the lock in hopes of identifing an alternative path. If the speculative path works—or a valid alternative is located—the appropriate series of swaps and version/CRC updates are calculated and issued as a batch of RDMA writes, one row at a time, followed by (an ordered set of) lock releases. If no valid path exists within the currently locked rows the client releases its locks and tries again, conducting another speculative search on the updated cache contents.

This entire process repeats until success, a client determines there is no viable cuckoo path within a maximum search depth (we use a depth of five in our experiments, at which point the insert operation returns an error indicating the table is full), or a failed client is detected. If cuckoo paths were to randomly span the table it is unlikely that an alternate valid path would exist within the locked rows when speculation fails. In the next subsection, we describe how RCuckoo uses dependent hashing to dramatically increase the likelihood that an alternate path exists.

3.3 Locality

In a traditional cuckoo hash, the two locations for a given key are deliberately independent which allows the table to be filled quite full before inserts begin to fail. In RCuckoo the distance between keys' two cuckoo hash locations is a tunable parameter. Increased locality has two direct benefits: it decreases the number of MCAS operations necessary to acquire the relevant locks and increases the probability that both of a keys' locations can be read with a single covering read. It also reduces the region of the index table likely to be spanned by cuckoo paths, which speeds up inserts, but leads to hot spots that limit the table's expected maximum fill factor. Experiments show that an optimal locality setting can dramatically decrease the number of round trips required to perform inserts in RCuckoo while maintaining high (90%+) maximum fill factors.

In RCuckoo, the primary location for a key is chosen uniformly at random, while the second is offset from the first by uniformly random value drawn from a probabilistically bounded range, where the range is likely to be relatively small. We start with a base hash[3], $h()$, and use it to implement three independent hash functions $h_1()$, $h_2()$, and $h_3()$. (In our implementation we use a different salt for each of the three functions.) We compute the two locations L_1 and L_2 for a key K as

$$L_1(K) = h_1(K) \mod T,$$

$$L_2(K) = L_1 + (h_2(K) \mod \lfloor f^{f+\mathcal{Z}(h_3(K))} \rfloor) \mod T,$$

where T is the size of the index table in rows, $\mathcal{Z}(x)$ is the number of trailing zeros in x, and f is a parameter that controls the expected distance between the two hash locations. (In a sharded deployment, the second location is restricted to the same shard by "wrapping around" the offset accordingly.) The particular formulation is not important, but the upshot is exponentially fewer keys have secondary locations at increasing distances from their primary. The probabilistic aspect is crucial, as any fixed bound on the distance between hash locations leads to low maximum fill factors (on the order of 10–15% in our experiments).

Figure 4(a) shows the distance between hash locations as a CDF for different values of f, while Figure 4(b) shows that larger f enables higher fill prior to the first insertion failure. In our evaluation we set $f = 2.3$ based on this empirical data. As shown in the figure, for index tables with eight entries per row, RCuckoo delivers an expected max fill of greater than 95% with a 68% probability that a key's locations are located five or fewer rows apart.

Decreased distances between hash locations naturally lead to shorter cuckoo paths when combined with our breadth-first search approach. Using $f = 2.3$ and a table size of 100-K rows, Figure 4(c) shows that when filling the table to 95% full, slightly more than half of insertions do not require any cuckooing, and 95% of insertions require cuckoo paths that span 32 or fewer rows while

[3] We use xxHash [7] in our implementation.

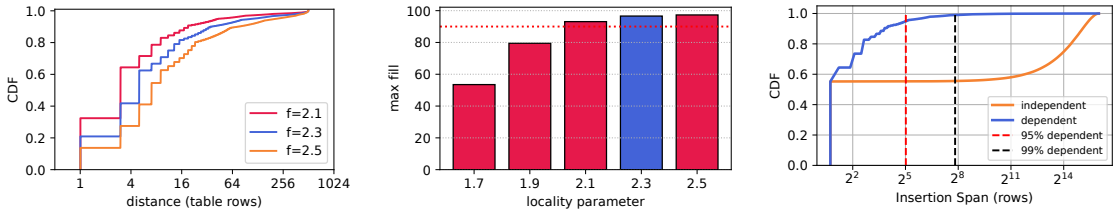

Figure 4: **(a)** CDF of distances between cuckoo locations for different locality settings using RCuckoo's dependent hashing. **(b)** Fill percentage before insertion failure for different locality settings (average of 10 runs, negligible variance). 90% fill indicated by dashed red line. **(c)** CDF of cuckoo spans for dependent and independent hashing. A cuckoo span is the distance between the smallest and largest index in a cuckoo path.

nearly 99% span 256 or fewer. Conversely, with independent hashing, insertions that require any cuckooing at all almost always result in spans of 2 K rows or more.

3.4 Locking

While RCuckoo reads are lock free, updates and especially inserts depend critically on locking performance.

3.4.1 Lock granularity

Increased locality decreases the number of round trips required for lock acquisition. Recall the lock table is a linear array of lock bits and each bit locks one or more table rows. As mentioned previously, RCuckoo implements lock acquire and release using RDMA masked compare-and-swap (MCAS) operations that can update 64 bits at a time. To avoid deadlock RCuckoo acquires locks in increasing order. For any given operation, clients group the necessary locks into the smallest number of sets as possible (where each set is an attempt to acquire one or more locks within a single 64-bit span) and issue MCAS operations one at a time in order of their target address. Clients continuously spin on lock acquisitions and only move to the next MCAS operation after the current one succeeds. Due to this one-MCAS-per-round-trip acquisition procedure, lock granularity is critical to performance.

If, as in Figure 4(c), almost 99% of cuckoo spans are 256 rows or less, and each lock protects four rows, almost all insertions can have their locks acquired with a single MCAS (lock-table accesses do need to be byte aligned). Of course, increasing the number of rows covered by a single lock can lead to false sharing, forcing additional retries to acquire the necessary locks. Figure 5 shows the results of a representative experiment where 8 clients are concurrently filling a 512-row table to 95% full. We report the 99th-percentile (i.e., the most expensive inserts when the table is nearly full) number of round trips required to acquire the locks necessary to perform an insertion as a function of both lock granularity (i.e., number of rows per lock, on the x-axis) and lock size (i.e., the number of locks that can be accessed with a single MCAS operation, on the y-axis—RCuckoo's single-bit locks correspond to 64 locks per message shown on the bottom row).

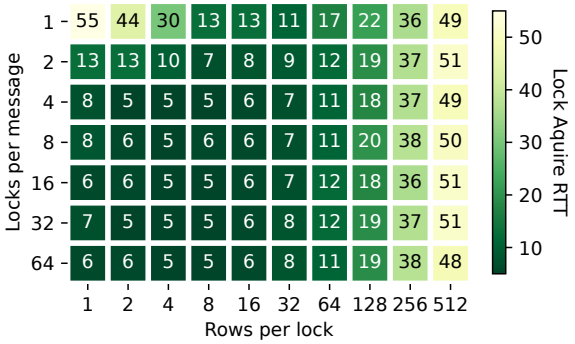

Figure 5: 99th-percentile round trips required per insert in a 512-row table when filling to 95%. 512 buckets per lock corresponds to a single global lock.

While there is some noise due to experimental variance, the far-right column shows that a single global lock results in high contention (as there is only one lock in the system, it does not matter how many locks can be acquired per message). Conversely, the top left corner shows that, despite the lack of false sharing when a lock corresponds to exactly one row, the inability to acquire more than one lock at a time leads to a large number of round trips. Under these conditions, the sweet spot falls in the range of 2–16 rows per lock. In our experiments we use 16 rows per lock as, when combined with our choice of f, a single MCAS suffices for the vast majority of insertions.

3.4.2 Virtual locks

While Figure 5 suggests that RCuckoo could employ larger locks (e.g., 8–16-bits per) without increasing the number of round trip times required to acquire them, there is an additional design constraint that drives our choice of single-bit locks. Specifically, to improve locking per-

formance, RCuckoo locates the lock table in NIC device memory which delivers $3\times$ higher throughout on contented addresses than host memory (Figure 1(c)). It is also lower latency as operations to device memory avoid a PCIe round trip. Unfortunately, NIC memory is limited (to 256 KB on our ConnectX-5s), so this choice bounds the size of the lock table and drives our single-bit design.

To allow RCuckoo to support tables with more than 64 M rows, we implement a *virtual* lock table where multiple logical locks map to a single physical lock. Concretely, we map a logical lock l drawn from a table of size L to a physical location p in a bit-array of size P by computing $p = l \mod P$. Mapping multiple virtual locks to a single physical lock introduces yet another source of false sharing, but allows us to support arbitrarily large tables. When employing virtual locking, clients performing an insert first map rows to virtual locks, then to physical locks, then sort them into groups.

4 Fault tolerance

In keeping with the rest of its design, RCuckoo handles failures in a fully disaggregated manner as well. We depend upon the RDMA hardware to handle network failures and focus exclusively on clients which can *fail-stop* mid-operation. Server failure can be addressed by employing client-driven replication on top of RCuckoo. While there may be opportunities to integrate replication into RCuckoo itself, we defer such an exploration to future work. In RCuckoo, client failure is only of concern if the failure occurs while the client was holding one or more locks, i.e., in the middle of a mutating operation (i.e., update, delete, or insert); hence, RCuckoo detects client failures by noticing that a pending mutation does not complete in a timely fashion. Any client that encounters such a situation endeavors to recover the stranded lock and repair the impacted portion of the index table. The remainder of this section describes how RCuckoo clients detect faults, reclaim stranded locks, and, if necessary, repair the index table. Finally, we discuss additional measures that can be employed to prevent stale writes if desired.

4.1 Failure detection

Clients detect failures by setting a timeout when attempting repeated lock acquisition or read requests. Because RCuckoo operations are designed to require only a few round trip times, a client performing a successful mutating operation will complete and release its locks extremely rapidly. Conversely, a client that is unable to acquire all the locks required for an insert operation releases those they do hold before trying again. Hence, it is extremely unlikely that repeated attempts to acquire a lock or perform an untorn read will fail continuously.

Of course, there is a possibility that a given row is highly popular, leading to high lock contention and/or repeatedly torn reads. Clients distinguish this case by consulting the CRC for the row they are unable to successfully read or lock. Because each mutation increases the version number, even updates that replace an entry with the same value will result in a different CRC. Clients declare a false positive and restart their failure timer if a CRC changes between attempts.

We expect client failures to be relatively rare, so set our fault timeout conservatively. Failure timers must allow for worst-case locking time, second-search time, and RDMA message transmission time. We bound locking time; search and message propagation are both measured in single-digit microseconds on our testbed. To guard against the possibility that network conditions lead to high rates of RDMA retries we set the maximum RDMA operation retry number to three. In this context, we set the failure timeout to 100 ms in our experiments, orders of magnitude above the 99th-percentile insert time of 50 μs.

4.2 Repair leases

RCuckoo recovers stranded locks one lock at a time; if a client fails holding multiple locks recovery may be conducted by multiple clients at different times depending on their access patterns. RCuckoo's lock table does not maintain records of ownership, so there is no way to "transfer" lock ownership from the failed node to a recovery node in the table itself. Instead, clients acquire a *repair lease* that grants exclusive permission to reclaim locks on a region of the index table. The index table is broken into n regions so repairs can be executed in parallel.

RCuckoo maintains a lease table in RDMA-registered main memory on the server. Lease entries contain a $(\log n)$-bit lease ID, a set flag, the lease holder's 48-bit queue pair ID (which RDMA ensures is unique for a given server), and an 8-bit counter (incremented on each acquisition). A lease is considered free if the set bit of the current entry in the lease table is zero. Clients attempt to acquire the lease using RDMA CAS operations to ensure mutual exclusion. Upon successful acquisition, a client completes the repair (described below) and then relinquishes the lease by clearing the set bit. Leases are revoked (to handle the case of a failed recovery node) using a timeout mechanism similar to normal locks. If a client times out while attempting lease acquisition it claims it for itself (again, using CAS to resolve any races) and marks

the lease holder as failed (see Section 4.4).

4.3 Table repair

All modification operations write new entries as a cuckoo path; updates and deletes have a path of length one. As described in Section 2.3 cuckoo paths are executed by first claiming an open entry at the end of the path and proceeding backward along the path, cuckooing entries forward one-by-one until the new entry is written at the beginning of the path. Client failures can occur at any point along an insertion path; a failed client can leave the table in one of four distinct states based on how far along it was:

1. A duplicate entry exists and one has a bad CRC,
2. A duplicate entry exists and both have correct CRCs,
3. No duplicate exists but one row has a bad CRC, or
4. No duplicate exists and no rows have a bad CRC.

The last case can occur if a client fails prior to issuing any updates to the table or if it fails after updating all the rows but before releasing the locks. In either case recovery is trivial: a client with the repair lease can simply unlock the stranded lock. Recovery from the other three cases requires modification to the index table.

To repair the table a client first detects in which state the table is and then transitions the table forward through the states with a deterministic sequence of operations so that failures during recovery can be repaired by a subsequent client. A client determines the state by issuing reads to all rows protected by the stranded lock. It then proceeds one-by-one through each entry within the rows, checking both hash locations for the corresponding key (one of which may not be in the locked rows) for duplicates or a bad CRC. Because RCuckoo updates one row per RDMA write, there can be at most one duplicate or bad CRC.

Clients repair the table by transitioning though the states one step at a time. To move from state 1 to 2, the client writes a new CRC for the bad duplicate. The table can be transitioned from state 2 to 4 by clearing the duplicate entry in the second (i.e., pointed to by $L_2(K)$) location. Finally, the table can be transitioned from state 3 to 4 by recalculating and writing a new CRC to the impacted row. After a client has issued its repair sequence it unlocks the reclaimed lock and returns its lease.

From a correctness perspective, once all rows have a valid CRC and there are no duplicates, the table is usable again. Clearly the new value being inserted into the table by the failed client is lost, but this is indistinguishable from the case that the client failed before attempting the insert. If the client was in the middle of cuckooing values up the path, a subset of the values were moved from their primary cuckoo location to their secondary location, but reads check both locations in any case, so the entry will still be located. Finally, because duplicate entries are freed, no space in the table is lost.

4.4 Preventing stale writes

The one remaining concern is that a supposed-failed client could just be slow, and may yet attempt to complete its cuckoo path despite the fact that its locks were reclaimed. Our failure timeout is deliberately set many orders of magnitude larger than the expected operation completion time, but we cannot completely rule out the possibility. Large-scale deployments can implement a separate liveness protocol to identify stalled clients and prevent such black swan events.

Specifically, a portion of remote memory could be used to store a datastructure that each client must update with some frequency so failed (or unreasonably slow) clients can be identified by their failure to update their entry in a timely manner. Such a protocol is straightforward to implement with one-sided RDMA operations, but we have not found the need to implement it in our testbed—we have never seen a stale write that was delivered with a delay anywhere close to approaching our timeout value.

Once a failed client is identified, real-world deployments have many ways to ensure the client ceases operation, but it is interesting to consider providing such functionality within RCuckoo itself. Unfortunately, at the time of writing the Infiniband specification does not allow clients to modify each other's RDMA permissions.[4] To the best of our knowledge, the only current alternative is to reset a failed client's queue pair by crafting an invalid packet and sending it to their queue pair at the server [33, Attack 2]. For this attack to work the packet sequence number of the invalid packet must match expected sequence number at the receiver so 2^{24} packets must be sent to ensure the connection is corrupted successfully.

5 Evaluation

We evaluate RCuckoo by directly comparing its performance in terms of throughput and latency against representative state-of-the-art (partially) disaggregated key/-value stores. When accessing sufficiently large values, all systems can max-out our testbed's 100-Gbps link rate, so we focus on workloads with small key/value pairs that remove the bandwidth limitation, exposing the

[4] Type-II memory windows enable clients to remove their own permissions using `SEND_WITH_INV`, but not another client's.

(in)efficiency of each system's management and synchronization techniques.

When values are stored inline, RCuckoo outperforms existing systems while delivering competitive insert latencies. Using fault injection, we show that our distributed approach to client failure detection and recovery enables RCuckoo to sustain high throughput even though 100s of clients are failing per second. Finally, we justify our design decisions through a series of micro-benchmarks. Specifically, we quantify the benefit RCuckoo extracts from its locality enhancement before measuring the impact of index-table entry size.

5.1 Implementation

We have built two separate versions of RCuckoo, an 8.7 K-line C++ implementation tuned for high performance and a 12 K-line Python implementation that simulates RDMA operations to facilitate correctness testing. Both implementations will be made available on GitHub at publication. We report results using our C++ implementation which requires OFED-4.9 to support masked CAS operations and device-mapped memory on ConnectX-5 NICs. All experiments use 64-KB client index-table caches and a virtual lock table at the server.

5.2 Testbed

We conduct our evaluation on an 9-node cluster of dual-socket Intel machines. Each CPU is an Intel Xeon E5-2650 clocked at 2.20 GHz. Each machine has 256 GB of RAM with 128 GB per NUMA node. All machines have a single dual-port ConnectX-5 attached to a 100-Gbps Mellanox Onyx switch. In our RCuckoo experiments we use one sever as the memory server and the rest a client machines spreading threads evenly across machines.

We compare RCuckoo against three recent RDMA key/value stores with different designs, FUSEE [38], Clover [40], and Sherman [41]. While none have the exact same assumptions or feature set as RCuckoo, each represents an apt comparison point for different aspects. To avoid biasing our evaluation, we consider the same workloads (YCSB) as the authors of the previous systems.

FUSEE is a fully disaggregated key/value store that represents the closest available comparison point to RCuckoo. While both employ only 1-sided RDMA operations, FUSEE eschews locking in favor of optimistic insertions. FUSEE clients use CAS operations to manage fixed, 64-bit index table entries that contain pointers to values stored in extents. Due to its reliance on CAS operations, FUSEE is unable to support inlined storage of small values like RCuckoo, forcing all reads to require two round trips. Unlike RCuckoo, FUSEE is designed to support replication. To remove the overhead of replication, we deploy FUSEE with a single memory node.

Clover is only partially disaggregated—it requires a metadata server to manage its index structure—but can deliver higher read performance than FUSEE on read-only workloads. Clover is designed to leverage remote persistent memory and implements both reads and updates using one-sided RDMA operations. Moreover, unlike FUSEE—and similar to RCuckoo—Clover reads are self verifying. In contrast to prior comparisons [38] that force clients to consult the metadata server on each read, we allow Clover to take advantage of its client caching to achieve maximum performance on read-heavy workloads.

Sherman is the highest-throughput distributed key/-value storage system of which we are aware that employs locks. Sherman maintains a B-tree that spans multiple servers and supports range queries, a feature none of the other systems—RCuckoo included—provide. On the other hand, Sherman clusters are not fully disaggregated: each node in a cluster is a peer with many CPU cores and a single memory core that is responsible for servicing allocation RPC calls from clients. As such, Sherman does not encounter the same bandwidth bottlenecks as the other systems because requests are partitioned across machines.

5.3 Performance

We start by considering throughput and latency on the classical YCSB workloads which employ varying mixes of read and update operations before turning to the more complex insert operation. RCuckoo delivers the highest performance on reads and updates across all settings, while insert performance varies as a function of table fill factor. Even in the worst case, however, RCuckoo limits insert I/O amplification to around $2\times$.

Throughput. Figure 6 shows YCSB throughput for RCuckoo, FUSEE, Clover, and Sherman on three different YCSB workloads. For each system, we allocate a 100-M-entry table and pre-populate it with 90 M entries that each consist of a 32-bit key and 32-bit value (we consider larger sizes in Section 5.5). We plot the aggregate throughput of a variable number of clients concurrently accessing entries according to a Zipf(0.99) distribution.

In a read-only (YCSB-C) workload, FUSEE suffers from its extent-based value storage. RCuckoo, Clover, and Sherman perform similarly at low-to-moderate levels of concurrency, but they separate at scale. Sherman's read algorithm is more complex than RCuckoo's leading to lower top-end performance. Clover's client-side caching shines under this skewed workload, where almost all reads

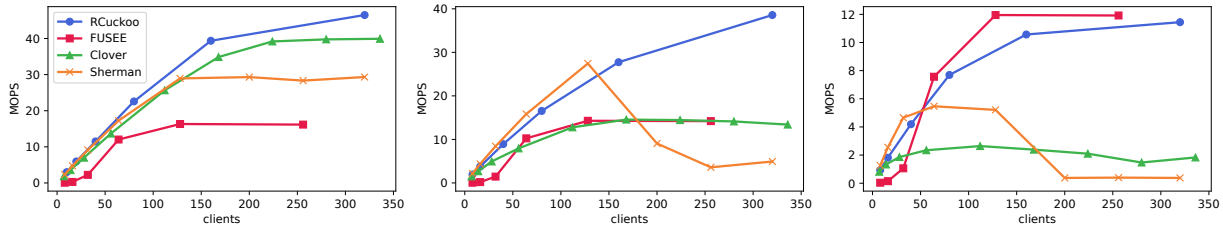

Figure 6: Throughput as a function of the number of clients for three different workloads (Zipf θ=0.99): **(a)** Read only (YCSB-C), **(b)** YCSB-B 95% read, 5% update and **(c)** 50% read 50% update (YCSB-A).

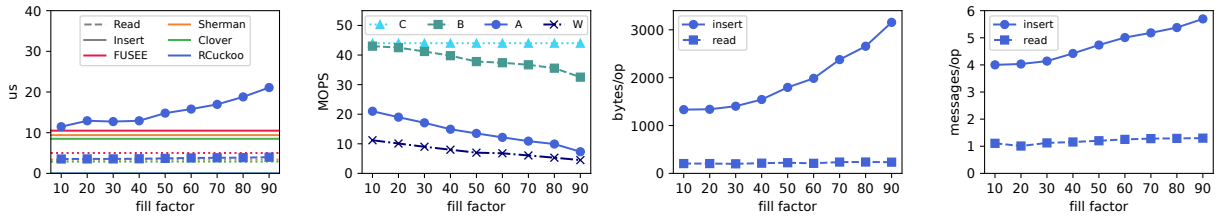

Figure 7: Insert performance as a function of fill factor. **(a)** Throughput for four different insert workloads, **(b)** median operation latency, **(c)** mean operation size, and **(d)** mean per-operation RDMA message count under workload A.

hit in a client's index cache, requiring only a single read for the value; its performance degrades under a more uniform workload (not shown). RCuckoo, on the other hand, reads inlined values in a single round trip regardless of the distribution, leading to the highest performance.

Increased update rate slows all systems. Even with only 5% updates (YCSB-B), the picture changes dramatically. Sherman performs well at low levels of concurrency due to its single-round-trip reads, but hits a severe bottleneck due to lock contention on the skewed access pattern. (Sherman improves—but does not surpass RCuckoo—for uniform workloads, not shown, where lock contention is less of an issue.) Caching is less effective with updates, bringing Clover's throughput in line with FUSEE.

On the 50/50-mixed YCSB-A workload RCuckoo and FUSEE perform similarly, although we are unable to scale FUSEE past 250 clients in our testbed while RCuckoo continues to scale. Sherman begins to suffer from lock contention even earlier, topping out around 5 MOPS before collapsing. (Absolute performance improves as Zipf skew decreases—not shown—but the trend remains.) Clover performs worst under write-heavy workloads due to its inability to effectively leverage caching with a constantly changing index structure.

Latency. Latency varies dramatically depending on operation for all systems, each of which optimizes for reads. For RCuckoo, insert is by far the most involved operation, but it remains highly performant. To evaluate insert performance we run workloads with a mix of reads and inserts. Figure 7 considers performance on workloads that exclusively use inserts (rather than updates); as with YCSB nomenclature A is 50/50 read/insert; B is 95/5; C is read-only; and W is insert only. Inserts become more expensive as the table fills, so we pre-populate the table with a varying number of entries and report insert performance as a function of the table's initial fill factor.

As a baseline we collect the read and insert latencies for all systems under light load (Figure 7(a)). Read latency is nearly identical for all systems save FUSEE as it makes a read to both the index and extent. Insert times vary: Clover and Sherman use two-sided RDMA operations for insert and both need to perform allocations and set up metadata for the requesting client. FUSEE is slightly slower, roughly the same as RCuckoo's best case. As the table fills, however, cuckoo paths grow in length causing RCuckoo insert operations to require additional round trips to find valid cuckoo paths. Insert operations at maximum fill take roughly twice as long as at empty.

Insert I/O amplification. Figure 7(b) shows impact of table fill on insert throughput at heavy load (320 clients). As the index table fills, cuckoo paths become longer leading to increased contention and additional bandwidth consumption. In each case (except read-only C) RCuckoo's performance declines with fill factor. In the insert-only W case RCuckoo's performance drops from a high of 11.5 MOPS in a nearly empty table to 4.5 MOPS at a 90% fill factor. As a point of comparison, FUSEE's maximum insert-only performance is 9.1 MOPS on our testbed, although it is independent of fill factor. While FUSEE out-performs RCuckoo at high fill factors, we observe that insert-only workloads are rare in practice [27]. Figures 7(c) and (d) show the impact of fill factor on the band-

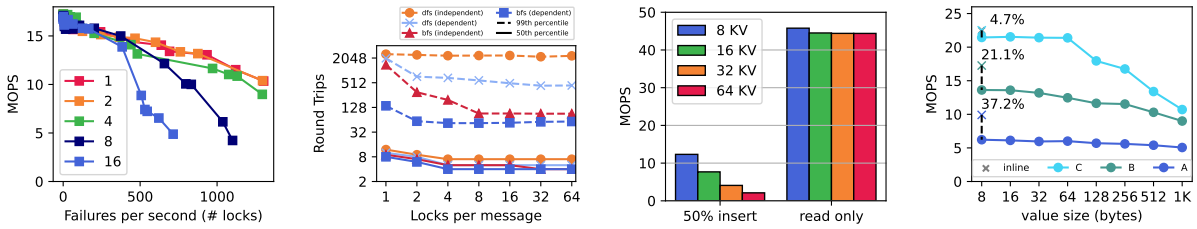

Figure 8: RCuckoo microbenchmarks: **(a)** YCSB-A throughput vs. client failure rate, **(b)** round trip times required to acquire locks on insert, **(c)** throughput vs. key/value-entry size for 50% insert 50% read, and YCSB-C (read-only) workloads, and **(d)** extent performance for value sizes up to 1 KB (with 8-byte inline performance plotted with $\times$s; relative performance improvement depicted with dashed black lines and labeled accordingly).

width cost (at most 2$\times$) of each operation and the number of RDMA messages ($\leq$1.5$\times$) they require to complete.

5.4 Fault tolerance

RCuckoo runs at nearly full throughput during realistic failure scenarios and remains functional in the face of hundreds of failures per second. We emulate client failures by performing a partial insert operation that randomly truncates the batch of RDMA operations (including lock releases), leaving the table in one of the states listed in Section 4.3. Figure 8(a) shows that throughput remains high until about 500 client failures per second, at which point lock granularity begins to play a significant role; finer-grained locks are easier to recover leading to less throughput degradation. As a point of reference, we observe that RDMA itself struggles to handle churn of this magnitude: a server can only establish approximately 1.4 K RDMA connections per second [23].

5.5 Microbenchmarks

Having established RCuckoo's superiority over prior systems and demonstrated its robustness to client failure, we now evaluate the impact of particular design choices.

Locality enhancement. Figure 8(b) illustrates the dramatic benefit RCuckoo extracts from its dependent hashing combined with a BFS cuckoo-path search strategy. To focus on longer cuckoo paths, we pre-populate a 100-M entry table to 85% and then report both the median and 99th percentile round trips per insert key/value pairs until the table is 95% full as a function of lock granularity. While median performance is on the same order, the 99th-percentile insert takes an order of magnitude fewer round trips with dependent hashing and BFS as opposed to independent hashing and DFS as used in prior cuckoo hash systems [20, 25, 32]. As before (c.f. Figure 5), performance is similar with four or more locks per message.

Entry/value sizes. Inlined key/value entries enable single-round-trip reads. However large entries increase bandwidth consumption for inserts. Figure 8(c) shows the effect of entry size on throughput under 50% insert and read-only (YCSB-C) workloads. Insert is a bandwidth-limited operation on our 100-Gbps testbed, while read performance (and update/delete, not shown) is largely unaffected by entry size. Extent entries are slightly slower: Figure 8(d) shows YCSB throughput as a function of value size from 8 to 1024 bytes on 6 client machines with 120 cores. Read performance becomes link-rate limited after about 64 bytes. For comparison, we show the performance of the 8-byte inlined values used elsewhere in the evaluation on this configuration and compute the difference. Inlined entries have two sources of performance gain: they avoid the overhead of reading and writing to extents which increases with value size, but, more importantly they avoid additional rounds trips on cache misses. YCSB-B sees a 21% performance improvement from inlining while YCSB-A gains 37% (YCSB-C has misses).

6 Conclusion

In this work we design and implement a lock-based cuckoo hash table for passive remote memory. Using dependent hashing, a carefully designed locking protocol, and the latest RDMA NIC features we achieve single-round-trip reads, update operations that require two round trips when uncontested, and insert operations that require only two round trips in the median case. Even in the face of high contention and nearly full tables, client caching limits I/O amplification. Moreover, our step-by-step insert protocol enables fully disaggregated failure detection and recovery.

LITESHIELD: Secure Containers via Lightweight, Composable Userspace μKernel Services

Kaesi Manakkal, Nathan Daughety[†], Marcus Pendleton[†], Hui Lu
The University of Texas at Arlington, [†]Air Force Research Laboratory (AFRL)

Abstract

This paper introduces LITESHIELD, a new userspace isolation architecture for secure containers that reexamines the boundary between user applications and system services. LITESHIELD decouples traditional guest kernel functionality into modular userspace microkernel (μkernel) services that interact with guest applications via low-latency, shared-memory-based inter-process communication (IPC). By serving most Linux syscalls in userspace, LITESHIELD enforces a significantly reduced user-to-host interface, with just 22 syscalls, achieving strong isolation comparable to virtual machines (VMs) while avoiding the complexity of hypervisors and hardware virtualization. LITESHIELD further provides a POSIX-compatible runtime with fine-grained syscall interception to support legacy applications and enables composable μkernel services that can integrate specialized userspace components (e.g., networking and filesystems). Our implementation demonstrates that LITESHIELD delivers strong isolation with performance comparable to traditional containers.

1 Introduction

Due to high portability, high density, and low operational cost, containers have been widely used for packaging, isolating, and multiplexing cloud applications. In contrast to virtual machines (VMs) (i.e., hypervisor-based virtualization), containers execute applications directly on the native host OS [8, 53, 61] and leverage kernel-level features, such as namespaces [23], cgroups [16], and seccomp [20], to enforce *isolation* between containerized applications. While the lack of guest OSes and virtual hardware abstraction makes containers *lightweight*, they cannot be directly adopted as the isolation mechanism in multi-tenancy clouds due to *weak isolation* – sharing the same host results in a large attack surface, e.g., 300+ system calls, or syscalls, in Linux. That is precisely why, in today's production systems, containers are deployed within VMs for strong isolation [13, 37].

To address the tension between isolation and performance, recent efforts [28, 56, 62] adopt the technique of *minimization*, including tailoring a VM's kernel with minimal components [28], linking a hosted application into a tiny unikernel image under a single address space [56], and attaching a userspace guest kernel (with a substantial portion of the Linux surface) to a container for VM-like isolation [62]. While these efforts have blurred the isolation boundaries of VMs and containers, they share some common limitations. *First*, maintaining a full guest kernel, even a minimized one, for each hosted entity remains inefficient. *Second*, different applications require access to specific functionalities of the guest kernel, rendering a "one-size-fits-all" guest kernel impractical, if not impossible. *Third*, since some guest kernels have been minimized or even degraded to provide system functions at the same level as userspace applications [56], these approaches rely solely on hypervisors for isolation. However, hypervisors have their share of vulnerabilities [27].

In this paper, we reexamine the isolation boundaries between user/kernel space for applications and kernel/system services and explore a new isolation architecture for secure containers, called LITESHIELD, to achieve *lightweight yet strong isolation*. Inspired by the microservices architecture, LITESHIELD decouples the closely-coupled guest kernel and its hosted applications, or *guest applications*, as loosely-coupled entities. Such decoupling allows the guest kernel to operate as a collection of userspace microkernel (μkernel) services, each running as regular userspace processes. Communication between μkernel services and guest applications is facilitated through efficient userspace inter-process communication (IPC), eliminating costly syscalls.

The isolation architecture in LITESHIELD achieves *strong isolation with minimal overhead*. First, LITESHIELD achieves strong isolation by blocking direct host kernel access for guest applications. Instead, they are served by userspace μkernel services: By serving system services (e.g., networking and filesystems) in the userspace, the *user-to-kernel* interface – i.e., between μkernel services and the host – is significantly

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2025-0650. Dated 06 Feb 2025.

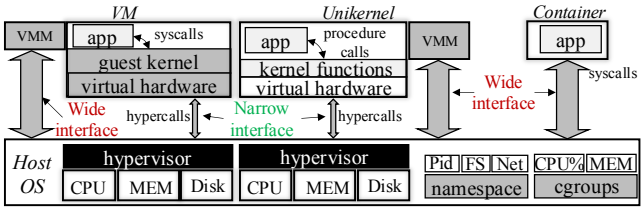

Figure 1: Comparisons of three representative isolation architectures: VMs, unikernels, and containers.

reduced (e.g., from 300+ syscalls to 20+) and comparable to VMs (e.g., 20+ hypercalls and 60+ VMExits). Even if a malicious guest application exploits a μkernel service (via userspace IPC), its access is limited to a restricted userspace process (i.e., defense in depth like VMs). As communication between guest applications and μkernel services is facilitated through userspace IPC, LITESHIELD removes the hypervisor and further reduces the attack surface. Further, by hosting system services in userspace, LITESHIELD replaces expensive cross-boundary invocation overheads (e.g., syscalls or VMExits/VMEntries) with fast (cache-to-cache) IPC. Last, LITESHIELD supports composable μkernel services, enabling seamless integration of specialized userspace approaches [41,44,47,48] to deliver highly efficient userspace system services, instead of relying solely on general-purpose, monolithic, and hard-to-optimize in-kernel services.

To ensure compatibility with existing commodity kernels (e.g., Linux) and legacy applications, LITESHIELD addresses several challenges: First, the Linux kernel's implementation restricts certain syscalls (e.g., process and memory management) from being executed in a separate process, complicating the operation of μkernel services as independent userspace processes. To address this, LITESHIELD categorizes syscalls into *delegable syscalls*, which are redirected to LITESHIELD's μkernel services for processing, and *non-delegable syscalls*, which are trapped, monitored, and validated before being executed within the same process via an arbitration mechanism. To further support legacy applications, LITESHIELD provides a POSIX-compatible library that supports runtime injection and fine-grained syscall interception, enabling seamless redirection of *delegable syscalls* from legacy applications to userspace μkernel services, without any binary modifications. Last, to achieve high performance, LITESHIELD employs a userspace IPC mechanism with a shared memory region and polling-based threads to facilitate low-latency communication between guest applications and μkernel services.

Our current implementation of LITESHIELD supports most of the Linux kernel syscalls in userspace required by regular guest applications (i.e., those not running with root privileges) and achieves a thin *user-to-host* interface with only 22 syscalls that need the support of the host kernel (compared to 20+ hypercalls and 64 VMExits for KVM-based VMs), while significantly reducing both the software codebase (eliminating the need for a hypervisor and QEMU-based emulator) and hardware complexity (requiring no hardware virtualization). We have ported an existing userspace network stack, `f-stack` [9], and implemented an `ext2`-like userspace filesystem as userspace networking and filesystem μkernel services. Porting `f-stack` to LITESHIELD only required 400+ lines of code. By leveraging lightweight userspace μkernel services and fast shared memory-based IPC between guest applications and μkernel services, LITESHIELD delivers performance comparable to traditional containers.

2 Motivation

2.1 Cloud Native and Isolation

IT companies are under constant pressure to simplify their product development with shortened production cycles to adapt to changing markets and diverse demands. Cloud-native technologies are poised to tackle this pressing challenge. First, developers decompose a traditional monolithic application into graphs of *single-purpose, loosely-coupled* microservices. As each microservice focuses on a small subset of the monolithic application's functionality, this microservices-based architecture reduces development complexity and increases code velocity [1, 3, 4, 6, 12]. Further, cloud-native platforms deploy, manage, and scale microservices completely for cloud tenants, further liberating them from the management of virtual servers (i.e., server*less* for tenants). The use of cloud-native technologies is becoming pervasive: Companies like Amazon, Netflix, Twitter, Uber, and eBay have adopted the microservices architecture [5, 7, 10, 17, 26]. In addition, a proliferation of serverless platforms enables a simple way, i.e., via Function-as-a-Service (FaaS), to build and execute cloud-native applications [2, 24, 25, 35, 36].

Isolation ensures safe resource sharing by preventing cloud tenants from accessing each other's shared resources. Without enforcing isolation, a malicious user could steal sensitive information from victims [54, 60, 63, 64], or an aggressive user might degrade the performance of others [49].

State-of-the-art virtualization techniques provide isolation via full-blown VMs [14, 58], micro-VMs [28, 62], containers [8, 53, 61], microkernels [30, 43, 52], and unikernels [31,40,42,57]. As illustrated in Figure 1, VM-based virtualization achieves isolation through a *virtual hardware interface*, allowing each VM to operate with a fully functional guest operating system (OS). Since the virtual hardware interface differs from real hardware, it is further supervised by another software layer, the *hypervisor*. The virtualization architecture provides a *strong* security boundary between sandboxed applications in VMs due to: 1) a minimal attack surface between VMs and the native host (e.g., tens of hypercalls or VMExits); and 2) defense-in-depth, where both the guest OS and hypervisor contribute to security. However, this defense-in-depth approach introduces non-trivial performance overhead by layering guest kernels and hypervisors, resulting in costly inter-

DISTRIBUTION STATEMENT A. Approved for public release:
Distribution unlimited. Case Number AFRL-2025-0650. Dated 06 Feb 2025.

actions across multiple layers of the virtualization stack for CPU, memory, and I/O virtualization. Microkernels improve isolation by minimizing kernel functionality and shifting OS services, such as file systems and drivers, to userspace, reducing the attack surface and improving fault isolation. Notably, seL4 [43] offers formal verification guarantees, while systems like Barrelfish [30] and Arrakis [52] extend this model to multicore and I/O-optimized architectures. Though well-suited for specialized, high-assurance systems, microkernels often face challenges with performance due to IPC overhead and supporting legacy applications. These factors limit usability in general-purpose cloud-native environments.

In contrast, containers execute applications directly on the native host OS [8, 53, 61]. Kernel-level features, e.g., namespaces [23], cgroups [16], and seccomp [20], enforce isolation between containerized applications. While the lack of virtual hardware abstraction makes containers lightweight, they cannot be directly adopted as the isolation mechanism in multi-tenant clouds due to *weak isolation* – i.e., sharing the same host results in a large attack surface (e.g., 400+ system calls, or syscalls, in Linux). While modern OSes have a "whitelisting" mechanism (e.g., `seccomp`) allowing containers to transition into a restricted mode with a narrowed syscall interface, the common problem is that it is difficult to determine what syscalls an application may use. Default whitelisting policies still tend to be large, e.g., 250+ syscalls [21].

Recent efforts [28, 50, 62] aim to balance isolation and performance through *minimization*. For example, AWS's Firecracker [28] optimizes a VM's kernel by including only essential components and adopting a simplified I/O model. NEC's LightVM [50] integrates a hosted application into a minimal unikernel image within a single address space for greater efficiency. Google's gVisor [62] employs a userspace guest kernel, incorporating a significant portion of the Linux interface, to provide VM-like isolation for containers.

2.2 Limitations

Unfortunately, cloud native presents new and pressing challenges to existing virtualization techniques. *1) High performance overhead:* Unlike monolithic applications, a cloud-native application consists of numerous distributed microservices, each requiring sandboxing, which significantly amplifies the performance overhead and memory footprint. Moreover, virtualization overhead becomes more pronounced compared to monolithic applications, as each hosted microservice is typically smaller and more ephemeral (e.g., high startup overhead). *2) Generality vs. specialization:* The increasing diversity of microservices necessitates specialized system services, such as customized network stacks [51] or specialized file systems [47]. However, existing virtualization techniques for isolation continue to rely on general-purpose, one-size-fits-all guest kernels. While these kernels are often highly optimized [28], they struggle to meet the varied and specific requirements of diverse microservices. Furthermore, despite recent advancements in high-performance networking and file systems [41, 47, 51], there is no practical way to seamlessly integrate these technologies with general applications or microservices. *3) Large attack surface.* Although the user-to-host interface for VM-based virtualization is thin, the code responsible for virtualization and isolation remains large. This includes both *the hypervisor*, which resides in the host kernel (i.e., type-2 hypervisor) and interacts with hardware mainly for CPU and memory management, and *the QEMU-based Virtual Machine Monitor* (VMM), which operates in userspace primarily for device emulation. According to the Common Vulnerabilities and Exposures (CVE) database, 184 vulnerabilities have been reported in major hypervisors (e.g., Xen, KVM, Hyper-V) since 2007, with 33% of these occurring in the past 1.5 years. Additionally, the VMM is huge (e.g., QEMU-based VMM has more than 1.4 million lines of code) and can access the host via the whole syscall interface.

2.3 Threat Model and Assumptions

In this paper, we focus on security vulnerabilities and isolation mechanisms in general-purpose monolithic kernels (e.g., Linux). We share the common isolation assumptions as VMs/unikernels [56, 62]: We trust fundamental hardware-based protections – such as page tables and CPU execution modes – that ensure strong isolation between different processes and between user and kernel execution within the same process. We focus on software deficiencies in host kernels, guest kernels, and hypervisors that can be exploited through their exposed *user-to-host* interfaces, namely, system calls and hypercalls, which constitute the main attack surface. Therefore, our threat model is that one malicious user could break out of the isolation by compromising the *user-to-host* interface. Two metrics are used to evaluate the attack surface: 1) the size of the user-to-host interface and 2) the amount of code accessible through the interface. Other attacks, such as covert channels and side channels, pose security risks by enabling unauthorized communication and information leakage through unconventional pathways. Existing software-based isolation approaches, including VMs, microVMs, unikernels, and others, are susceptible to these attacks. Although eliminating all side and covert channels is challenging due to the complexity of hardware and software interactions, existing measures, such as secure hardware designs, strict resource isolation, and the introduction of system randomness, can be orthogonally applied to software-based isolation approaches.

3 Design of LITESHIELD

We present LITESHIELD, a novel sandboxing architecture providing *strong yet lightweight* isolation for secure containers. Drawing inspiration from the microservice architecture, LITESHIELD offers *on-demand, composable* guest kernel/system services to cloud-native applications, functioning

DISTRIBUTION STATEMENT A. Approved for public release:
Distribution unlimited. Case Number AFRL-2025-0650. Dated 06 Feb 2025.

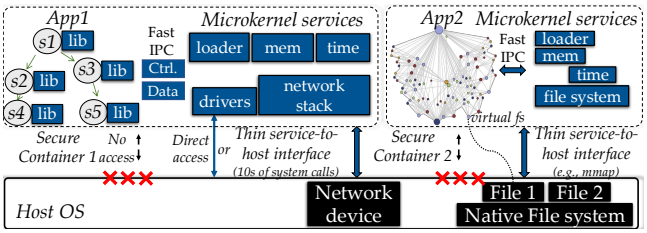

Figure 2: Architecture of LITESHIELD.

as userspace microkernel (μkernel) services. (Figure 2).

LITESHIELD's core innovation lies in decoupling guest applications from their hosting guest kernels, running them as separate userspace entities. Each application process acts as a client, while all required μkernel services are combined to provide system services. Clients interact with userspace μkernel services through fast inter-process communication (IPC) channels (§3.2). System calls made by a guest application are intercepted and redirected to the appropriate userspace μkernel service, which handles the request mostly within the userspace while only contacting the host kernel for (a limited number of) privileged operations, resulting in a thin *user-to-host* interface (comparable to VMs). To prevent malicious applications from bypassing the interception library and making direct system calls to the host kernel, LITESHIELD employs `seccomp` [20], effectively blocking unauthorized "direct" syscalls.

LITESHIELD inherits advantages from the microservices architecture, such as modular development, flexible deployment, and rapid iteration. Userspace μkernel services can be gradually and individually developed, extended, replaced, customized, and integrated with other existing/ongoing userspace systems [41, 47, 51]. In addition, while hardware specialization is accelerating in cloud [18], LITESHIELD can quickly support specialized hardware (e.g., GPU, smart NICs, and persistent memory) with userspace support, making new, advanced hardware accessible by specific cloud-native applications (e.g., machine learning tasks).

3.1 Strong Isolation via Thin Interface

As shown in Figure 2, LITESHIELD achieves a level of isolation comparable to VMs and unikernels, maintaining a similarly *thin user-to-host interface* (i.e., requiring tens of syscalls to the host, compared to 300+ for containers).

First, guest applications have no direct access to the host kernel. LITESHIELD enforces this restriction by using `seccomp` to block all direct syscalls from guest applications, i.e., by applying a `seccomp` profile that denies all syscalls by default. Second, userspace μkernel services are permitted to access the host kernel when necessary. To ensure that the *user-to-host* interface remains *thin*, `seccomp` is also applied to these services, allowing only a minimal set of explicitly defined syscalls through a restrictive profile. The rationale is simple: "the more done in userspace, the less needed in the kernel". For example, the unikernel approach [56] reduces

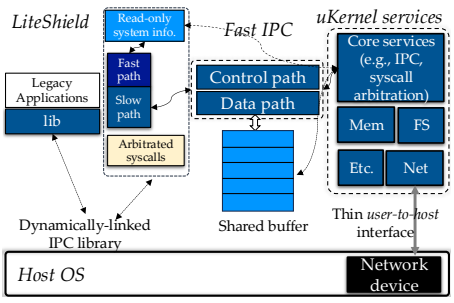

Figure 3: Fast userspace inter-process communication (IPC).

syscall or hypercall usage to fewer than ten by shifting most system functions into userspace. Similarly, LITESHIELD performs most guest kernel functions, such as file and filesystem management, networking, and IPC, entirely within userspace, thereby minimizing interactions with the host kernel and achieving a thin *user-to-host* interface.

Unlike the unikernel approach, which embeds guest kernel functions in the same address space as guest applications, LITESHIELD executes these functions within more flexible and independent μkernel services. However, certain syscalls, namely *non-delegable* ones, must be executed within the context of the same process, such as process management (e.g., `fork`, `clone`, `wait`, and `exit`) and memory management (e.g., `mmap`, `munmap`, `mprotect`, `msync`, and `madvise`). A straightforward solution would make the kernel LITESHIELD-aware by introducing kernel support to convert *non-delegable* syscalls to *delegable* ones, allowing them to execute in the context of another process. LITESHIELD, instead, focuses on compatibility with the *unmodified* Linux kernel and realizes an *arbitration* mechanism to handle the execution of the non-delegable syscalls. Specifically, LITESHIELD permits guest applications to execute non-delegable syscalls by explicitly allowing them in the `seccomp` profile. However, it leverages Linux's `ptrace` mechanism to trap and monitor these syscalls through LITESHIELD's core μkernel service (§3.3). When a guest application is launched, it is registered as a tracee of the core μkernel service before execution begins. Thus, any subsequent invocation of a non-delegable syscall is intercepted by the core service, allowing LITESHIELD to perform sanity checks or other forms of inspection [34, 38] before permitting the syscall to proceed. This mechanism enables fine-grained monitoring of non-delegable syscalls while maintaining compatibility with the existing Linux kernel.

Since guest applications can only access the host kernel via LITESHIELD, even if a malicious guest application exploits a bug in a μkernel service of LITESHIELD (e.g., through IPC channels), it can only gain access to a restricted userspace process (i.e., defense in depth). As the communication between guest applications and μkernel services is through userspace IPCs or arbitrated syscalls, LITESHIELD eliminates the hypervisor, further minimizing the attack surface for isolation.

DISTRIBUTION STATEMENT A. Approved for public release:
Distribution unlimited. Case Number AFRL-2025-0650. Dated 06 Feb 2025.

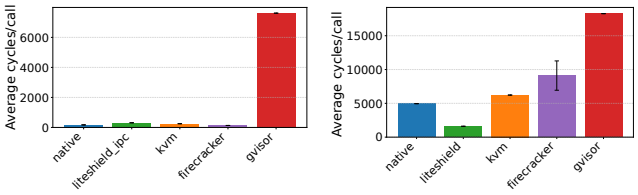
3.2 Lightweight Isolation via Fast IPCs

One key goal of LITESHIELD is to provide strong isolation with much *less* overhead than VM/unikernel-based isolation to *legacy* applications, better, with performance comparable to that of "lightweight" containers.

Containerized applications request system services via *syscalls* from the kernel space. This mechanism is actually costly, as it involves same-core user/kernel mode transitions, cache pollution, and data movement across the kernel/user space, consuming *microseconds* [55]. In addition, the "one-size-fits-all" monolithic kernel services could be suboptimal for many new application scenarios [45, 46]. The generality of monolithic kernels makes optimization difficult, and vertical integration efforts are often broken by upstream changes [51]. On the other hand, recent userspace and hybrid approaches [32, 39, 41, 44, 47, 48, 59] have been proposed to mitigate such overhead by redistributing functions between user and kernel space, demonstrating superior performance compared to in-kernel services. Following this direction, LITESHIELD runs most kernel services in userspace, achieving a thin user-to-host interface (and strong isolation) while also enabling the potential for high performance through various specialized userspace approaches.

Guest applications request system services from *userspace* μkernel services through IPC channels, instead of syscalls. As shown in Figure 3, LITESHIELD develops a *high-performance shared-memory-based IPC mechanism* for fast system service delivery. *First*, each application is assigned a shared memory buffer. When an application makes a request, it places the syscall number and arguments in the shared buffer and toggles a flag to let the μkernel services know that a request has been made. Once the request has been completed, the μkernel service puts the response in this buffer and toggles the flag to let the guest application know it is done. This approach draws inspiration from existing userspace communication techniques, e.g., RDMA, and incorporates a *polling-based* mechanism to reduce communication latency: A core *μkernel service for IPCs* employs a dedicated polling thread to continuously monitor for incoming IPC requests from guest application processes. Upon detection of a request, this thread promptly handles it – by forwarding it to one of the composable userspace μkernel services (e.g., networking or file systems). Similarly, application processes use another polling thread to actively wait for and immediately process responses from the IPC μkernel service. *Second*, LITESHIELD leverages a multi-core system (common today) to place application processes and userspace μkernel services on separate cores – i.e., avoiding same-core context switches. This separation precludes context switching on the same core and further minimizes communication latency between guest applications and μkernel services. Since the context switch overhead for userspace processes is typically lower than that of virtual CPUs, LITESHIELD's userspace solution is expected to outperform VMs even with core multiplexing. *Finally*, the communication latency under the proposed shared-memory-based IPC mechanism mainly hinges on the memory access latency. If the cores for the application and the userspace μkernel services are situated on the same CPU, this configuration can capitalize on the last-level cache (LLC) to expedite IPC (i.e., cache-to-cache transfers that typically require only tens of CPU cycles [55]).

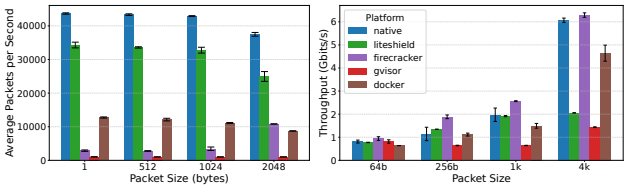
Moreover, LITESHIELD provides a POSIX-compatible library that combines `LD_PRELOAD` and the binary translation capabilities of the `libsyscall_intercept` library [15]. The `LD_PRELOAD` mechanism allows the library to be injected into the address space of legacy applications at runtime, enabling it to override standard library functions (i.e., `glibc`) and intercept system calls. Meanwhile, `libsyscall_intercept` provides fine-grained control over syscall interception by hooking directly into the syscall execution path using inline hooking and binary rewriting techniques. This combined approach enables LITESHIELD to dynamically link the library to legacy applications – without any modifications to the binaries – and intercept delegable syscalls. The intercepted syscalls are redirected to the IPC shared buffer, where LITESHIELD facilitates communication with its μkernel services.



Like FlexSC [55], LITESHIELD aims to improve syscall performance by rethinking the traditional syscall interface. However, they take different architectural approaches. FlexSC introduces exception-less system calls that batch syscall execution and decouple it from the application thread, reducing kernel traps and improving throughput on multicore systems. In contrast, LITESHIELD decomposes traditional kernel functionality into userspace μkernel services and uses fast userspace IPC and selective syscall trapping (via ptrace) to intercept and redirect syscalls, maintaining compatibility with unmodified Linux and legacy applications.

3.3 Userspace μKernel Services

As illustrated in Figure 3, LITESHIELD's μkernel services are divided into two categories: core services and composable services. Core services, such as IPC, syscall arbitration, time management, and memory management, provide essential μkernel functionality required by every guest application. In contrast, composable services, including file, device, and networking management, are provided on demand. Integrating existing and new userspace approaches into LITESHIELD as composable μkernel services is straightforward.



We have integrated the `DPDK`-based userspace network stack, `f-stack` [9], into LITESHIELD. First, we extended LITESHIELD to fetch syscall requests from the IPC shared buffer and enqueue them in a separate operation queue for `f-stack` to process. Further modifications were made to `f-stack`'s main network processing loop to monitor the operation queue and handle any received network requests. Once processed, the results are placed back into the IPC shared buffer, where the guest application can retrieve them.

DISTRIBUTION STATEMENT A. Approved for public release:

(a) `getpid`. (b) `read`.

Figure 4: Syscall latency comparisons.

(a) UDP. (b) TCP.

Figure 5: Network performance comparisons, on UDP and TCP protocols, with different packet sizes.

`f-stack` primarily processes packets in userspace, interacting with the underlying network device only when necessary (e.g., for sending packets) through a limited syscall interface (e.g., `read` and `write`). Each instance of `f-stack` is bound to a software `tap` device, enabling the sharing of a physical network card across multiple containers. Last, `f-stack` supports direct use of a physical NIC for scenarios requiring dedicated access. We have also implemented and integrated a userspace filesystem, compatible with `ext2` [22], into LITESHIELD.

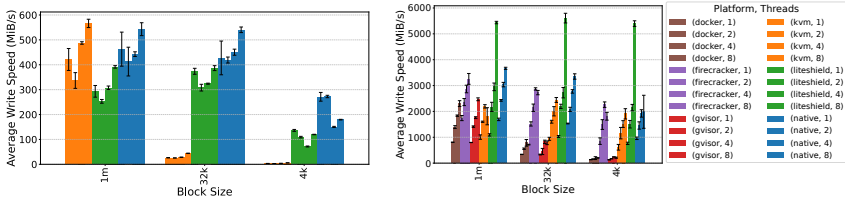
Table 1: Ptrace overhead for non-delegable syscalls.

Syscall	Syscall lat (μs)	Ptrace lat (μs)	Ptrace overhead
mmap	0.220	25.485	99.1%
fork	40.553	35.656	46.8%
clock_nanosleep	56.896	23.256	29.0%
futex	0.254	15.476	98.4%

4 Evaluation

We have implemented LITESHIELD in approximately 7,000 lines of C/C++ code [1]. Currently, LITESHIELD supports the redirection or arbitration of around 170 Linux kernel syscalls, including 142 delegable and 28 non-delegable ones. Most of the remaining unsupported syscalls (approximately 132) require root privileges from guest applications. LITESHIELD's modular design allows for the incremental addition of support for these syscalls. The *user-to-host* interface in LITESHIELD is thin, requiring only 22 syscalls – compared to 60+ VMExits for KVM-based VMs and 250+ syscalls in the default `seccomp` whitelist for containers. Please refer to Appendix A for a more detailed breakdown. We have evaluated the effectiveness of LITESHIELD by comparing it with state-of-the-art isolation mechanisms, including Docker containers [8], KVM-based VMs [14], Firecracker [28], and gVisor [62].

Testbed. We conducted our experiments on a platform with an Intel Xeon Gold 6430 CPU, 96GB DDR5 RAM, and a Micron 7450 NVMe SSD (ext4), running Ubuntu 22.04 with Linux kernel 5.15. Hyperthreading was disabled, and resources were configured to avoid bottlenecks. KVM tests used 16 vCPUs, 32GB RAM, and a virtio disk in direct sync cache mode with the same OS as the host. gVisor [62] (v1.10.1) was tested in systrap mode with Docker support, while Firecracker [28] (v1.10.1) was tested with an Ubuntu 24.04 root filesystem on Linux kernel 5.10, configured with 16 vCPUs and 32GB RAM. Docker containers and LITESHIELD were constrained to 16 cores and 32GB RAM using `cgroup` [16].



Syscall latency. We evaluated syscall performance using two representative syscalls: a simple syscall, `getpid`, and a complex syscall, `read`. Figure 4a shows the average latency of invoking `getpid` one million times – LITESHIELD achieves significantly lower latency than the user-level isolation mechanism gVisor due to its fast IPC mechanism, while maintaining comparable latency to other VM-based approaches for this simple syscall. Figure 4b illustrates the average time to read 1 byte from each block of a 4GB file. For this complex syscall, LITESHIELD outperforms VM-based approaches, as `read` triggers VMExits in VMs, incurring high context-switch overhead. Further, LITESHIELD surpasses native performance due to its *specialized, lightweight* userspace filesystem.

Ptrace overhead. We evaluated the performance impact of LITESHIELD's `ptrace`-based arbitration mechanism for non-delegable syscalls. As shown in Table ??, we selected one representative syscall from each of the four main classes of non-delegable syscalls: process management, memory management, timing, and locking. On average, `ptrace` introduces 15–35μs of overhead, with the effect being more pronounced for lightweight syscalls (e.g., `mmap` and `futex`) and less significant for heavier ones (e.g., `fork` and `clock`). We note that these syscalls are generally invoked infrequently. In future work (§5), we plan to convert these non-delegable syscalls into delegable ones to eliminate this overhead.

Userspace networking. We evaluated the performance of LITESHIELD's userspace network stack, ported from `f-stack`. Figure 5a illustrates UDP network performance (packets/second) with a client sending UDP packets of various sizes to a server hosted under different isolation approaches. We used a pair of connected virtual interfaces (i.e., `veth`) to connect the virtual NICs of the client and server. LITESHIELD outperforms all other isolation mechanisms, with performance slightly below native, due to the highly optimized userspace network stack provided by `f-stack`. Figure 5b shows TCP performance using `iperf` [11], with one instance as the client and another as the server hosted under those same isolation

(a) Direct IO. (b) Cached IO.

Figure 6: Performance for writing a 4GB file with various threads and block sizes.

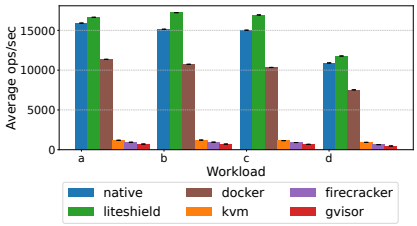

Figure 7: `YCSB` [33] performance on Redis [19] with different workloads.

approaches. While LITESHIELD delivers comparable performance for small packets, it falls behind the microVM approach (e.g., Firecracker) for larger packets because `f-stack` lacks the `GRO` feature. `GRO` reduces packet processing overhead for large packets by merging multiple small packets before processing, but it may introduce latency for small packets, highlighting the lack of a "one-size-fits-all" solution. With LITESHIELD, however, guest applications can select μkernel services tailored to their specific requirements.

Userspace filesystem. We evaluated the performance of LITESHIELD 's userspace filesystem, developed from scratch to emulate the functionality of an in-kernel `ext2` filesystem. Using `fio` [29] (version 3.28), we conducted two types of write I/O tests: 1) cached I/O, where data is written to the page cache and asynchronously flushed to disk, and 2) direct I/O (with `O_DIRECT`), which bypasses the page cache and reaches the disk directly. The `fio` benchmarks were run with multiple threads accessing a single 4GB file using various block sizes.

For VM-based approaches (e.g., gVisor and Firecracker), direct I/O (`O_DIRECT`) bypasses the VM's page cache but can still be buffered by the host's page cache, causing double caching and hindering direct persistence to disk. In contrast, with userspace isolation, LITESHIELD completely eliminates double caching. As shown in Figure 6a, LITESHIELD achieves higher write performance than KVM (we explicitly configured QEMU to enforce direct writes for its disk) and native setups for smaller block sizes, with slightly lower performance for very large block sizes (e.g., 1MB). For cached I/O, Figure 6b shows that LITESHIELD demonstrates better scalability than other approaches as the thread number increases. This is because LITESHIELD's userspace filesystem has a greatly simplified and efficient page cache mechanism.

Real-world applications. We evaluated the performance of a real-world application, Redis [19] v6.0.16, on LITESHIELD (with both networking and filesystem μkernel services) using YCSB v0.18.0 [33] by executing four distinct workloads: Workloads A (50% reads, 50% updates), B (95% reads, 5% updates), C (95% reads, 5% inserts), and D (50% reads, 50% read-modify-write). Figure 7 shows that LITESHIELD achieves higher performance compared to native execution. This improvement is primarily due to the reduced overhead of IPC versus traditional syscalls, particularly for complex operations. In contrast, this overhead in alternative isolation solutions, such as Firecracker and gVisor, is more pronounced, resulting in inferior performance.

5 Conclusions and Future Work

We present LITESHIELD, an effort to explore to what extent guest applications can be isolated in userspace without requiring kernel or application modifications. LITESHIELD achieves this by decoupling guest applications from their guest kernels and offering guest kernel services as a collection of userspace μkernel services. It ensures strong isolation through a thin user-to-host interface and delivers high performance with specialized userspace μkernel services.

Despite its effectiveness, LITESHIELD has several limitations that suggest directions for future work. First, the `ptrace`-based arbitration mechanism introduces overhead for non-delegable system calls. While we consider this a reasonable trade-off to achieve performance, compatibility, and isolation, future kernel support could eliminate this overhead by converting non-delegable syscalls into delegable ones. Rather than modifying the host kernel to introduce new context-aware variants of these syscalls, we are exploring a more transparent solution: leveraging a kernel module to detect whether non-delegable syscalls originate from LITESHIELD's μkernel services. When such calls are identified, they could be dynamically converted into context-aware syscalls. Furthermore, statically linked applications, including those with custom `libc` implementations or inline assembly system call instructions, may bypass LITESHIELD's interception library, resulting in failures due to `seccomp` blocking. To address this issue, we are exploring a "hotpatching" technique that disassembles system call instructions in statically linked processes and replaces them with hooks that redirect the calls to LITESHIELD's IPC mechanisms.

6 Acknowledgments

We thank our shepherd, Kevin Pedretti, and the anonymous reviewers for their valuable feedback. We also thank Fotis Antonatos for his early contributions to this project. Accelerating Nested Virtualization with HyperTurtle

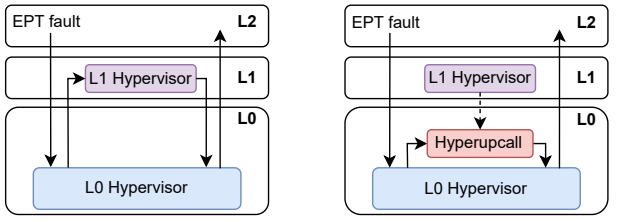
Ori Ben Zur[1], Jakob Krebs[1], Shai Aviram Bergman[2], and Mark Silberstein[1]

[1]Technion - Israel Institute of Technology
[2]Huawei Zurich Research Center

Abstract



Nested virtualization provides strong isolation but incurs non-trivial performance costs. Prior works alleviate some overheads but suffer from limitations such as intrusive code changes or reduced control over nested virtual environments. We present HyperTurtle, a general approach to accelerate nested virtualization. It reduces the number of costly world switches between the virtualization layers, the primary source of performance overheads. HyperTurtle *offloads* the execution of certain parts on the critical path of the virtualized hypervisor, encapsulating them as *eBPF* programs and executing them safely in the context of the bare-metal hypervisor. Thus, HyperTurtle reduces the performance cost of world switches whilst retaining control over nested VMs. We show that HyperTurtle can be used to optimize a variety of OS subsystems and apply it to memory management, networking, and application profiling. HyperTurtle achieves significant performance improvements in micro and macro-benchmarks, for example, 5× faster EPT fault handling, which translates to up to 27% faster boot-time of Kata containers, without requiring intrusive code changes to the virtualization infrastructure.

1 Introduction

Virtual machine-based containers that rely on *CPU virtualization capabilities* to achieve isolation offer a more secure alternative to process-level containers. For example, Kata containers, used by several cloud vendors [1, 42, 64], are lightweight VMs that expose the Kubernetes management interface to facilitate adoption. Kata containers offer strong isolation to allow tenants to execute untrusted third-party code, which is a central requirement of serverless runtimes [1] in cloud computing systems.

In practice, VM-based containers are often deployed as *nested* VMs [31, 50, 57, 58], which is convenient for consolidating workloads and provides more flexibility. In such a nested virtualization scenario, a guest VM (L1) runs its own hypervisor to manage container VMs (L2).

Unfortunately, nested virtualization incurs substantial performance overheads [11], mainly due to the excessive number of transitions between the virtualization layers, commonly called *world switches* [11]. The transitions are necessary since the hypervisor running in a virtual machine needs to execute privileged instructions to manage the nested VMs, but it cannot do so without the bare-metal hypervisor [11].

(a) Vanilla nested virtualization

(b) Nested virtualization with HyperTurtle

Figure 1: The world switch problem in nested virtualization. When a nested virtual machine (L2) performs a `vmexit`, the virtualized hypervisor (L1) must handle it. However, since it is virtualized itself, the event handling is forwarded to L0, forcing an additional world switch. HyperTurtle reduces the number of the world switches by offloading the handling of such events as eBPF programs to L0.

Fig. 1a illustrates the world switch problem. Every time the execution of the nested VM (L2) requires the hypervisor's intervention (e.g., EPT faults, emulation of hardware features), L2 transitions to the virtualized hypervisor (L1). This transition requires forwarding of the `vm-exit` to the bare-metal hypervisor (L0). Hence, there are *at least four* world switches overall. In contrast, non-nested virtualization requires only two world switches. Moreover, in some common performance-critical cases, the number of world switches is higher. For example, EPT fault handling requires *six* world switches if the physical memory of L2 is not present (see §4.3), vs. only two switches in the non-nested case.

These additional world switches cause substantial performance degradations. For example, prior work has shown that each world switch takes about 1μs, and comprises about 33% of the total `vm-exit` handling time [60].

Moreover, as we explain in §3, some of L0's `vm-exit` handlers are much more expensive in the nested scenario vs. the non-nested one, e.g., 3.3× (0.78μs vs. 2.77μs) and 2.9× (5.7μs vs. 16.7μs) for `cpuid` hypercall and non-maskable interrupt handling respectively (see Tab. 1), thus their negative impact on the nested VM performance is even higher.

Prior work has explored several techniques for reducing nested virtualization overheads [11, 31, 45, 58, 60]. Direct Virtual Hardware (DVH) [45] bypasses L1's I/O stack by exposing virtual devices from L0 directly to L2, similar to passthrough in non-nested setups. DVH improves I/O performance, but retains other nesting overheads and prevents L1 from enforcing policies on I/O paths such as traffic shaping [17]. Other systems that use hardware-assisted virtualization, such as SVT [60], reduce switching overheads by co-scheduling L1 and L2 on sibling hyperthreads, but rely on simultaneous multithreading (SMT), which is being phased out and becoming unavailable [2,36]. Software-based systems like PVM [31], X-Containers [57], and CKI [58] decouple L0 from nested execution through syscall redirection, library OSes, or hardware-isolated compartments within L1, but introduce compatibility and performance issues or require hardware changes. Finally, Peer-Pods [5], Free-The-Turtles [63], and Dichotomy [62] sidestep nesting entirely, at the cost of hypervisor-level control and orchestration flexibility.

We present **HyperTurtle**, a general approach to accelerating nested virtualization with minimal code modifications to both L0 and L1. HyperTurtle reduces the number and cost of world switches by offloading certain parts of the L2 `vm-exit` handling logic from L1 to L0 (see Fig. 1b). Notably, it encapsulates relevant functionality as an *eBPF* program loaded into and executed by L0 when handling L2's `vm-exits`. To achieve this, HyperTurtle enables L1 to hook into L0's `vm-exit` handling logic, which executes the eBPF that implements the relevant functionality of the L1 hypervisor, such as EPT fault handling. Not only does this mechanism eliminate the respective world switches, but it also obviates the need for emulating CPU virtualization features necessary for handling the event in L1. The eBPF bytecode undergoes the standard kernel verification when loaded by L0 to ensure safe execution. Thus, HyperTurtle improves the performance of nested virtualization with minor changes to L0 and L1 hypervisors, it is hardware agnostic, and keeps L1 in full control of L2.

The idea of offloading guest functionality to a hypervisor via eBPF was first introduced in Hyperupcalls [4]. However, adopting it to accelerate nested virtualization poses a few non-trivial challenges. First, eBPF programs cannot use locks or unbounded loops and cannot perform arbitrary memory accesses due to safety constraints, complicating the implementation of complex functionality such as EPT fault handling. Second, L1's address space and data structures are not accessible to eBPFs running in L0. Last, a naive approach where L0 may host eBPFs that belong to different L1 hypervisors may compromise isolation. For example, attaching a L1's eBPF program to L0's physical network interface enables it to receive the network traffic of L0 as well as other L1's.

HyperTurtle solves these challenges, demonstrating how eBPFs can be used to accelerate three specific subsystems of high practical importance where nested virtualization incurs particularly high overheads: EPT fault handling, network I/O, and application performance profiling. In each case, we show how to expose the relevant L1's state to an eBPF program via *eBPF maps*, develop *helper functions* that enable direct and safe access to L1's data structures from the eBPF context, implement the respective eBPF program, and leverage HyperTurtle infrastructure to safely attach it to the appropriate hooks in the L0 kernel.

We show that HyperTurtle offers substantial performance benefits in all three scenarios, and provides a generic way to reduce both `vm-exits` and I/O overheads. Specifically, moving the EPT fault handling into L0 allows L2 physical memory to be paged in without trapping to L1, resulting in a 5.1× reduction in EPT fault handling latency on average. This reduction accelerates Kata container launch times by an average of 27%.

Running L1-controlled networking with eBPF in L0 enables the usage of DVH without compromising L1's control over L2 networking. This enables 33% average latency reduction compared to the two-level network virtualization previously required to achieve the same level of control over L2 network stack. Thus, HyperTurtle achieves a 72% throughput increase at 500μs in the memcached latency-throughput benchmark, making the performance of nested Kata containers on par with regular containers, while retaining full compatibility with the Kubernetes Container Network Interface despite the use of DVH. Lastly, HyperTurtle enables profiling nested virtual machines from L1 with a reduction in sampling latency by 7×.

Importantly, HyperTurtle is practical and easy to maintain, as it achieves high performance with modest modifications limited mostly to the KVM module, and its most complex EPT fault handling hyperupcall is only 560 LOC.

The HyperTurtle source code and evaluation scripts are available at https://github.com/acsl-technion/hyperturtle.

2 Background

This section introduces the necessary background in nested virtualization and the previous work we build upon.

2.1 Nested Virtualization

We refer to a bare-metal hypervisor, a virtualized hypervisor running in a virtual machine, and a guest virtual machine managed by the virtual hypervisor as L0, L1, and L2, respectively.

In nested virtualization, L1 cannot directly access the CPU's virtualization hardware extensions, which are only available to L0. Thus, L0 emulates these features for L1 by trapping virtualization-related instructions executed by L1.

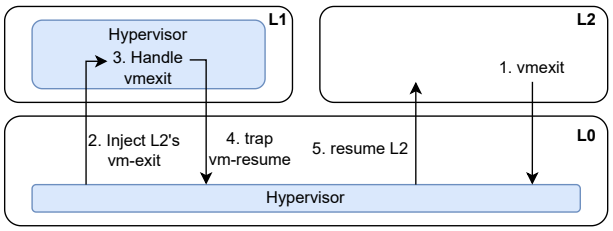


Figure 2: L0 runs the nested VM on L1's behalf. L0 injects all events that cause L2 to exit into L1.

Effectively, this results in L0 running L2-related procedures on L1's behalf, forwarding all virtualization-related events to L1. This process is entirely transparent to L1 and L2. When L2 triggers a `vm-exit`, the CPU exits to L0, which injects the event to L1. This emulation doubles the number of world switches compared to non-nested virtualization. Fig. 2 illustrates the event forwarding. Often, the number of world switches may be higher (as, for example, in the case of EPT faults), and their costs may differ. We discuss this in §3.

Memory management in nested virtualization is also more complex. In non-nested virtualization, L0 maintains L1's physical memory space, mapping guest physical addresses (gPA) memory to host physical (hPA). However, an additional level of indirection is necessary for nested virtualization, as L2 addresses are mapped to L1 addresses, which are then mapped to L0 addresses. The guest's memory can be backed by anonymous, or file-backed memory via a shared-memory file system such as `shmem`. File-backed memory enables the *Virtual Machine Monitor* (VMM) to share the memory of the guest with another process. Kata containers utilize this with virtiofsd [61] for file system virtualization, providing a shared file system between the containers and the host.

Similarly, device virtualization adds another level of indirection. Consider, for example, the virtualization of a Network Interface Card (NIC). VirtIO [56] is a popular choice of the network para-virtualized device in non-nested virtual systems, as it facilitates VM migration and network changes without the guest's cooperation. L0 exposes the NIC backed by VirtIO to L1 VMs. This para-virtual approach requires the translation of I/O events from physical devices in the host to virtual devices. In the nested virtualization scenario, there are two layers of para-virtual devices, one managed by L0 exposed to L1, and another by L1 exposed to L2.

2.2 eBPF

eBPF (extended Berkeley Packet Filter) allows users to dynamically load and safely run code in the kernel. To use eBPF, the user compiles restricted C code into eBPF bytecode. An object file with the bytecode can be loaded into the kernel and linked (or *attached*) to pre-existing function calls, *hooks*, in the kernel. The Linux kernel exposes many hooks. In particular, eXpressDataPath (XDP) and Traffic Control (TC) are popular hooks in the network stack, used, for example, to implement DDoS protection [21], load balancing [49], and observability [14]. eBPF uses key-value data structures, called *shared maps*, to share data between eBPF programs and user-space applications. The eBPF program defines the maps and the kernel allocates them when loading the program.

The kernel has a built-in verifier that checks the safety of eBPF programs. However, the verification restricts the expressiveness of eBPF programs. The verifier checks the bounds of memory accesses, disallows unbounded loops, and restricts the use of locks, e.g., by non-root users.

Helper functions allow the eBPF programs to request services from the kernel or query its data structures [46]. The Linux kernel exposes a limited set of functions to eBPF programs, which can be divided to 5 main types: (i) map access (`bpf_map_lookup_elem()`) (ii) time & perf utilities (`bpf_ktime_get_ns()`, `bpf_perf_event_read_value()`) (iii) network stack integration (`bpf_redirect()`) (iv) syscall–like services (`bpf_get_current_pid_tgid()`) (v) arbitrary data access (`bpf_probe_read()`).

Not all functions are available to every eBPF program. E.g., a networking-related helper function is not available to a tracing-type eBPF program. Moreover, a program's set of available functions can be restricted with the Linux capability system [47], and some helper functions require special permissions (e.g., arbitrary data access helper functions).

2.3 Kata Containers

Tenants of public cloud systems may serve as service providers to third-party users [3]. While containers are common and the most convenient way to manage computational resources for such services, their isolation guarantees are often insufficient to run third-party code. Kata containers solve this issue. They offer the level of isolation of hardware virtualization but retain the same control interface as regular containers. They execute an application in a lightweight virtual machine, yet run a special agent to allow access to that application and maintain the management interface compatible with popular container management systems such as Kubernetes [42].

From the cloud provider's perspective, Kata containers run as nested virtual machines. Unfortunately, the overheads associated with such deployments are too high, up to 3× slower [45, 57] than non-nested setups, forcing users to sacrifice stronger isolation advantages for better performance. Thus, HyperTurtle's primary goal is to improve the performance of nested virtualization and make it an attractive alternative to containers.

3 Analysis

We first analyze the latency of world switches in isolation, and then show their performance impact in three important practical cases: EPT fault handling, networking and profiling. We use the same evaluation setup as in §5.

Exit Reason	L1 → L0 [μs]	L2 → L0 [μs]
nop hypercall	0.85	2.82
`vm-write`	1.1	—
`vm-enter`	8.0	—
`cpuid`	0.78	2.77
EPT Fault	4.8	3.7 ± 0.8
Non-maskable interrupt	5.7	16.7

Table 1: L0 `vm-exit` handling duration, measured from `vm-exit` of the VM to the next `vm-enter`. All measurements are with CoV $< 1\%$, except for EPT fault from L2.

3.1 Understanding World Switch Costs

World switches between L0, L1 and L2 may occur in a variety of execution scenarios, such as the invocation of privileged CPU instructions by L2 or L1. Notably, L2 always traps into L0, which forwards the event to L1. Some world switches are voluntary, i.e., when para-virtual I/O devices notify the L0 to perform an I/O event. This notification is implemented as a hypercall, which initiates a voluntary world switch.

At the CPU level, world switches require flushing of the CPU execution pipeline, saving the VM's registers into the Virtual Machine Control Structure (*VMCS*) data structure, and loading the hypervisor registers from the VMCS structure. These operations lead to non-negligible overheads. Vilanova et al. [60] show that these overheads amount to about 33% of a 10μs-long emulation of the `cpuid` instruction.

Moreover, the handling latency of the `vm-exit` associated with each world switch may vary significantly depending on the cause of `vm-exit`, due to the execution of different code paths. Tab. 1 shows the latency of handling `vm-exits` in a few different scenarios. For example, handling a non-maskable interrupts is the most expensive. Notably, most transitions from L2 to L0 are more expensive than those from L1. This is caused by the need to inject the `vm-exit` from L0 to L1 and the manipulation of many of L0's own data structures.

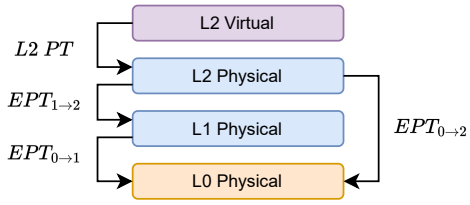
Takeaway: World switches are expensive, and their latency varies depending on their cause. They are more expensive when triggered from L2 than from L1.

So far, we have discussed the costs of world switches in isolation. Next, we focus on three specific scenarios to show how world switches affect their end-to-end performance in a nested virtual machine.

3.2 EPT Faults

Memory management is a key culprit of the nested virtualization tax, as the additional virtualization layer triples the number of world switches required to handle Extended Page Table (EPT) faults. To understand the origin of this overhead, we detail the implementation of the EPT fault mechanism for a nested guest in KVM.

Fig. 3 illustrates the hierarchy of page tables in nested virtualization. As with the non-nested virtualization, L0 maintains



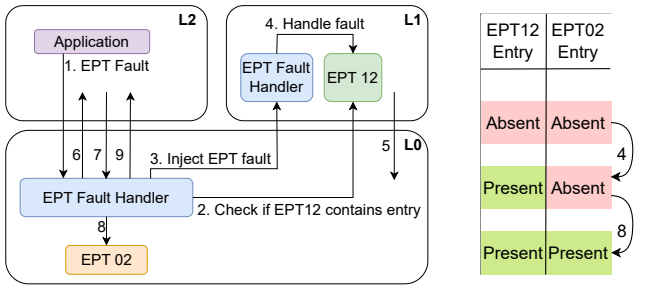


Figure 3: Page table hierarchy in nested virtualization

(a) EPT fault handling in nested virtualization, see the text for details.

(b) L2-PA mapping. Steps refer to (a).

Figure 4: EPT fault handling in nested virtualization

an EPT, called $EPT_{0\to1}$ [1], from L1 physical addresses (L1-PA) to L0 physical addresses (L0-PA). However, unlike non-nested virtualization, L1 maintains an EPT, called $EPT_{1\to2}$, from L2 physical addresses (L2-PA) to L1 physical addresses (L1-PA). As CPUs do not support a 3-dimensional page-walk, L0 *shadows* $EPT_{1\to2}$ and maintains $EPT_{0\to2}$ which translates L2-PAs directly to L0-PAs. L0 lazily creates $EPT_{0\to2}$ while running L2.

Fig. 4a walks through the EPT fault handler, while Fig. 4b illustrates the state of $EPT_{1\to2}$ and $EPT_{0\to2}$ throughout. L2 encounters an EPT fault due to a missing $EPT_{0\to2}$ entry, which triggers a `vm-exit` to L0 ❶. L0 checks if a valid mapping appears in $EPT_{1\to2}$ ❷. If it is missing, L0 injects the EPT fault into L1, and enters L1 immediately thereafter ❸. L1 handles the EPT fault by mapping the address in $EPT_{1\to2}$ ❹. L1 tries to resume L2, trapping again into L0 ❺. L0 enters L2 ❻, which re-executes the instruction that triggered the EPT fault. Since $EPT_{0\to2}$ still contains a non-present entry, another `vm-exit` occurs ❼. L0 once again walks $EPT_{1\to2}$ ❽, finds the entry, and fixes $EPT_{0\to2}$ with the value from $EPT_{1\to2}$. L0 then re-enters L2 ❾, resuming execution. This procedure requires a total of *six* world switches, compared to only *two* in non-nested virtualization.

We measure the EPT fault latencies incurred by a VM when faulting in 1GiB of consecutive memory with and without nesting. Tab. 2 shows the results. We observe that nested EPT faults experience 5.1× and 5.3× latency increase over the non-nested scenario for the average and 99p latencies, respectively, demonstrating the costs of additional world switches.

[1] This notation is adopted from [11]. The first digit is the virtualization layer that manages the table for the layer denoted by the second digit.

	L2 VM	L1 VM	Slowdown
Average Latency [us] ↓	28.39	5.58	5.1×
99p Latency [us] ↓	49.13	9.35	5.3×

Table 2: EPT-fault Latencies in demand paging (lower is better).

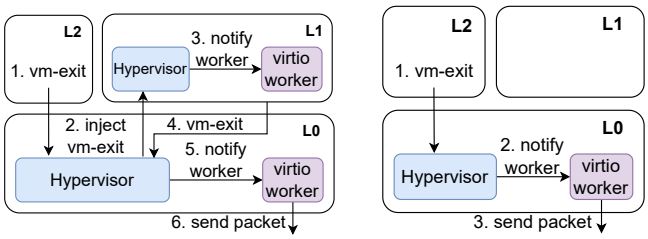
Impact on startup time. EPT faults occur most frequently early in the VM's life cycle because memory has not been allocated yet. Therefore, the EPT fault handling performance directly impacts the startup time. In the context of nested virtualization, this metric is particularly important for Kata containers, as their usage scenarios are identical to regular containers, i.e., short lifetime and on-demand dynamic deployment [1], thus requiring low startup latency.

To demonstrate the impact of the EPT fault handling on the boot time of a nested VM, we measure the startup time of a Node.js application with a Linux Ubuntu image in a Kata container. We define *startup time* as the time from issuing the startup command until the application responds to a network request. Starting the Kata container in a non-nested scenario takes 0.7 seconds, compared to 1.5 seconds as a nested VM. The latency breakdown shows that the EPT faults account for 14% (0.1 seconds) and 46% (0.69 seconds) in the non-nested and nested cases respectively, highlighting the importance of reducing the EPT fault handling costs.

Takeaway: World switches cause large overheads in EPT fault handling in nested virtual machines, with a significant end-to-end impact, e.g., on the startup time.

3.3 Networking

Network I/O from L2 to the world outside the physical server must be performed via L0 which manages physical NICs. In a simple approach, called `Nested-VirtIO`, L1 mediates between L2 and L0. L0 exposes a virtual NIC to L1 ($vNIC_{01}$), which in turn creates its own vNIC ($vNIC_{12}$) and exposes it to L2. Under the hood, L1 connects and forwards traffic between $vNIC_{01}$ and $vNIC_{12}$. Both vNICs are virtioNICs.



A more sophisticated approach, called *Direct Virtual Hardware*, `Direct-Assignment` [45], utilizes QEMU's IOMMU emulation, where L0 exposes multiple vNICs to L1, allowing it to connect $vNIC_{01}$ directly to L2, effectively removing L1 from the L2 network data path. Indeed, Tab. 3 shows significant performance benefits of `Direct-Assignment` over `Nested-VirtIO` - with latency reduced by 40% and 37% for mean and 99p respectively, and throughput increased by 44%. Both setups utilize the vhost-net [59] driver in the hypervisors.

To understand this performance gap, we review the chain of events when L2 sends a single packet via `Nested-VirtIO` and via `Direct-Assignment` in Fig. 5a and Fig. 5b respectively.

In `Nested-VirtIO`, ❶ L2 executes an MMIO write to notify $vNIC_{12}$ of the pending packet, which triggers `vm-exit` to L0. ❷ L0 injects `vm-exit` to L1's hypervisor, which forwards L2's request to ($vNIC_{12}$)'s virtio worker thread ❸. The latter

	Nested-Virtio	Direct-Assignment	Relative
Avg Latency [us] ↓	90.21	54.52	0.60×
99p Latency [us] ↓	106	67	0.63×
Throughput [Gb/s] ↑	12.1	17.4	1.44×
CPU Usage [%] ↓	100	196	1.96×

Table 3: UDP round-trip latency of packets with 1-Byte payload using netperf; TCP throughput with iperf3.

(a) First packet transmission with `Nested-VirtIO`

(b) First packet transmission with `Direct-Assignment`

Figure 5: Comparison of single packet transmission in `Nested-VirtIO` and `Direct-Assignment`

tries to transmit the packet ❹, triggering a `vm-exit` from L1 to L0 due to a similar MMIO write. L0's hypervisor forwards the request to $vNIC_{01}$'s virtio worker ❺ which sends it via the physical NIC ❻.

This process is much shorter in `Direct-Assignment`: ❶ L2 executes an MMIO write to notify ($vNIC_{02}$), which triggers a `vm-exit` to L0. L0's virtio worker sends the packet ❷ via the physical NIC.

The overheads of `Nested-VirtIO` stem from the higher number of world switches: we observe a total of *three* world switches to transmit a packet using `Nested-VirtIO` compared to *one* world switch with `Direct-Assignment`.

Unfortunately, `Direct-Assignment` effectively disables the control of L1 over L2 networking, by removing L1 from the L2 network control path. Thus, L1 cannot affect the policies of network management operations for its L2 guests, such as routing, monitoring, and traffic shaping, which are essential for the proper operation of containers.

Takeaway: World switches in L2 network stack cause significant overheads. `Direct-Assignment` *reduces the overheads, but it does not allow L1 to control L2's network policies.*

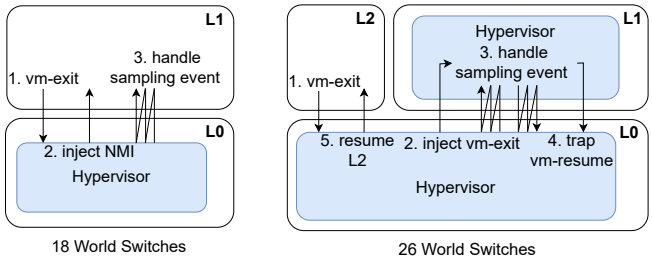
3.4 Application Profiling

Profiling is broadly used to find bottlenecks in development and production systems, with some vendors, such as Netflix [30] and Google [55] continuously profiling their production applications. Moreover, all large cloud providers, such as AWS, Google Cloud, and Azure [8, 20, 27, 28] offer profiling utilities to their tenants.

Setup	L0 → L1	L1 → L1	L1 → L2
Latency [μs] ↓	5.66	25.63	60.68

Table 4: Profiler sampling latency in different settings.

Sampling profilers periodically interrupt a program and sample the programs state, as well as hardware performance monitoring counters (PMCs). Notably, sampling-based profilers are popular because they introduce minimal execution overhead, causing between $1\% - 3\%$ slowdown for most applications [20, 38].



Each *sampling event* begins with an interrupt, caused by the overflow of a PMC, which counts cycles since the last event and ends when the profiled program resumes execution. During the event, the state of the running program is sampled and the PMC is reprogrammed. From a performance perspective, profiling an application inside a container and running on bare-metal hardware is the same as profiling a regular application. Profiling an L1 from L0 requires a single `vm-exit` for each sampling event.

However, profiling inside a VM causes a dramatic slowdown. Tab. 4 compares the average latency of handling a sampling event when profiling L1 from L0 ($L0 \rightarrow L1$), a container from L1 ($L1 \rightarrow L1$) and a nested VM from L1 ($L1 \rightarrow L2$). We observe that the latency of ($L1 \rightarrow L2$) is about twice as large as the latency of ($L1 \rightarrow L1$), and almost $8\times$ higher than profiling a VM from L0.

We now analyze the sequence of events that occur when profiling a container (Fig. 6a) and a nested VM (Fig. 6b) from L1. In the former case, KVM emulates the HW counters by exposing virtual registers. L0 traps the L1 when the latter tries to access them. The flow is as follows: ❶ The HW counter triggers an interrupt, which triggers a `vm-exit` to the host (L0). ❷ The host injects a similar interrupt to the L1, and enters L1. ❸ As part of the interrupt handling routine, L1 reprograms the HW counter and performs multiple accesses to MSRs, bringing the total world switch count to *18*.

Profiling an application in a nested virtual machine incurs higher overheads. ❶ The HW counter triggers an interrupt, which triggers an exit from L2 to L0. ❷ L0 injects a similar interrupt to L1, and enters L1. ❸ As part of the interrupt handling routine, L1 reprograms the HW counter, accesses MSRs and performs the `vmread` and `vmwrite`, which access the VMCS, overall triggering 22 world switches. ❹ L1 executes the `vm-enter` instruction, which triggers an exit to L1. ❺ L0 emulates the `vm-enter` instruction and enters L2, which brings the total number of world switches to *26*.

Interestingly, the performance discrepancy between profiling a nested VM or a container stems not only from the number of world switches but also from their higher costs for the nested case. Our measurements show that 7.8 μs are spent by L0 injecting the NMI into L1, additional 8μs on the emulation of L1's execution of the `vm-enter` instruction.

(a) Profiling a container in L1 (b) Profiling a Kata container in L1

Figure 6: Comparison of world switches when profiling a standard container versus a Kata container from L1.

Takeaway: Excessive world switches and their increased cost cause high overhead when profiling an L2 VM from L1.

These diverse examples motivate us to build a generic infrastructure to reduce the aforementioned overheads of nested virtualization, as we describe next.

4 Design & Implementation

HyperTurtle pursues the following design goals:

1. **Performance:** Eliminate excessive world switches,
2. **Control:** Retain L1's ability to enforce policies on L2,
3. **Non-intrusiveness:** Minimize L0 modifications,
4. **Generality:** Provide a hardware-agnostic approach generalizable to optimize different OS subsystems.

HyperTurtle offloads a subset of L1 hypervisor functionality into L0 thus minimizing excessive world switches (Goal 1). HyperTurtle leverages *hyperupcalls*, i.e., eBPF programs, to safely execute L1's code in L0. Thus, L1 fully controls the offloaded logic executed in L0, implying that it retains full control over L2 (Goal 2). As the eBPF subsystem already exists in L0's kernel, the only L0 modifications required are the export of nested virtualization-related information to be accessible to the hyperupcall eBPF function via helper functions, and the addition of an installation mechanism for eBPF programs from L1, achieving Goal 3. Last, HyperTurtle's implementation is modular, making it applicable to accelerate different subsystems according to the user's choice, as we empirically demonstrate in the rest of the paper (Goal 4).

We focus our efforts on KVM, as the da-facto standard for virtualization in Linux, however, we believe that the design principles are applicable to Xen-based VMs. Additionally, we limit our design to a single level of nesting, leaving further design choices, such as the choice of the layer to which a hyperupcall should be installed for future work.

4.1 Design Overview

HyperTurtle comprises the eBPF offloading infrastructure, new hooks in L0, new eBPF helper functions and the mechanisms for sharing data between L1 and eBPFs.

The offloading mechanism allows L1 to install the relevant eBPF in L0 via a hypercall. It exposes two main features: *load* a program into L0 and *link* the program to the hook.

A program is first loaded into L0 and verified by its eBPF verifier. L1 then attaches the hyperupcall to a hook in L0, which is invoked as part of L0's logic for handling L2 events.

Design recipe. Each subsystem requires its own design to reduce the associated world switch overheads via eBPFs. However, each such design follows a general recipe which comprises three key steps:

1. **Sharing information:** Exposing necessary information between L1 and the eBPF program for its operation. L1 might need to be modified and L0 might need to expose new helper functions to assist the hyperupcall.
2. **Hook into L0:** Implementing a hook in the L0 hypervisor to intercept and handle specific events.
3. **Develop eBPF program:** Writing the desired functionality as an eBPF program that will run in its own isolated context from L0.

We now explain the infrastructure shared by all hyperupcalls and then delve into the eBPFs for accelerating EPT fault handling, network control of L1, and application profiling.

4.2 Hyperupcalls Infrastructure

eBPF maps and L1 memory access. HyperTurtle employs shared eBPF maps for L0-L1 data sharing, instead of the packet-based communications in Hyperupcalls, to support concurrent access to shared data. To achieve this, HyperTurtle adds a new hypercall to create a shared-memory PCI device which exposes array eBPF maps from L0 to L1.

In addition, we introduce a new helper function in L0, `bpf_probe_read_hyperupcall`, to enable eBPFs to access L1's physical memory. This function is safe, in that it verifies that the address is valid and mapped to L1. In addition, it guarantees isolation between the eBPFs installed by different L1 VMs, ensuring that each eBPF can only access the memory regions of the L1 to which it belongs.

Hyperupcall registration. An L1 guest registers a hyperupcall to the L0 hypervisor via a hypercall interface. L1 provides the compiled eBPF program and the hook to attach it. L0 uses the existing eBPF registration mechanism in the Linux kernel to verify, load and link the hyperupcall. For improved security, L1 might also request to install an eBPF from a set of eBPFs vetted by L0 in advance.

In contrast to the original hyperupcall infrastructure where the registration is implemented in a single hypercall, we separate the loading and linking into two hypercalls. This allows linking a single hyperupcall to multiple hooks and avoids duplicate loading, e.g., for networking-related hyperupcalls.

Security. HyperTurtle may be used with two security models: 1. L1-provided eBPFs secured by L0's eBPF verifier or stricter alternatives such as Prevail [25]. 2. Cloud vendor-vetted eBPFs, loaded only if signed and verified (e.g., via Hornet [13]). The latter model provides more strict security where necessary. With both models, HyperTurtle ensures eBPFs can access only their own L2s and memory; and subsystem-specific isolation mechanisms are detailed in the following sections.

4.3 EPT Fault Handling

To combat high EPT fault latencies, we implement a hyperupcall which can map a non-present $EPT_{1\rightarrow2}$ entry during a nested guest's EPT fault. Our implementation targets the *file-backed* memory virtualization backend, which is commonly used in QEMU and Cloud Hypervisor [33], and adopted by Kata Containers [42]. It relies on the `shmem` virtual file system, and enables shared memory between the host and guest. This backend typically works in conjunction with a user-space daemon, such as virtiofsd [61], to support shared file systems outside the VMM (see §2.1).

4.3.1 Sharing Information

The key design challenge of the EPT fault hyperupcall is managing the shared state between L1 and the hyperupcall running in L0. The design must account for L1 physical memory allocation, race conditions, as well as the consistency of L2's physical memory mappings that may arise as the VMM and other processes access L2's memory (e.g., virtiofsd [61]).

Memory allocation. Since allocating memory from the hyperupcall's eBPF context is too complex, we use a pre-allocated *memory pool*. Specifically, L1 maintains a pool of allocated frames in an eBPF map which is accessible from the hyperupcall. The hyperupcall falls back to the traditional EPT fault mechanism if the pool is empty. L1 replenishes the memory pool either asynchronously using a background kernel thread or synchronously in batches when L1 is called to serve a `vm-exit`. Our experiments show that using a pool size of 4096 frames suffices to avoid synchronous replenishment. We therefore use a 4096 frame pool size throughout the paper.

Consistency with L1. The hyperupcall must prevent potential inconsistencies between $EPT_{1\rightarrow2}$ and other data structures in L1, such as the VMM's page table and L1's KVM internal data structures. For example, due to races on L1 virtual addresses (L1-VA) which correspond to an L2-PAs.

To notify L1 of changes the hyperupcall makes to $EPT_{1\rightarrow2}$, it exposes a cyclic fault log called the *hyperupcall fault log* to L1 via a shared map, to which it logs the L2-PA it maps. On the next `vm-exit` entering L1, L1's KVM faults the L1-VAs corresponding to the entries in the fault log into the VMM's address space. If the log is full, the hyperupcall falls back to the original EPT fault mechanism. To make the hyperupcall aware of mappings performed by the VMM, the VMM's `cr3` register is copied to a shared map. Access to the `cr3` enables the hyperupcall to walk the VMM's page table using the `bpf_probe_read_hyperupcall` helper function and check whether the faulted address has a preexisting mapping.

To prevent race conditions, we wrap the hyperupcall with a lock. A failure to acquire the lock results in a fallback to the traditional EPT fault mechanism due to the limitations of eBPF lock implementations (see §2.2).

The lock is exposed to L1 via a shared map, allowing L1's KVM to acquire the lock when handling an EPT fault in L1.

Finally, to create a coherent memory mapping between the hyperupcall and users of the L2's file backed memory (e.g., L1's hypervisor and the virtiofsd daemon), we *wrap* the `shmem` page fault handler with the following logic: (1) Acquire the hyperupcall's lock (spinning if necessary). (2) Walk $EPT_{1\to2}$ to check if the hyperupcall already mapped this page. If it has, map it to L1. (3) Call the original page fault handler. (4) Log the L2-PA which corresponds to the fault to a cyclic buffer, called *page fault log*, which is also a shared map. Step (2) is necessary because the hyperupcall might have created a mapping that is not yet visible from L1 (because an exit from L2 to L1 hasn't occurred yet). To minimize its size, the VMM purges the log on the next `vm-exit` from L2. The maximal log size is equal to the number of L2 frames to prevent overflows. Future work may optimize this design.

4.3.2 L0 Hook

We place the hyperupcall hook in L0's handling of L2's EPT fault, during step ❷ from Fig. 4a, which allows L0 to call the hyperupcall upon the discovery of a non-present entry in $EPT_{1\to2}$. The hyperupcall then maps a new L1 frame to L2, and allows L0 to finish the fault handling and resume the execution of L2, avoiding excessive world switches.

4.3.3 eBPF Program

The hyperupcall receives the faulting L2-PA as well as the fault type (read or write), and then performs the following steps, wrapped within the hyperupcall lock:

1. Walk L1's VMM's page table to check if a mapping exists for the L1-VA that corresponds to the L2-PA that triggered the fault. If a mapping exists, return an EPT entry pointing to the appropriate L1-PA.
2. If the L2-PA is in the page fault log (faulted in by an external process in L1), fall back to the traditional EPT fault mechanism.
3. Create a new EPT entry using a frame from the hyperupcall's memory pool.
4. Write the new entry into $EPT_{1\to2}$ and the fault log.

After the hyperupcall returns, L0 continues to handle the EPT fault as $EPT_{1\to2}$ is now present.

4.4 Fast L2 Networking with L1-Controlled Policies

The `Direct-Assignment` method, introduced by DVH [45], improves performance, but takes away L1's control over L2's network traffic. HyperTurtle allows L1 to install eBPF programs on L0's network interfaces, enabling it to regain control by attaching hyperupcalls to the virtual devices used by L2. While this represents a relatively simple use case for hyperupcalls, it demonstrates how HyperTurtle can restore control without sacrificing performance.

Fig. 7 explains the operation of the networking subsystem using `Direct-Assignment` with eBPFs in the L2's network data path. As per the general recipe (see §4.1) — we *share*

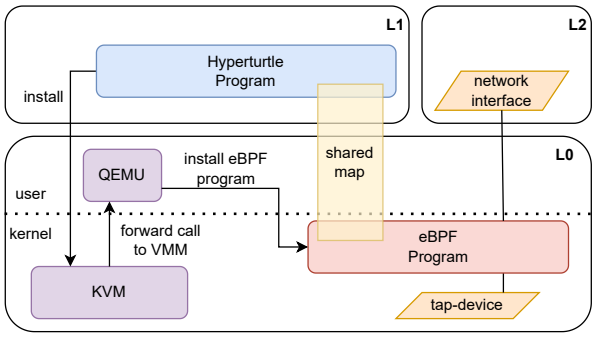


Figure 7: Networking eBPF in the L2 data path

information via shared maps and *hooks* are supplied by L0's eBPF infrastructure [15]. We *implement* the following proof-of-concept eBPF programs to showcase L1's ability to control L2 network policies.

- *Pass* simple eBPF program that does not perform any processing,
- *Stateless Firewall* filters packets based on their source IP address,
- *Rate Limiter* caps the rate of L2's incoming traffic based on data throughput and packet count. The limit can be dynamically configured at runtime by L1,
- *TCP-Top* allows L1 to monitor all TCP connections of L2. It is a modified version of inspector-gadget's `tcptop` program [34].

Isolation & Multiple L2s. HyperTurtle ensures that the eBPF programs can run on the data path of virtual interfaces owned by the L1 VM that installed them. Thus, it guarantees that L1 cannot interpose on the traffic on the interfaces it does not own. Moreover, HyperTurtle utilizes the available per-vNIC hooks to allow L1 to load a different eBPF program to each L2 it manages.

4.4.1 Compatibility Layer with Container Management

Kubernetes (k8s) is a prime candidate as a cluster management tool for nested VMs [23, 42]. In particular, Kata containers support management by k8s, but using `Direct-Assignment` breaks the compatibility with k8s and prevents L1's control over the k8s network required for monitoring and policing with tools such as Clilium [14].

To deploy HyperTurtle in k8s clusters, we integrate dynamic `Direct-Assignment` interface management via a custom *Container Network Interface (CNI)* plugin [7]. The plugin implements configuration of a k8s network by creating and configuring network interfaces as requested by k8s in the initialization process of a k8s pod (management unit of k8s). The L1 administrator may then install the eBPFs to implement the network functions explained before.

Fig. 8 presents the dynamic interface creation. In step ❶, the user requests k8s to create a new pod. To create the pod, K8s requests new NIC from the CNI plugin ❷ which internally requests it from L0 via a hypercall interface ❸.

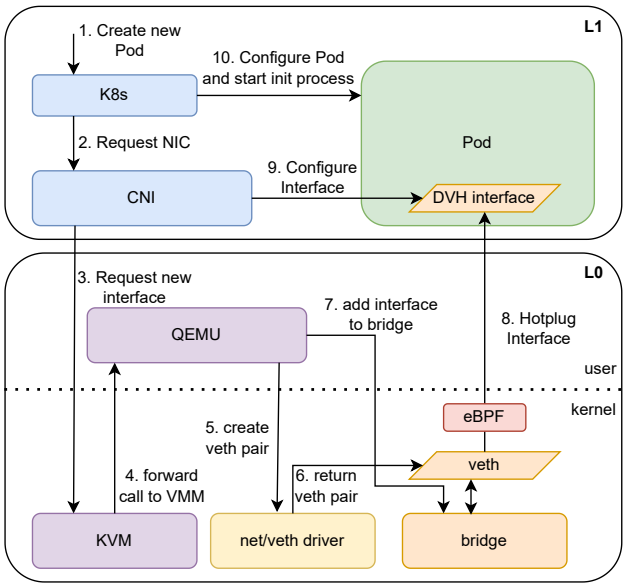

Figure 8: Dynamic virtual interface creation with k8s for spawning a new pod with a DVH network interface. The pod in L1 may be a regular container or a Kata container.

KVM receives the hypercall and forwards it to QEMU ❹, which creates the new vNIC ❺. The L0 kernel creates the interface ❻, such that QEMU attaches it to a predefined bridge ❼, and dynamically hotplugs the interface to L1 via the standard QEMU mechanisms ❽. Meanwhile, the CNI plugin waits for the new interface to appear, and then assigns the correct network namespace and configures the addresses according to k8s' request ❾. Finally, after CNI plugin returns, and k8s starts the pod's init process ❿.

Due to the modular design of the CNI plugin, it also allows the management of VM interfaces and is compatible with other projects without additional implementation efforts.

4.5 Profiling

The hyperupcall to accelerate profiling does not require any information from L1, but it needs to share the samples with the application running in L1. Following the recipe from §4.1, we adopt an approach similar to perf [59] and *share information* via a shared map as a ring buffer which holds the samples. The buffer must be emptied periodically by L1 to allow the profiler to continuously log samples. Additionally, we added a new eBPF helper function, `vcpu_probe` which reads L2's registers, allowing L1 to easily view it's L2 state from within the hyperupcall.

We utilize the preexisting profiling *hook* in Linux to define the hyperupcall, using perf's system call interface to register the hyperupcall's eBPF program as a sampling event. When L1 registers the hyperupcall, is specifies the frequency at which it wants the profiler to run.

After registration, the eBPF program is the periodically called and can sample the guest. Our proof-of-concept profiler *implementation* samples the guest's instruction pointer via new helper function, and logs them onto the ring buffer.

Isolation. We inherit the isolation guarantees from the perf's system call, as it allows us to control the sampler only when the process currently running is in the guest mode.

4.6 Summary of Code Modifications

Tab. 5 highlights the modest code modifications in the respective subsystems required to implement HyperTurtle infrastructure and the hyperupcalls to accelerate the described subsystems. Specifically, the L0 VMM, e.g., QEMU, implements the registration process, requiring the addition of the registration hypercalls. HyperTurtle's EPT fault handling mechanism requires additional eBPF hooks in the L0 kernel that expose the EPT handler routine to the eBPF subsystem. The L0 kernel modifications are limited to exporting additional functions in the memory subsystem and addition of hooks. Lastly, the implementation requires minor additions to the L1 kernel, almost exclusively to the KVM kernel module and the eBPF framework. The implementations of all three hyperupcalls in eBPF are minimal.

In summary, HyperTurtle requires modest changes to the kernel and relatively small amount of eBPF code to achieve its goal of significantly reducing the number of world switches.

4.7 Other usecases

We briefly outline a number of other scenarios where HyperTurtle's approach can be beneficial.

Faster Networking. It is possible to utilize XDP's AF-XDP socket to route traffic directly from the network driver network functions from L2 VMs to L0 to further improve performance.

Storage Devices. Similarly to networking, storage devices may be directly assigned from L0 to L2. By allowing eBPF function that run on L0 to access the file mapping information on L1, files could be read into L2 directly from L0.

SmartNICs. Offloading eBPF programs from L1 to smart NICs can significantly improve performance, thereby completely removing network virtualization logic from the CPU and boosting the performance of nested virtual machines.

Direct Execution and Scheduling. DVH [45] implemented direct execution of nested guests from an idle state of both L1's and L2's vCPU. This can be expanded upon and generalized with hyperupcalls, as L1 may ask L0 to run the L2 vCPU without entering and exiting L1. This is most relevant on over-commited systems running latency sensitive applications such as memcached, as well as when L2 is running co-routines on different vCPUs.

4.8 Limitations

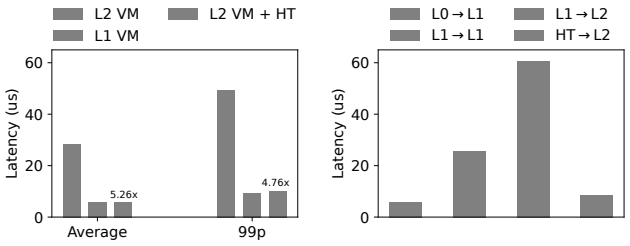
Complex functions, e.g., access to L1's file system, are difficult to implement using eBPFs due to the complexity of synchronizing concurrent access with L1. For the same reason it is unclear how to implement full-offloading without a fallback to L1.

Level	Codebase	Size [LoC]	Description
L0	Kernel/KVM	151	Hyperupcall Infrastructure (see §4.2) and EPT fault hook (see §4.3)
L0	Kernel/eBPF	119	Addition of new helper functions (see §4.5 and §4.2)
L0	QEMU	616	Installer for Hyperupcall programs (see §4.2)
L0	QEMU	159	Dynamic `Direct-Assignment` interface creation (see §4.4.1)
L1	Kernel/mm	32	Support `shmem` backed memory (see §4.3)
L1	Kernel/KVM	653	Exposing data to hyperupcalls (see §4.3)
L0	eBPF	566	EPT fault hyperupcall (see §4.3)
L0	eBPF	263	Networking hyperupcalls (see §4.4)
L0	eBPF	59	Profiler hyperupcall (see §4.5)

Table 5: Code changes necessary to implement HyperTurtle

Our EPT fault hyperupcall implementation does not support allocating huge pages. EPT faults of huge pages are scarce, and therefore accelerating the faults with a hyperupcall has no big performance impact. Additionally, the hyperupcall cannot map pages from L1's page cache unless they are already mapped to L1's VMM page table. Last, it does not yet support multiple EPT-fault hyperupcalls simultaneously. Thus, only one L1 may use the hyperupcall for a single L2. This limitation stems from using a global L0 eBPF hook, but can be eliminated by storing a per-L2 handler in L0's KVM. We leave the implementation for future work.

5 Evaluation



Setup. Tab. 6 describes the setup in all the experiments unless stated otherwise. We pin vCPUs and vhost threads to different physical cores in a single NUMA node, and only one vhost thread is used in each hypervisor. We report average results of ten benchmark iterations. For some benchmarks, we describe the underlying distribution; however, for some microbenchmarks, we only receive statistical aggregates from the tooling and thus cannot report more detailed information. As discussed in §4.2, our modifications in L1 are limited to its kernel, which makes HyperTurtle compatible with different VMMs. As in prior work [32] we use Cloud-Hypervisor [33] as the Kata container's VMM for its high performance and support for pass-through devices. These are not supported by competing VMMs such as Firecracker [1]. Cloud-Hypervisor has better startup times and higher networking performance compared to QEMU. All nested virtualization benchmarks are conducted inside Kata containers [18, 31, 64]. For the network benchmarks, the load generator runs on a bare-metal machine connected directly via a network cable to the system under test. While all presented empirical results use Kata containers, HyperTurtle is fully compatible with classical VMMs on L1 and classical VMs as L2.

5.1 Microbenchmarks

EPT Fault Handling. We evaluate the EPT fault hyperupcall by creating a Kata container, faulting in 1GiB of memory and measuring the latencies of the EPT fault. We compare 3 configurations: (1) L2 VM: a vanilla nested VM, (2) L2 + HyperTurtle: a nested VM with the EPT fault hyperupcall, (3) L1 VM: a non-nested VM – the performance upper bound.

Component	Specification
Bare-Metal Hypervisor (L0)	2×Xeon Silver 4216 (16-core, 2.1GHz); 512GiB RAM; Nvidia MT27710; SMT off;
Nested Hypervisor (L1)	12 vCPUs; 64GiB RAM; QEMU VMM
L1/L2 Baseline (Kata Container)	1 vCPU; 2GiB RAM; Cloud-Hypervisor VMM
Networking	virtio+vhost; tx zero-copy enabled
Boot Parameters	idle=poll; nopti

Table 6: Evaluation Setup

(a) Average and 99p EPT fault latencies. (lower is better).

(b) Latency of a profiler sampling event time in different configurations (lower is better).

Figure 9: EPT Fault and profiling latency microbenchmarks (lower is better). HT ≙ HyperTurtle.

§5.1 compares the average and 99p EPT fault latencies across the listed configurations. HyperTurtle reduces the latency of an EPT fault of the vanilla nested VM by a factor of 5.25× and 4.76× for the average and 99p latency respectively. Furthermore, it has the same average latency of an EPT fault for the non-nested L1 VM, and is only 8% slower in the 99p.

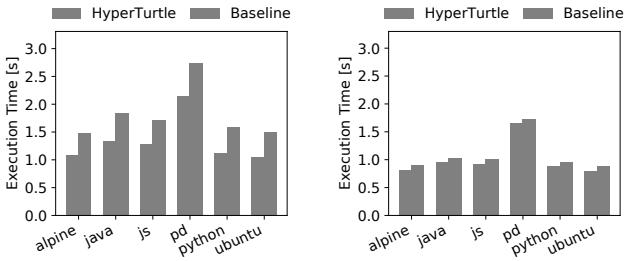
Networking. HyperTurtle enables the use of DVH with the same level of control as `Nested-VirtIO`. However, its design introduces additional computation on each packet due to the execution of the respective eBPF programs in L1's data path.

We measure the UDP round-trip-time latency and TCP throughput, and compare the following configurations: (1) `Nested-VirtIO`: vanilla nested VM, (2) `Direct-Assignment`: best-case performance with DVH but without L1's control, (3) HyperTurtle + Pass: nested VM with HyperTurtle's hyperupcalls mechanism, but with an empty hyperupcall, (4) HyperTurtle + Firewall: nested VM with HyperTurtle with a `firewall` hyperupcall, which allows L1 to enforce a firewall policy on L2's network.. The `pass` and `firewall` hyperupcalls are detailed in §4.

All configurations utilize a single vhost thread in L0, and `Nested-VirtIO` utilizes another vhost thread in L1.

We use Netperf's `UDP_RR` benchmark with 1-byte UDP payload to measure network latency [41]. We measure the maximum achievable throughput with iperf3 [40]. As our goal has been to stress the eBPF code the most, we need 3 vCPUs in the Kata container for the throughput testing to saturate the vhost thread. With a single vhost thread it becomes the bottleneck without achieving line rate. Similar throughput limits have been observed by Firecracker [1].

Tab. 7 compares the average and 99p network latency and throughput. HyperTurtle + Firewall has a 11% higher average latency than `Direct-Assignment` (60.53μs vs 54.5μs) and 33% lower average latency than `Nested-VirtIO` (60.53μs vs. 90.2μs). The eBPF firewall itself causes this overhead, as HyperTurtle + Pass has near identical ($p = 0.5\%$) performance to `Direct-Assignment` (55μs vs. 54.5μs). Thus, HyperTurtle's infrastructure only has a minor impact on network latency, and the major source of overhead is the eBPF program itself.



Profiling. We profile GUPS application with a 4MiB working set running in the Kata container on top of L1. We set the profiler sampling frequency to 1000Hz (default in Intel VTune) and compare the following configurations:

1. *L0* → *L1*: Perf profiler profiling a Kata container running in L0. Represents optimal performance.
2. *L1* → *L1*: Perf profiler profiling a container running in L1 from L1.
3. *L1* → *L2*: Perf profiling L2 from L1 (vanilla baseline).
4. *HyperTurtle* → *L2*: HyperTurtle profiler profiling L2.

§5.1 presents the profiling sampling event handle times. Compared to *L1* → *L2*, *HyperTurtle* → *L2* reduces the handling time by 7.15×, and is only 16% slower than the optimal.

5.2 Macrobenchmarks

Kata container startup time. We measure the time it takes a web server invoked in a Kata container to boot and respond to a single request. We evaluate different container images, as these may have a significant effect on the startup time [19], as well as both 4KiB and 2MiB page sizes. Importantly, even when 2MiB pages are used, the Kata runtime in L1 still maps the L2's kernel to its physical address space using 4KiB pages, hence HyperTurtle improves performance by lazily mapping these pages. The page sizes in L1 and L2 are identical, such that an L2 frame corresponds to a single L1 page. We discuss the challenges of huge pages in §4.3.

(a) 4KiB Pages (b) 2MiB Pages

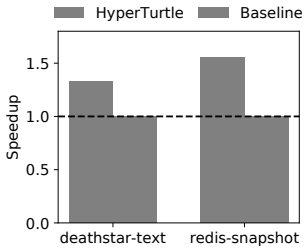
Figure 10: Kata container startup latencies for different applications, with and without HyperTurtle (lower is better). pd ≙ Python with pandas, $CoV < 5\%$.

Fig. 10 compares the startup time of a nested VM with and without HyperTurtle. We observe that HyperTurtle reduces the L2 startup time by 27% and 8% on average when running with 4KiB and 2MiB pages respectively.

Next, we compare the behavior of larger applications - an instance of Redis with a 1GiB persistent snapshot, and the TextService application from the DeathStarBench suite [24]. Fig. 11 shows 55% and 35% performance improvements respectively. Running other micro services from the DeathStarBench resulted in similar performance (not shown).

Nginx. To evaluate web server performance, we deploy Nginx [52] and serve the GCC manuals with 10 concurrent connections using ApacheBench [22], following DVH's methodology [45]. We compare the performance of different hyperupcalls and include `Direct-Assignment` as an upper bound of performance. Fig. 12a shows that HyperTurtle increases throughput by 45% when using the *TCP-Top* and the *rate limiter* hyperupcalls - from 1.24$KQPS$ to 1.8KQS, with near-identical performance to `Direct-Assignment`.

Redis. We evaluate HyperTurtle's impact on Redis's [53] throughput, using memtier_benchmark [54], under its default mixed GET/SET workload. Fig. 12b shows that HyperTurtle increases throughput by up to 65% compared to `Nested-VirtIO`, while all non-`Nested-VirtIO` are within 6% of each other.



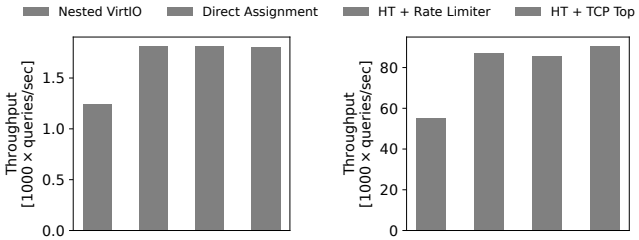


Figure 11: The launch time of a Kata containers running Redis with a 1GiB persistent snapshot, and a TextService microservice from the Deathstar suite (higher is better). $CoV < 5\%$.

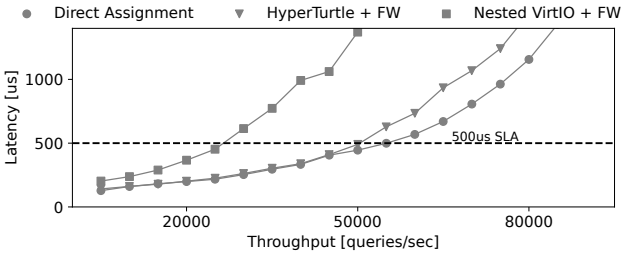
Metric	Nested-VirtIO	Direct-Assignment	HyperTurtle + Pass	HyperTurtle + Firewall
Average Latency [μs] ↓	90.2	54.52 (×1.6)	55.0 (×1.6)	60.5 (×1.5)
99p Latency [μs] ↓	106.0	67.0 (×1.6)	67.0 (×1.6)	73.0 (×1.4)
Throughput [Gb/s] ↑	12.1	17.4 (×1.4)	17.3 (×1.4)	17.1 (×1.4)

Table 7: Network latency and throughput. Values in parentheses are improvements relative to Nested-VirtIO. The CoV is below 10% in all the experiments.

(a) Nginx (b) Redis

Figure 12: Evaluation of throughput in NGINX and Redis. Other Hyperupcalls show similar performance and are thus omitted.



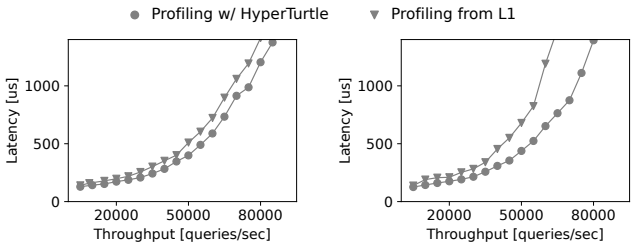


Figure 13: Memcached throughput-99p latency.

Memcached. We use Memcached to show HyperTurtle's effect on latency-sensitive applications. We use mutilate [43] as a load generator and Facebook's ETC load [6] as query distribution. We examine HyperTurtle with a Firewall eBPF, and then compare the effects of profiling Memcached from L0 and L1. All reported results are the average of 10 runs, and have a standard deviation less than 0.1. Fig. 13 compares the $99^{th}p$ latency in throughput-latency plot following the methodology of the IX project [10].

HyperTurtle provides consistent throughput improvements, notably at the 500μs SLA from 29$KQPS$ to 50$KQPS$. All while supporting L1-controlled network functions. HyperTurtle's throughput is only 9% lower than Direct-Assignment at 500μs (50$KQPS$ vs 55$KQPS$), which we attribute to the eBPF firewall application itself. We conclude that HyperTurtle enables the usage of L1-controlled eBPF network functions, such as firewalls, with performance on par with DVH.

We use the same setup to evaluate the HyperTurtle profiler, as the tail latency of Memcached is sensitive to sampling-based profilers. Fig. 14 compares Memcached performance when profiling at frequencies of 1000Hz (Intel Vtune profiler's recommendation [38]) and 4000Hz (Linux perf's default [59]). At a rate of 4000Hz, HyperTurtle profiler achieves 26% higher throughput (42$KQPS$ to 53$KQPS$) at 500μs query latency. Decreasing the sampling rate to 1000Hz reduces the throughput gain to 12% (49$KQPS$ to 55$KQPS$). We conclude that HyperTurtle is effective in reducing the overhead of profiling of applications running in nested virtual machines.

(a) 1000Hz (b) 4000Hz

Figure 14: 99p latencies of Memcached get requests during profiling with 1KHz and 4KHz sampling rates. Both setup use Direct-Assignment networking.

6 Related Work

Hyperupcalls [4] suggested the idea of safely executing L1 code in L0. It was suggested as a mechanism which facilitates complex communication between the L1 and L0, which increased performance and flexibility.

Nested virtualization. The overheads of nested virtualization are a well-known problem, exposed since the first implementation by the Turtles project [11].

There have been several efforts to reduce the number of world switches to improve the nested virtualization performance. NEVE [44] proposed a series of architectural changes to the ARM architecture, aimed at reducing the overhead of nested virtualization by reducing the number of vm-exits. Intel introduced VMCS shadowing [35] with their Haswell lineup of processors, allowing L0 to not trap L1 on every execution of vm-write and vm-read instructions.

DVH [45] is a collection of optimizations, including direct assignment of L0's virtual I/O devices and timers to L2. This effectively removes L1 from the control and data path. However, it limits deployment scenarios because L1 can no longer enforce policies on L2 I/O operations.

SVT [60] suggested utilizing SMT to run L0, L1 and L2 each in a different hardware thread. This approach allows for fast world-switching, which improves performance.

However, it does not reduce the increased handle times which are present in nested virtualization. Moreover, SVT requires CPU support for simultaneous multi-threading, which is often missing [2, 16], and will likely become unavailable in future CPUs [36, 37]

Virtualization-based containers. Kata containers [42] is a container runtime which utilizes microVMs for improved sandboxing. This allows the creation, destruction, and overall management of micro-VMs based on standard container images. By complying with the Open Container Initiative (OCI) interface, it achieves compatibility with Kubernetes.

Multiple works have suggested software virtualization as a cloud-native container sandboxing mechanism. LightVM [48] and X-Containers [57] propose to use Xen-based virtualization. While LightVM relies on Unikernels for container images, X-Containers uses a Linux-based Library OS. PVM [31] presents a hypervisor for software-virtualization, specially built for nested virtualization. It utilizes shadow paging and runs a para-virtual Linux guest These approaches, however, suffer from the known shortcomings of software virtualization, which has declined in popularity [9]. X-Containers [57] require the nested guest to use a specialized library OS, and PVM [31] utilizes syscall redirection and shadow paging for the nested guest, which lead to poor performance in syscall-intensive applications such as Redis and SQLite [58].

CKI [58] suggested an addition to the Protection Keys for Supervisor hardware extension, to create an isolated environment within the L1 kernel. With this approach, L2's kernel runs in a sandbox within L1's kernel, improving performance compared to traditional software-based solutions. This approach requires hardware modifications, so it cannot be used with existing systems. gVisor [29] takes a different approach to container isolation. It intercepts and handles system calls in a separate userspace process, which provides stronger isolation between containrs at the cost of higher overheads compared to traditional container runtimes.

HyperTurtle can be used to accelerate these approaches as well, as they all suffer from increased overheads from the multiple virtualization layers present in the cloud.

Avoiding nested virtualization. Some systems aim to avoid nested virtualization entirely. Peer-Pods [5] leverage cloud APIs to deploy Kata containers without nesting, while Free-The-Turtles [63] and Hyper-V [51] expose guest-level VM management interfaces. These approaches, however, give up hypervisor-level resource control, such as memory overcommitment across L2s within a single L1 VM — reducing deployment flexibility. Dichotomy [62] sidesteps nesting overhead by rapidly migrating the L2 VM between a minimal host hypervisor and a full-featured user hypervisor using memory remapping. However, it is incompatible with scenarios where L1 must remain continuously active, such as those involving Kubernetes orchestration. Out-of-Hypervisor [12] proposes exposing hardware virtualization features directly to the guest OS to support advanced tasks like checkpointing.

HyperTurtle offers the convenience of full compatibility with existing deployments and tooling, while enabling significant performance gains.

eBPF. There exists a variety of eBPF applications, especially in the form of network functions. HyperTurtle enables the compatibility of DVH with many eBPF network functions: BMC [26] implements eBPF Memcached read-cache. Cilium [14] provides powerful observability for Kubernetes clusters as eBPF programs. HyperTurtle provides the compatibility between `Direct-Assignment` and Kubernetes network introspection through Cillium. XDP [39] present an eBPF hook in the network device driver, enabling packet processing early in the kernel's network stack. Similarly, XRP [65] used eBPF to offload storage lookups from user space to the kernel, reducing the overhead of the kernel storage stack.

7 Conclusion

HyperTurtle proposes a general approach to accelerating nested virtualization by reducing the number of world switches. The idea is to use hyperupcalls, small eBPF programs, that encapsulate the relevant L1 hypervisor functionality and are invoked by L0 without transitioning to L1 when handing L2's `vm-exit`. We demonstrate the effectiveness of HyperTurtle to reduce the overheads and the startup time of applications in nested Kata conatiners. We show substantial performance gains enabled by relatively modest code changes, and believe that HyperTurtle is a practical solution that can be further effective in many nested virtualization scenarios.

Abstract

To support diverse GPU applications and ensure their performance, it is crucial to ensure compatibility, isolation, and maximizing utilization. However, existing approaches are limited to CUDA runtimes and have vulnerable isolation, where the misbehavior or crash of a single application disrupts all other applications sharing the same GPU. Moreover, existing solutions fail to efficiently orchestrate the applications.

Our investigation reveals that the limitations in compatibility and isolation stem from the user-space design of existing GPU-sharing solutions. To address these issues, we propose **KRYPTON**, a kernel-space GPU-sharing scheme that ensures compatibility and isolation. KRYPTON intercepts GPU command buffers at the kernel level to provide virtual GPU devices. Rather than relying on fixed GPU resource allocation, it employs efficient spatio-temporal sharing, enabling performance guarantees while improving resource utilization. Experimental results show that KRYPTON reduces the required GPU number by 32.1% compared with SOTA baselines, while providing robust compatibility and isolation.

1 Introduction

GPUs are widely used for many workloads, like AI services [10, 15], scientific computing [38, 59], video rendering [27, 36], et. al. Since many such tasks are lightweight and require only a fraction of a GPU to achieve their performance targets (e.g., throughput, end-to-end latency) [22, 35, 37, 44, 45, 54, 63, 80], co-running them on the same GPU greatly improves the resource efficiency [19, 23]. For instance, Amazon has commenced delivering video content utilizing fractional GPUs [22] and AI workloads also operate with fractional GPUs [39, 72]. GPU jobs may rely on different runtimes, although they share the host operating system (OS) and drivers. For instance, AI services and scientific computing often rely on CUDA runtimes [20], video and game rendering often rely on graphic runtimes such as Vulkan [29] and OpenGL [14].

*Equal contribution.

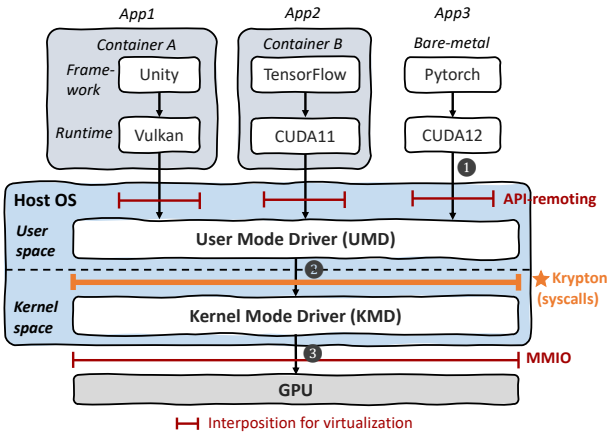

Figure 1: The system stack of virtualizing and sharing a GPU.

An efficient GPU sharing scheme should be capable of co-locating jobs with different runtimes (**compatibility**), while providing performance and fault isolation (**isolation**) for the co-located jobs. Fault isolation means that a job's crash would not destroy other co-located jobs. Performance isolation includes satisfying the isolated compute and memory requirements of tenants. To virtualize/share a GPU, the general principle is to intercept and interpose an interface, enabling the modification or extension of its behavior. Figure 1 shows the system stack of virtualizing a GPU. As observed, GPU vendors leverage the User Mode Driver (UMD) in user space to receive API calls (❶). The UMD communicates with the kernel mode driver (KMD) in kernel space via system calls, such as `ioctl` and `write` (❷). The KMD, in turn, interacts with the GPU hardware through memory-mapped I/O (MMIO) (❸).

There are already many prior works on co-locating the jobs that rely on the same runtimes on a GPU. They often intercept API calls above UMD [43, 66, 72, 76], or trap MMIO below KMD [65, 67, 68], providing poor compatibility. Intercepting user-space API calls and remote them, referred to as API-

remoting, requires adapting a large number of API interfaces for different runtimes and a large amount of manpower for maintenance, while trapping and simulating frequent MMIO access undermines performance (e.g., 100× or more [67,77]).

In terms of performance isolation, TGS [72], Orion [66], and GaiaGPU [43] adopt time-sharing, while GPUlet [35] and GSlice [39] adopt spatial-sharing based on Nvidia's Multi-Process Service (MPS) [2]. With time-sharing, GPU time slices may interfere due to the non-programmable nature of GPU context switching. With spatial sharing, co-located jobs share the GPU contexts and global memory bandwidth, suffering from poor fault isolation or performance guarantees. A job's crash would break entire GPU context, destroying all the co-located jobs. Nvidia's Multi-Instance GPU (MIG) [7] achieves hardware-level isolation by partitioning the GPU spatially. However, it sacrifices flexibility in resource management due to pre-defined resource splits.

Two key insights motivate this work. First, to ensure compatibility and low overhead, interposition and scheduling should be shifted to kernel space in host OS. As illustrated in Figure 1, kernel-space interposition eliminates the need for adapting to diverse runtimes and avoids frequent MMIO trapping, while enabling comprehensive control over GPU access. Second, instead of weighing between assigning fixed and unshared resources and resolving interference in shared resources, there is more room to directly guarantee application performance targets (such as throughput or latency). Avoiding rigid resource quotas allows for more flexible resource orchestration, reducing GPU fragmentation and improving overall resource utilization.

It is non-trivial to achieve the above design. Intercepting and remoting all functions passed from UMD to KMD in kernel space is infeasible, as these interface layers are proprietary and not disclosed by vendors. It is challenging to find a universal mechanism to capture all requests to GPU without analyzing and simulating the unveiled functions. In terms of orchestrating resources, allowing time and spatial sharing simultaneously is beneficial to reduce the GPU fragments, as it expands the orchestration space. However, with the large space, it is challenging to identify the appropriate allocation that ensures the performance target of all the applications, while minimizing the GPU fragments.

We therefore propose **KRYPTON**, a sharing scheme that comprises *an offline profiler,* a *kernel-space interception module*, a *performance feedback controller*, and a *spatio-temporal orchestrator*. The offline profiler can obtain the performance of each application with different configurations of resource provisioned, aiming for better resource allocation (§3.2). The interception module hijacks the access control to the GPU of the operating system instead of intercepting individual API calls (§3.3). For each of the co-running applications, the feedback controller (§3.4) monitors its real-time performance with the allocated hardware units and time slices. It adjusts resources adaptively to guarantee performance. We call the given hardware units, time slices, and memory allocated to an application to be an "IGPU" (isolated GPU). The hardware units are allocated with MIG that can spatially divide an A100 GPU into seven (or fewer) instances, while the time slices and memory are allocated with the kernel-space interception module. The spatio-temporal orchestrator proposes a two-stage bin-packing algorithm that orchestrates IGPUs to improve the overall utilization while promising the performance (§3.5).

We have implemented KRYPTON and evaluated it on Nvidia A100 and RTX4090 GPUs. Its effectiveness is tested with multiple versions of CUDA and Vulkan runtimes. Experimental results show that KRYPTON reduces the required GPU number by 32.1%, compared with SOTA GPU sharing systems, while maintaining the target throughput. The relative error of applications' performance is merely 3.3% on average. The main contributions are three-fold:

1) The design of kernel-space interception that ensures compatibility and isolation to use GPU. The interposition supports various runtimes and drivers.

2) The design of a feedback-based performance control policy. With adaptive time slice allocation in real-time, the performance of applications can be guaranteed.

3) The design of a spatio-temporal orchestration policy that efficiently reduces GPU fragments. KRYPTON cuts down the number of GPUs while ensuring the performance targets of the co-located applications.

2 Investigating GPU Sharing

In this section, we introduce the prevalent techniques in supporting existing GPU-sharing solutions and investigate their weaknesses, thereby motivating KRYPTON.

2.1 Techniques beneath GPU-sharing

Existing GPU sharing solutions require the GPU resource management capability as fundamental for the ability to "share". They leverage either time sharing supported by API-remoting [43, 64, 66, 72], spatial sharing supported by MPS [39, 42, 81] or MIG [53], or a combination of them [35].

All these techniques provide process-level resource management. API-remoting-based methods intercept GPU function calls of tenants to let them run in a temporal round-robin manner. MPS [2] merges the CUDA contexts of different processes into a unified context. Then multiple processes can run on the GPU simultaneously with the compute resource controlled. MIG [7] is a hardware-isolated solution for Nvidia computing GPUs. MIG divides a GPU into fully isolated instances with separate compute and memory resources but it only supports GPU partitioning with fixed configurations.

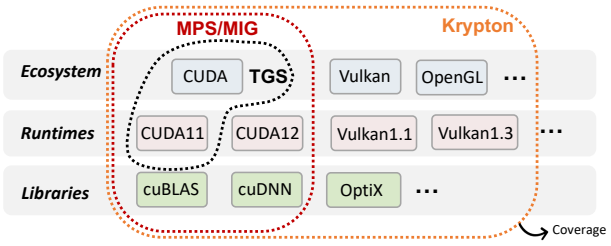

Figure 2: Software coverage of GPU sharing methods.

2.2 Poor Compatibility and Isolation

2.2.1 Limited Compatibility

Compatibility refers to the capability of the sharing mechanism to cover as many software scenarios as possible without much effort for adaptation. As depicted in Figure 2, the software functionalities an Nvidia GPU can support can be categorized into various ecosystems, runtimes and libraries.

API-remoting methods [43,55,64,66,72,76] do not promise robustness to the diversity and evolution of interposed interfaces, because they can only hijack explicit APIs of user-space runtimes. Thus, achieving compatibility in API-remoting methods is costly: Various ecosystems such as CUDA, Vulkan, and OpenGL offer fundamentally different interface APIs. Besides, user-space runtimes often undergo frequent updates, and this is particularly evident in the CUDA ecosystem, where Nvidia has released more than 70 versions of the CUDA runtime so far [21]. With each new version, API changes can introduce significant variations, requiring continuous adaptation of the API-remoting mechanism to maintain compatibility.

Beyond the core CUDA runtime, there are numerous dynamic libraries within the CUDA ecosystem. Since API-remoting methods rely on intercepting APIs, they must be updated frequently to accommodate changes in these libraries' interfaces. Because of the large effort to maintain compatibility, many API-remoting sharing systems only cover a subset of the software. For example, TGS [72], as an API-remoting sharing system, only supports CUDA11.2 runtime.

MPS-based methods, although have no requirements to adapt for different libraries, are also limited for CUDA applications and cannot be used for graphic runtimes (e.g. OpenGL, Vulkan) [2]. MIG as another vendor solution, although can provide fully isolated compute and memory system for each tenant, also targets CUDA applications and lacks key features on A100 machines(e.g., support for graphic APIs, device P2P communication) [5]. Thus, limited in poor compatibility, existing GPU sharing platforms only target applications using CUDA (e.g., deep learning workloads).

2.2.2 Weak Isolation under Threat

We design a threat model to reveal the poor isolation using existing GPU-sharing methods. In our threat model, we assume an adversary is a program that has legitimate access to a GPU shared with other tenants. The program can initialize an arbitrary number of processes to access the GPU. To examine the isolation of existing solutions, we run all 8 benchmarks based on CUDA runtime in Table 2 respectively as the victims.

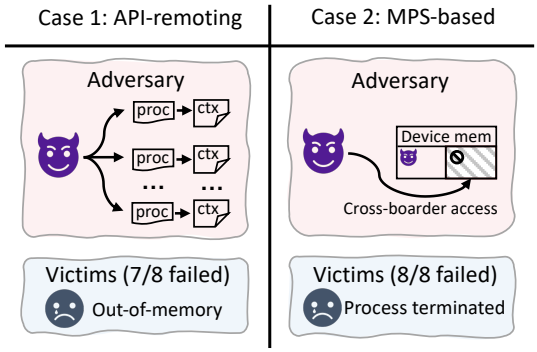

Figure 3: The adversary fails the victims with different sharing mechanisms.

In TGS [72], a GPU sharing system sits on API-remoting, victims suffer out-of-memory errors in 7 out of 8 cases and the adversary simply spawns 48 processes that use the GPU through CUDA runtime (Figure 3(a)). This is because user-space API-remoting cannot hijack implicit memory-related commands (e.g., the CUDA context creation implicitly allocates about 400MB of GPU memory), potential memory contentions occur and break isolation among applications. The processes in the adversary program allocate device memory implicitly for the extra GPU contexts, which encroach the provisioned memory of the victims.

In GPU-sharing systems based on MPS (e.g., GSlice [39]), if the adversary performs a cross-boarder GPU memory access, then all 8 victims crash due to the fatal GPU memory error (Figure 3(b)). Such error propagation problem has also been reported in prior researches [73, 81]. The key reason for the error propagation is that MPS funnels kernels from separate processes and runs them in the same context.

The experimental results show that API-remoting and MPS-based methods do not promise isolation, because API-remoting methods ignore implicit GPU operations and co-running applications share the same GPU context with MPS. MIG-based methods can promise isolation, benefiting from the stringent hardware-level isolation.

2.2.3 Potential Solution

To achieve compatibility and isolation, we investigate the workflow of using a GPU as shown in Figure 4. The workflow is analyzed from the codes open sourced by Nvidia [12]. Prior researches [17, 18, 50, 51, 67] have similar observations.

Specifically, applications use runtime APIs (e.g., CUDA, Vulkan) to generate tasks (kernels, data transfers, etc). The

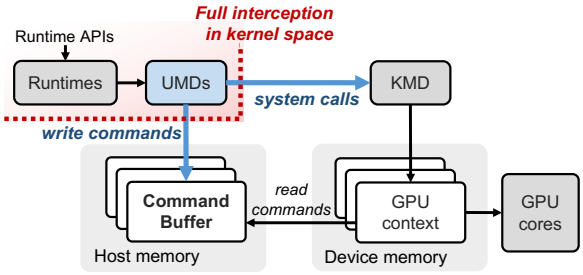

Figure 4: The workflow of using a GPU.

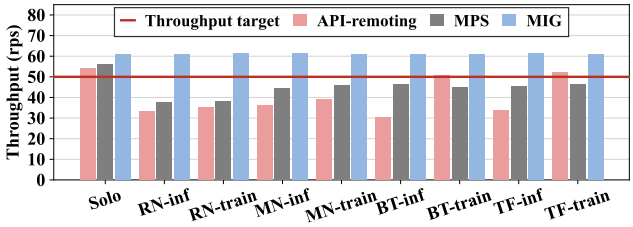

Figure 5: The practical throughput of a ResNet50 inference application with a 50 rps throughput target when co-located with another application using different GPU sharing mechanisms. The 'Solo' pertains to the scenario where the ResNet50 inference application runs stand-alone.

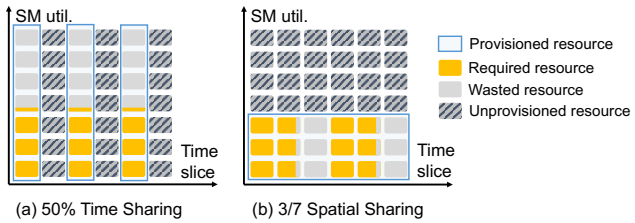

Figure 6: Resource utilization in time and spatial sharing when the *ResNet50*'s throughput target is achieved.

runtime APIs are parsed and forwarded to *User Mode Drivers (UMD)* and UMDs write commands to *Command Buffers*. The commands cover the control of the GPU, including commands to copy data from the host to the device memory, launch kernels, and so forth. The UMD then uses system calls to guide the *Kernel Mode Driver (KMD)* to inform the GPU to read commands from command buffers. Typically, a command buffer is bonded to a GPU context that encapsulates all the resources needed to execute operations on the GPU, including distinct address space, memory allocations, etc. The GPU contexts are isolated, as they do not share address space. We therefore get the first insight.

Insight-1: Kernel space interception is capable of enabling compatibility and isolation. Based on the observation above, we confirm that it is a good option to intercept command buffers and system calls in kernel space to take full control of the entire GPU. The compatibility across runtimes is then guaranteed naturally because all commands pass the command buffers. To promise isolation among applications, all processes run within their isolated GPU contexts and all memory-related operations can be precisely recorded and controlled in kernel space.

2.3 Inefficiencies in Achieving Performance Target and High Utilization

Even when co-running applications without accounting for compatibility and isolation, existing methods still fail to guarantee the performance of co-located applications and the efficient utilization of GPUs. To demonstrate these shortcomings, we conduct two experiments to present these inefficiencies.

2.3.1 Achieving Performance Target

In this experiment, we use a *ResNet50* inference application as a tenant on an A100 GPU to illustrate the performance violations caused by existing methods. First, we profile the resource quotas (e.g., time slices or SMs) required by the ResNet50 inference application to meet its performance target of 50 requests per second. For instance, ResNet50 requires 32% of the time slices to achieve this target. Next, we co-run the ResNet50 with other benchmarks listed in Table 2 using current methods. The co-running benchmarks use the remaining resource quotas.

Figure 5 illustrates the performance of ResNet50 when API-remoting, MPS, and MIG techniques are employed to share the GPU with other benchmarks. In the figure, the x-axis represents the benchmarks co-running with ResNet50. As observed, the throughput of ResNet50 drops to 30.6 RPS with API-remoting and 37.5 RPS with MPS. This decline is attributed to shared resource contention, such as global memory bandwidth. Consequently, API-remoting and MPS fail to guarantee the performance of co-located applications.

2.3.2 Achieving High Utilization

Figure 6 presents the GPU resource utilization when the performance target for *ResNet50* is set to 80 RPS, and the required resources are allocated using temporal-sharing (API-remoting) and spatial-sharing (MIG).

Specifically, while ResNet50 requires 50% of the temporal quota to achieve the target performance of 80 RPS using the API-remoting method, the average SM utilization is only 44%. Similarly, when ResNet50 uses a 3/7 fractional GPU instance under the MIG method, only 62% of the GPU instance's time slices are needed to achieve the desired throughput. This demonstrates that with the time-sharing method, applications cannot fully utilize all SMs, and with the spatial-sharing method, they cannot fully utilize allocated time slices.

These wasted computing resources (SMs, GPU time slices) are also GPU fragments, in addition to memory fragments.

In summary, although MIG guarantees the performance target as shown in Figure 5, it results in low GPU utilization due to its coarse-grained resource partitioning. MPS enables fine-grained resource usage but faces severe performance violations. Meanwhile, the API-remoting method experiences both performance violations and low GPU utilization.

2.3.3 Potential Solution

While the above results highlight the low utilization of current methods, they also reveal an opportunity to address this issue through spatio-temporal orchestration. For instance, if ResNet50 could utilize 44% of SMs with 50% time slices, or 62% of time slices on a 3/7 GPU instance, its performance target could be met precisely.

Insight-2: Spatio-temporal orchestration may bring higher utilization. Since we expand the adjustable parameter of GPU partitions into two dimensions of spatial and temporal, there exist multiple resource configurations to satisfy the performance target of a workload and the flexibility in orchestration is increased.

2.4 Challenges

It is non-trivial to achieve the potential solutions mentioned above in an efficient way.

For kernel-space interception, it is difficult to obtain the command buffer address because it is unveiled and not exposed by vendors. This requires us to accurately analyze the behavior of the KMD to create GPU context and malloc command buffer. We have to trace and manipulate the command buffers delicately to handle their dynamic address across processes and ensure their consistency.

For spatio-temporal orchestration, it is challenging to find the optimal orchestration plan to maximize the GPU utilization, because the orchestration space increases significantly with both spatial sharing space and time sharing space. Moreover, an efficient orchestrator is required to identify the resource allocation for all the co-located applications simultaneously while guaranteeing performance targets and minimizing GPU fragments at the same time.

3 KRYPTON Methodology

We therefore propose KRYPTON that promises the compatibility, isolation and performance targets of co-located applications, while reducing the GPU fragments.

3.1 Overview of KRYPTON

Figure 7 shows the design of KRYPTON. To find appropriate GPU resources for applications, each application is first

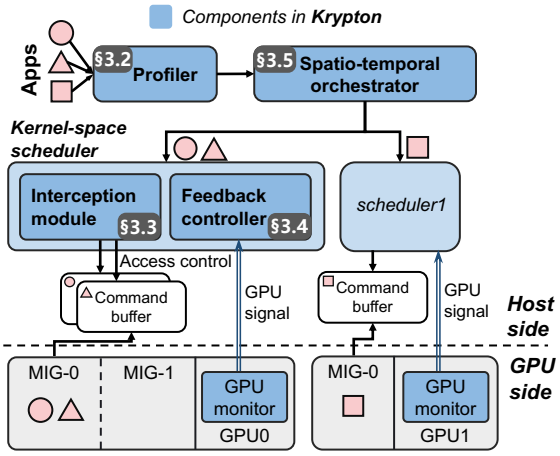

Figure 7: The overview of KRYPTON.

profiled with an offline profiler (§3.2). Prior works on GPU sharing [35, 41] also require offline profiling to attain information on applications. After each application specifies its performance target (e.g., throughput, end-to-end latency), the spatio-temporal orchestrator of KRYPTON then assigns GPU resources for the applications and deploys them properly to guarantee their performance targets (§3.5). The applications can either run in bare metal or be wrapped in containers and use their own runtimes.

The GPU resources include hardware units, GPU time slices, and device memory. The hardware units are divided using MIG, while time slices and device memory are allocated using kernel-space schedulers, with each scheduler managing the resources on the corresponding physical GPU. Each scheduler comprises the interception module (§3.3) and the feedback controller (§3.4). The interception module manages the access control of command buffers of applications to achieve time-sharing of the GPU. It also realizes GPU memory management in kernel space. The feedback controller leverages the GPU hardware's real-time signal from GPU monitors to adaptively adjust the time slices of applications to ensure performance-aware GPU sharing. It promises that the co-located applications will not impact each other and achieve the performance target.

3.2 Offline Profiling

It is important to understand the performance of applications under different resources. We use offline profiling to achieve this. The profiling is simple and non-intrusive to applications.

3.2.1 Performance Profiling of Applications

We use IGPU(s,t,m) to represent the GPU resources assigned to an application, where s is the quota of assigned GPU hardware units (i.e., the streaming multiprocessors, memory band-

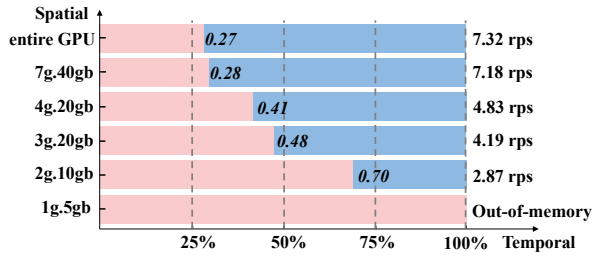

Figure 8: The performance chart of a Transformer-XL training job (bs=8) on A100 GPU. The configurations within the blue region can promise a throughput target of 2 rps. The x-axis represents the time slice quota and the y-axis represents spatial configurations.

width, cache and memory that are partitioned using MIG), t is the quota of assigned GPU time slices, and m is the assigned GPU memory size.

For static workloads such as training and offline rendering, the throughput can be treated as the performance metric, and the profiler records the throughput of an application on every possible IGPU configuration, represented as $Thr(s,t,m)$. For workloads that use GPU dynamically such as large language model serving, the profiler can still explore the maximum capability (e.g., tokens/s) that each IGPU configuration can offer the application as the guaranteed performance.

The profiler collects the performance of applications within a fixed configuration set. Specifically, for an Nvidia A100 GPU, the throughput of each application is collected on 6 different configurations IGPU$(s_i, 100\%, m_i)$, including the entire GPU and 5 types of MIG instances (7g.40gb, 4g.20gb, 3g.20gb, 2g.10gb and 1g.5gb*). The throughput is recorded as $Thr(s_i, 100\%, m_i)$, correspondingly. Besides, the memory consumption of applications is also recorded. Then the throughput of applications with various spatial and temporal quotas can be estimated directly with the profiled data, calculated as $Thr(s,t,m) = Thr(s,100\%,m) \times t$. The formula holds when strong isolation can be achieved and the throughput is proportional to the GPU time slice quota.

3.2.2 Find Feasible Configurations

KRYPTON leverages the profiled performance to find feasible resource configurations. As an example, Figure 8 reveals the feasible configurations that can satisfy the throughput requirement of a Transformer-XL training workload. The workload requires 6196MB GPU memory thus it cannot be offloaded on a 1g.5gb instance. Larger MIG instances can accommodate the workload. For example, in a 3g.20gb MIG instance, configurations with time slice quota larger than 48% can guarantee the throughput target of the workload. If a tenant has a preferred resource configuration, it can also bypass offline profiling and directly designate the required configuration.

*Nvidia A100 40GB can be sliced into 7 instances. 4g.20gb represents a MIG instance that uses 4/7 of hardware units and 20GB device memory.

3.3 Kernel Space Intercepting

IGPUs' hardware units are spatially assigned through MIG. To assign GPU time slices and device memory to an IGPU, KRYPTON leverages interception in kernel space.

3.3.1 Command Buffer Interception

To share a GPU temporally, KRYPTON intercepts the access to GPU command buffers without resolving specific commands. Specifically, KRYPTON hijacks the access control of the GPU, by identifying the addresses of command buffers, and controlling the access permission of the command buffers.

Command buffer address. It is non-trivial to obtain the address of command buffers since it is wrapped in Nvidia's kernel mode driver. We identify that the command buffer address is assigned through the `ioctl` system call every time a GPU context is created. We then intercept the `ioctl` calls and if the argument corresponds to the memory object allocation of GPU engines, we record the address of the memory object as one piece of the command buffer. Note that multiple command buffers and GPU contexts can be possessed by one process and the command buffers' addresses remain unchanged until destroyed.

Modify access permission of command buffers. The interception module locks the command buffers of a process when it is not permitted to control the GPU and unlocks them when the process is active.

As shown in Figure 9, to lock the command buffer of a process ❶, the interception module changes the protection flag of the corresponding memory page to read-only through the `do_mprotect_pkey` function, which is the kernel's internal implementation of the `mprotect` system call [24]. Then, whenever a user-space process tries to write to its GPU command buffer to launch kernels or submit other operations ❷, it will cause a segmentation fault. We lead the fault signal to a pre-registered user-mode signal handler ❸. The signal handler then inquires the interception module in a blocking manner to check if it is authorized to write to the command buffers ❹. It restores the process's execution once the command buffer is unlocked ❺.

Since we only handle the command buffers that interact with the GPU, the other CPU work of the process would not be influenced compared with techniques that directly pause the whole process [52]. The mechanism of command buffer interception is also promising for other PCIe devices that leverage command buffers (e.g., AMD GPUs [16]).

3.3.2 GPU Memory Management

KRYPTON also intercepts memory-related commands such as device memory allocation to precisely manage the device

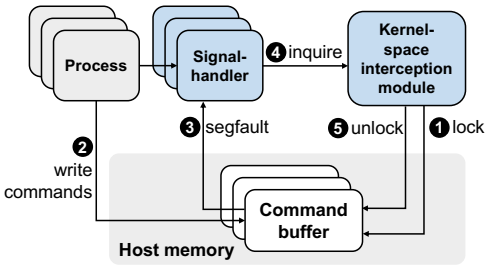

Figure 9: The interception of command buffer.

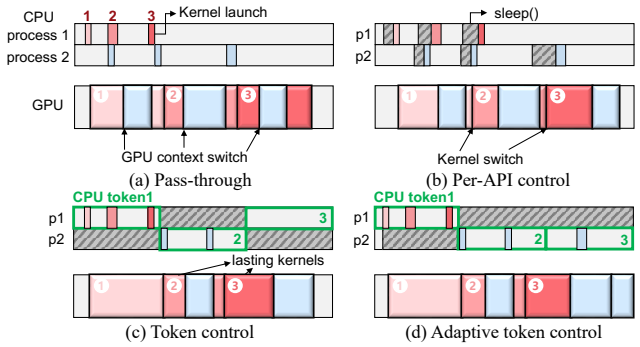

Figure 10: GPU execution pattern with different scheduling policies. Two processes share the GPU, and the kernels from different processes (red and blue) are interleaved with each other on the GPU.

memory usage of IGPUs. Those commands are triggered by UMD as `ioctl` system calls and KRYPTON also intercepts them in kernel space. Compared to the user space interception, the kernel space interception method can handle implicit memory allocation requests, such as those occurring during GPU context creation. KRYPTON leverages a central memory allocator to manage all device memory-related requests and records the actual memory usage of each workload. Requests either be passed through directly or return an error when the provisioned memory quota is exceeded.

3.4 Performance Guarantee with Feedback Control

The performance with time-sharing is promised by precisely controlling their allocated time slices. Since vendor driver and hardware scheduler monopolize the GPU context switch ability, KRYPTON controls the GPU time slice resources used by each process by managing *CPU tokens*. When a process possesses a token, it is permitted to utilize the GPU. Through the management of CPU tokens, we can schedule and govern the time slice resources of the GPU. On this basis, we make further adaptive adjustments to the control of CPU tokens in accordance with the feedback signals from GPU monitors.

3.4.1 Token Control at Host Side

Due to the unveiled internal control mechanism and varying architectural design of commodity GPUs, it is difficult to modify drivers to realize GPU time slice allocation. The GPU context switch is decided by the driver as shown in Figure 10(a) when processes use GPU in pass-through mode.

To this end, researchers exploit to control GPU time slice usage at the host side. Some works schedule with per-API control policies [43, 72, 76]. They adjust the kernel launch rate by adding sleep time between the API trap and the API emulation as shown in Figure 10(b). The sleep duration is determined by the kernel properties (i.e., CUDA block number). In some other work, the host treats the time that the CPU holds the token as the GPU time [56]. However, because of the asynchronous execution manner of the GPU, limiting the CPU token window length for an application cannot promise to achieve the same limitation on the GPU time. For example, if long kernels are launched within the first CPU token window as Process 1 illustrated in Figure 10(c), then with the launched kernels residing on the GPU, process 1 would occupy longer GPU time slices than expected, squeezing the GPU time slices that should have been assigned to process 2 in the second token window.

We observe that it is possible to adjust the GPU time slice allocation by controlling CPU tokens adaptively. As shown in Figure 10(d), since Process 1 occupies more GPU time slices than anticipated, the CPU token within the third time window is compensated to Process 2. Such an adaptive CPU token control can promise precise GPU utilization, thereby guaranteeing the required performance. It is achievable by leveraging GPU feedback information.

3.4.2 Control GPU Utilization with Feedback

With real-time GPU utilization signal as feedback, KRYPTON compensates for applications with lower-than-expected utilization and constrains the usage of overused applications. This is achievable by using Nvidia's user-space hardware management libraries (e.g., Nvidia's NVML [13], DCGM [9]) to monitor the per-process GPU time slice utilization[†], which is the sum of the GPU utilization of all GPU contexts created by the process.

We are then able to control the GPU usage of applications adaptively with the GPU utilization information as feedback, following Algorithm 1. Specifically, the CPU token is allocated by the scheduler and the scheduler guarantees that only one application can hold the token at any given time. The activated application is the one that has the lowest relative GPU utilization compared to the promised time slice quota. Such an elastic policy can fully utilize the GPU and promise

[†]The percentage of time slices the process uses the GPU, with at least one SM computing.

Algorithm 1 Adaptive CPU token control policy

```
function SELECTAPP(app_list)
    while true do
        UpdateAppUtil(app_list, Utils)
        selected_app = argmin(app_list.(util/quota))
        Activate(selected_app)
        Pause(app_list\selected_app)
        CPUSleep(token_length)
function UPDATEAPPUTIL(app_list, GPUUtil, ProcessUtil)
    if Monitor == DCGM then
        last_selected_app.util += GPUUtil
    if Monitor == NVML then
        for app ∈ app_list do
            for p ∈ app.process_list do
                app.util += app.p.ProcessUtil
    for app ∈ app_list do
        MovingAverage(app.util)
```

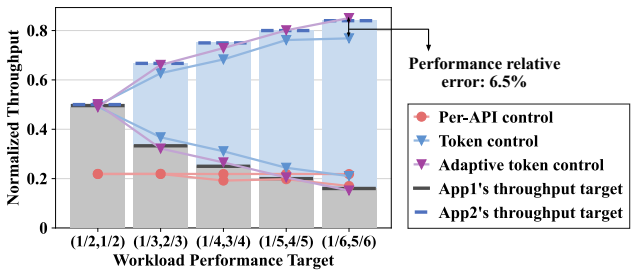

Figure 11: The effectiveness of different scheduling policies on satisfying performance targets. Two ResNet50-bs32 inference applications (App1 and App2) share an Nvidia A100 GPU and have different performance targets. The fractions annotated on the x-axis represent the ratios between the target throughput and the stand-alone throughput of App1 and App2, respectively.

applications' performance simultaneously.

When the GPU load of an application is light, its GPU utilization may be lower than the assigned proportion of CPU tokens. To avoid always selecting such an application, we regard the application as fully occupying a GPU time slice if only its own is observed within that time slice, no matter how much it occupies that GPU time slice.

With the above design, the proposed adaptive CPU token control policy can precisely promise performance as shown in Figure 11. In particular, the token length is set to 100*ms* in KRYPTON unless otherwise stated. Adaptive token control promises an average relative error no larger than 0.9% compared with the performance target. Without feedback control, the throughput of co-located applications deviates from the performance target and the relative error is 5.3% on average. The per-API control policy [43] performs even worse and can not isolate the throughputs as expected.

3.5 Spatio-Temporal Orchestration

The goal of the orchestration is to reduce the number of GPUs to use, while maintaining the performance requirements of workloads. It is non-trivial to allocate appropriate resources for workloads and improve overall cluster utilization. Suppose there are M workloads to be orchestrated and there are N configurations for each workload. In this case, there are total N^M possible IGPU configurations. To place M workloads onto P GPU instances, there are also P^M possibilities. The search space complexity for orchestrating M workloads is as large as $O(N^M P^M)$.

3.5.1 Resource Defragmentation Strategy

To reduce the searching complexity, we design a two-stage bin packing algorithm that heuristically searches for a near-optimal orchestration plan, aiming to minimize the GPU fragments. The searching process is an offline procedure as shown in Figure 12. (1) Initialization: each workload is assigned a qualified IGPU that has the minimum spatial resources. (2) Temporal packing: KRYPTON tries to fuse the IGPUs that have the same spatial configurations to reduce the idle time slices. (3) Fragment reduction: KRYPTON further reduces the temporal fragments within the IGPUs, by migrating workloads from spatially smaller IGPUs to spatially larger IGPUs. Specifically, for IGPUs with the same spatial configurations, we sort them in descending order of the left time slice proportion and attempt to migrate. In this way, IGPUs with large temporal fragments are first eliminated. Note that, the memory residual of IGPUs is also considered during the migration. (4) Instance packing: When the MIG instances are finally determined, bin-packing is used to allocate MIG instances to reduce the number of used GPUs. Note that we do not need to pack the real IGPU instances or migrate workloads in reality in each step, but only need to orchestrate applications following the final result of this planning algorithm.

The complexity of the proposed two-stage bin-packing algorithm is $O(MP)$.

3.5.2 Workloads on Multi-GPU

KRYPTON also allows workloads to use more than one GPU. When the application itself can run on multiple GPUs, KRYPTON can use fewer GPUs to satisfy the performance. For example, if a distributed training workload requires 2 GPUs to run but only aims for 60% of the solo throughput, KRYPTON can assign 60% of the time slices on each physical GPU to it. KRYPTON carefully aligns the tokens to use different GPUs in kernel space, because the workload running on isolated GPUs may communicate with each other through NCCL [6], and correlated GPUs must be active simultaneously. When searching for the orchestration plan, the configuration of workloads that use multi-GPU should remain unchanged.

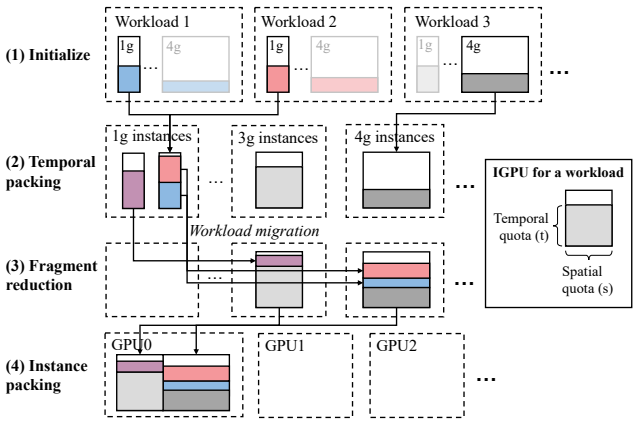

Figure 12: Steps of the resource defragmentation strategy.

4 Implementation

We implement the kernel-space interception and performance feedback controller in 3K lines of C code and the spatio-temporal orchestrator is composed of 1K lines of Python code.

The kernel-space scheduler is implemented as a loadable kernel module within the Linux operating system. Moreover, the scheduler does not interfere with the GPU driver. Users can either install the open source kernel module driver [12] or directly install the official drivers. The entire system has no requirement to modify the application code, imposing zero programming burden on users.

In kernel space, for each GPU instance, there is a corresponding simulated device file `/dev/igpu` which is mounted to the device file `/dev/nvidia`. When processes within the container try to access the Nvidia device files, the requests are forwarded to the simulated device file and controlled by the interception module of the kernel space scheduler. The kernel space thread calls the `do_mprotect_key` to modify the protection flag of a virtual space address. Since the `do_mprotect_key` API is not exported by the Linux kernel, we leverage the kallsyms mechanism to find its symbol.

The kernel module additionally controls the device file to interact with the signal handlers and the GPU monitor. Specifically, the blocking check of the signal handler sends the `read` system call to the device file to inquire if it is activated. The GPU monitor delivers the GPU utilization information through the `ioctl` system call to the feedback controller in kernel space. The GPU monitor runs as an independent daemon process in user space. When the GPU is not in the MIG mode, the `nvmlGetProcessUtilization` API from the NVML library is enabled. When the MIG mode is enabled, the DCGM library is used as the monitor since NVML's functions are not fully supported with MIG. Applications run in docker containers. Each container compiles a dynamic linked library when initialized and adds it to the `LD_PRELOAD` environmental variable. Then the container can interact with the kernel space through the dynamic library.

Table 1: Hardware and software specifications.

System Overview	
CPU	Intel Xeon Silver 4216 64-core
GPU	Nvidia A100 40GB & 2 GeForce RTX 4090
Kernel version	5.15.0-91-generic
Operating System	Ubuntu 20.04
Docker version	24.0.7
Nvidia Driver	550.90.07
Runtimes	CUDA 12.1, Vulkan 1.3
AI framework	Pytorch 2.2.1

Table 2: Benchmarks used in the evaluation ($*$ represents batch size = 16 due to the large GPU memory usage).

Application	Type	Throughput (rps)		Memory (MB)	
		bs=8	bs=32	bs=8	bs=32

Throughput requirement	R1	[2/3, 1/2, 1/3, 1/6, 1/12]			
	R2	[1/2, 1/4, 1/6, 1/8, 1/10]			

5 Evaluation of KRYPTON

In this section, we evaluate KRYPTON in reducing the required GPU number while promising the compatibility, isolation and performance of co-running workloads.

5.1 Experimental Setup

Table 1 shows the specifications of the experimental platform. To justify the compatibility, as shown in Table 2, the used applications cover AI applications (inference and training) that use CUDA runtime [20] and rendering applications [30] that use Vulkan runtime [29]. Each application runs in a separate container equipped with Nvidia Container Toolkit [25]. For each application, there are two sets of throughput requirements: *R1* and *R2*. For example, the $2/3$ throughput requirement represents that the throughput target is set to be $2/3$ of the solo throughput running on an entire physical GPU.

We compare KRYPTON with baselines that ensure isolation: *Temporal* [8, 28], *Best-fit-MIG*, and *GPUlet-MIG* [35]. With *Temporal*, workloads share the GPU temporally, with each workload allocated a fixed quota of time slices [8, 28]. The quota represents the minimum calculated time slice required

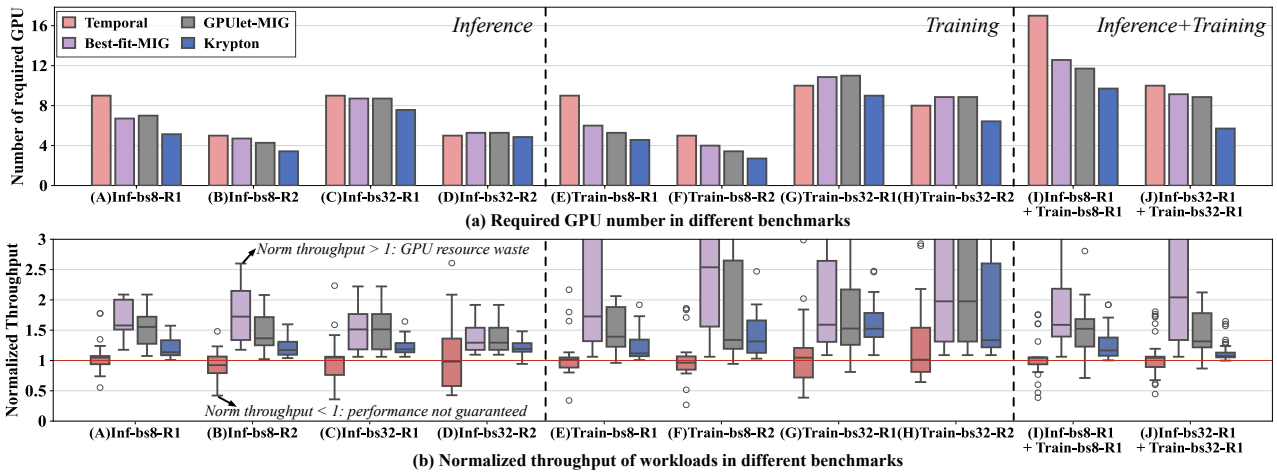

Figure 13: Comparison between KRYPTON and other methods in reducing GPU number and promising performance.

to meet the specified throughput target. With *Best-fit-MIG*, each workload is assigned the smallest MIG instance capable of satisfying its performance requirements. MIG instances are bin-packed for placement within the cluster. This approach is equivalent to the greedy best-fit algorithm described in GPUlet [35]. With *GPUlet-MIG*, GPUlet [35] identifies the optimal spatial configuration of a workload and packs workloads in temporal duty cycles. It is originally implemented using MPS. We have improved GPUlet using MIG and let workloads share a GPU instance temporally as *Temporal*.

We use two metrics in the evaluation. For evaluating the resource efficiency, we use the metric "**number of required GPUs**" to deploy workloads while guaranteeing their performance target. Fewer GPUs indicate better GPU utilization. For evaluating the performance, we use the metric "**normalized throughput**" of applications (the actual throughput normalized to the throughput target). As long as the normalized throughput is larger than 1, the performance target is promised. Note that, if a benchmark's normalized throughput is too high, it may harm the utilization of the whole system. This is because excessively high throughput often indicates over-allocation of resources, resulting in wastage.

5.2 Overall Performance

We build 10 test cases to cover scenarios involving inference jobs co-running, training jobs co-running, and inference jobs co-running with training jobs. The case for runtimes other than CUDA is evaluated in Section 5.3. For easing of description, a test case is named in the form of "Inf/Train-bs8/32-R1/R2". For instance, "Inf-bs8-R1" represents the case that 20 workloads co-run (4 inference models $\times$ 5 workloads with different throughput requirements as R1 for each model). The batch size of workloads in "Inf-bs8-R1" is 8 and the throughput requirement list R1 is in Table 2. There are 20 workloads in inference-only (A-D) and training-only (E-H) test cases, and 40 workloads in test cases I and J.

Figure 13(a) shows the number of required GPUs to host the workloads in the 10 test cases. As observed, KRYPTON reduces the total required GPU number by 32.1%, 23.1%, and 20.5% compared with *Temporal*, *Best-fit-MIG*, and *GPUlet-MIG*, respectively. The reduction of the required GPU number indicates the improvement of GPU utilization. We can also observe that KRYPTON performs better when the batch sizes of are small, since small workloads are more prone to be packed together, thereby reducing the GPU fragments. KRYPTON also performs better when the number of workloads is large, as the increasing workload number helps to fulfill GPUs.

Corresponding to Figure 13(a), Figure 13(b) shows the normalized throughputs of the workloads in each test case. As observed, some workloads' performance is not promised with *Temporal*, because it lacks feedback control, leading to interference among GPU time slices. The performance targets are guaranteed with *Best-fit-MIG*, *GPUlet-MIG* and KRYPTON. Workloads have the highest throughput with *Best-fit-MIG*, because it configures each workload to independently use a MIG instance. A higher normalized throughput above 1 indicates wasted GPU fragments, as a workload may not need a whole MIG instance. *GPUlet-MIG* reduces the fragments by allowing GPU partitions with the same spatial quota to fuse temporally. However, since the configurations of workloads are fixed in *GPUlet-MIG*, GPU fragments are still not fully explored. KRYPTON leverages the property that the throughput target of a workload can be promised by various configurations, thereby further reducing the fragments temporally and spatially. The average normalized throughput of KRYPTON is the closest to 1, which indicates that the workloads have fully utilized the allocated resources.

To understand how the workloads are actually orchestrated, Figure 14 shows the orchestration of the workloads with

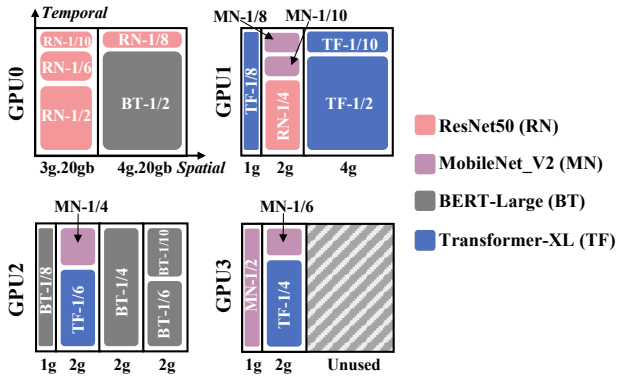

Figure 14: Spatio-temporal orchestration of workloads in the Inf-bs8-R2 benchmark on 4 A100 GPUs. The horizontal dimension refers to the partitioning strategy of spatial resources (MIG instances) and the vertical dimension refers to the temporal partitioning ratio.

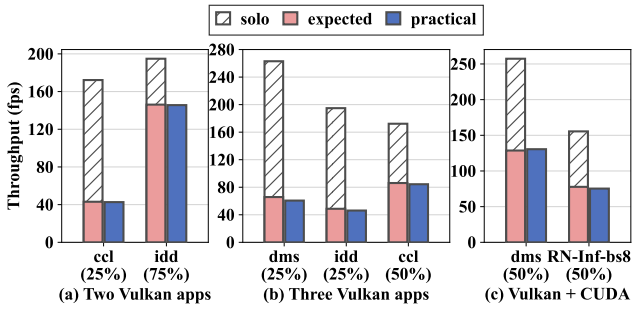

Figure 15: The performance of KRYPTON with Vulkan.

KRYPTON in the test case Inf-bs8-R2. As observed, the spatio-temporal orchestration of KRYPTON can efficiently deploy the 20 workloads onto 3.4 A100 GPUs, while promising the performance targets.

5.3 Performance with the Vulkan Runtime

This subsection evaluates the effectiveness of KRYPTON for runtimes beyond CUDA. Since both API-remoting and MIG do not support other runtimes (e.g., Vulkan), *Temporal*, *Best-fit-MIG* and *GPUlet-MIG* cannot run here. Meanwhile, only time-sharing is enabled in KRYPTON in this case.

In this experiment, we evaluate scenarios where two Vulkan applications co-run, three Vulkan applications co-run, and a Vulkan application co-runs with a CUDA-based AI application. Figure 15 presents the results for three example combinations, with other combinations yielding similar outcomes. As shown, the average relative error in applications' throughput, compared to their performance targets, remains below 3.4%. This demonstrates that KRYPTON can effectively support multiple runtimes through kernel-space interception.

5.4 Effectiveness of Feedback Controller

This subsection evaluates the effectiveness of the performance feedback controller of KRYPTON in promising the performance targets. We compare KRYPTON with the pass-through method [25], the user-space API-remoting method GaiaGPU [43], and KRYPTON w/o adaptive control, a variant of KRYPTON that disables the adaptive token control policy introduced in §3.4.2. In this experiment, we let 2, 4, and 8 *RN* training jobs (batch size = 32) time-share an entire A100 GPU. The feedback controller is responsible for ensuring the performance targets.

Figure 16(a) shows the achieved normalized throughput of the co-running applications. The pass-through method cannot promise the throughput target, and the relative throughput error is 53.6% compared with the throughput target. The overhead of GaiaGPU is large, resulting in a 24.2% lower throughput of applications than expected. In KRYPTON w/o adaptive control, the throughput of applications deviates from the target and the relative error is 21.6% on average. After applying the adaptive control policy, the relative error of applications' throughput is merely 3.0% on average.

In more detail, Figure 16(b) showcases the GPU utilization when two applications co-run within two minutes. GPU utilization is strongly correlated with the throughput of applications. A closer GPU utilization to the expected normalized throughput indicates a more accurate assurance of performance. As shown, the utilization curve for KRYPTON with adaptive control shows less volatility and maintains a steadier rate, closer to the target utilization levels (25% and 75%), suggesting that KRYPTON outperforms the other methods.

We also evaluate KRYPTON in a multi-GPU scenario by launching a Transformer-XL distributed training job on two RTX4090 GPUs. We set its throughput target to 10%, 20%, $\cdots$, 100% of its solo throughput and then assign it the corresponding temporal quota. Experimental results show that the throughput of the distributed training workload is still proportional to the time slice ratio assigned and the relative error of throughput is only 1.8%.

5.5 Guaranteeing the Latency QoS

KRYPTON could also be used to provide services that have latency-related Quality-of-Service (QoS).

Assume an application is active for 50ms and asleep for another 50ms with token control. In this scenario, the requests that arrive within the active token can be delivered to the GPU properly. Otherwise, they may wait 50*ms* and violate the QoS target that is smaller than 50*ms*. Reducing the token length implies more frequent switching between applications, which would increase overhead.

We use the inference of Transformer-XL with different batch sizes to show the performance of the latency QoS guarantee. The arrival rate of the requests follows the Poisson

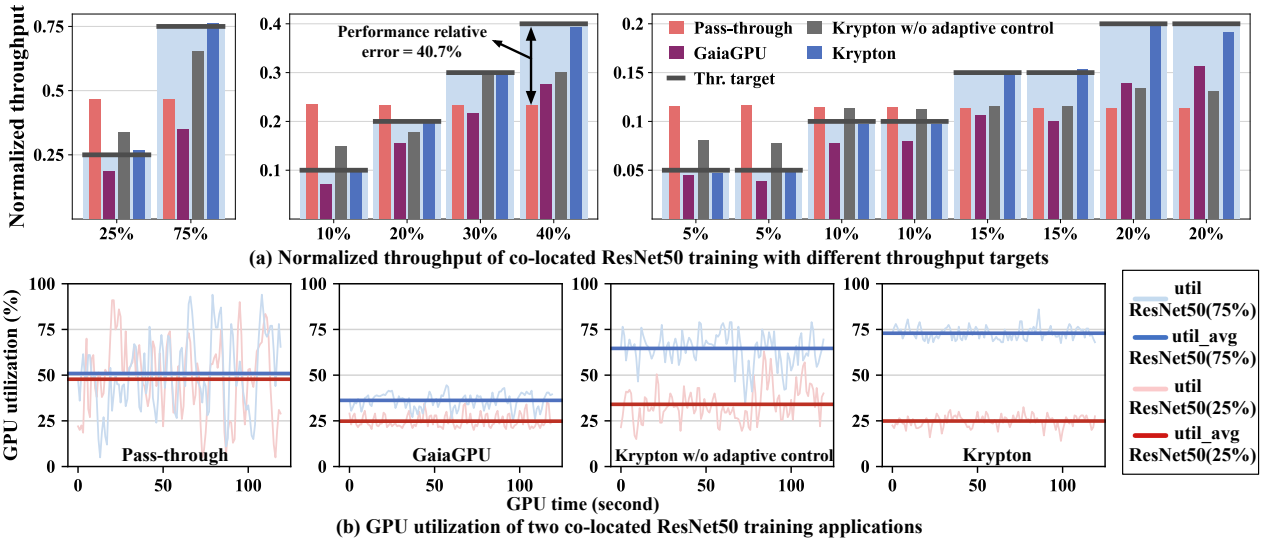

Figure 16: Comparison of different methods in promising the performance target of ResNet50 training applications.

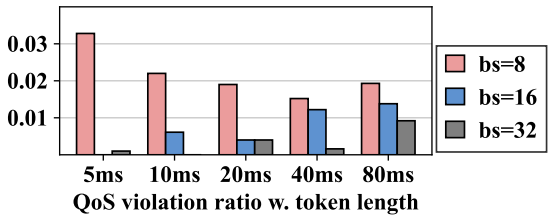

Figure 17: The QoS violation ratio and overhead of KRYPTON with different token lengths.

distribution as MLPerf [61], and the input rps is half of the maximum throughput that the service can achieve. The QoS target is set to the p99 latency, which means there will be 1% QoS violation in this original setting. When the performance requirement is halved, we halve the input rps and assign 50% time slices to the service correspondingly. We check if KRYPTON can still promise the original QoS target.

As shown in Figure 17, for smaller batch size, QoS violations increase as token lengths decrease. This trend arises because shorter tokens introduce more overhead, which affects smaller batches where individual request latencies are inherently low. In contrast, larger batch sizes exhibit an increase in QoS violations with longer token lengths. This is because tasks with larger batch sizes can hardly be finished within a single time slice. Thus, longer token lengths lead to extended waiting times for tasks to acquire time slices, thereby increasing the likelihood of QoS violations.

Overall, the average QoS violation rate across all configurations is measured at 1.23%, underscoring KRYPTON's ability to guarantee latency-related QoS targets.

5.6 Elastic GPU Sharing

KRYPTON guarantees an application's performance regardless of the co-running applications. When applications are assigned fixed GPU time slices using feedback control, the average throughput relative error of a Transformer-XL-Inf-bs8 workload is 1.3% when it co-runs with different applications.

The adaptive token control algorithm (Algorithm 1), however, can further improve performance, by allowing an application to use the unused time slices of its located GPU instance. Compared with methods that provide fixed GPU time slices to workloads, the elastic sharing characteristic improves the performance of workloads as much as possible. As shown in Figure 18, when a ResNet50-Train-bs32 job runs on a GPU alone, its utilization can approach 99%. When a new task Transformer-XL-Inf-bs8 arrives, the two jobs will share the complete GPU instantly. A utilization burst can be observed when a new task arrives. This is because the scheduler always selects the workload that has the lowest relative utilization as introduced in Algorithm 1. The burst only lasts several seconds, and the scheduler can then adaptively adjust the time slices assigned to each workload afterward.

5.7 Overhead

Except for the overhead related to CPU token as discussed in §5.5, KRYPTON does not introduce extra overhead when monitoring utilization. KRYPTON does not break the original logic of context switching handled by the vendor driver. As for the overhead at the host side, KRYPTON's kernel module occupies 4.8MB of CPU memory, mainly storing the information of running processes. Besides, the GPU monitor has to occupy a CPU thread to communicate with the kernel module.

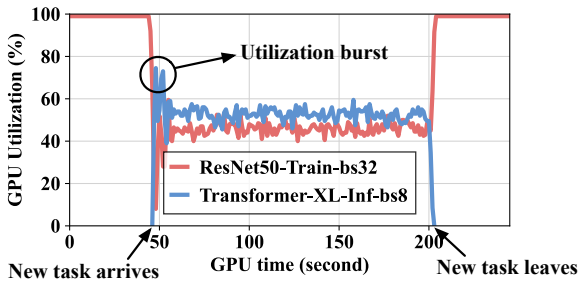

Figure 18: Elastic sharing of a GPU.

6 Related Works

GPU Sharing on Cloud. There are many works on multiplexing a GPU to deploy applications in specific scenarios (e.g., AI training [31, 48, 54, 57, 71, 74], AI inference [37, 39, 42, 44, 63], cloud gaming [34, 79]). The applications are deployed either in virtual machines, or lightweight environments such as bare-metal and containers. To control the GPU usage inside virtual machines, full virtualization [65, 67, 77] and mediated pass-through [60, 68] intercept the hardware interface of the GPU (MMIO). Paravirtualization [4, 40] necessitates a custom driver in every supported guest OS for the virtual device. GPU sharing across containers or bare-metal vastly uses API-remoting to manage GPU resources. The host decides whether or when to pass the intercepted call. GaiaGPU [43], qcuda [55], and vcuda [64] all leverage API-remoting in user space to restrict the applications' resources to use CUDA. TGS [72] and Orion [66] co-locate production jobs and opportunistic jobs based on API-remoting on a GPU.

Resource management in GPU sharing. Typically, GPU sharing techniques can be classified to be time sharing [11, 43, 64, 72] and spatial sharing [1, 2, 7, 32]. **Time sharing** is the default pattern when the GPU is shared in the pass-through mode [70, 75]. The GPU controls the GPU context switch in a round-robin manner [11, 32, 33]. Nvidia proposes vGPU GRID [26] to share the GPU among VMs with fixed quotas temporally. Some virtualization works [51, 67] customize hardware drivers and apply various scheduling schemes [47, 56, 67] to share a GPU temporally. **Spatial sharing** methods such as MPS [2] and MIG [7] manage the SM and memory resources in GPU sharing. To fully utilize the GPU, efforts in spatio-temporal sharing have also been explored vastly. Existing works either leverage multiple streams [1, 3] to multiplex a GPU within an application [54, 71], or leverage MPS to achieve so [39, 78]. There are also other works [45, 49, 58] that collaborate with the efforts in code compilation to multiplex a GPU. However, these works do not consider the isolation demand of tenants.

7 Discussion

KRYPTON has been deployed within the production environment. In actual practice, the minimum splittable GPU time slice ratio is set at 1%, and the minimum unit of memory allocation is 1MB. In this section, we shall deliberate on how KRYPTON maintains system security and the potential limitations it may encounter.

System Security. The kernel-space scheduler of KRYPTON is designed and implemented as a loadable kernel module (LKM), and we do not have to make any changes to the kernel or Nvidia driver. Therefore, KRYPTON maintains equivalent security guarantees to other LKM-based approaches. To date, no security risks associated with kernel-space interception have been reported that could introduce system vulnerabilities. Additionally, KRYPTON has been deployed in production-scale data center clusters featuring thousands of GPUs, operating reliably for over one year.

Limitations. KRYPTON does not support real-time spatial resource re-configuration with MIG. This may pose a potential constraint when a dynamic application is required to manage fluctuating workloads. For instance, in the case where the load of a large language model serving application decreases and demands fewer resources, the scheduler within the KRYPTON is unable to directly and elastically recycle the resources of the tenant. The live migration of GPU resources while ensuring continued isolation remains a promising area for future research.

8 Conclusion

In this paper, we propose KRYPTON, a kernel-space GPU sharing system that promises the compatibility and isolation of applications that share GPUs. KRYPTON intercepts GPU command buffers at the kernel level to provide virtual GPU devices. We design a feedback-based performance control policy to guarantee the performance of applications. Leveraging the spatio-temporal orchestration policy, KRYPTON reduces GPU fragments, thereby reducing the required number of GPUs for workloads. We evaluate KRYPTON with numerous applications and benchmarks. KRYPTON reduces the required GPU number by 32.1% compared with state-of-the-art systems.

AnchorNet: Bridging Live and Collaborative Streaming with a Unified Architecture

Deployed Systems Track

Abstract

Collaborative streaming has emerged as a popular mode in modern live streaming applications. In the meanwhile of improving interactivity between broadcasters and viewers, it requires the live streaming architecture to smoothly switch between two streaming modes (*e.g.*, traditional live streaming with a single broadcaster and collaborative streaming with at least two collaborative broadcasters). In this paper, we present AnchorNet, the new live streaming architecture for one of the most popular streaming applications. The core of AnchorNet is a unified stream path from the broadcaster to the viewer, enabling the host broadcaster of a live channel to switch between streaming modes within a continuous application session. It also proposes audio stream splicing techniques to further minimize unpleasant audio glitches during streaming mode switching. Practical deployment shows that AnchorNet can significantly reduce rebuffering during mode switching by over 60%, and increase user engagement by up to 3.83%.

1 Introduction

Thanks to advanced social media platforms (*e.g.*, Instagram, TikTok, Twitch, *etc.*), live streaming is no longer exclusive to large events and professional media production, and has become easily accessible to individual broadcasters with their own camera and microphone feeds [1]. Furthermore, driven by user needs for enhanced interactivity and engagement, collaborative streaming has been an integrated feature on many platforms (*e.g.*, [2–4]). A viewer has the opportunity to share personal stories with other audience when invited by host of a live channel as a collaborative broadcaster (co-broadcaster). Multiple hosts can audio/video chat with each other (*e.g.*, online karaoke) while streaming together to their perspective channels.

Compared with traditional single-broadcaster live streaming[1], collaborative streaming presents media contents from multiple co-broadcasters, and induces several new challenges to the live streaming architecture.

- It introduces the task of stream mixing. The live streaming architecture needs to determine where to mix media streams of co-broadcasters before they are rendered at viewers. There is no optimal choice among the three options: on broadcaster side, on server side, or on viewer side. Each of them faces tradeoffs between user experience and cost.
- It requires the WebRTC stack to fulfill more stringent latency requirements between co-broadcasters. Considering that many major applications still heavily rely on RTMP and HTTP-based ingest and distribution for the basic live streaming mode [5–7], a possibly additional protocol stack increases the implementation complexity.
- A live channel should be able to smoothly switch between the two streaming modes. As the host broadcaster interacts with different viewers and friends, viewers should perceive as little choppy audio or frozen video as possible.

As one of the primary social media platforms, TikTok adopts server-side stream mixing to serve over 1 billion users. Such a design choice aims to avoid setting barriers on user device performance, and to mitigate server-side burdens from serving massive stream subscriptions.

Our first-generation live streaming architecture, DualNet, as its name suggests, is based on decoupled implementations for live and collaborative streaming. Of the two modes, we first launched live streaming. Therein, a broadcaster directly publishes an RTMP stream to CDN for cost-effective distribution to viewers. Like many live streaming platforms [8, 9], AAC audio codec [10] is used end-to-end. Then, when extending to collaborative streaming several years later, we leveraged RTC media servers to exchange RTP streams between co-broadcasters. Similar to many RTC applications [11–14], co-broadcasters change to Opus audio codec [15], because it has superior encoding latency, compression ratio, and error resilience. Meanwhile, to be compatible with the original live streaming mode, RTP streams from a live channel are mixed and transcoded to an AAC-encoded RTMP stream on the server side as the ingest to CDN for distribution.

DualNet resulted from our engineering decision not to alter basic live streaming implementation while additively rolling out collaborative streaming. However, it makes switching between the two streaming modes quite complicated. Due to its decoupled form, viewers effectively subscribe to two different streams when a channel switches between live and collaborative streaming, which follow different publishing and ingest paths to CDN. The two modes also require different transport protocols and audio codecs to be used by broadcasters. Consequently, audio and video rebuffering tends to occur during mode switching. What is worse, optimizations atop

*Wei Zhang is the corresponding author: zhangwei.666@bytedance.com

[1] Henceforth, when referring to mode of live streaming, we directly use live streaming to represent the scenario with a single broadcaster.

such a decoupled architecture usually involve complicated coordination between multiple components, each corresponding to a separate internal code repository. That adds to both development and maintenance overheads.

Therefore, as our user traffic continues to expand, we seek to evolve TikTok's live streaming architecture, and build AnchorNet in order to toggle the streaming mode more smoothly. While doing so, we retain the design choice of server-side stream mixing in collaborative streaming. Lessons learned from DualNet further yield three objectives.

- We prefer to preserve an identical publishing path to CDN in both streaming modes. Each live channel only ingests to a single CDN node, eliminating origin re-addressing during a host broadcaster session. That facilitates in-order delivery of packets belonging to different modes.
- The broadcaster may maintain the same application session throughout the streaming process. Otherwise, upon entering a new streaming mode, the switchover delay from ramping up a separate congestion controller increases the risk of rebuffering. That requires the broadcaster to rely on the same set of application and transport protocols.
- No valid audio signal is lost, and audio glitch is minimized even if host broadcaster of a channel changes audio codec along with streaming mode. That is not possible with the broadcaster simply switching the codec, because of encoder delay [16] inherent to most audio encoding algorithms.

AnchorNet unifies the architecture for basic live streaming and collaborative streaming, and meets all the above objectives. We do not claim it to be the optimal solution in all cases. Yet it provides insights on the feasibility of large-scale collaborative streaming deployment based on server-side stream mixing. To the best of our knowledge, we are the first to share practical experiences on extending live streaming architecture to support collaborative streaming. Our main contributions are highlighted as follows.

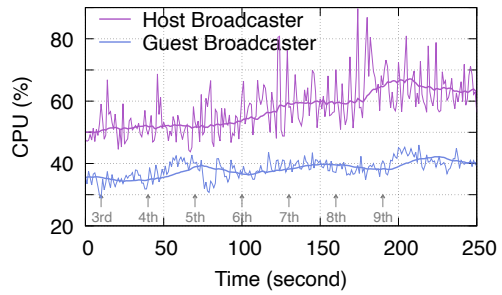
- The AnchorNet architecture uses RTC servers as the bridge between broadcasters and CDN, so that the channel host publishes to the same CDN node in an uninterrupted session when the streaming mode switches repeatedly.
- We propose audio sample-level operation techniques to resolve inherent issues of audio codecs such as encoder delay. Through coordination between broadcaster and RTC server, the host broadcaster's audio samples in different streaming modes can be seamlessly spliced, *e.g.*, no silence is inserted and no valid audio signal is discarded.
- We evaluate the performance of AnchorNet in large-scale practical deployment. Compared with DualNet, it significantly improves the smoothness of user experience, *e.g.*, the rebuffering time during streaming mode switching is reduced by over 60% and up to 78.9%. That also contributes to a 2.15% and 3.44% increase in per co-broadcaster and per viewer engagement, respectively.

This work does not raise any ethical issues.

2 Design Choice on Where to Mix Stream

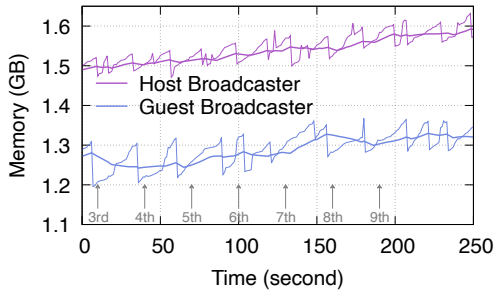
In fact, we have implemented all three options on stream mixing aimed at various application scenarios. For example, co-broadcasters fetch and render each other's streams independently, effectively leveraging viewer-side stream mixing. We start with a comprehensive analysis of the rationale behind the foremost design choice in both generations of our live streaming architecture: server-side stream mixing before delivering to viewers in collaborative streaming.

2.1 Server Side *vs.* Broadcaster Side



With broadcaster-side stream mixing, the host broadcaster of a live channel uploads at least two streams in collaborative streaming: one personal stream fed to the other co-broadcasters, the other mixed stream for viewers. It offers several advantages over server-side stream mixing.

- The server side only has two roles: 1) RTC SFU (Selective Forwarding Unit) that forwards streams between co-broadcasters, and 2) CDN for distribution to viewers. No stream mixing is needed, saving cost on server machines.
- The host broadcaster controls timing and smoothness of switching between streaming modes at the source. The above two server-side roles remain largely independent. So does the development of live and collaborative streaming.



However, we assess that its issues outweigh the advantage.

- Broadcaster-side stream mixing increases computation overhead and battery power consumption on user device. The maximum number of co-broadcasters may thus be limited by the performance of user device. We do not want to discourage potential users, *e.g.*, those with relatively moderate smartphones. Nor do we like such a barrier when we extend to more complex streaming scenes in the future.
- The broadcaster will have to maintain two uplink connections in collaborative streaming. In case of restrictive first-mile bandwidth, the bitrate received by viewers will approximately be halved compared to that in live streaming mode. Besides, the congestion controllers of the two connections compete with each other, impacting stability of both.
- Compared with the server-side option, the stream mixing task is delayed by an one-way latency at the access link, while waiting for the host broadcaster to gather the streams of other co-broadcasters from the connected SFU. The tail latency over 100 milliseconds on the rapidly fluctuating access link [17, 18] makes viewer experience more fragile.

To show its overhead more intuitively, we evaluate a broadcaster-side stream mixing prototype. When we increase the number of co-broadcasters from 2 to 9, the trends of CPU and memory usage on the host and the first guest co-broadcaster are shown in Figure 1. Taking the difference of their CPU usage at the start of the trial, the stream mixing task needs about 15% CPU time at the host broadcaster. Having 7 more co-broadcasters consumes 15% CPU time on the

(a) CPU usage

(b) Memory usage

Figure 1: Overhead of broadcaster-side stream mixing: measurements start with a host broadcaster and a 2nd co-broadcaster, with the join time of subsequent co-broadcasters explicitly marked (30-second average CPU/memory usage shown in thicker lines)

host's device, and less than 5% on the guest co-broadcaster. In the end of the trial, the host broadcaster consumes an additional 25% CPU time on average compared with the guest co-broadcaster, and the temporary CPU usage even reaches 90%. Meanwhile, the host needs more than 250 MB memory in extra. All co-broadcasters (including the host) use Xiaomi 14 smartphones in our test. The 25% CPU time fully occupies 2 out of the 8 CPU cores. That would exceed the capacity of some low-price smartphones released several years ago.

In addition, there can easily be at least an order of magnitude more viewers than co-broadcasters per channel. Therefore, server-side cost of stream mixing may be amortized by serving a large number of viewers, generating positive ROI (Return on Investment) given our user population.

2.2 Server Side *vs.* Viewer Side

The so-called viewer-side stream mixing actually does not involve the task of mixing and transcoding co-broadcasters' streams. Instead, each viewer directly renders multiple streams after decoding them. Thus, its most important advantages are shorter end-to-end delay and reduced server-side computation. By fetching independent co-broadcasters' streams to viewers, it also has the benefit of a customizable user interface. Its issues are listed below.

- The media streams of co-broadcasters can be distributed to viewers via SFU or CDN. An SFU-based realization effectively implements a live channel as a multi-party conference room [19, 20]. It requires us to deploy dramatically more RTC servers to accommodate all the viewers, and signal the connection and disconnection of each co-broadcaster to orders of magnitude more users. So it is not as viable as CDN-based distribution, where we can leverage plenty of 3rd-party CDN providers to lower our expenses.
- In collaborative streaming, a viewer needs to subscribe to the same number of streams as co-broadcasters. Even if we ignore the complexity of signaling those streams to all the viewers, multiple per-co-broadcaster streams tend to lower compression efficiency [21] and consume more bandwidth than a mixed stream. That pulls up bandwidth cost on both server side and viewer side.

We do not list the issue of requirements on viewer device performance. Because unlike the broadcaster and server-side options, viewer does not need to re-encode and forward the received streams. As demonstrated by CPU and memory consumption of the guest co-broadcaster in Figure 1, receiving, decoding and rendering streams of several co-broadcasters only mildly raises the pressure on device performance.

Again, there is usually a disparity in the order of magnitude between the number of viewers and co-broadcasters. It is not uncommon for a live channel to have thousands of concurrent viewers. At that scale, the increased bandwidth cost by viewer-side stream mixing may outweigh its savings of computation overhead compared with server-side stream mixing.

We should note that our considerations on where to mix streams represent one perspective among many. We notice some platforms make the same choice of server-side stream mixing (*e.g.*, Tecent TRTC [22], Alibaba ApsaraVideo RTC [23]), but developers may find client-side options more suitable provided different deployment focus.

3 Background

3.1 Decoupled DualNet Architecture

Our first-generation live streaming architecture is depicted in Figure 2. We strengthen several key points here.

RTC server roles. A proportion of server instances are used as RTC servers. They may be assigned two roles, including SFU and MCU (Multipoint Control Unit) media servers. Similar to a typical multi-party conferencing setup, cascaded SFUs forward RTP streams between co-broadcasters without decoding them [20]. Each live channel further selects an MCU to gather co-broadcasters' RTP streams from SFUs, where compute-intensive tasks such as steam mixing are accomplished. The MCU server also ingests the mixed stream to CDN in collaborative streaming.

Broadcaster codecs. In our DualNet implementation, the audio codec used by broadcasters is statically determined by the streaming mode, *i.e.*, AAC in live streaming and Opus in collaborative streaming. The video codec should otherwise

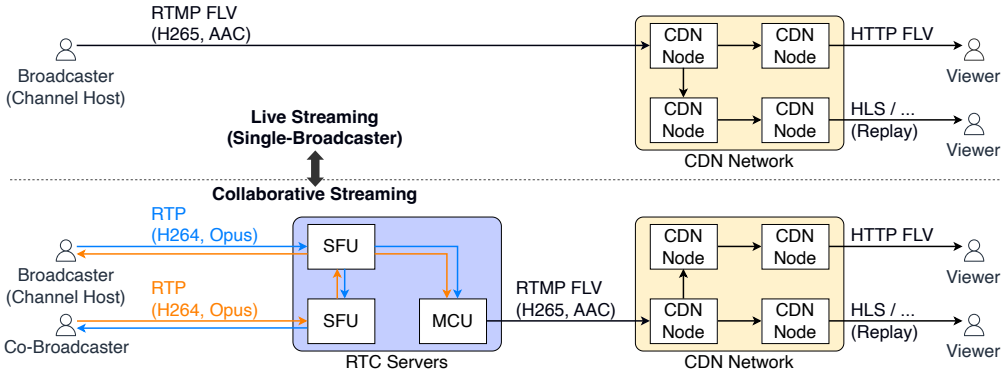


Figure 2: DualNet live streaming architecture

adapt to capabilities on various devices. As exemplified in Figure 2, the host broadcaster of a channel may negotiate a different video codec with invited co-broadcasters (H264) from the one already used by ongoing live streaming (H265).

Consistent codecs to viewers. From the perspective of CDN, the output audio and video codecs of a channel remain unchanged throughout each broadcast. If a host broadcaster changes codecs upon entering collaborative streaming, the RTC MCU media server should conduct transcoding while mixing streams (H264/Opus to H265/AAC in Figure 2) and ensure codec consistency. Then, when the channel returns to live streaming mode, its host broadcaster may also switch back to original codecs. Without changing codecs, broadcasters can always adapt some detailed configurations, *e.g.*, they can use larger GOP (Group of Pictures) and enable B-frames in reaction to decreased access bandwidth.

Distribution Protocols. Technically, any protocol supported by CDN can be used for distribution to viewers, *e.g.*, RTP if leveraging recent CDN feature of low-latency streaming [24]. We use HTTP FLV to ensure backward compatibility, because it has served our live streaming viewers for years at the time we rolled out collaborative streaming. In the meanwhile, CDN may record and store the live streams in other formats (*e.g.*, HLS). The host broadcaster of a channel can make some history live clips available for on-demand replay afterwards.

3.2 Issues of DualNet

To motivate architecture redesign, we elaborate on critical issues of DualNet during streaming mode switching.

CDN ingestion node change. In live streaming mode, the broadcaster queries an edge CDN node through DNS. When it comes to collaborative streaming, our logically centralized scheduling backend allocates an ingestion node in CDN based on proximity of the MCU server. Although the allocation refers to the edge node assigned in live streaming, it may still have to select a different node. Below are two example scenarios where that happens.

- There are CDN PoPs (Points of Presence) but no RTC servers in the country of the broadcaster. Detouring to the same CDN ingestion node as in live streaming mode induces additional transport delay.
- The MCU server and the original edge CDN node belong to two poorly peered ISPs, and the path between them suffers from high packet loss or fluctuating RTT.

Thus, CDN may have to splice two RTMP streams ingested from different locations into a single stream for distribution. That increases engineering workloads and risk of rebuffering.

Different publishing paths. Even if a channel always ingests to the same CDN node, the two streaming modes still have separate publishing paths from the broadcaster to the ingestion node. In particular, the publishing path in collaborative streaming involves multiple transport connections, running over two transport protocols. There is not necessarily a straightforward way to coordinate and migrate states between several independent congestion controllers, not to mention the delay from establishing a new connection at least during the first streaming mode switching. In the worst case, both the RTP streams from co-broadcasters and the mixed stream by MCU have to go through slow start upon entering collaborative streaming, leading to degraded bitrate and even rebuffering. Additionally, inconsistent delay on the two publishing paths is likely to cause out-of-order arrival of media frames, *e.g.*, the first collaborative streaming frame may arrive at the ingestion node earlier than the last live streaming frame. That adds to the complexity of session switchover.

Implementation ossification. Ironically, DualNet's decoupled implementations for the two streaming modes leave us with multiple tightly coupled components, complicating optimization of user experience during streaming mode switching. For instance, to adapt to updated interfaces of a 3rd-party CDN provider, both our broadcaster-side and RTC server SDKs must be modified. Moreover, the application logic at the broadcaster calls separate SDKs for live streaming and collaborative streaming. In large-scale systems, that often results in ossification. For more efficient iteration of new features and optimizations, we are devoted to reduce inter-component coupling by a unified live streaming architecture.

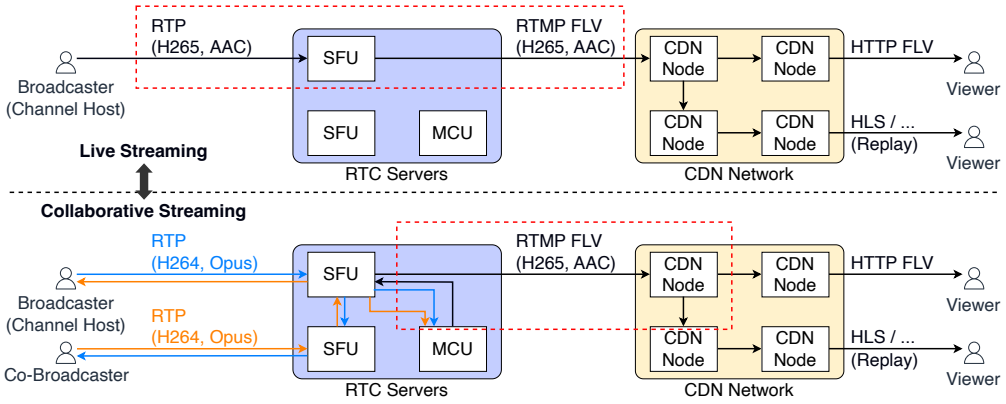

Figure 3: AnchorNet live streaming architecture (Key differences from DualNet marked in red dashed boxes)

4 AnchorNet Architecture

We name the new live streaming architecture AnchorNet (Figure 3). Drawing lessons learned from the first-generation architecture, it follows one most important principle, *i.e.*, to unify the publishing path from the broadcaster to CDN. For that purpose, RTC SFU is introduced into the publishing path as the "anchor" in both streaming modes. That not only alleviates the challenges of aligning two streams from separate paths, but also helps mitigate coupling between components.

In this section, we walk through key details of AnchorNet, focusing on our underlying considerations.

4.1 Same Publisher to CDN

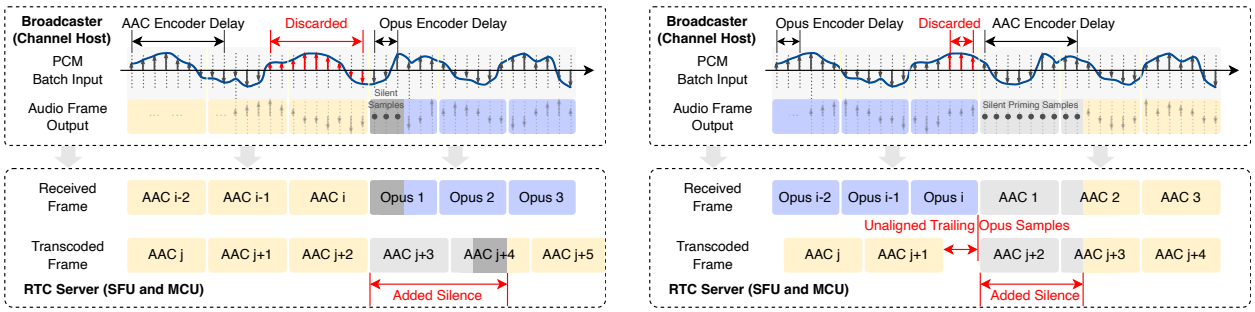
A unified publishing path should have the same publisher to CDN in both streaming modes. Provided server-side stream mixing in collaborative streaming, if the channel host is the publisher, the mixed stream will have to be forwarded back to the broadcaster before being published to CDN. That shares many drawbacks of broadcaster-side stream mixing (§2.1). Thus, the RTC server should act as the publisher to CDN.

Then, among the two roles of RTC server, MCU is not involved in live streaming mode. According to our current traffic data, live streaming still accounts for a much higher volume than collaborative streaming. Therefore, we assign the CDN publisher role to SFU media server. As shown in Figure 3, an MCU server paired with a channel feeds the transcoded mixed stream back to the SFU serving the host broadcaster, instead of directly ingesting to CDN as in DualNet. However, the round trip between SFU and MCU induces additional delay to collaborative streaming, especially considering that MCU servers are mostly centrally deployed now. We anticipate that the additional delay may decrease with increasing deployment of edge computing servers [25–28]. Yet at the moment, we rely on the jitter buffers within CDN and at the viewer to prevent such a round trip from inducing rebuffering when switching from live to collaborative streaming.

We also note that when switching between streaming modes, SFU should guarantee that the ingestion node in CDN sees consecutive sequence numbers.

4.2 Protocols for CDN Ingest

With an RTC SFU media server sitting between the broadcaster and CDN on the publishing path, there are two scenarios where a protocol needs to be selected: 1) the protocol used by the broadcaster to publish to SFU, and 2) that used by the SFU to ingest to CDN.



First, given that co-broadcasters exchange streams using RTP, we escalate RTP to be the unified uplink protocol for broadcasters across the two streaming modes. By doing so, a channel host can broadcast a continuous RTP stream in the same session while switching between modes, without the need to establish another transport connection. A side benefit is that the live streaming mode can leverage self-developed and optimized congestion control algorithms in user-space, instead of limited to those less frequently updated algorithms supported by kernel on user devices.

As for the ingest protocol from SFU to CDN, an important objective is to ensure compatibility with most CDN providers. Considering that RTMP-based ingest has been supported by almost all CDN providers [29–32] for years and Internet paths between RTC and CDN servers tend to be more stable than first/last-mile access links, SFU continues to use RTMP to push media streams to CDN. A benefit of using RTMP as the ingest protocol is that it requires minimal modification to our previous implementation on CDN and viewer side.

4.3 Selection of Audio Codecs

The principal differences between AnchorNet and DualNet are explained above in §4.1&4.2. On that basis, we stick with the selection of audio codecs in DualNet. On the broadcaster side, Opus is used for collaborative streaming, and AAC is used for live streaming. On the server side, AAC is used for CDN ingest. Correspondingly, MCU needs to transcode and mix Opus audio streams of all co-broadcasters of a channel into an AAC stream in collaborative streaming.

We do not adopt an all-Opus scheme, mainly because the AAC codec is still much more widely compatible with RTMP,

(a) Live streaming to collaborative streaming

(b) Collaborative streaming to live streaming

Figure 4: Problems of switching streaming mode without coordination (Other guest co-broadcasters' streams are omitted from received and transcoded frames. Also, low-level details such as overlapped MDCT transform window are not shown.)

albeit some explorations into extending RTMP to support contemporary codecs including Opus [33]. Considering that, we did not unify the host-side audio codec to Opus, either. That would extend the expense of MCU transcoding from collaborative streaming mode only to both streaming modes. It could lead to a significant server-side cost increment, because the duration of live streaming is generally longer than collaborative streaming in our production environment. In the long term, we would certainly like to have a single audio codec in most cases, regardless of the streaming mode.

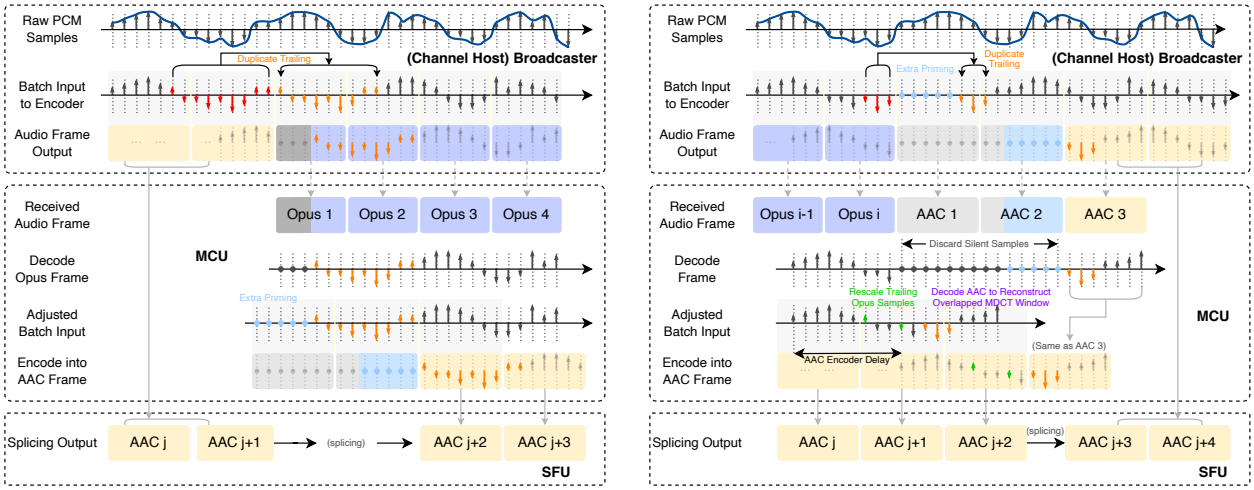
4.4 Mitigated Ossification

AnchorNet does not eliminate coupling components totally. As will be explained in §5, the broadcaster and the RTC servers still need to coordinate in audio stream splicing. However, it mitigates implementation ossification, indeed. The broadcaster logic always runs on RTC SDK now, and does not need to maintain two sets of transport protocols and congestion control algorithms depending on the streaming mode. More importantly, with RTC SFU as the only CDN publisher, the broadcaster does not directly interact with CDN any more. That simplifies many tasks such as scheduling among multiple CDNs and debugging between server-side and broadcaster-side issues. To be specific, we contract with different 3rd-party CDN providers for enhanced fault tolerance. When a CDN cluster of a provider encounters connection issues in the ingest direction, both fault localization and temporary blacklist update happen on server side in AnchorNet. No patches to user-facing modules are needed as with DualNet.

5 Audio Stream Splicing

In AnchorNet, the RTC SFU needs to splice the audio/video stream from the host broadcaster (live streaming) and the mixed stream from the MCU server (collaborative streaming) when the streaming mode is toggled. For convenience, we refer to the streaming mode before and after a mode change as the *egress* and *ingress streaming mode*, respectively. The codec used by the host broadcaster is called accordingly as the *egress* and *ingress codec*, as well.

For video streams, the host broadcaster always switches the streaming mode at the frame boundary. It suffices to comply with two packet forwarding paths (*i.e.*, with and without MCU) depending on the streaming mode. The last frame of the egress streaming mode can directly be followed by the first frame of the ingress streaming mode. In comparison, as illustrated in Figure 4, smooth audio stream splicing is by no means as straightforward as that, owing to challenges inherent to the audio encoding algorithms.



5.1 Challenges from Audio Codec

5.1.1 Encoder Delay

At a high level, each fixed-duration input batch of PCM (pulse-code modulation) samples generates an audio frame that lasts for the same duration. However, if we look at the serialized output sample sequence by the decoder, it generally starts with several silent samples, leading to an encoder delay between the input and output indices of the same raw sample. One of the most important reasons for such an encoder delay is the overlapped window while conducting MDCT (modified discrete cosine transform) [15, 16, 34], which is adopted universally by many encoding algorithms. Briefly, when transforming time-domain samples represented by an audio frame to frequency domain, the transform window is overlapped with the subsequent frame to avoid audio artifacts at window boundaries. To properly output an audio frame for the first input batch (*e.g.*, with insufficient samples on its own to fill an entire transform window), an encoder conducts priming [34], by inserting silent samples before the first raw input sample.

If the host broadcaster were to rigidly switch between AAC and Opus and the MCU server did not process the received PCM samples any further before transcoding, the encoder delay would cause two issues in Figure 4. First, the host broadcaster starts every ingress streaming mode with a leading silence, resulting in perceivable audio glitch. The silent samples are introduced:

1. by ingress codec on host broadcaster's user device, and
2. by MCU at the start of transcoding upon entering collaborative streaming.

(a) Live streaming to Collaborative streaming

(b) Collaborative streaming to Live streaming

Figure 5: Audio stream splicing when switching between the two streaming modes (In collaborative streaming, stream mixing happens in the step marked *Encode into AAC Frame*. The streams of other guest co-broadcasters, as well as other details such as overlapped MDCT window and the SFU between host broadcaster and MCU, are not shown for brevity.)

Codec (Profile)	Frame Size	Priming Samples
AAC (HE-AAC v1 [35])	2048	5058
Opus (48 kHz [36])	960	325

Table 1: A Typical Codec Configuration in TikTok

Moreover, as exemplified in Table 1, the number of priming samples may not be an integer multiple of audio frame size. Simply dropping audio frames containing such samples is very likely to lose valid audio signals.

Second, tail samples of the egress codec, which are still un-encoded in the encoding buffer when the host broadcaster triggers a streaming mode switch, will be discarded. The number of discarded samples equals the number of inserted leading silent samples, and may not be divisible by the frame size. So even if most codec libraries support flushing remaining tail samples, that induces padded silence in the last frame and is not an ideal solution, either.

5.1.2 Inconsistent Frame Sizes

Another challenge in stream splicing is the inconsistent frame sizes between AAC and Opus (*e.g.*, 2048 *vs.* 960 as in Table 1). When exiting collaborative streaming, the trailing samples decoded from Opus frames may not fill an entire AAC frame (Figure 4b). Without any optimization, the MCU server either discards or flushes those samples, with both choices generating similar glitches in the host broadcaster's audio due to encoder delay (§5.1.1).

5.2 Splicing Techniques

Broadcaster-server coordination is necessary to mitigate potential audio glitches due to encoder delay and inconsistent frame sizes. Four PCM sample-level optimization techniques are proposed here. They operate on the audio stream of the host broadcaster, before it is mixed with other co-broadcasters' audio streams. Figure 5 shows when and where they take effect in the whole stream splicing process.

5.2.1 Extra Priming to Avoid Partial Silent Frames

If the encoder delay is a multiple of frame size, the priming samples will be encoded into different frames from the raw input samples. Then, the server side can safely skip leading silent frames in the ingress streaming mode without losing valid audio signals. We thus supplement N_{extra} extra priming samples to the transcoding or ingress codec, aiming at:

$$(N_{priming} + N_{extra}) \mod frame_size = 0.$$

Take the setup in Table 1 as an example. When entering collaborative streaming, MCU precedes the decoded Opus samples with an additional 761 silent samples, forming an extra priming of 1086 samples (including 325 Opus priming samples already inserted by host broadcaster). Similarly, when switching back to live streaming, the host broadcaster adds the same extra priming of 1086 samples to its AAC codec. In both cases, there will be 3 leading silent AAC frames, enabling smooth stream splicing starting from the 4th AAC frame.

Extra priming, as well as the other techniques, require the knowledge on encoder delay and frame size. We obtain and store their value during codec initialization.

5.2.2 Duplicate Trailing Samples at Host Broadcaster

To avoid tail samples of the egress codec from being discarded, the host broadcaster duplicates those samples into the ingress codec. That is achieved by maintaining the most recent audio samples fed to the currently used codec in a trailing sample ring buffer. The buffer is bound to the codec, and

its size equals the codec's encoder delay (*e.g.*, length of 325 samples for Opus if following the setup in Table 1). When the streaming mode changes, the ring buffer of the egress codec will be freed once sample duplication is complete.

Importantly, MCU does not need to be aware of trailing sample duplication. It simply treats the duplicated samples as raw audio samples.

5.2.3 Rescale Trailing Opus Samples at MCU

Algorithm 1: Transcoding and Sample Rescaling

```
1  N = 0 ;
2  Initialize buffer Q with N_extra^AAC extra priming samples ;
3  while streaming mode is collaborative do
4      s_pcm = Decode(next Opus frame) ;
5      remove_priming(s_pcm) ;      // 1st frame only
6      Q.push(s_pcm) ;
7      N = N + |s_pcm| ;
8      while N > 1.5 · l_AAC do  // l_AAC: frame size
9          Q.pop(l_AAC) ;   // batch input to codec
10         N = N − l_AAC ;
11 Rescale remaining raw samples to l_AAC samples ;
12 Q.pop(l_AAC) ;  // N_extra^AAC samples remains in Q
```

Extra priming guarantees that the first raw audio sample in collaborative streaming is the first frame in a transcoded frame. On that basis, as long as the number of raw samples (excluding extra priming) fed for transcoding is a multiple of AAC frame size, there will be no unaligned trailing samples decoded from Opus frames. Since the raw Opus samples are not controlled by the MCU, it needs to rescale the trailing samples to enforce the condition. Algorithm 1 outlines its behaviors in collaborative streaming mode.

Upon entering collaborative streaming, the MCU server initializes a pre-encode buffer with N_{extra}^{AAC} extra priming samples required by its AAC codec. It stores raw samples decoded from Opus frames (excluding priming samples in the first frame) in the buffer. Whenever there are more than 1.5 times the frame size (l_{AAC}) of raw samples in the buffer, it pops a batch as the input to AAC codec. Hence, in the end of collaborative streaming, the number of raw Opus samples in the buffer lies between $0.5 \cdot l_{AAC}$ and $1.5 \cdot l_{AAC}$. The MCU up-samples or down-samples them to exactly l_{AAC} samples, and feed one last input batch to AAC codec. Such rescaling inevitably deviates from the original timescale of input samples. Algorithm 1 keeps the extent of deviation below half an AAC frame (*e.g.*, around 20 ms under frame size of 2048 and 48 kHz sampling rate), and induces only minimal negative influence on the output audio effect.

5.2.4 Reconstructing Overlapped MDCT Window

The pre-encode buffer is initialized with extra priming samples, but trailing sample rescaling only aligns raw samples to an integer multiple of frame size. Therefore, after the last batch of input to AAC codec in Algorithm 1 (line 12), there will be N_{extra}^{AAC} samples left in the buffer, equal to extra priming inserted in the beginning of collaborative streaming (line 2). At the same time, there are un-encoded samples by the codec due to encoder delay. To finish encoding all decoded Opus samples, a simple method is to directly feed the remaining rescaled samples to the encoder and flush the codec. Silent samples will be padded automatically, and rescaling ensures that the last rescaled sample is the last sample represented by the final transcoded AAC frame. However, such a frame will not be encoded based on an MDCT window overlapped with the first non-priming live streaming frame, which should be the next frame after stream splicing.

To avoid audio artifacts therein, we pad raw audio samples from the first non-priming live streaming frame to the pre-encode buffer before feeding remaining samples to AAC codec. That reconstructs overlapped window for the final transcoded AAC frame, so that it will splice into the live streaming stream more smoothly. For that purpose, MCU should receive and decode the first several live streaming frames from SFU (Figure 5b).

We note that the MCU does not need to reconstruct MDCT window when switching from live to collaborative streaming. With duplicate trailing samples (§5.2.2), the last live streaming AAC frame is guaranteed to have a transform window overlapped with the first collaborative streaming frame.

5.3 Scope of Application

Discussion in this section so far is based on selection of audio codecs as explained in §4.3. In fact, the above challenges and optimization techniques are universally applicable to broadcaster-side and server-side stream mixing, regardless of the audio codecs used by the broadcaster and MCU.

Specifically, both broadcaster-side and server-side stream mixing require decoding co-broadcasters' audio streams to mix their PCM samples. The re-encoding process following that is subject to influence of encoder delay and overlapped MDCT window. For instance, leading silence is always generated upon entering collaborative streaming. Thus, even in the extreme case where the same audio codec and codec profile are used in both streaming modes, extra priming and reconstructed MDCT window are still indispensable for seamless audio stream splicing. Trailing sample duplication and rescaling would also be necessary if different profiles of the same codec are used for live and collaborative streaming.

6 Micro-Benchmark

Before practical deployment, we verify the effectiveness of AnchorNet in optimizing user experience during streaming mode switching with small-scale experiments. We compare it with DualNet, as well as two other popular live streaming applications. The two competitors represent two design choices on streaming architecture. According to packet dump analysis, Competitor-1 adopts viewer-side stream mixing, and imple-

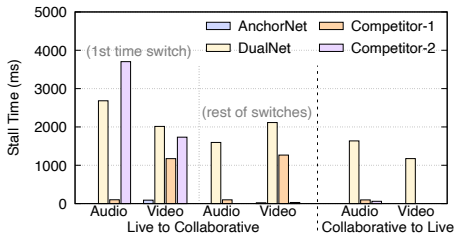


Figure 6: Stall per streaming mode switch

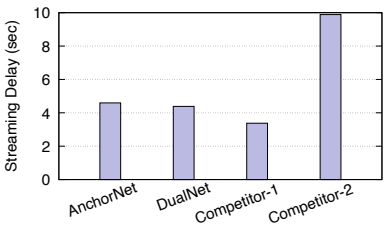

Figure 7: Live streaming E2E delay

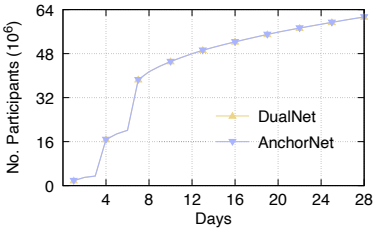

Figure 8: Num. of users in A/B test

ments both live and collaborative streaming with a unified RTC stack. Competitor-2 is based on server-side stream mixing, and similar to DualNet, requires the host broadcaster to establish separate connections for the two streaming modes.

Because the maximum number of co-broadcasters allowed varies across different applications, we test the most basic scene with only two co-broadcasters (*i.e.*, host plus an invited guest). We use three Xiaomi 14 smartphones as channel host, guest co-broadcaster, and viewer, respectively. In each trial, the host starts in live streaming and triggers mode switching 6 times by repeatedly inviting and hanging up on the guest co-broadcaster, while the viewer stays in the channel. We place the three devices at the same location and connect them to the same dedicated office WiFi, so that the evaluation reflects native performance of the architecture (*e.g.*, without influence of weak access network, overlay path computation policy, and bitrate adaptation strategy, *etc.*).

Rebuffering. As an indicator of rebuffering time per streaming mode switch, we measure the overall duration of audio and video stalls at the viewer in a 10-second period before and after each switch.[2] We report average results across multiple trials in Figure 6. Obviously, upgrading to AnchorNet brings superior mode switching experience. Thanks to the optimized audio splicing techniques, it encounters no audio rebuffering in all cases. AnchorNet also outperforms the other tested schemes regarding video rebuffering. In comparison, DualNet always suffers from second-level stalls for both audio and video. Competitor-1, although based on viewer-side stream mixing, consistently experiences a short audio pause of around 100 ms in every switch. Notably, Competitor-2 induces a long stall when the channel switches to collaborative streaming for the first time, but performs comparable to AnchorNet in subsequent streaming mode switching. Correspondingly, we notice that Competitor-2 starts each live streaming viewer session in media audio mode, and changes to call mode [37] when the channel first switches to collaborative streaming. It stays in call audio mode afterwards. We infer that some implementation-specific module restart is triggered in that process, causing the long rebuffering.

Streaming Delay. Then, we compare the broadcaster-to-viewer streaming delay of the tested schemes. For convenience of calculation, we put a timer in the camera of the host broadcaster, and record the difference between the displayed time at the host and the viewer multiple times during each trial. As shown in Figure 7, the streaming delay of Competitor-2 more than doubles that of AnchorNet, possibly due to a much larger jitter buffer within the network. That may contribute to Competitor-2's rebuffering performance during streaming mode switching, which is quite close to AnchorNet other than the long stall in the first switch to collaborative streaming. Competitor-1, leveraging a unified RTC stack, achieves the shortest delay under 4 seconds. AnchorNet and DualNet are not far behind, with AnchorNet being slightly higher due to the round trip between the RTC SFU and MCU. Such a streaming delay, together with the least perceivable glitches during streaming mode switching, delivers satisfying ROI for a commercially large-scale deployed system like TikTok.

[2]The same as [20], we filter instances of audio and video stalls using empirical thresholds of 80 ms and 200 ms, respectively. Micro stalls below the thresholds are ignored.

7 Evaluation

7.1 User Experience Gains

Currently, we are in the process of deploying AnchorNet. To compare it with DualNet, we present QoS and QoE results from one of our large-scale A/B tests in production environment. The test was conducted in 2024Q4 and lasted for 4 weeks. It involved almost the same number of users served by AnchorNet and DualNet, respectively (Figure 8). Table 2 summarizes the performance of AnchorNet relative to DualNet. All listed metrics are statistically significant under a confidence level of at least 95%. More detailed analysis and results are presented as follows, with the data normalized against the maximum value from respective metric.

Rebuffering during mode switching. Similar to §6, we first look at rebuffering during streaming mode switching, which is the most important category of metrics AnchorNet aims to optimize. Unsurprisingly, AnchorNet significantly reduces both the duration and count of video/audio rebuffering. Figure 9 showcases the trend of video rebuffering throughout the 4-week period. In the case of switching from live streaming to collaborative streaming, each viewer session encounters 60.3% shorter stall duration and 60.1% less stall count on average under AnchorNet. When switching back to live streaming, AnchorNet's gains on the same two metrics reach 78.9% and 78.5%. It is normal that the gains from practical A/B test are not as extreme as achieved in our benchmarking

Rebuffering during mode switching (per viewer session)	Live to collaborative streaming		Collaborative to live streaming	
	Rebuffering Count	Rebuffering Duration	Rebuffering Count	Rebuffering Duration
	Video: −60.1% Audio: −64.5%	Video: −60.3% Audio: −67.4%	Video: −78.5% Audio: −76.3%	Video: −78.9% Audio: −77.1%
User engagement (daily active time)	Host streaming	Co-broadcaster streaming	Viewer watching	
	+0.53%	+2.15%	+3.83%	
Live streaming mode only	Rebuffering	Host-side push FPS	Host device pressure	
	Video: +13.47% Audio: +11.02%	+3.11%	CPU: −1.33% GPU: +0.80% MEM: +0.31%	

Table 2: A/B Test Results (Metrics on which AnchorNet outperforms DualNet are marked by underlined numbers)

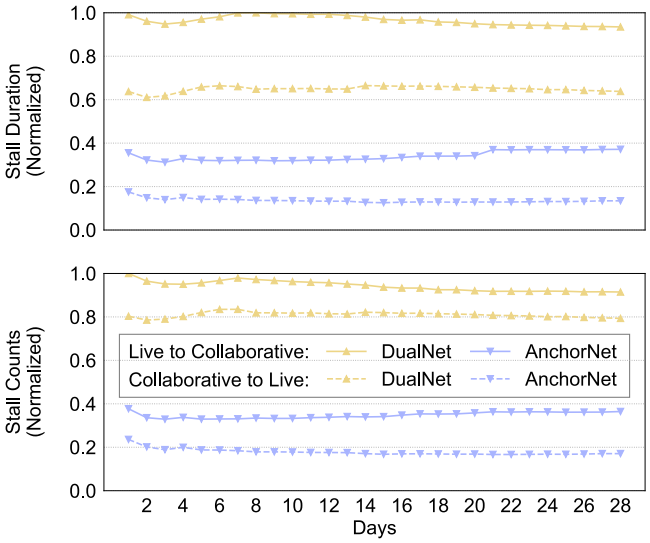

Figure 9: Duration and count of video rebuffering per viewer session

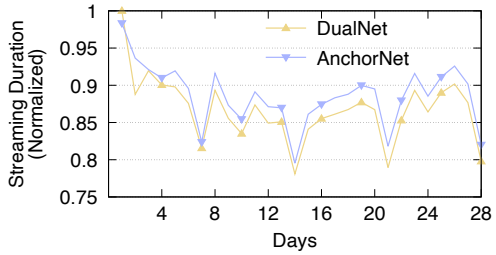

Figure 10: Daily active time per co-broadcaster

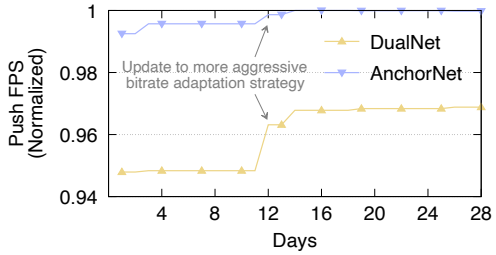

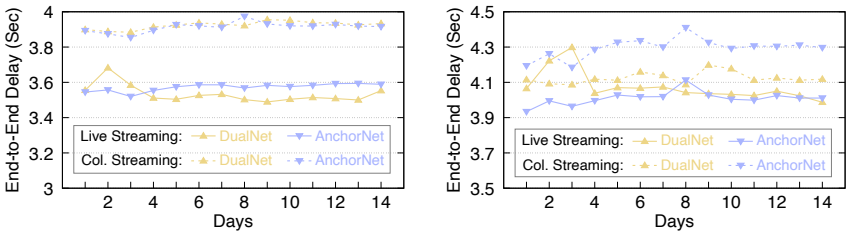

Figure 11: Push FPS in live streaming mode

test in §6. That is mainly because users' access links are much more complicated than our ideal setup. Audio rebuffering also follows a similar trend, so we omit due to limited space.

User engagement. Frequent rebuffering during streaming mode switching may cause some impatient users to quit, leading to impaired user retention and stickiness and even commercial loss. We expect a smoother switching experience, while making our users more satisfied, can ultimately improve user engagement. Fortunately, that is validated by the A/B test. AnchorNet increases the daily active time for all user roles, *i.e.*, 0.53% for channel host, 2.15% for guest co-broadcaster, and 3.83% for viewers. More intuitively, as illustrated in Figure 10, AnchorNet outperforms DualNet in terms of daily duration each co-broadcaster stays in collaborative streaming throughout the A/B test. We note that the active time of each viewer session encompasses every streaming mode switching of the watched channel. The reduction of viewer-side rebuffering during streaming mode switching cannot directly contribute to increment in viewer watching duration. Thus, the longer active time as in Table 2 reflects true user engagement growth.

Live streaming mode improvements. As explained in §4.2, viewer's experience in the live streaming mode may benefit from leveraging optimized user-space congestion control algorithms. Indeed, thanks to better resistance against uplink fluctuations (*e.g.*, random packet losses), AnchorNet lowers video and audio rebuffering in live streaming mode by as high as 13.47% and 11.02%, respectively (Table 2). The average frame rate pushed by channel hosts is increased by 3.11%, as well. It is worth nothing that we rolled out a more aggressive broadcaster-side bitrate adaptation strategy on the 12th day of the A/B test. AnchorNet maintains its advantage in push FPS (video frames per second ingested by the host in live streaming mode) after that (Figure 11). Meanwhile, since congestion and flow control are moved from kernel to user-space, AnchorNet puts slightly higher pressure on the host device, *e.g.*, it consumes 0.31% more memory in live streaming. The reduction of CPU consumption by 1.33% in Table 2 is because we prioritize hardware codec acceleration in our AnchorNet implementation, which leads to a 0.8% increment in GPU usage. We regard those slight increments as acceptable compared to gains in rebuffering and frame rate.

(a) Global (b) A selected country

Figure 12: End-to-end streaming delay

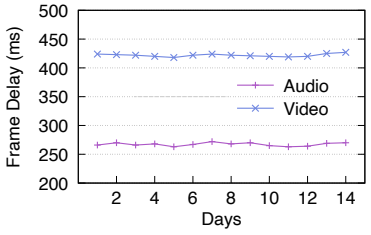

Figure 13: SFU-MCU round trip (including MCU processing time)

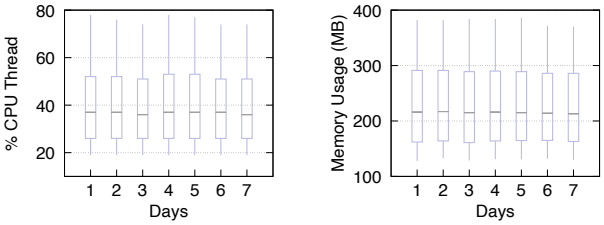

7.2 Server-Side Stream Mixing Feasibility

To provide exhaustive practical insights, we also demonstrate the performance and overhead of server-side stream mixing, which is common in both AnchorNet and DualNet.

End-to-end delay. As explained in §4.1, a concern in AnchorNet is the additional delay due to the round-trip between SFU and MCU in collaborative streaming. We track the end-to-end streaming delay in a two-week period in December 2024 in Figure 12. It turns out that on a global scale, AnchorNet has an average streaming delay comparable to DualNet (Figure 12a). This is because DualNet conservatively reserves a large jitter buffer at CDN upon entering collaborative streaming in reaction to the rebuffering during streaming mode switching. In many cases, that happens to counteract or even surpass the increased delay due to the SFU-MCU round trip in AnchorNet. Nevertheless, in those areas far from the nearest MCU cluster, AnchorNet may experience a longer collaborative streaming delay than DualNet due to the additional round trip. For example, Figure 12b shows the streaming delay in such a selected country. In collaborative streaming, AnchorNet raises the end-to-end delay by 170 ms on average compared with DualNet. We plan to further optimize on that front with wider edge MCU deployment in the future.

Stream mixing delay. Another observation from Figure 12 is that collaborative streaming has an end-to-end delay hundreds of milliseconds longer than live streaming mode. Besides the transport delay on the SFU-MCU round trip, such a delay gap also includes the time consumed by stream mixing and transcoding at MCU. Figure 13 presents the average per-frame delay in collaborative streaming between SFU and MCU. In AnchorNet, that delay is concealed by CDN and viewer-side jitter buffers. As explained in §8, we also adjust the playback speed at the viewer when switching between streaming modes to further avoid rebuffering.

Stream mixing overhead. At last, to quantify stream mixing overhead, we record average CPU and memory usage for each stream mixing task. Such a task is initiated when a live channel enters collaborative streaming, and terminated when the channel exits collaborative streaming. The whole streaming session of a host broadcaster may start multiple stream mixing tasks. Figure 14 shows the two metrics at different percentiles over one week in December 2024. In the median case, each task costs less than 0.4 logical CPU core and 220 MB memory. For a server instance with 128 threads (64 physical CPU cores) and above 500 GB memory, 100 such MCUs may accommodate up to 15 $\sim$ 30K concurrent collaborative streaming channels. According to our own assessment, we consider such server machine costs as affordable.

(a) CPU Overhead (b) Memory Overhead

Figure 14: Overhead per stream mixing task (Results at 10th, 25th, 50th, 75th, 90th percentile at dipicted)

8 Deployment Experiences

8.1 User Experience Optimization

AV synchronization. The switching of streaming mode comes with a change in user interface layout, *e.g.*, between a full screen view of the host broadcaster and a grid gallery of all co-broadcasters. In our internal subjective tests, we find that it is hard to notice momentary video stalls during such a layout change. Therefore, we can inject artificial video rebuffering (*i.e.*, by re-encoding or replaying several previous video frames) when switching the streaming mode for the purpose of AV (audio-to-video) synchronization. While doing so, we still try to deliver seamless audio, and manage to "conceal" video rebuffering during UI transitions.

Adaptive playback speed. Adaptive playback speed control [38, 39] has been a common technique in live streaming to resist rebuffering. In AnchorNet, it is also used to handle the gap of end-to-end streaming delay between the two streaming modes. When switching to collaborative streaming, the viewer-side player may slow down the live streaming playback, if the remaining buffered frames has the risk of being exhausted before arrival of the first collaborative streaming frame. When switching to live streaming, the player may otherwise speed up the playback to lower the end-to-end delay.

Adaptive video bitrate. On the publishing path to CDN, the (co-)broadcaster adjusts the video resolution and bitrate according to not only available uplink bandwidth, but also

real-time device performance. Just like insufficient bandwidth, conditions such as low battery power and overheating also cause bitrate degradation. Simulcast [20] is another option for adaptive bitrate between co-broadcasters. We do not activate simulcast in AnchorNet to save bandwidth consumption on broadcaster side. On the distribution path to viewer, we rely on CDN to transcode the mixed stream into lower-bitrate versions, to accommodate viewers with a weak access network.

8.2 Tradeoff between Experience and Cost

After fulfilling the dominant majority of users, we tend to prioritize cost control over the pursuit of extreme QoE.

RTC server distribution. When analyzing issues of our first-generation architecture in §3.2, we exemplify a scenario where there are only CDN PoPs but no RTC servers in a country. That is a common result of lowering server-side cost. For CDN distribution, we can consume standard service from 3rd-party providers in addition to constructing our own clusters. Yet for RTC servers, we need to purchase server instances to deploy our server-side SDK. The latter is often more expensive. Furthermore, we do not need RTC servers to be distributed as widely as CDN PoPs, because non-RTC services (*e.g.*, on-demand short video streaming) currently account for a significantly higher traffic volume at TikTok. At this stage, we geographically plan RTC clusters so that end-to-end latency of our RTC services satisfy industry norms.

Streaming protocol selection. Aimed at sub-second level end-to-end delay, some pioneering CDN and cloud providers have supported end-to-end WebRTC-based live streaming [30, 40–42]. However, that is not yet universally supported, *e.g.*, it is listed as a beta feature at some providers [43]. Therefore, WebRTC-based streaming service is usually more expensive than more mature RTMP ingest and HTTP distribution [44]. As of now, some CDN providers double their charges for WebRTC-based distribution over traditional distribution [45, 46]. Although end-to-end WebRTC can further reduce the streaming delay, that only brings marginal benefits considering that AnchorNet already satisfies most of our viewers' latency requirements. Therefore, we stick to the choices of RTMP ingest and HTTP distribution for now.

8.3 Future Direction: Enhanced Flexibility

AnchorNet adopts a fixed publishing path (*e.g.*, SFU as CDN publisher, stream mixing on server side) and static streaming protocols (*e.g.*, RTMP ingest, HTTP distribution), to lower implementation complexity and balance server-side cost. As AnchorNet approaches full deployment, we plan to introduce more flexibility to our streaming architecture.

Flexible stream mixing spot. AnchorNet effectively implements viewer-side stream mixing between co-broadcasters. Each co-broadcaster receives other co-broadcasters' streams from the connected SFU, and renders them altogether. To balance server-side cost and user experience more flexibly, AnchorNet can be combined with the other two stream mixing choices accordingly. For example, for a host broadcaster using a recently released high-performance smartphone, we can offload stream mixing to the broadcaster side when the number of co-broadcasters is below a small threshold. In certain use cases urging tight end-to-end latency (*e.g.*, e-commerce), a proportion of high-value customers may utilize viewer-side stream mixing, by pulling (co-)broadcasters' streams from SFU using RTP instead of HTTP FLV.

There are also many other open research problems not listed here that are orthogonal to streaming architecture design. For example, the subjective QoE study based on a unified system like AnchorNet will need to synthesize different user roles with possibly heterogeneous requirements (e.g., co-broadcasters as RTC users, and viewers as non-RTC streaming consumers).

9 Related Works

Stream splicing. One of the early discussions on the stream splicing problem dealt with the switching between television programs. Some works [47, 48] proposed to splice the video streams of two programs at the boundary of two video frames. Since audio signals before and after program switching come from different sources, a short gap is acceptable. In the context of VoIP, [49–52] worked on switching audio codec amid an ongoing session, *e.g.*, selecting the optimal codec based on network conditions. They focused more on the audio fidelity (*e.g.*, MOS, Mean Opinion Score) achieved by different codecs, and did not eliminate the audio frame-level glitches as we do in §5. Similar codec switching was also studied in video streaming [53–55]. Different from the audio case, seamless video can be ensured as long as the codec switching does not break the completeness of individual video frames.

CDN streaming architecture. CDN-based content distribution has been extensively studied aimed at both on-demand web contents (*e.g.*, DASH video [56]) [57–60] and live streaming [61–63]. Recently, the surge of real-time communication poses the requirement for low-latency delivery. To fulfill more stringent end-to-end latency, LiveNet [24] presented a flat CDN architecture with dynamically optimized per-live stream overlay distribution paths. In addition, some evolved CDN architectures were explored. PCDN [64] enabled end users to download from multiple more affordable edge nodes in parallel for better server-side cost-effectiveness. Tian *et al.* proposed to offload user traffic to cheaper alternative edge nodes (*e.g.*, user-leased set-top boxes) [65]. Those works are complementary to AnchorNet, but they mostly focused on the live streaming mode only, *e.g.*, each viewer subscribes to a live stream with a single broadcaster.

RTC conferencing architecture. A typical scenario of interactive real-time communication is multi-party conferencing. On that front, some early-stage WebRTC implementations adopted a P2P approach [66, 67], letting end users directly connect to each other without intermediate server participation.

While scaling to larger conferences, most service providers deploy the MCU or SFU architecture using media servers. From the perspective of where to mix streams, MCU belongs to server-side stream mixing, and SFU enforces viewer-side stream mixing. SFU can be utilized by simulcast [19, 20, 68] to adapt to heterogeneous access links at different participants, *i.e.*, each publisher uploads the same stream in different bitrates, and SFU determines which to forward. With lower server-side computation overhead, SFU has been the dominating architecture in modern multi-party video conferencing [20, 69, 70]. In AnchorNet, co-broadcasters effectively form a multi-party conference room connected via SFUs, and an MCU is leveraged towards the viewers of a channel. As explained in §2.2, the latter choice is mainly owing to the fact that the number of viewers per live channel may be dramatically larger than that of participants per conference room.

First/Last-mile transport optimization. Another research direction that are orthogonal to AnchorNet is the optimization of transport protocols and congestion control algorithms targeted at fluctuating first/last-mile access links. Multipath transport protocols attract widespread attention due to its ability to combine bandwidth of different links and avoid temporary latency inflation on a specific link [71–74]. Congestion control algorithms are specifically designed to satisfy low latency requirements of live media contents [75–77]. A big category of works adopt learning approaches to adapt to complicated network characteristics. For example, Antelope [78] trained a machine learning model to dynamically select the congestion control algorithm best suited for given network conditions. SLVS [79] tuned the bitrate for live streaming by learning from various network features. AutoRec [80] took advantage of the on-off pattern in the transmission of live streams in an online learning-based loss recovery policy.

10 Conclusion

In this paper, we share the design and deployment of AnchorNet, TikTok's new live streaming architecture. Built on basis of our first-generation architecture, DualNet, we set smooth switching between live and collaborative streaming as the top objective of AnchorNet. For that purpose, it unifies the publishing path from the broadcaster to CDN by placing RTC servers between them, and leverages various splicing techniques to avoid audio glitches induced due to inherent codec issues such as encoder delay. AnchorNet significantly outperforms DualNet in our large-scale A/B test. More importantly, AnchorNet, representing our own design perspectives, provides practical insights on operating a live streaming service on a global scale.

Abstract

Text-to-image (T2I) generation using diffusion models has become a blockbuster service in today's AI cloud. A production T2I service typically involves a serving *workflow* where a base diffusion model is augmented with many ControlNet and LoRA adapters to control the details of output images, such as shapes, outlines, poses, and styles. In this paper, we present KATZ, a system that efficiently serves a T2I workflow with many adapters. KATZ differentiates compute-heavy ControlNets from compute-light LoRAs, where the former introduces significant computational overheads while the latter is bottlenecked by loading. KATZ proposes to take ControlNet off the critical path with a ControlNet-as-a-Service design, in which ControlNets are decoupled from the base model and deployed as a *separate, independently scalable service* on dedicated GPUs, thus enabling ControlNet caching, parallelization, and sharing. To hide the high LoRA loading overhead, KATZ employs *bounded asynchronous loading* that overlaps LoRA loading with initial base model execution by a maximum of K steps, while maintaining the same image quality. KATZ further accelerates base model execution across multiple GPUs with *latent parallelism*. Collectively, these designs enable KATZ to outperform the state-of-the-art T2I serving systems, achieving up to 7.8× latency reduction and 1.7× throughput improvement in serving SDXL models on H800 GPUs, without compromising image quality.

1 Introduction

Text-to-image (T2I) generation using diffusion models is a transformative AI technology that enables the creation of high-quality, contextually accurate images from textual descriptions. This technology has gained immense popularity, with a plethora of commercial T2I services available in the cloud, such as DALL·E [9], Midjourney [5], and Firefly [11].

A production T2I service is typically deployed as a *workflow* consisting of multiple components. At its core is a base stable diffusion model [19, 32, 39]. This model is trained to produce a coherent image through a *reverse diffusion process* [40]: it starts with an image composed of random noises and progressively denoises this random input in iterations, until the output image aligns with the provided text description. A base diffusion model is often augmented with various *adapters* to better control the details of the output images, such as shapes, outlines, poses, and styles. Fig. 1 illustrates the effects of using ControlNet [69] and LoRA (Low-Rank Adaptation [28]), the two most popular adapters used in production. ControlNet allows users to input a reference image to guide the spatial composition of the generated image; LoRA produces an image with customized stylistic effects. In our production platform, over 98% of requests demand at least one ControlNet, and over 95% utilize at least one LoRA (§3).

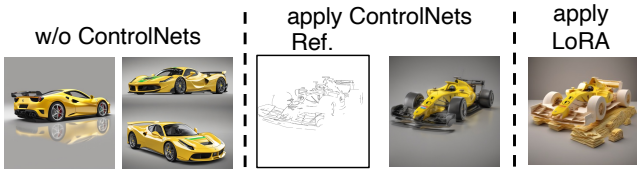

Figure 1: Effects of ControlNet and LoRA in image generation with SDXL under the same prompt: racing game car, yellow Ferrari. **Left**: without ControlNet, the generated images can have different compositions. **Center**: ControlNet uses a reference image to control the composition. **Right**: using LoRA to generate image in a papercut style.

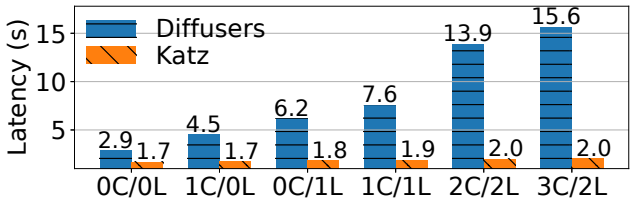

Figure 2: **C**ontrolNets and **L**oRAs introduce additional latency overhead. In each workflow, a base SDXL [39] model is augmented with m ControlNets and n LoRAs (mC/nL), served by DIFFUSERS [50] and KATZ on H800 GPUs.

However, the use of adapters poses new performance challenges. To illustrate this problem, we configure a T2I workflow where a base SDXL model [39] is augmented with a varying number of ControlNets and LoRAs. We depict in Fig. 2 the serving latency of these workflows (blue bar). Compared with serving the base model alone (zero ControlNet and

*Equal contributions.

LoRA, or 0C/0L), serving it together with many adapters results in significant delay, which is increasing as more adapters are in use. This delay comes from two sources. **First**, as the desired ControlNets and LoRAs vary across requests, they must be fetched from storage and loaded into GPU memory, introducing non-trivial loading overhead. In our platform, on average each request undergoes loading one ControlNet and one LoRA, which accounts for 37% of the end-to-end serving latency (§3). Given the large population and sizes of these adapters, pre-caching all of them in GPU memory is *infeasible*: our production trace reports nearly 150 distinct ControlNets (∼3 GiB each) and 14,500 LoRAs (hundreds of MiB each) requested by users for the SDXL model [39]. **Second**, ControlNet serving is compute-intensive: on an H800 GPU, adding one ControlNet to the serving workflow extends the generation latency by 1.6 seconds, which is 1.6× longer than serving the base SDXL model alone (Fig. 2). As more ControlNets are utilized, their computational overhead accumulates, leading to a significant latency increase (Fig. 2).

Despite these challenges, efficiently serving a T2I workflow with many adapters has been largely unexplored; prior works [12, 30, 50, 56] primarily focus on improving the serving latency and image quality of a single diffusion model. In this paper, we propose KATZ[1], a system that efficiently serves a T2I workflow where a base diffusion model is augmented with many ControlNets and LoRAs, a typical setting in production deployment. Driven by a characterization study in a production platform (§3), KATZ employs three key designs to optimize the per-request serving latency [9, 12].

ControlNet-as-a-Service. Efficient ControlNet serving requires addressing the GPU loading and computational overhead. Our characterization study reveals that ControlNets exhibit the *skewed popularity*; that is, a small number of ControlNets (9–11%) are invoked frequently by a large number of user requests (95–98%). Caching these popular ControlNets in GPU memory largely eliminates the loading overhead, with only modest memory footprint. To accelerate computation, KATZ *concurrently executes* ControlNet(s) with the base model on *multiple GPUs*, achieving *close-to-ideal speedup* compared to the current sequential execution scheme [50].

KATZ proposes *ControlNet-as-a-Service* to enable ControlNet caching and parallelization. It decouples ControlNets from the base model and deploys them as a *separate, independently scalable service on dedicated GPUs*. It only caches a small number of top popular ControlNets in GPU memory, eliminating the loading overhead by a large degree. To request certain ControlNets, users simply invoke this service, which executes the requested ControlNets in parallel with the base model. This design additionally enables ControlNet sharing, where a single ControlNet can be multiplexed by multiple base models.

[1]Our system is named after Morris Katz, the world's fastest painter according to the Guinness World Record.

Bounded asynchronous LoRA loading. Unlike ControlNet, LoRA is compute-light and LoRA loading is the main performance bottleneck. Given their large populations, LoRA adapters are usually maintained in storage (local disk or remote memory) and must be brought into GPU memory on-demand. Caching top popular LoRAs offers limited benefits as LoRA popularity exhibits a *heavy-tailed distribution* (§3.2).

To address this challenge, we analyze the T2I generation process and find that LoRA computations take effect largely in the *later stages* of the denoising process (§6). Based on this observation, we propose to hide the LoRA loading overhead through *bounded asynchronous loading* (BAL). That is, while the requested LoRAs are being loaded into GPUs, KATZ simultaneously executes the base model to early start the image generation process by *up to K* steps, after which the LoRA adapters must be patched to the base model to continue the remaining generation steps. By tuning the asynchronous bound K, KATZ effectively overlaps LoRA loading with base model execution, while achieving the same image quality as synchronous loading (§9.2).

Latent parallelism for CFG computation. KATZ also exploits parallelization opportunities to accelerate base model execution. As mentioned earlier, T2I generation is essentially a denoising process, where the diffusion model progressively refines a *latent tensor* through multiple steps [19, 32, 39]. Each step performs classifier-free guidance (CFG) [27], where the input latent tensor is duplicated and the two replicas are respectively denoised, one guided by the text prompt (conditioned denoising) and the other unguided (unconditioned denoising); the two denoised latent tensors are then aggregated by computing a weighted sum. As conditioned and unconditioned denoising have no dependency, KATZ parallelizes them on two GPUs. This technique, which we call *latent parallelism*, is also applied to accelerate CFG computation in ControlNet serving. Latent parallelism, together with kernel-level optimizations, collectively accelerate base model execution by 1.8× (§9.5).

We have implemented KATZ on top of HuggingFace Diffusers [50] and evaluated its performance using text prompts from PartiPrompts [64]. Our evaluation encompasses SDXL [39], a popular UNet-based diffusion model [42] in production [12, 46], and two diffusion transformer (DiT) models [19, 32, 38]. Evaluation results demonstrate that KATZ outperforms the state-of-the-art T2I serving systems, including Diffusers, Nirvana [12], and DistriFusion [30], reducing the average serving latency by up to 7.8× and improving the throughput by up to 1.7× (§9.2). To comprehensively assess the quality of the generated images, we engaged 75 human users and confirmed that KATZ produces images of the same quality as Diffusers [50], a lossless baseline. Our contributions are summarized as follows:

- We present the first characterization study in a production T2I platform and identify new challenges of serving base diffusion models with ControlNet and LoRA adapters.

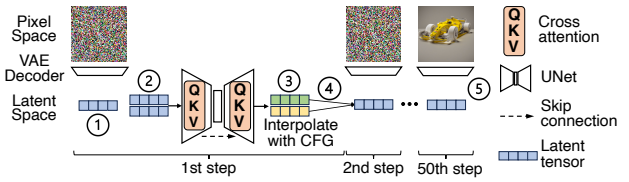

Figure 3: Image generation using a stable diffusion model. Time and token embeddings are ignored for simplicity.

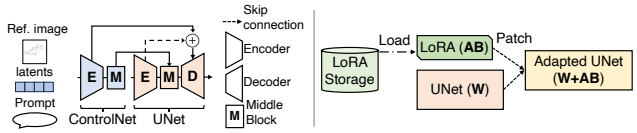

Figure 4: Serving a diffusion model with ControlNet (**Left**) and LoRA (**Right**).

- We propose a holistic approach with three key designs to systematically optimize the T2I serving workflow, including ControlNet-as-a-Service, bounded asynchronous LoRA loading, and latent parallelism for CFG computation.
- We develop KATZ, an optimized serving system for T2I applications that achieves significant speedup without compromising image quality (Fig. 15).

KATZ and the production trace have been open-sourced at https://github.com/modelscope/Katz.

2 Background

In this section, we give a primer to diffusion-based T2I generation and the use of two popular adapters, ControlNet and LoRA, for enhanced generation control.

Diffusion model. A typical stable diffusion model [15, 39, 41] consists of three main components: a text encoder [40], a convolutional UNet model [42], and a decoder-only variational autoencoder (VAE). The model generates images through an iterative denoising process illustrated in Fig. 3. Given a text prompt, the text encoder encodes the prompt into token embeddings. The image generation process then begins by initializing a *latent tensor* filled with *random noise* (①), which is progressively refined by the UNet over multiple denoising steps guided by the token embeddings. To steer the image generation towards the desired outcome, the UNet employs classifier-free guidance [27] (CFG). Specifically, at each denoising step, the UNet duplicates the latent tensor into two replicas (②); one replica is denoised *conditionally*, taking into account the token embeddings, whilst the other is denoised *unconditionally*. Intuitively, the unconditioned latent representation captures the general image distribution, whereas the conditioned representation incorporates specific context given by the text prompt (③). The two latent tensors are then combined by computing a weighted sum, yielding an interpolated latent representation for further refinement in the next step (④). Upon completion of the denoising process, the final interpolated latent tensor is sent to the VAE decoder to render the output image (⑤).

ControlNet. Users often find it challenging to control the details of output images because text prompts alone are insufficient to precisely specify complex layouts, compositions, and shapes. ControlNet addresses this issue by augmenting a base diffusion model with additional input conditions, such as edge maps and depth maps, which specify the desired spatial composition of the generated images. As illustrated in Fig. 1-Center, ControlNet enables users to provide a reference edge map, allowing the base model to generate a Ferrari that adheres to the specified spatial composition.

Fig. 4-Left illustrates a simplified workflow of applying a ControlNet in the image generation process. ControlNet has a similar architecture to the UNet encoder blocks and middle block, with additional zero convolution operators [69]. It is applied to each encoder level of the UNet backbone. In each denoising step (Fig. 3), ControlNet takes as input the text prompt, the encoded reference image, and the latent tensor. The outputs, which contain the processed features of the reference image, are then incorporated into the skip-connections and middle block of the UNet backbone, guiding the image generation process to conform to the reference image. In practice, users can apply multiple ControlNets to a single base model, in which the outputs of these ControlNets are simply summed up and applied to the corresponding backbone UNet blocks [69].

Low-Rank Adaptation (LoRA) is another popular adapter that allows for generating images in a customized style (Fig. 1-Right). LoRA is a parameter-efficient approach to adapting the base model for domain-specific tasks [28]. Specifically, given a pre-trained base model with weight matrix $\mathbf{W} \in \mathrm{R}^{H_1 \times H_2}$, LoRA introduces two low-rank matrices $\mathbf{A} \in \mathrm{R}^{H_1 \times r}$ and $\mathbf{B} \in \mathrm{R}^{r \times H_2}$, where $r \ll \min\{H_1, H_2\}$ is the LoRA rank. One can simply patch the LoRA weights to the base matrix, i.e., $\mathbf{W}' = \mathbf{W} + \mathbf{AB}$, and use the adapted diffusion model $\mathbf{W}'$ to generate stylized output with the desired visual characteristics, as illustrated in Fig. 4-Right.

Other adapters. Our work primarily focuses on ControlNet [69] and LoRA [28], the two most popular adapters in production environments (§3). Meanwhile, there are many emerging adapters [29, 52, 62, 68, 70] introduced by the research community to enhance image generation. These adapters can be broadly categorized into two classes. The first comprises adapters that operate in tandem with the base model during inference, akin to ControlNet. Examples include IP-Adapter [62] and BrushNet [29]. The second class consists of adapters that augment the base model by incorporating parameter-efficient patches, similar to LoRA [28], including Fooocus Inpaint [68] and IC-Light [70]. Because of the similarity, the techniques developed for expedited ControlNet and

Adapters	Number	Service A	Service B
ControlNet	0	0	1.9%
	1	30.5%	25.1%
	2	69.5%	69.9%
	3	0	3.1%
LoRA	0	0.2%	7.2%
	1	8.8%	73.6%
	2	91%	19.2%

Table 1: The distribution of the number of ControlNets and LoRAs used by each request in two production services.

LoRA serving can be easily extended to the two classes of emerging adapters, which we discuss in §10.

Limitations of current T2I serving systems. Diffusion-based T2I workflow serving should provide low latency to allow real-time user interaction to better support multi-round prompt editing and image fine-tuning [9, 12]. DIFFUSERS is the state-of-the-art system that supports T2I serving workflow with ControlNets and LoRAs [50]. It generates images of original quality but incurs significant latency overhead, especially as more adapters are being used (Fig. 2). Recently proposed T2I serving systems, such as NIRVANA [12] and DISTRIFUSION [30], focus solely on optimizing base diffusion model inference. NIRVANA [12] proposes to skip the first κ denoising steps by using a pre-cached image generated from a similar prompt to replace the randomly initialized noise latent (Fig. 3). DISTRIFUSION [30] uses multiple GPUs to a diffusion model to accelerate image generation. It splits the latent (② in Fig. 3) into small patches and parallelizes the computation on multiple GPUs, outperforming tensor parallelism [44] with improved communication efficiency [30]. We will show in §9 that these systems, though efficient in base model inference, fall short in workflow serving with many adapters, resulting in extended latency and quality loss.

3 Characterization Study

In this section, we present a characterization study on a 20-day workload trace collected in May and June 2024 on a production platform[2]. The trace contains more than 500k inference requests to two core T2I services for online retailing applications. Our characterization not only reflects the deployment scenarios of diffusion models in production, but also reveals the inefficiency of current T2I serving systems.

3.1 ControlNet Characterization

Prevalence. Table 1 shows the distribution of the number of ControlNets utilized by each request in two services. ControlNet is used by almost all requests for image generation control; approximately 70% of these requests utilize two or more ControlNets simultaneously.

[2] https://modelscope.cn/datasets/mental2008/T2I-Model-Serving-Request-Trace

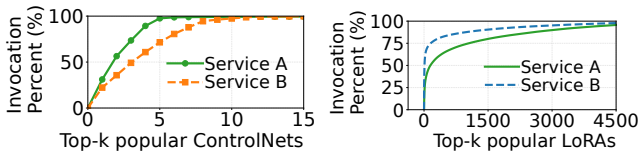

Figure 5: **Left**: ControlNet has a small population and exhibits a skewed popularity; the long tail of the graph is truncated for a better presentation. **Right**: LoRA has a large quantity and exhibits a long-tailed distribution in popularity.

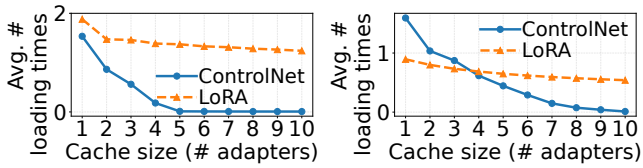

Figure 6: Configuring a larger LRU cache effectively eliminates the adapter loading overhead for ControlNets, but not for LoRAs. **Left**: Service A; **Right**: Service B.

Skewed popularity. Compared to a large quantity of requests, only 141 ControlNets are used in two services, where Service A offers 47 distinct ControlNets and Service B provides 94. These ControlNets exhibit a severe skewness in access frequency. As shown in Fig. 5-Left, the top-5 most popular ControlNets (11% in population) account for 98% of total invocations in Service A. When it comes to Service B, the top-8 most popular ControlNets (9% in population) contribute to 95% of total invocations.

The need for ControlNet caching. ControlNets are large in size (3 GiB each) and usually maintained in remote storage, introducing significant loading overhead. Given that ControlNets have a limited quantity and skewed popularity, caching a small number of top popular ControlNets in GPU memory effectively eliminates the loading overhead for most requests. To illustrate this, we configure an LRU cache of varying size for ControlNet caching. We replay the trace and measure the average number of times that the desired ControlNets are not resident on GPU and must be fetched from storage (i.e., cache miss) when serving two consecutive requests that desire different ControlNets. As illustrated in Fig. 6 (blue curves), caching only a handful of top popular ControlNets is sufficient to eliminate the loading overhead for both services (top-5 for Service A and top-8 for Service B). Similar results are observed if we replace the LRU cached with an LFU (Least Frequently Used) cache.

Computational overhead. ControlNet is compute-heavy as it shares a similar architecture to the UNet encoder and middle block (§2). As illustrated in Fig. 2 (blue bars), augmenting the base diffusion model with one ControlNet increases the serving latency by 1.6× (up from 2.9 seconds to 4.5 seconds). As more ControlNets are utilized, their computational overhead accumulates because current T2I serving systems [50] *se-*

quentially compute the outputs of the requested ControlNets before executing the base model at each denoising step.

3.2 LoRA Characterization

Prevalence. Similar to ControlNet, the majority of T2I requests utilize one or two LoRAs to stylize the generated image, as summarized in Table 1. Specifically, over 90% of requests in Service A desire two LoRAs, while nearly 93% of requests in Service B demand at least one LoRA.

Long-tailed popularity distribution. Compared to ControlNets, LoRAs have a significantly larger population but smaller sizes. Our trace reports 6,980 distinct LoRAs for Service A and 7,463 LoRAs for Service B. Each LoRA is a few hundreds of MiB. Unlike ControlNets, the popularity of LoRAs follows a *long-tailed distribution*; that is, a significant portion of LoRA invocations are contributed by a large number of *less popular* adapters, as illustrated in Fig. 5-Right. In Service A, 6,968 LoRAs (99.8% of the total 6,980) each account for less than 1% of invocations. Similarly, in Service B, 7,449 LoRAs (99.8% of the total 7,463) each contribute to less than 1% of invocations.

Ineffective LoRA caching. Given the long-tailed popularity distribution of LoRAs, caching the top popular LoRA adapters offers *limited benefits*. To demonstrate this, we configure an LRU cache of varying sizes for LoRA caching. We replay the trace and measure the average number of times that the desired LoRAs are not available on GPU and must be brought from storage (i.e., cache miss) when serving two consecutive requests that demand different LoRAs. As illustrated in Fig. 6 (orange curves), configuring a larger LRU cache only slightly reduces the loading overhead caused by cache misses. We also measure the cache misses with an LFU cache and observe similar results. For Service B with a cache size of 10, LRU and LFU achieve comparable average loading times due to cache misses, at 0.54 and 0.57, respectively. Intuitively, LFU favors LoRAs with high long-term popularity and LRU prioritizes LoRAs with high short-term popularity. However, due to the dynamic nature of LoRA invocation patterns and their long-tailed distribution, predicting invocation traffic remain challenging, making approaches fall short.

As another evidence, Fig. 7 depicts a scatter plot illustrating the number of requests served on each node in the trace and the number of *unique* LoRAs utilized by those requests on that node. We observe the linear correlation between the two numbers, invalidating the benefits of LoRA caching. Our production system hence chooses not to cache LoRAs but loads them from storage in an on-demand fashion.

LoRA loading and patching overhead. Compared to ControlNets, LoRAs are compute-light and LoRA serving is bottlenecked by the loading and patching overhead (Fig. 4-Right). Our measurements show that fetching two LoRAs (total size of approximately 800 MiB) from a remote distributed cache

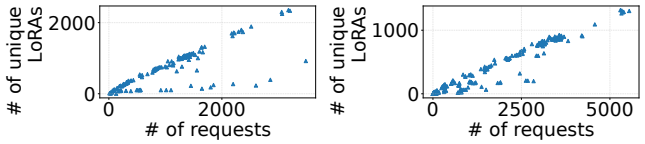

Figure 7: Scatter plots illustrating the number of requests received on each worker node (X-axis) against the number of unique LoRAs required by those requests (Y-axis). **Left**: Service A; **Right**: Service B.

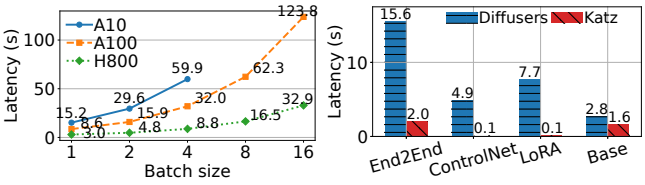

Figure 8: **Left**: Ineffective Batching for SDXL inference. **Right**: End-to-end latency and component breakdowns for a 3**C**/2**L** request, using Diffusers [50] and KATZ on H800.

takes more than one second, delaying the base model serving by 34% (up from 2.9 seconds to 3.9 seconds). In addition, simply patching LoRA weights to the base model, as implemented in existing systems [37, 50], incurs high overhead, which we elaborate in §6.

3.3 Characterizing Base Model Serving

Currently, UNet-based diffusion models, such as SDXL [39], are predominately deployed to handle the majority of requests in production platforms. These models are supported by a plethora of well-trained ControlNets [69] and LoRAs [28]. In the meantime, there is an emerging trend of deploying transformer-based diffusion models (DiT) [19, 32], but the development of corresponding adapters remains lagging behind at the moment. In this paper, we primarily focus on UNet-based models; our observations and optimization designs also apply to the transformer backbone.

Ineffectiveness of batching. Diffusion model serving is computationally intensive, as evidenced by our experiments with varying batch sizes for a standard SDXL model [39] on NVIDIA A10, A100, and H800 GPUs (Fig. 8-Left). Across all three GPUs, doubling the batch size results in an approximately 2× in serving latency, indicating minimal benefits from batching. In fact, generating a single image already saturates the computational resources of a high-end GPU. According to [30], the computational cost of generating a 1024×1024 image with SDXL requires 676T FLOPS, where the token length involved in SDXL's transformer computations can reach up to 4096, resulting in a high computational load. Consequently, production T2I services typically configure a constant batch size of 1 to minimize serving latency. That being said, we expect more performance gains from

Notation	Description
S	Number of denoising steps
M	Number of ControlNets used
N	Number of LoRAs used
$T_{\mathrm{C}_i}^{\mathtt{Load}}$, $T_{\mathrm{C}_i}^{\mathtt{Comp}}$	Time to load and compute **C**ontrolNet C_i
$T_{\mathrm{L}_j}^{\mathtt{Load}}$, $T_{\mathrm{L}_j}^{\mathtt{Patch}}$	Time to load and patch **L**oRA L_j
$T_{\mathrm{Enc}}^{\mathtt{Comp}}$	Time to compute the text encoder inference
$T_{\mathrm{VAE}}^{\mathtt{Comp}}$	Time to compute the VAE decoder inference
$T_{\mathrm{B}}^{\mathtt{Comp}}$	Time to compute the base model inference
$T_{\mathrm{B}^*}^{\mathtt{Comp}}$	Optimized base model inference time

Table 2: Notations used to model T2I inference latency.

batching when using more powerful GPUs.

Dominated CFG computation. To understand the computation of the base diffusion model, we break down its execution and find that over 90% of the inference time is spent on CFG computation (§2). Current CFG implementation employs *latent batching*. That is, at each denoising step, the latent tensor is duplicated and the two replicas are fed into the base model to perform conditional and unconditional denoising in *one batch* on a GPU. However, as the two denoising operations are compute-heavy, batch-executing them yields minimal benefits. In fact, latent batching results in up to 1.7× slowdown in base model serving compared to our optimized design (§9.5).

3.4 Latency Overhead of Current Systems

To sum up, current T2I systems serve the base model and the associated adapters in a *sequential execution pipeline*. Specifically, assume a request utilizing m ControlNets and n LoRAs. Upon request arrival, the system loads all the desired ControlNets and LoRAs into GPU memory, followed by patching the n LoRAs to the base model. The system then encodes the text prompt and proceeds to the denoising process in S steps. At each step, it sequentially executes the m ControlNets and the LoRA-patched base model to generate a latent representation. The final latent representation is then sent to the VAE decoder to generate the output image. The end-to-end workflow serving latency is given by Eq. (1), where the notations are defined in Table 2:

$$T = \underbrace{\sum_{i=1}^{M} T_{\mathrm{C}_i}^{\mathtt{Load}} + \sum_{j=1}^{N} (T_{\mathrm{L}_j}^{\mathtt{Load}} + T_{\mathrm{L}_j}^{\mathtt{Patch}})}_{\text{time to load and patch adapters}} + \underbrace{T_{\mathrm{Enc}}^{\mathtt{Comp}} + (\sum_{i=1}^{M} T_{\mathrm{C}_i}^{\mathtt{Comp}} + T_{\mathrm{B}}^{\mathtt{Comp}}) \times S + T_{\mathrm{VAE}}^{\mathtt{Comp}}}_{\text{computation time for multi-step image generation}}. \quad (1)$$

Our characterization identifies efficiency issues concerning ControlNet loading ($\sum_{i=1}^{M} T_{\mathrm{C}_i}^{\mathtt{Load}}$), sequential ControlNet execution ($\sum_{i=1}^{M} T_{\mathrm{C}_i}^{\mathtt{Comp}}$), slow LoRA loading ($\sum_{j=1}^{N} T_{\mathrm{L}_j}^{\mathtt{Load}}$) and patching ($\sum_{j=1}^{N} T_{\mathrm{L}_j}^{\mathtt{Patch}}$), and inefficient latent batching in base model execution ($T_{\mathrm{B}}^{\mathtt{Comp}}$), collectively accounting for up to 99% of end-to-end serving latency (Fig. 8-Right).

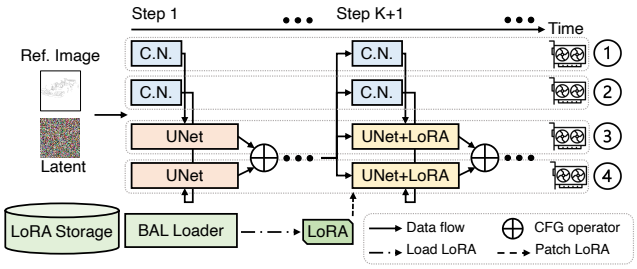

Figure 9: KATZ utilizes 4 GPUs to serve a base model with 1C/1L, two for the base and two for the **C**ontrol**N**et (**C.N.**).

4 Design Overview

To address the efficiency issues identified in §3, we propose KATZ, a system that efficiently serves a T2I workflow with many adapters. KATZ employs three key designs. **First**, to reduce the overhead of ControlNet loading and computation, KATZ introduces ControlNet-as-a-Service, enabling ControlNet caching and parallelization in a unified design (§5). **Second**, to mitigate LoRA loading and patching overheads, KATZ overlaps LoRA fetching with base model execution for a bounded steps (bounded asynchronous LoRA loading or BAL), and uses an efficient method to quickly patch LoRA adapters (§6). **Third**, KATZ accelerates CFG computation by concurrently executing conditional and unconditional denoising operations on two GPUs, a technique called *latent parallelism*, together with kernel-level optimizations (§7). Fig. 9 illustrates an example of serving a base diffusion model with one ControlNet and one LoRA (1C/1L). Latent parallelism is applied to accelerate both the base model and the ControlNet, each using two GPUs; LoRA is asynchronously loaded, in parallel with initial base model execution for up to K steps before patching to hide the loading overhead.

In practice, the loading and computational overhead associated with ControlNets and LoRAs are virtually eliminated in KATZ (Fig. 8-Right), reducing the end-to-end workflow serving latency from Eq. (1) to

$$T = T_{\mathrm{Enc}}^{\mathtt{Comp}} + T_{\mathrm{B}^*}^{\mathtt{Comp}} \times S + T_{\mathrm{VAE}}^{\mathtt{Comp}}. \quad (2)$$

Collectively, our designs achieve up to 7.8× reduction in latency (Fig. 8-Right) and 1.7× throughput improvement, without compromising image quality (more in §9.2).

While we present KATZ primarily based on diffusion models with the UNet backbone, our designs also apply to the recently proposed diffusion transformers (DiTs) [19, 32, 38].

5 ControlNet-as-a-Service

For ControlNet serving, the main overhead comes from adapter loading and computation, which is tightly coupled with base model execution: as more ControlNets are utilized, their overheads accumulate (§3.1). We address this problem with a principled ControlNet-as-a-Service approach.

ControlNet-as-a-Service. Unlike existing systems, KATZ decouples ControlNet execution from the base diffusion model and deploys ControlNets as a *separate, independently scaled service* on *dedicated* GPUs. This design provides three benefits. **First**, by deploying ControlNets as an independent service, multiple ControlNets can execute in parallel with the base model on multiple GPUs and synchronize only at the end of each denoising step (details to come), effectively hiding their computational overhead. **Second**, the service can easily track the popularity of each ControlNet and cache a small number of top popular ones in GPU memory, which is sufficient to eliminate the loading overhead given their skewed popularity as identified in §3.1. **Third**, the separated ControlNet service can be shared among many T2I workflows in a multi-tenant system, enabling a single ControlNet to be multiplexed by many base models and scaled out according to the request load.

ControlNet parallelization. Without changing the data flow between ControlNets and the base model, KATZ partitions the entire compute graph of image generation into a *serial* part and a *parallel* part. For the UNet-based SDXL model [39], the *serial* part consists of the one-time computation of the text encoder, one-time computation of the VAE decoder, and UNet decoder computations of denoising steps (§2). The *parallel* part consists of the computations of UNet's encoder and ControlNet(s) at each denoising step (Fig. 4-Left). KATZ distributes the computation of the *parallel* part across multiple GPUs. As illustrated in Fig. 9, it deploys the base UNet model on one set of GPUs and each ControlNet on a different set, operated as a separate service. At each denoising step, the UNet encoder and ControlNet(s) initiate computation concurrently. Upon completion of the UNet middle block inference, the UNet decoder *synchronously* awaits the outputs from ControlNet(s) before its computation, thereby preserving the original data dependencies (Fig. 4-Left). The ControlNet(s) then becomes idle for next invocation.

Performance analysis and optimization. To achieve maximum speedup for parallel computing, it is important to (1) balance the load of concurrent computing tasks and (2) minimize their communications to reduce the synchronization overhead. The first requirement is naturally met in ControlNet parallelization: given that ControlNet shares the same model architecture as the UNet's encoder block and middle block, with the only difference being the additional zero convolution operators [69], their computation load is well balanced, leading to almost the same execution time when running on homogeneous GPUs. Regarding the second requirement, we measure a medium to low data transfer between the base model and the associated ControlNet, e.g., only 108 MiB for SDXL. With high-speed interconnect, such as NVLink [7] and InfiniBand [6], the communication overhead is negligible (e.g., less than 1 ms for SDXL over NVLink). In this scenario, ControlNet parallelization achieves 1.42× speedup

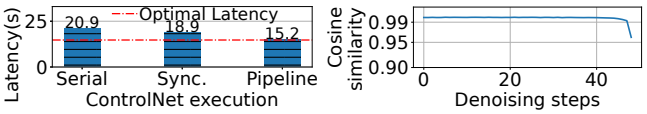

Figure 10: **Left**: Image generation latency using various ControlNet execution schemes on AWS `g5.2xlarge` instances with 10 Gbps network bandwidth (Serial: no parallelization; Sync: synchronous ControlNet parallelization; Pipeline: pipelined asynchronous parallelization). **Right:** Average cosine similarities of ControlNet outputs between two adjacent steps, which are calculated across the channel dimension.

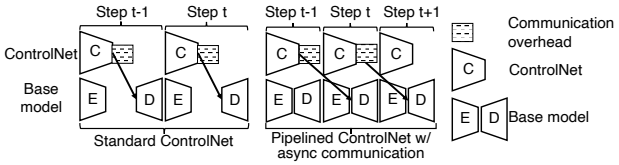

Figure 11: An illustration of ControlNet parallelization (**Left**) and its asynchronous pipeline implementation over slow links (**Right**). The middle blocks are omitted for simplicity.

over NVLink and 1.34× speedup over InfiniBand 400 Gbps link, either on A100 or H800 GPUs, closely matching the ideal speedup of 1.45× given by Gustafson's law [24].

However, when high-speed GPU interconnections are unavailable, communication may become a bottleneck (Fig. 10-Left). In this scenario, we propose *pipelined asynchronous parallelization* to hide the communication overhead. Our key observation is that the output tensor generated by a ControlNet in two adjacent denoising steps are *nearly identical*, with cosine similarity over 0.99 almost all the time, as illustrated in Fig. 10-Right. Based on this observation, we can relax the synchronization requirement between the base model and ControlNets to establish an *asynchronous pipeline*, while still achieving the same image quality. That is, at each denoising step t, the base model performs computation based on the *stale* ControlNet output generated at step $t-1$, which have already been transferred to the base model's GPU during the previous step. Fig. 11 illustrates ControlNet parallelization and its asynchronous pipeline implementation over slow links, where the latter achieves close-to-ideal speedup in our experiments (Fig. 10-Left). We will show in §9.3 that slightly relaxing the synchronization requirement for ControlNet parallelization leads to no quality loss.

Applicability to DiT. ControlNet parallelization is a generic technique that also applies to the emerging DiT-based models, such as SD3 [19] and Hunyuan-DiT [32]. This is because ControlNets for the DiT backbone share the same model architecture as the base model and their data dependencies are analogous to that of their UNet counterparts. One can hence expect the same efficacy for DiT-based models (§9.7).

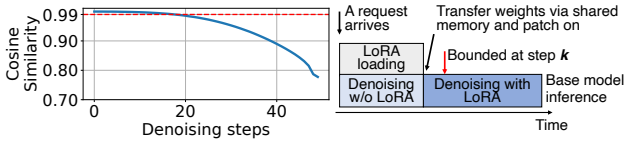

Figure 12: **Left**: Cosine similarities between the latents generated with LoRA and those without LoRA at each denoising step. **Right**: Bounded asynchronous LoRA loading.

6 Efficient LoRA Serving

Motivation. As discussed in §3.2, LoRAs are stored in an external storage (e.g., local disk or remote cache). To apply a LoRA for stylizing the image generation, the system first fetches the adapter from storage and loads it into host memory. After that, it patches the adapter to the base diffusion model by merging its weights with the parameters of the base model. Both LoRA loading and patching incur significant overhead, which accumulates as more LoRAs are utilized (Fig. 2). We address these two problems in this section.

Bounded asynchronous LoRA loading (BAL). We analyze image generation with LoRA and observe a general trend: the effect of LoRA computation is initially imperceptible but, after certain steps, becomes increasingly significant. We empirically validate this by executing the image generation process twice, with and without LoRA. We calculate the cosine similarity between the output tensors generated with and without LoRA at each denoising step and depict the result in Fig. 12-Left. The cosine similarity consistently exceeds 0.99 in initial steps, indicating that LoRA exerts minimal effects during this stage. However, after a certain step (20 steps in this case), the similarity starts to plunge, a turning point at which LoRA effects kick in and become increasingly significant moving forward. Fig. 13 further visualizes the denoising process of image generation with and without LoRA. The initial denoising steps constitute a *semantics-planning stage* [12, 34, 45, 72], wherein the model determines the image composition and layout, generating visual semantics aligned with the text conditions [12, 72]. LoRA computation is less relevant and can be safely excluded during this stage (Fig. 13-Bottom). The remaining generation steps constitute an *artistic-planning stage* with image details gradually emerging, e.g., color, texture, and artistic style [12, 72]. LoRA plays a crucial role in this stage and must be included (Fig. 13-Bottom).

Driven by this observation, KATZ proposes overlapping LoRA loading with base model execution in the initial semantics-planning stage, as shown in Figures 12-Right and 13-Bottom. When a request arrives, KATZ asynchronously loads the requested LoRA(s). In the meantime, it *early-starts* the base diffusion model inference to perform image generation without LoRA. To ensure no quality loss, KATZ imposes an asynchrony bound K for overlapping LoRA loading with base model inference: in the worst case, if the requested LoRAs have not been loaded at the $(K+1)^{\text{th}}$ denoising step, the base model waits until the loading completes. The loaded LoRAs are then patched to the base model to continue the remaining generation steps.

Determining the asynchrony bound. Ideally, we should choose a large asynchrony bound K to maximally overlap LoRA loading with base model inference, subject to no quality loss. KATZ employs a profiling method to optimally determine the asynchrony bound K. Given a base model and a LoRA, KATZ offline calculates the cosine similarity between the latent tensors generated with and without LoRA at each denoising step, akin to those in Fig. 12-Left. It then sets K to the step at which the similarity starts to drop below a predefined threshold, e.g., 0.99. In our evaluation, we profile and set $K = 10$. Our experiment on A100 and H800 GPUs shows that LoRA loading completes mostly before the predefined step K, effectively hiding the adapter loading overhead (c.f. 0C/0L and 0C/1L in Fig. 2).

Efficient LoRA patching. Existing systems [50] use the PEFT [37] framework to merge LoRA weights with base model parameters. For a layer in the base stable diffusion model that will be patched with LoRA, PEFT *creates* a new LoRA layer to *replace* the original layer in the base model. The newly created LoRA layer augments the corresponding base model layer by incorporating LoRA weights and configurations. However, this *create-and-replace* operation incurs high overhead, taking 2 seconds for a LoRA of 341 MiB and occupying additional GPU memory. Although maintaining a separate copy of LoRA weights in the new augmented layer facilitates convenient LoRA training and efficiently patching off LoRA weights after image generation, we find it unnecessary. As a serving system, KATZ does not require the capability to

support LoRA training. Besides, our characterization study reveals that the time interval between two consecutive requests is long enough (over 1 second) to patch off LoRAs. Therefore, KATZ chooses to merge LoRA weights with base model parameters *in place*. This design eliminates the latency overhead caused by the *create-and-replace* operation and saves GPU memory without storing separate LoRA weights.

Applicability to DiT. Our design for efficient LoRA loading and patching is agnostic to the architecture of the base model, and can hence be applied directly to accelerate image generation in DiTs [19, 32].

7 Optimized Base Model Execution

With the overhead of adapters effectively addressed in §5 and §6, we now turn to accelerating base model inference, the last bottleneck in image generation. Given that diffusion model serving is computationally intensive that saturates a high-end GPU even with a small batch size of 1 (§3.3), we explore parallelization opportunities to accelerate CFG computation on multiple GPUs. We also incorporate kernel-level optimizations tailored for diffusion model computation and its interaction with adapters to further enhance performance.

Latent parallelism for diffusion model. As explained in §2, diffusion model uses the CFG technique to better align image generation with textual descriptions at each denoising step, where an input latent tensor is duplicated and undergoes two denoising operations, one conditioned on the texts and the other unconditionally. The two latents are then combined by computing a weighted sum, yielding an interpolated latent as the output. As conditioned and unconditioned denoising have no dependency, they can be performed in parallel on two GPUs, which we call *latent parallelism*. As illustrated in Fig. 9, KATZ maintains two instances of the base diffusion model on two homogeneous GPUs. At each denoising step, KATZ duplicates the input latent tensor (② in Fig. 3) and feeds the two replicas into the two base model instances to perform conditioned and unconditioned denoising in parallel. As the two computations have balanced load, they complete at the same time, and their outputs are then interpolated as a weighted sum through a synchronous communication.

The simple yet effective latent parallelism strategy can accelerate the base diffusion model inference of a request by 1.4–1.9×, depending on the GPU capability and model size. The performance gains are more pronounced with larger base models and lower-end GPUs (details in §9.5). Latent parallelism incurs little overhead because 1) computations on different GPUs are uniform and finish at almost the same time, and 2) the communication overhead is minimal, mainly comprising the transfer of a small latent ($<$ 1 MiB). However, the speedup achieved by latent parallelism may come at the expense of per-GPU throughput when the denoising computation of a single latent does not saturate a GPU. Latent parallelism also applies to the emerging DiT models as they employ the same CFG technique in image generation.

Compatibility with adapter optimizations. Latent parallelism can be naturally applied to accelerate CFG computation in ControlNet serving, as ControlNets are architecturally similar to the base model (§5). Fig. 9 illustrates an example where KATZ utilizes 4 GPUs to serve a base diffusion model and one ControlNet, both with latent parallelism. Meanwhile, the base model also utilizes BAL to overlap LoRA loading with base model computation at each denoising step.

Kernel-level optimizations. KATZ includes several kernel-level optimizations to further enhance performance, including a customized CUDA Graph [21] implementation and specialized CUDA kernels tailored to diffusion models. CUDA Graph is particularly suitable for T2I inference, as it uses a constant batch size of 1 (§3.3). Given the nearly homogeneous requested image resolutions in our production platform, we only need to maintain a small number of CUDA Graphs resident in GPU memory. Furthermore, we adapt the original CUDA graph to accommodate ControlNet parallelization. Specifically, we tailor the base model and segment it as distinct CUDA Graphs according to its data dependencies with ControlNets. Beyond existing optimized attention kernels [1], KATZ provides kernel optimizations specific to UNet-based diffusion models, including an optimized `GEGLU` activation operator by fusing `GELU` and matrix multiplication operations, and a fused operator that combines `GroupNorm` and `SiLU` operators to mask the latter's overhead.

8 Implementation

We have implemented KATZ on top of Diffusers [50], a PyTorch-based diffusion model inference framework that integrates state-of-the-art model optimization techniques. KATZ is written in 5.5k lines of Python and 2.4k lines of C++/CUDA code, where ControlNet-as-a-Service, BAL, and latent parallelism are implemented in Python, whilst customized CUDA operators are written in C++/CUDA. KATZ performs LoRA loading in separate processes and utilizes shared memory to transfer LoRA weights from the loading processes to the base model serving process for efficient (parallel) data transfer.

9 Evaluation

We evaluate KATZ's performance in terms of serving latency and image quality. Evaluation highlights include:

- KATZ achieves efficient serving performance without degrading image quality, accelerating T2I generation by up to 7.8× compared with state-of-the-art baselines (§9.2).
- KATZ's ControlNet-as-a-Service design decouples ControlNets from the critical path of a T2I workflow, achieving a *close-to-ideal* speedup (§9.3).

- KATZ effectively eliminates the LoRA loading and patching overheads, leading to consistent serving latency that matches LoRA-free execution (§9.4).
- With latent parallelism and kernel optimizations, KATZ achieves 1.7× speedup in base model inference (§9.5).
- KATZ increases the per GPU-minute throughput by up to 1.7× (§9.6) and generalizes to DiT-based models (§9.7).

9.1 Experimental Setup

Model and serving configurations. Unless otherwise specified, we use SDXL [39] as the base diffusion model. SDXL and its variants are widely deployed in production systems [12], including ours, and have comprehensive support for adapters. We use the default settings to generate images, where the number of denoising steps is set to 50 and the image resolution is 1024×1024. The ControlNets [3] and LoRAs [47–49] used are provided by HuggingFace. By default, we run experiments on NVIDIA H800 GPUs and configure synchronous ControlNet parallelization for KATZ (§5).

Baselines. We consider the following three baselines:

- DIFFUSERS is a standard baseline for T2I workflow serving with support of ControlNets and LoRAs [50].
- NIRVANA [12] is a strong baseline that skips the first κ denoising steps by using a pre-cached image given by a similar prompt. We use two configurations, $\kappa = 10$ (NIRVANA-10) and more aggressively $\kappa = 20$ (NIRVANA-20).
- DISTRIFUSION [30] is a strong baseline that utilizes multiple GPUs to accelerate base diffusion model inference. We extend it to support ControlNets on multiple GPUs. For a fair comparison, we configure DISTRIFUSION to use no fewer GPUs than KATZ.

Serving metrics. Our evaluation mainly concerns two metrics, *serving latency* and *image quality*. For serving latency, we measure the end-to-end latency of generating an image based on a given text prompt. For image quality, we use the following quantitative metrics, which are considered essential and widely used in measuring image quality [12,39,64,71,73].

- CLIP [25,40] score evaluates the alignment between generated images and their corresponding text prompts. A higher CLIP score indicates better alignment (↑).
- Fréchet Inception Distance (FID) score [26] calculates the difference between two image sets, which correlates with human visual quality perception [12]. A low FID score means that two image sets are similar (↓).
- Structural Similarity Index Measure (SSIM) score [55] measures the similarity between two images, with a focus on the structural information in images. A higher SSIM score suggests a greater similarity between the images (↑).

Like [12,39], we conducted a user study with 75 participants to evaluate the image quality based on their visual perception.

Workloads. KATZ is designed to reduce the serving latency of text-to-image requests associated with many adapters. To evaluate this, we measure per-request serving latency across different adapter configurations on provisioned instances, eliminating the impact of request queuing and model scaling due to load spikes. We configure the batch size to 1 due to the limited batching effect (§3.3). The requests use text prompts in Google's PartiPrompts (P2) [64], a popular benchmark for image generation tasks [36,39,64]. P2 provides a rich set of prompts, including simple and complex prompts across various categories (e.g., Animals, Scenes, and World Knowledge) and challenging aspects (e.g., Detail, Style, and Imagination). We serve each request with several adapters, following our production trace (Table 1).

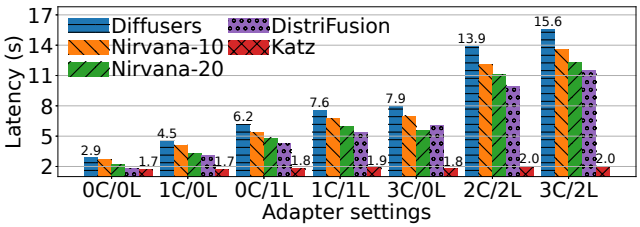

Figure 14: End-to-end serving latency with m ControlNets and n LoRAs (mC/nL). GPU allocation for DISTRIFUSION and KATZ is as follows: 0C/0L and 0C/1L configurations use two GPUs, 1C/0L and 1C/1L use four GPUs, and 3C/0L and 3C/2L use eight GPUs. For the 2C/2L configuration, KATZ uses six GPUs, while DISTRIFUSION requires eight GPUs. All other baselines use a single GPU across all configurations.

9.2 End-to-End Performance

Serving latency. We vary the number of adapters in a workflow and compare the average serving latency of KATZ and each baseline in Fig. 14. KATZ outperforms existing systems in all settings, achieving up to 7.8× speedup over DIFFUSERS and 5.7× speedup over DISTRIFUSION, the strongest baseline. Compared to the four baselines, KATZ exhibits a largely stable latency as more adapters are utilized in a workflow, the result of its design that decouples adapters from the critical path. In the absence of adapters (0C/0L), KATZ's latent parallelism and kernel optimizations (§7) accelerate base model inference by 1.7× and 1.3× compared to DIFFUSERS and the aggressive NIRVANA-20, respectively. Note that KATZ even outperforms DISTRIFUSION, a system that also parallelizes diffusion model inference on multiple GPUs, by 1.1× thanks to the kernel optimizations. We further compare DISTRIFUSION's parallelism with KATZ's ControlNet parallelism with the same number of GPUs in the settings of 1C/0L and 3C/0L. KATZ outperforms as the ControlNet parallelism design is based on the computation and communication characteristics of ControlNets while DISTRIFUSION is adapter agnostic.

Image quality. We compare the quality of images generated by KATZ and each baseline. Since our ControlNets-as-a-

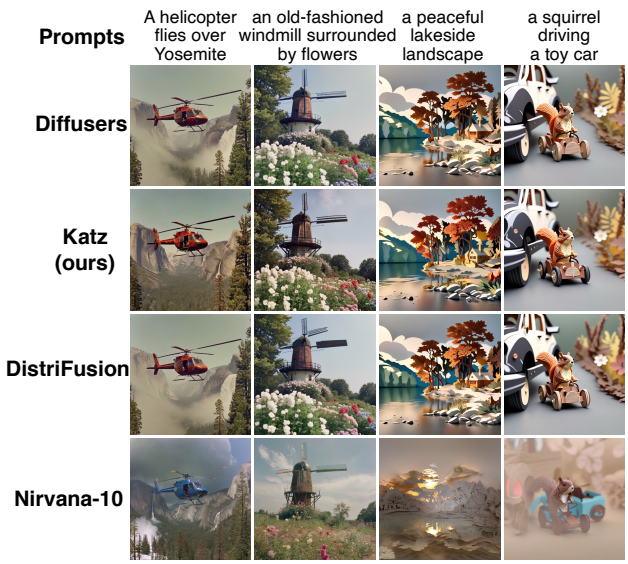

Figure 15: Examples of images generated by each baseline.

LoRA Setting	System	CLIP(↑)	FID (↓)	SSIM (↑)
One LoRA: Papercut [48]	DIFFUSERS	34.1	-	-
	NOLORA	32.9	11.4	0.63
	NIRVANA-10	33.5	9.5	0.45
	NIRVANA-20	33.7	10.9	0.44
	DISTRIFUSION	34.0	1.7	0.86
	KATZ (ours)	34.1	2.1	0.83
Two LoRAs: Filmic [47] + Photography [49]	DIFFUSERS	34.2	-	-
	NOLORA	31.3	13.4	0.67
	NIRVANA-10	33.3	9.0	0.51
	NIRVANA-20	32.8	9.4	0.47
	DISTRIFUSION	34.1	2.9	0.86
	KATZ (ours)	34.1	3.1	0.82

Table 3: Quantitative evaluation on image quality.

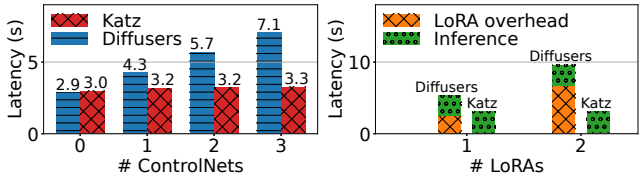

Figure 16: **Left**: Microbenchmark on ControlNets. **Right**: Microbenchmark on LoRAs.

Service design with synchronous parallelism makes no modification to image generation, we focus on evaluating the LoRA effects. Two settings are considered: the first uses a single LoRA to generate images in a papercut style [48], while the second employs two LoRAs to generate images in a combination of William Eggleston photography style and filmic style [47, 49]. We use the prompts in P2 [64] that emphasize vivid details in images.

***1)* Quantitative evaluation.** Table 3 shows the CLIP, FID, and SSIM scores achieved by each baseline. CLIP scores measure the alignment between generated images and their corresponding prompts [8]. The results indicate that DISTRIFUSION and KATZ exhibit good performance in terms of alignment, rivaling DIFFUSERS's standard lossless workflow.

FID and SSIM scores focus on comparing the generated images with the standard images ("ground truth"). Therefore, we use the images generated by DIFFUSERS as the ground truth, as it represents the original T2I serving workflow. We include the NOLORA baseline for reference, which utilizes no LoRA in image generation. In Table 3, DISTRIFUSION and KATZ achieve comparable performance and outperform others, indicating that they generate images highly similar to those generated by DIFFUSERS. NIRVANA-10 and NIRVANA-20 fall short because they generate an image based on the contents of a cached image, which is selected only based on the prompt similarity. Even with the same prompt, the visual contents in cached images can be drastically different (see Fig. 1-Left) and may not align with the style of LoRAs. Fig. 15 presents real examples generated by each baseline, where images generated by DIFFUSERS, KATZ, and DISTRIFUSION are almost visually indistinguishable, whereas NIRVANA-10 fails to match the quality of DIFFUSERS.

***2)* Qualitative evaluation.** We conducted a user study involving 75 participants to compare the quality of images generated based on human visual perception. The participants are mainly university students. We consider DIFFUSERS, NIRVANA-10, and KATZ in this part since quantitative evaluation shows image quality of NIRVANA-20 is not nearly as good as that of other baselines and DISTRIFUSION can match the quality of DIFFUSERS. Inspired by Chatbot Arena [74], we constructed an online arena that *randomly* presents a pair of two images to users, offering four options: both images are acceptable, neither is acceptable, image 1 is acceptable, or image 2 is acceptable. Participants made their selections based on both the degree of image alignment with the prompt and their subjective aesthetic preferences. We collected over 1.2k data points. The findings indicate that KATZ is capable of producing images of the same quality as DIFFUSERS, both with 70% acceptance rate. In contrast, NIRVANA-10's acceptance rate is below 50% due to its skipped denoising steps and not considering the impact of adapters during its prompt match process.

9.3 ControlNet-as-a-Service

We next evaluate the performance of KATZ's ControlNets-as-a-service design, with all other optimizations disabled. We compare KATZ with DIFFUSERS, as NIRVANA and DISTRIFUSION lack specialized designs for ControlNets. Fig. 16-Left illustrates the serving latency achieved by DIFFUSERS and KATZ, where KATZ achieves up to 2.2× speedup by distributing ControlNets computation across multiple GPUs. Note that in this case, KATZ employs synchronous ControlNet parallelization, generating identical images as DIFFUSERS.

Figure 17: Sample images generated using sync. and async. ControlNet scheme, along with images without ControlNets.

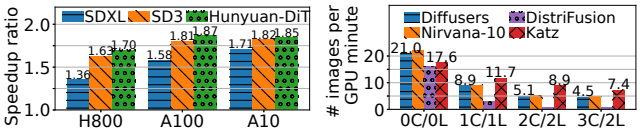

Figure 18: **Left**: Speedup ratio of latent parallelism on different GPU types and base models. **Right**: Serving throughput with m ControlNets and n LoRAs (mC/nL).

Figure 19: Sample images generated by SD3 (left) and Hunyuan-DiT (right) using LoRAs [4, 10].

To further analyze KATZ's speedup, we apply Gustafson's law [24], which quantifies the theoretical speedup in execution time for a task that benefits from parallel computing. Let N denote the number of processors, and let s and p represent the time fractions spent executing the serial and parallel parts of the program ($s+p=1$). The theoretical speedup S from parallel computing is $S=s+pN$ [24]. In the context of T2I generation with ControlNets, the serial parts comprise the computation of decoder blocks in UNet, while the parallel parts include the computation of UNet's encoder blocks together with middle block and ControlNets (§5). When using three ControlNets, the serial parts account for $s=0.55$ and the parallel parts take $p=0.45$, leading to a theoretical speedup of 2.35×. KATZ achieves 2.2× speedup and is near optimal.

Pipelined asynchronous parallelization. We next evaluate the performance of pipelined asynchronous ControlNet parallelization in the absence of high-speed GPU interconnect. We deploy the base model and one ControlNet on two AWS `g5.2xlarge` instances, each with one A10G GPU and a 10 Gbps network [2]. Fig. 10-Left illustrates the serving latency, where the asynchronous scheme achieves *close-to-ideal* performance by pipelining communication and computation, outperforming the synchronous scheme by 1.25×. Besides, images generated by the two schemes are visually indistinguishable regarding composition and quality (see Fig. 17). The synchronous and asynchronous scheme achieve CLIP scores of 33.5 and 33.7, respectively. Compared to the sync scheme, the async has an FID of 2.7 and an SSIM of 0.77.

9.4 Optimizations for LoRA Serving

We now evaluate KATZ's design for efficient LoRA serving, excluding other optimizations. We only include DIFFUSERS because other baselines have no specialized design for LoRAs. As described in §6, DIFFUSERS requires two steps to patch on a LoRA: loading the adapter from storage and then merging its weights to the base model via a create-and-replace operation [37]. This approach is inefficient. As shown in Fig. 16-Right, with a single LoRA (341 MiB), it increases the latency by 80%; with two LoRAs, one 341 MiB and the other 456 MiB, it results in 2.1× slowdown. KATZ addresses this performance issue with BAL and efficient LoRA patching (§6), collectively reducing the LoRA loading and patching overhead to 230 ms, negligible in practice.

9.5 Optimizations for Base Model Inference

We also evaluate the proposed optimizations for accelerating base diffusion model inference without adapters. Fig. 18-Left compares KATZ with DIFFUSERS and shows the speedup ratios achieved by latent parallelism on different GPUs, excluding kernel-level optimizations. The gains of latent parallelism are more pronounced on less capable GPUs, achieving speedup ratios of 1.36×, 1.58×, and 1.71× on H800, A100, and A10 GPU, respectively. Although the design of latent parallelism results in imperfect scaling—achieving less than a 2× speedup with 2× GPUs—when combined with other optimizations, KATZ can deliver up to a 1.7× throughput improvement for LoRA-dependent requests (Fig. 18-Right). On the basis of latent parallelism, enabling kernel-level optimizations (§7) additionally yields 1.24× speedup. Collectively, these two optimizations enable KATZ to outperform all baselines regarding base model inference (0C/0L in Fig. 14).

9.6 Serving Throughput

KATZ is primarily designed to minimize serving latency, but it also achieves superior serving throughput for workflows with many adapters. Fig. 18-Right illustrates the request serving throughput of each baseline, measured as the number of images generated per minute of GPU time. When the workflow involves many adapters, KATZ achieves higher throughput (up to 1.7×) compared to other baselines, benefiting from its efficient design of LoRA loading and patching (§6). However, when there is no adapter (0C/0L), KATZ and DISTRIFUSION fall short in throughput as parallelizing base model inference on two GPUs does not saturate their compute capabilities; NIRVANA-20 sometimes achieves good throughput due to its aggressive design, albeit at the cost of image quality loss.

9.7 Generalization to DiT-based Models

KATZ's three designs naturally extend to the DiT backbone, which we evaluate with SD3 [19] and Hunyuan-DiT [32]. First, ControlNet-as-a-Service leads to close-to-ideal speedup. Compared to DIFFUSERS, KATZ achieves speedup ratios of 1.23× and 1.46× for SD3 and Hunyuan-DiT, each with one ControlNet, closely matching the theoretical upper bounds of 1.27× and 1.50× given by the Gustafson's law [24]. Second, BAL effectively overlaps adapter loading with base DiT inference, eliminating the LoRA overhead. User study confirms that images generated by KATZ and DIFFUSERS are visually indistinguishable regarding quality with sample images presented in Fig. 19. Finally, latent parallelism accelerates CFG computation of DiTs, as shown in Fig. 18-Left, achieving even more significant speedup than that of SDXL (UNet).

10 Discussion and Related Works

Generalization to other adapters. As discussed in §2, KATZ can support adapters beyond ControlNet and LoRA. For adapters [29, 62] that share architectural similarities with the base diffusion model, ControlNet-as-a-Service (§5) decouples them from the base and deploys them on dedicated GPUs, enabling caching, parallelization, and sharing. For adapters [68, 70] that incorporate parameter-efficient patches, BAL (§6) can effectively mitigate the overhead associated with model loading and patching. Latent parallelism (§7) applies to the base diffusion model and is adapter-agnostic.

T2I diffusion model inference. In §2, we have presented existing serving systems for T2I workloads [12, 30, 50]. Besides, several works expedite image generation by reducing redundant computations in the denoising process [35, 36, 57]. Yet, these works only optimize the base model inference and overlook the significant latency overhead introduced by adapters. Our work is the first to analyze this problem and addresses the system inefficiencies caused by the use of adapters in T2I serving. It is hence orthogonal to the existing optimization solutions for base diffusion models.

Serving systems with adapters. In the domain of LLMs, pioneering research [16, 31, 43, 58] has designed efficient systems to serve base LLMs with adapters. Despite their effectiveness, these LLM-focused systems are inadequate for diffusion models due to their fundamental differences. First, these systems focus solely on LoRAs, without considering ControlNets which are specialized for diffusion models (§3.1). Second, the LoRAs associated with diffusion models are significantly larger in size and quantity than those for LLMs [16], necessitating external LoRA storage and incurring orders of magnitude higher loading overhead (§3.2). Third, these systems emphasize multiplexing a single base LLM to serve multiple LoRAs simultaneously. Yet, batching yields *minimal* benefits in diffusion model inference (§3.3). Consequently, their optimizations become ineffective in our scenario.

Other model serving systems. Existing research on model serving systems focuses on optimizing latency [17, 53], throughput [14, 61], performance predictability [22, 67], and resources efficiency [23, 51, 60, 65]. These studies apply to various workloads, including graph neural networks [54] and large language models [13, 18, 53, 63]. KATZ is orthogonal to the aforementioned efforts, as T2I models have drastically different computation intensity and workflow.

In the context of online model serving, there exists a series of works to address various challenges such as model placement [33, 67], request scheduling [22, 67], and dynamic scaling [20, 59, 66], which are designed to manage load spikes in model serving systems. While KATZ focuses on per-request latency optimization, these scheduling and scaling approaches are complementary to KATZ and can be seamlessly integrated to effectively handle diverse request arrival patterns.

11 Conclusion

We presented KATZ, the first system that efficiently serves a T2I workflow with many adapters, such as ControlNets and LoRAs. KATZ introduces three novel designs: (1) ControlNet-as-a-Service that deploys ControlNets as a separate service on dedicated GPUs to enable caching, parallelization, and sharing, (2) bounded asynchronous LoRA loading and efficient patching, and (3) latent parallelism that accelerates CFG computation on multiple GPUs. Collectively, these designs decouple adapters from the critical path of a T2I workflow, while accelerating base model inference. Compared to existing systems, KATZ achieves up to 7.8× speedup and 1.7× improvement in throughput, while maintaining image quality.

Acknowledgment

Abstract

Scaling laws indicate that increasing model size enhances performance. The *Mixture-of-Experts (MoE)* architecture enables scaling model parameters to trillions while requiring only a sub-linear increase in training computations. However, the sparse activation of experts within MoE leads to substantial *All-to-All communications* and *imbalanced* computation workloads, which in turn can severely degrade training efficiency. In this paper, we develop PopFetcher, a scalable MoE training system with *popularity*-aided *expert-wise prefetching*, to address these communication and computation bottlenecks. Specifically, PopFetcher uncovers *skewed* and *correlated* patterns in expert selection, and implements a lightweight sliding-window technique to accurately predict the popularity of experts. As a result, PopFetcher facilitates dynamic identification of high-demand experts and *prefetches* them in the next layer during the execution of current *non-MoE computations*, thereby exploiting the *idle* network links to reduce dispatched tokens in upcoming All-to-All communications. PopFetcher rigorously formulates the end-to-end training latency and develops a tailored *pruning* strategy to derive the globally optimal prefetching scheme, which can restore both communication and computation balances based on the underlying network infrastructure. By *prioritizing* All-to-All data stream during the backward pass, PopFetcher significantly alleviates the communication blockage. Extensive experiments conducted on GPU clusters demonstrate that PopFetcher outperforms existing state-of-the-art systems, reducing training time by *15%-94.5%*.

1 Introduction

In recent years, Transformer-based *pre-trained language models (PLMs)*, such as BERT [8], GPT [5,29], and Llama [36,37], have achieved enormous success across various domains, including natural language processing [12], computer vision [9, 25], and machine translation [3]. The scaling law for PLMs demonstrates an empirical relationship between model size and performance [20], proliferating gigantic PLMs with up to trillions of parameters to enhance service quality. However, large-scale PLMs come at the cost of *sharply increasing* computational demands, often hitting the trainability wall [12]. In response to these challenges, the *Mixture-of-Experts (MoE)* architecture has garnered more and more interest [31]. MoE model, like DeepSeek [7], Qwen [35] and Phi [2], expands numerous sub-models or experts within Transformer framework, which are *sparsely activated* by a gate network, thus allowing for scaling model capacity while ensuring only a sub-linear increase in training computations. Substantial evidence also corroborates the potential of MoE in delivering performance on par with its dense counterparts [4].

Despite the benefits of MoE, its sparsely activated structure also presents unique challenges in model training [30]. As the number of experts grows, the memory requirement for MoE model also scales, often demanding hundreds of GB or even TB, far beyond the capacity of a single GPU (typically tens of GB). As such, *expert parallelism (EP)* has been proposed to train large-scale MoE models by placing various experts to different GPU workers for parallel processing [21]. Within each MoE layer, input tokens are dynamically routed to certain experts, who may reside on remote workers, incurring frequent cross-machine data transfers. Specifically, this process necessitates two All-to-All communication primitives on the critical path: first All-to-All operation dispatches input tokens to selected experts and the second collects the computation results back, as depicted in Figure 1. Since All-to-All communication is *time-consuming*, the MoE training, especially for large models, is often severely prolonged [40].

Considerable efforts have been devoted to addressing the communication bottleneck and enhancing MoE training efficiency [17, 22]. Common strategies include designing a balanced gate network to alleviate uneven expert workloads [44] or pipelining the All-to-All operation through token subdivision of communication tasks [32]. While these approaches can improve training performance, the volume of communication for token dispatching and collection *remains substantial*.

*Corresponding author: Xiong Wang (xiongwang@hust.edu.cn)

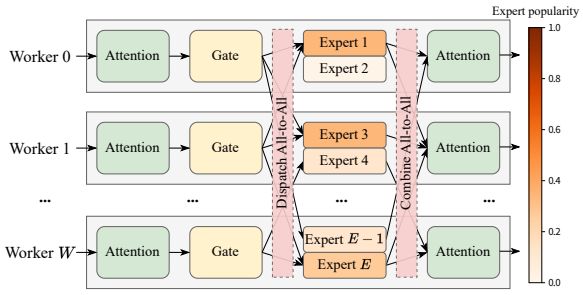

Figure 1: All-to-All communications during MoE training.

To minimize transferred tokens, FasterMoE [16] introduces a strategy to "shadow" partial experts to all GPU workers, which allows specific tokens to be processed locally, alleviating the need for external transmission. However, the periodic *broadcasting* of expert parameters can undermine the benefits of decreased token transmission due to potential communication cost and interference. Alternatively, Janus [24] attempts to optimize whether to fetch experts for tokens or send tokens to experts before the training starts, conditioned on their relative overheads. Yet, it struggles when the size of expert parameters or token data consistently exceeds the other. Currently, expert scheduling is mostly conducted concurrently with All-to-All communication, which may mitigate token transfers but also introduces *additional* communication overheads for expert scheduling. This raises a critical question: *Can we stagger expert scheduling with token dispatching to eliminate the interruption of expert scheduling and more effectively address the All-to-All communication bottleneck*? To answer the question, we face the following challenges.

First, to minimize the interference of expert scheduling on token dispatching, it is essential to retrieve the necessary experts before the training progresses to the current MoE layer. This requires *advanced* knowledge of expert statistics to facilitate timely expert retrieval. However, acquiring such information is challenging due to the dynamic training nature. Second, experts within the same layer often receive tokens that *vary greatly* in volume, which leads to considerable differences in performance gains when fetching different experts. Optimally deciding which experts to fetch from which worker involves modeling the training latency, yet the net effect of expert scheduling and token transmission is difficult to quantify. Third, All-Reduce operations among gradient aggregation can *compete for* limited network bandwidth with All-to-All communications, consequently delaying the backward computations. To enhance training efficiency, it is essential to schedule different network streams independently.

In this paper, we propose PopFetcher, an efficient MoE training system featured with *popularity* based *expert-wise prefetching*, to address the communication bottleneck and ensure balanced workloads. Specifically, PopFetcher employs a lightweight prediction to acquire the popularity of experts in each MoE layer, which effectively assists the expert prefetching design and remains uninterrupted to normal training. Building on this statistics, PopFetcher enables each worker to *preemptively* pull popular experts from neighboring workers in idle periods or to push local tokens to remote workers when fetching corresponding experts is costlier. This *hybrid pull-push* mechanism unleashes the potentials of processing tokens both locally and remotely. PopFetcher rigorously formulates the end-to-end training latency, incorporating both computation and communication costs, to optimize the prefetching of experts for each worker. As a result, PopFetcher can substantially reduce the volume of token dispatching in EP, while incurring *negligible interference* with All-to-All communication since experts are retrieved in advance. Moreover, PopFetcher *prioritizes* the All-to-All stream during the backward pass, which further alleviates the communication blockage. In summary, this paper makes the following contributions.

- We discover the *correlation* between expert selections across consecutive MoE layers, and further develop a *lightweight* sliding-window based prediction scheme to precisely access the popularity of experts. With these insights, we design PopFetcher, an efficient MoE training system with popularity-aided expert-wise prefetching, which enables a *preliminary* expert scheduling to address the All-to-All communication bottleneck.
- PopFetcher devises a hybrid paradigm of *expert pull and token push* for EP-based MoE training. Through a thorough analysis of end-to-end training latency, PopFetcher enables the identification of the optimal experts to be prefetched for each worker while also respecting their memory constraints. By coupling with the underlying network architecture, PopFetcher fully utilizes high-speed links for expert retrieval, which greatly mitigates prefetching time.
- PopFetcher *prioritizes* All-to-All communication stream over All-Reduce operation among prefetched experts. By effectively pipelining non-MoE All-Reduce tasks with MoE backward computations, PopFetcher significantly mitigates network contention and reduces communication blockages.
- Extensive experiments on real-world datasets show the superiority of PopFetcher in training throughput and latency. In particular, PopFetcher reduces training time by *15%-94.5%* than state-of-the-art systems.

2 Background and Motivation

We first introduce the preliminary of distributed training of MoE models, then present our motivation, as well as the opportunities and challenges of PopFetcher.

2.1 Background

2.1.1 Transformer-Based PLM

Transformer model [38] has been recognized as the fundamental architecture in sequence processing. A typical Transformer block includes an Attention layer and a *multi-layer percep-*

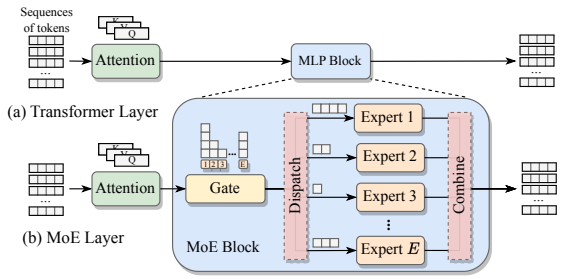

Figure 2: Structure of MoE block.

tron (MLP), generally comprising two *fully-connected (FC)* layers with a ReLU activation in between. Attention network transforms input tokens into query, key and value matrices, which then undergo processing via scaled dot-product attention, with outcomes being further channeled into the MLP. Output from MLP will be added to the block's input and normalized through a layer normalization. This standard configuration allows for stacking multiple identical Transformers to build powerful PLMs, like BERT [8] and GPT [5, 29].

2.1.2 MoE Architecture and Model Training

Despite the success of Transformer architecture, scaling PLM capacity remains challenging due to increasing computation demands for training. MoE model [31], illustrated in Figure 2, tackles this by dividing the dense MLP into multiple smaller, sparse experts, thereby exploiting the inherent sparsity of Transformer to scale model size with only a sub-linear increase in computation cost. During training, each input token is routed by a gate to one or more experts, typically employing top-k expert selection where k is often 1 or 2. Token dispatching to experts and the subsequent return of results are managed via All-to-All communication primitives.

Large-scale MoE models often far exceed the capacity of a single GPU. To facilitate the training of MoE, EP is adopted to distribute various experts from each MoE layer across different GPU workers [21]. Typically, the model layers that reside between MoE layers (e.g., Attention layer), referred to as non-MoE layers, are replicated on each worker, following a principle similar to that of data parallelism [19].

2.2 Motivation

Skewed expert activation leads to hot expert. In MoE architecture, the gate module's variability in routing input tokens often leads to an imbalanced workload among experts. As in Figure 3, which shows the expert selection distribution within a layer of MoE-GPT model [41], the pattern of token dispatching evolves considerably early in training but soon exhibits a trend towards *localized activity*, with minor variations between adjacent iterations. Despite attempts at balanced gating strategies, such as imposing capacity limits on each expert [21], certain experts consistently receive more tokens, placing heavier computations on GPUs hosting these *hot experts*. Such load imbalance is particularly pronounced in the frontier layers of the MoE architecture, whereas in deep layers, the load tends to stabilize and changes less dramatically. Emergence of hot experts requires an effective management of load distribution to avoid overburdening GPU workers.

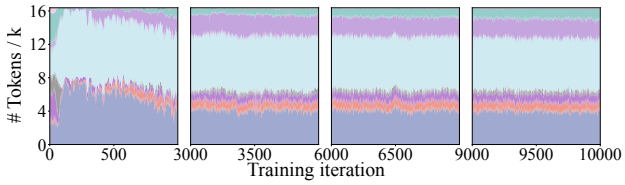

Figure 3: Skewed expert selection within a MoE layer (k on the y-axis represents units of 1000).

Table 1: Time consumption within a MoE layer.

# Layers	Batch size	# Experts	A2A Ratio
12	16	16	56.44 %
24	16	16	57.57 %
24	32	16	57.20 %
12	16	32	56.13 %
12	16	64	56.34 %

All-to-All communication bottlenecks in MoE training. During the training of MoE models, each token undergoes All-to-All communication twice per MoE layer, including token dispatching and subsequent output collection, which often leads to significant delays. Table 1 indicates that All-to-All communication can account for 50%-60% of the total time when training MoE-GPT across eight workers. The primary communication bottleneck arises from the *mandatory data synchronizations* in each MoE layer, where the commencement of expert execution and subsequent computations is delayed until all requisite tokens and their processed outputs are received. This synchronization is particularly problematic when hot experts are present, as their increased load further intensifies the network contentions. Therefore, a meticulously designed EP is critical to address synchronous execution challenge and reduce communication overhead.

Coarse-grained expert scheduling is insufficient. To enhance MoE training efficiency, replicating partial experts across multiple GPUs is adopted to alleviate the skewed computations on overloaded workers, allowing specific tokens to be processed locally by shadowed experts rather than being dispatched remotely [16]. While effective, broadcasting the expert parameters to all GPUs can introduce inadvertent delays due to data synchronizations. An alternative approach attempts to pull necessary expert parameters to the local GPU, which can decrease the need for pushing tokens to remote experts [24]. However, this method encounters significant limitations when expert parameters are substantially larger than input tokens, making pulling experts even more communication-intensive. Despite these efforts, existing *coarse-grained* MoE schemes still struggle with imbalanced computation loads and persistent All-to-All communication bottlenecks.

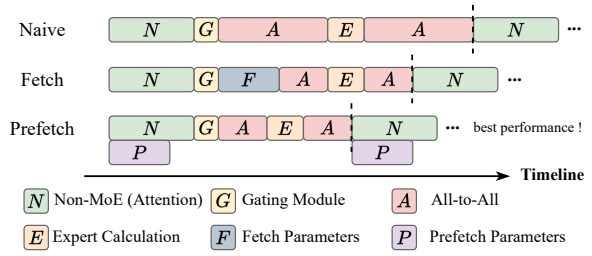

Figure 4: Execution timeline of different expert schedules.

2.3 Opportunities and Challenges

Addressing communication bottleneck while restoring computation balance is crucial for improving the efficiency of MoE model training. We next explore the opportunity to achieve this objective and highlight the potential challenges.

2.3.1 Opportunities

Efforts to promote MoE efficiency have typically pursued two orthogonal directions.

Model design. Literature reveals attempts to refine the MoE model architecture itself. For instance, GShard [21] incorporates a load balance loss to evenly distribute workloads across different GPU workers. Similarly, expert routing strategies [42] have been redefined to allow the gate module to select the top-k best-matching tokens, enhancing load balancing. While these methods aid in achieving more equitable workload distribution, they also risk *compromising model accuracy*, and the communication bottleneck *persists*.

System design. System-oriented approaches like FasterMoE [16] and FlexMoE [28] alleviate the adverse impact of load imbalance by shadowing or replicating popular experts. However, they can introduce *additional* overhead for parameter synchronization or system adjustment, potentially offsetting the benefits of improved workload distribution.

Despite these challenges, non-MoE components between MoE layers open up optimization opportunities. Figure 4 shows the data flow within a MoE layer, implying that during the computation in *non-MoE sections*, like the Attention layer, a worker utilizes only local input data, leaving network links underutilized. As training progresses, expert load variations tend to stabilize, offering a chance to use historical token distribution for expert prefetching. That is, we can proactively pull popular experts in next MoE layer from remote GPUs to a local worker in anticipation of their forthcoming selections, thus diminishing future All-to-All communication demands by using *currently idle* links.

2.3.2 Challenges

Prefetching hot experts during non-MoE computation phases is promising to minimize communication overhead and balance GPU workloads. However, it also presents unique challenges that need to be addressed.

How to accurately predict popular experts in next MoE layer? As training progresses, the load distribution across experts *changes dynamically*. For effective expert scheduling, it is crucial to develop a lightweight method that can accurately predict which experts will be in high demand in subsequent layers, yet challenging for their dynamic nature.

How to prefetch appropriate experts subject to worker capacity? Given the *limited memory* capacity of GPU workers, and the presence of multiple experts already on the local GPU, deciding which and how many experts to prefetch presents a dilemma. This decision must balance the benefits of expert prefetching against available memory resources.

How to manage additional cost associated with expert prefetching? While prefetching can be scheduled to overlap with non-MoE computations, it must adhere to the *data dependencies* of the MoE workflow. Ensuring that prefetched experts are prepared before the computation of the next layer begins can introduce additional synchronization overhead. Furthermore, the All-Reduce operation among prefetched experts may compete with All-to-All communication, potentially obstructing gradient computations in backward pass.

3 PopFetcher Overview

In this paper, we present PopFetcher, an advanced MoE training system with popularity based expert-wise prefetching, to decrease All-to-All communication overhead and ensure balanced GPU workload. PopFetcher maintains an expert pool on each worker to store both local expert parameters and those prefetched from remote workers. Figure 5 exhibits the system architecture of PopFetcher, which is primarily composed of three key modules: routing information collector, prefetching decision-maker, and asynchronous scheduling executor.

3.1 Routing Information Collector

Each worker node in PopFetcher is outfitted with a routing information collector to track and monitor the *runtime popularity* of experts. Specifically, this module records the gate selection details for each token across every MoE layer and updates the distribution of tokens routed to each expert. Based on this data, the collector renews the expert popularity within each MoE layer, as well as relaying to the prefetching decision-maker for more informed expert retrieval. Expert popularity compiled by each worker is promptly synchronized via torch.distributed.all_reduce to maintain consistency across all workers. Since the popularity vector is small, the synchronization overhead is negligible.

3.2 Prefetching Decision-Maker

The prefetching module periodically aggregates data from the routing information collector across all workers to discern the popularity of each expert. Considering that each GPU

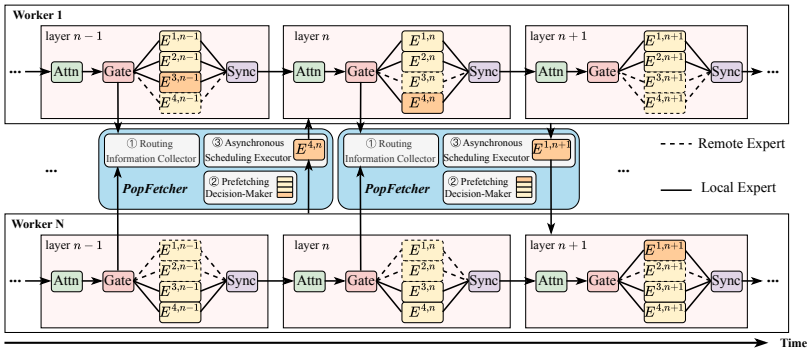

Figure 5: System architecture of PopFetcher.

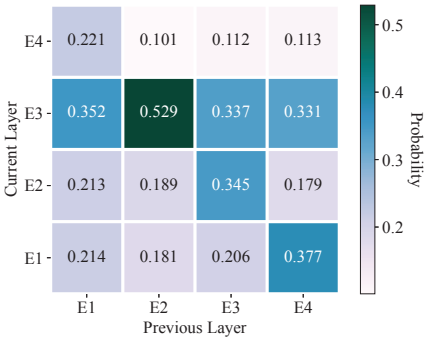

Figure 6: Expert correlation between MoE layers within an iteration (training MoE-GPT with four experts per layer).

worker already hosts local experts and corresponding activations from the forward pass, fetching all remaining experts is impractical due to memory constraints. Informed by the updated popularity statistics, the decision-maker crafts a *tailored* prefetching strategy for each worker within the confines of limited GPU memory. PopFetcher carefully orchestrates the decision-making process to avoid disrupting regular training activities, as routing information can be analyzed on the CPU concurrently with ongoing GPU-based training operations. Furthermore, PopFetcher decides on expert prefetching for the upcoming MoE layer to minimize the end-to-end training latency as the current layer progresses.

3.3 Asynchronous Scheduling Executor

The scheduling executor aims to utilize idle network links during MoE training by preemptively and asynchronously fetching experts from the next layer that are originally located on remote workers. This strategy reduces the volume of transferred tokens during All-to-All communications, thereby effectively addressing the communication bottleneck. Ideally, expert scheduling should coincide with the computations of current Transformer's non-MoE sections, i.e., the Attention layer, which ensures minimal overhead and *avoids interference* with the execution of the current MoE layer.

In general, the executor intelligently schedules experts for each worker by prioritizing hot experts from the global pool based on directives from the prefetching decision-maker. Consequently, PopFetcher not only alleviates the All-to-All communication volume but also ensures a balanced GPU workload. Considering that multiple experts can exist across different workers due to expert prefetching, PopFetcher concurrently performs All-Reduce operations for non-MoE layers and gradient computations for experts during the backward pass to reduce communication overhead. To further minimize the impact on backward All-to-All communication and avoid the computation blockage, we also prioritize the All-to-All data flows over the All-Reduce stream.

4 Lightweight Popularity Prediction

In this section, we will delve into a dynamic prediction for expert popularity, which is deemed to be both lightweight and accurate to enhance expert prefetching. Basically, expert activation is dynamically predetermined by the gate network in standard scenarios, which may limit the opportunities for system-level optimization.

4.1 Expert Correlation between MoE Layers

As mentioned earlier, the selection of experts by input tokens exhibits discernible regularity. Within a MoE layer, certain experts consistently attract more tokens, indicating their popularity, while others are chosen less frequently. Observations from Figure 3 also imply that experts who are popular at one point tend to maintain their popularity temporally.

Beyond individual MoE layers, there is also a correlation in expert selection across consecutive layers. Let us consider an expert index selected by a token in the i-th MoE layer as x, and in the subsequent $(i+1)$-th layer as x'. The tuple (x, x') then represents a set of correlated selections. Figure 6 illustrates the conditional probability of selecting expert x' in the current layer, given the selection of expert x in the previous layer. Outcomes reveal a distinct trend of expert selection between adjacent MoE layers, with *certain correlations* more prevalent than others. In essence, hot experts of the upcoming layer can often be predicted based on expert preferences in the preceding layer.

Although the popularity of experts and their correlations continue to evolve as training progresses, these changes tend to be gradual over time, which supports the effectiveness of early expert prefetching during non-MoE computations.

4.2 Expert Popularity Prediction

Achieving optimal computation and communication balance among workers hinges on accurately predicting expert popularity, a task complicated by its dynamic nature. To address

Table 2: Main notations.

Notation	Definition
N	# workers
K	# experts per layer on each worker
E_w^i	i-th expert on worker w
P_w	Computation throughput of worker w
$W_{n,w}$	Network bandwidth of link between workers n, w
I_w	# input tokens of worker w
B_w	# tokens received by worker w
B_w^i	# tokens sent to E_w^i
p_w^i	Popularity of E_w^i
H	Hidden size (length of embedding vectors)
α	Fraction of intermediate embedding in MLP
$\delta_{n,w}^i$	1 if E_n^i is prefetched by worker w, else 0

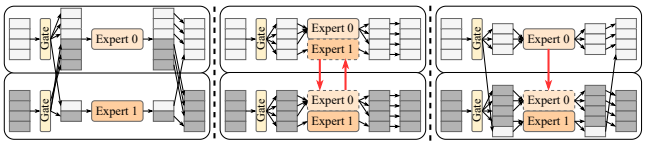
this while minimally interfering with normal training, we propose a sliding-window based prediction to pinpoint hot experts [6]. Specifically, the routing information collector routinely gathers runtime selection data from the gate network during the forward pass, which is then analyzed to update our current understanding of expert popularity.

Initially, we analyze the distribution of tokens over recent iterations, up to the *current MoE* layer:

$$p_{\text{seq}} = \frac{\text{\# tokens allocated in the past } s \text{ iterations}}{\text{\# tokens processed in the past } s \text{ iterations}} \quad (1)$$

Here s represents the size of the sliding window, which, based on our testing, is optimally set at 10 iterations. Our goal is to accurately predict expert popularity for the *upcoming MoE* layer, which involves incorporating the expert correlations, as illustrated in Figure 6. Let M signify the total number of tokens, with each token expressed by $T_m, m \in \{1, 2, \cdots, M\}$. Also, we denote the i-th expert on the j-th layer (i.e., Transformer block) as $E^{i,j}$, where each layer contains K' experts in total. Then, the correlation between any experts $E^{i,j}$ and $E^{h,j+1}$ can be evaluated by their conditional probability:

$$\Pr\left(E^{h,j+1} | E^{i,j}\right) = \frac{1}{M} \sum_{m=1}^{M} \Pr\left(E^{h,j+1} | E^{i,j}, T_m\right) \quad (2)$$



The expert popularity based on the correlation is given by:

$$p\left(E^{h,j+1}\right) = \sum_{i=1}^{K'} \Pr\left(E^{h,j+1} | E^{i,j}\right) p_{\text{seq}}^{i,j} \quad (3)$$

Eq. (3) enables an accurate, lightweight popularity prediction of experts in the subsequent layer by leveraging timely updated selection data from the preceding layer. As a result, our PopFetcher can dynamically adapt to changes in expert demand without overburdening the system.

5 Expert-Wise Prefetching and Scheduling

This section details our strategy for expert prefetching and scheduling given limited GPU memory. To aid our later presentation, we summarize the main notations in Table 2.

(a) Expert-centric (b) Data-centric (c) Hybrid-paradigm

Figure 7: Hybrid push-pull paradigm.

5.1 Hybrid Push-Pull Paradigm

Imbalances in communication and computation due to skewed expert selection substantially prolong MoE training. Previous attempts address this by either sending (pushing) tokens to experts (expert-centric) [12, 16, 21] or pulling experts to local GPUs (data-centric) [24], which, however, proves insufficient in managing the uneven token dispatching inherent in MoE architecture, as illustrated in Figure 7. Since these methods exclusively send tokens or pull experts, they fail to handle blockages during large data transmissions, as all data chunks are treated equally and scheduled simultaneously. To clarify, each expert module typically comprises a FeedForward Network with two Linear layers, featuring matrix dimensions of $H \times \alpha H$ and $\alpha H \times H$, respectively, with α commonly set to 2. Then, the parameter count for a single expert layer is $4H^2$. Using a float32 data type with $H = 1024$, the parameter reaches 16MB. Besides, cross-machine data transfer per token during two All-to-All communications is $2H$. Hence, we deduce that pulling an expert becomes more viable when the token transfer exceeds 2048 tokens. Otherwise, the conventional approach of sending tokens offers lower overhead.

We introduce a new hybrid push-pull strategy for tokens and experts, which combines the strengths of both expert-centric and data-centric frameworks. According to Figure 7, after tokens pass through the gate module, their dispatching to different workers varies significantly. By adopting a hybrid paradigm that *concurrently* pushes tokens and pulls experts, we can optimize data transfer based on the current token distribution among experts. Specifically, when the volume of tokens exceeds that of expert parameters, we opt to fetch experts towards the data; otherwise, we default to send tokens as expert parameters are less burdensome.

Our hybrid approach also includes expert prefetching to enable an advanced retrieval of remote experts. For this purpose, we need to accommodate two MoE computation patterns: local computation and prefetching computation. In local computation, tokens are sent to their specific experts for processing, with results returned to the originating node. Prefetching computation involves experts that are prefetched and available locally, eliminating the need to send out tokens over the network. However, prefetching computation introduces an extra step to ensure the logical integrity of model updates. That is, during backward pass, gradients of replicated experts must be sent back to the worker hosting the primary expert for global reduction. Gradient synchronization, while essential,

inevitably consumes network bandwidth and must be *factored into* prefetching decisions.

5.2 Problem Formulation

Our objective is to devise an optimal scheduling strategy that includes expert prefetching to minimize the training latency of *each MoE layer*. In this context, both communication and computation delays are predominantly determined by the performance of the slowest worker.

5.2.1 Training Latency without Prefetching

First, we consider the conventional case where expert prefetching is excluded, which can guide later analysis of our PopFetcher. Let B_w denote the number of tokens received by worker w, then we have $B_w = \sum_{n=1}^{N} T_{n,w}$, where $T_{n,w} = I_n \sum_{i=1}^{K} p_w^i$ accounts for I_n tokens from worker n based on expert popularity predictions $p_w^i, i \in \{1,2,\cdots,K\}$. For each MoE layer *within a Transformer*, token processing by an expert entails one GeMM operation during forward pass, and two in backward as gradients need to be computed for both the inputs and expert parameters. Moreover, the size of intermediate embedding vector between the FC layers is αH with H being the embedding size of each token. Thus, the total operations for two FC layers in MLP are $4B_w\alpha H^2$. Assuming data type in float32, each GeMM requires $\frac{4B_w\alpha H^2}{P_w}$, leading to a computation latency of $3 \times \frac{4B_w\alpha H^2}{P_w}$. Furthermore, forward and backward pass encompass a total of four rounds of All-to-All communications, with the communication latency given by $4H \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{B_{n,w}^i}{W_{n,w}}$, where $B_{n,w}^i$ denotes the number of tokens sent by worker n to expert E_w^i.

Therefore, the training latency of worker w is attained:

$$Lat_w^{\text{origin}} = 3 \times \frac{4B_w\alpha H^2}{P_w} + 4H \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{B_{n,w}^i}{W_{n,w}} \tag{4}$$

Since the overall latency depends on the slowest worker, the end-to-end training time of a MoE layer becomes

$$Lat^{\text{origin}} = \max_w \left\{ Lat_w^{\text{origin}} \right\}, w \in \{1,2,\cdots,N\} \tag{5}$$

5.2.2 Training Latency with Prefetching

Building on the derivation of Eq. (5), we continue to explore the impact of prefetching hot experts on training latency. Specifically, expert prefetching incurs two types of delays.

- Prefetched expert computation: this delay arises from fetching expert parameters from remote worker to local node for computation, which is influenced by the expert popularity and how many local tokens supposed to be routed to it.
- Model gradient reduction: the time required to reduce gradients of prefetched experts with primary experts.

We derive the training latency when experts are prefetched.

- **Forward pass**. (1) Computation time: the computation time for local tokens is $Comp_{\text{l}}^{\text{f}} = \frac{4B_w\alpha H^2}{P_w}$, while that for prefetched expert is given by $Comp_{\text{p}}^{\text{f}} = \frac{4\alpha H^2}{P_w} \sum_{n=1}^{N} \sum_{i=1}^{K} B_{n,w}^i \delta_{n,w}^i$, where the indicator $\delta_{n,w}^i$ signifies whether expert E_n^i is prefetched by worker w. (2) Communication time: the token transfer time amounts to $Comm_{\text{t}}^{\text{f}} = 2H \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{B_{n,w}^i (1-\delta_{n,w}^i)}{W_{n,w}}$.
- **Backward pass**. (1) Computation time: in the backward pass, local token computation time doubles to $Comp_{\text{l}}^{\text{b}} = 2 \times \frac{4B_w\alpha H^2}{P_w}$, and prefetched expert computation needs $Comp_{\text{p}}^{\text{b}} = 2 \times \frac{4\alpha H^2}{P_w} \sum_{n=1}^{N} \sum_{i=1}^{K} B_{n,w}^i \delta_{n,w}^i$. (2) Communication time: the token transfer $Comm_{\text{t}}^{\text{b}}$ mirrors that of the forward pass $Comm_{\text{t}}^{\text{f}}$, and the time for gradient reduction is $Comm_{\text{r}}^{\text{b}} = 2\alpha H^2 \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{\delta_{n,w}^i}{W_{n,w}}$.

Including the times $Comp_{\text{l}}^{\text{f}}, Comp_{\text{p}}^{\text{f}}, Comm_{\text{t}}^{\text{f}}$ in forward pass and those $Comp_{\text{l}}^{\text{b}}, Comp_{\text{p}}^{\text{b}}, Comm_{\text{t}}^{\text{b}}, Comm_{\text{r}}^{\text{b}}$ in backward pass, we characterize the latency for worker w:

$$\begin{aligned} Lat_w^{\text{prefetch}} = {} & 3 \times \frac{4B_w\alpha H^2}{P_w} + 3 \times \frac{4\alpha H^2}{P_w} \sum_{n=1}^{N} \sum_{i=1}^{K} B_{n,w}^i \delta_{n,w}^i \\ & + 4H \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{B_{n,w}^i (1-\delta_{n,w}^i)}{W_{n,w}} + 2\alpha H^2 \sum_{n=1}^{N} \sum_{i=1}^{K} \frac{\delta_{n,w}^i}{W_{n,w}} \end{aligned} \tag{6}$$

Recall our goal is to minimize the end-to-end latency, i.e.,

$$Lat^{\text{prefetch}} = \min \max_w \left\{ Lat_w^{\text{prefetch}} \right\}, w \in \{1,2,\cdots,N\} \tag{7}$$

Given the extensive number of global experts, such as 256 GPUs on Azure with 128 experts on each worker [30], the overhead of deciding whether to prefetch an expert is substantial, which needs further optimization.

5.3 Expert Prefetching Decision

Our objective now turns to solving the problem outlined in Eq. (7), focusing on optimizing the assignment $\{\delta_{n,w}^i\}$ of prefetched experts to GPU workers in an efficient manner.

5.3.1 Expert Prefetch Pruning

The primary challenge in designing expert prefetching is the vast search space associated with deciding experts for the next layer. To overcome the problem, we narrow down the search space through *expert pruning*, which effectively reduces the number of experts that need to be considered to at most $k \times N$, with k denoting the top-k expert selection of gate module.

- **GPU memory limitation.** Since each GPU has already hosted local expert parameters and intermediate activations, the aggregate size of experts that can be prefetched must not exceed its available memory. Then,

$$2\alpha H^2 \sum_{n=1}^{N} \sum_{i=1}^{K} \delta_{n,w}^i \leq Mem_w^{\text{free}} \tag{8}$$

- **Transfer time constraint.** Prefetching should ideally overlap with non-MoE layer computations, implying that the time taken to fetch expert needs to fulfill

$$2\alpha H^2 \sum_{n=1}^{N}\sum_{i=1}^{K}\frac{\delta_{n,w}^i}{W_{n,w}} \leq Time^{\text{non-MoE}} \tag{9}$$

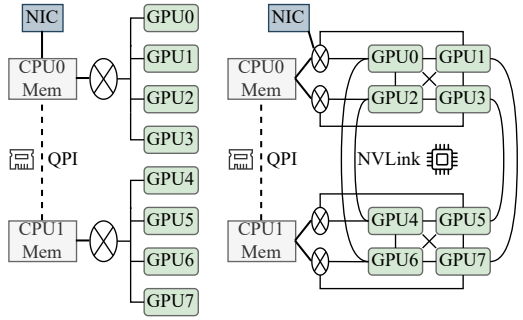
These constraints establish an upper bound r_w for the number of experts that can be feasibly prefetched:

$$\sum_{n=1}^{N}\sum_{i=1}^{K}\delta_{n,w}^i \leq r_w \tag{10}$$

Moreover, expert prefetching for any worker is supposed to reduce end-to-end training latency. Consistent with Eqs. (4) and (6), it implies the following difference is greater than 0:

$$\begin{aligned} Lat_w^{\text{origin}} - Lat_w^{\text{prefetch}} &= 4H\sum_{n=1}^{N}\sum_{i=1}^{K}\frac{B_{n,w}^i}{W_{n,w}} \\ -2\alpha H^2\sum_{n=1}^{N}\sum_{i=1}^{K}\frac{\delta_{n,w}^i}{W_{n,w}} &- \frac{12\alpha H^2}{P_w}\sum_{n=1}^{N}\sum_{i=1}^{K}B_{n,w}^i\delta_{n,w}^i \end{aligned} \tag{11}$$

Specifically, $Lat_w^{\text{origin}} > Lat_w^{\text{prefetch}}$ when the condition below holds true:



$$2(\varepsilon - 3\alpha H)B_{n,w}^i > \varepsilon\alpha H \tag{12}$$

Here, we use ε as shorthand for the compute-to-bandwidth ratio $\frac{P_w}{W_{n,w}}$ for conciseness. Prefetching is observed to enhance training efficiency only when ε exceeds $3\alpha H$, indicating a scenario with limited inter-worker bandwidth but potent GPU computing capability. For instance, NVIDIA DGX B200 is equipped with computing capacity of 72 petaFLOPS and NVLink connection with 400 Gb/s. Given a typical embedding size $H \in \{768, 1024, 2048, 4096\}$, it is clear that $\varepsilon > 3\alpha H$, namely expert prefetching is viable. In such cases, the tokens received by expert E_n^i, if prefetched, must satisfy

$$B_{n,w}^i > \frac{\varepsilon\alpha H}{2(\varepsilon - 3\alpha H)} \tag{13}$$

By combining Eq. (10) and Eq. (13), we prioritize prefetching experts based on their popularity until the GPU memory is fully utilized. The net time reduction achieved by prefetching a single expert is calculated as $4H\sum_{n=1}^{N}\frac{B_{n,w}^i}{W_{n,w}} - 2\alpha H^2\sum_{n=1}^{N}\frac{\delta_{n,w}^i}{W_{n,w}} - \frac{12\alpha H^2}{P_w}\sum_{n=1}^{N}B_{n,w}^i\delta_{n,w}^i$. As aforementioned in Figure 3, expert popularity tends to stabilize as training progresses. Therefore, in the mid-to-late stages of MoE training, it may not be necessary to assess each expert's prefetching needs in every iteration. Instead, a fixed prefetching strategy could be adopted, or the *frequency* of expert replanning is reduced, to further cut down on operational overhead.

Overview of PopFetcher mechanics. In summary, we illustrate the operational mechanics of PopFetcher. Conditioned on the end-to-end latency in Eq. (6), we aim to minimize the latency by searching the optimal expert prefetching solution. Given the exponentially growing complexity of the search space with increases in the number of machines and GPUs, we implement two key constraints to manage this complexity: GPU memory limitations as defined in Eq. (10) and constraints on expert transfer time as specified in Eq. (13). These constraints effectively prune the search space, allowing us to formulate a comprehensive global expert prefetching strategy. Specifically, for each set $\delta_{n,w}^i$ identified in our strategy, we execute prefetching of the i-th expert E_n^i on worker n to worker w during non-MoE layer computations.

(a) PCIe-only topology **(b)** NVLink-based topology

Figure 8: Different types of GPU machine topology.

5.3.2 Internal Expert Sharing among Local GPUs

In GPU clusters, links connecting various components often occupy *heterogeneous bandwidths*, as exemplified in Figure 8 which depicts the topology of a typical machine. Generally, GPUs within the same machine communicate through NVLink, with bandwidths reaching up to 1800GB/s, while those interconnected with the machine's main CPU via PCIe share a bandwidth of 64GB/s. For inter-server communication, machines are often linked through GDR NICs, with their bandwidths reaching 400Gb/s, where experts must be first pulled to local CPU memory via the NICs and then moved to the GPU memory through PCIe. Given this diverse network fabric, when a worker prefers to fetching experts from others, coupling with the heterogeneous connections can apparently enhance bandwidth utilization. Specifically, workers will prioritize sources connected by higher bandwidth links for retrieving their needed expert parameters.

Additionally, internal experts can be shared across all local workers using CPU memory. Once an expert is available on the same machine, PopFetcher bypasses the need for external fetching, i.e., workers directly access the expert from local CPU memory, to mitigate the overhead of expert prefetching. To achieve this, we maintain a cache manager for each server, which is responsible for sharing remote expert parameters among local workers and utilizes CPU memory as an intermediary to expedite the prefetching process.

In general, our scheduling scheme is designed to optimally

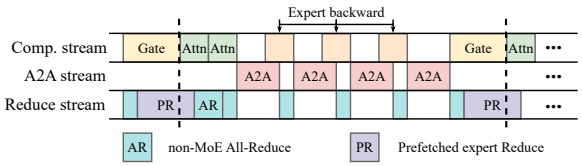


Figure 9: Pipeline scheduling of streams in backward pass.

retrieve experts through the fastest available links, regardless of the specific intra and inter-machine bandwidths. By leveraging the CPU memory, PopFetcher effectively circumvents the redundant transmission of expert parameters, thus enhancing the overall efficiency of MoE training system.

6 Stream Scheduling in Backward Pass

Due to expert prefetching, multiple copies of an expert may exist across different workers, requiring an additional All-Reduce operation during the backward pass. Typically, All-to-All communication for EP, All-Reduce gradient aggregation for non-MoE layers, and All-Reduce among prefetched experts are handled in *separate* process groups, which will initiate three distinct CUDA streams running concurrently. Without proper scheduling, these streams may compete for limited network bandwidth and GPU resources, potentially disrupting the normal flow of backward computation.

Ideally, strict priority should be assigned to All-to-All communication to minimize bandwidth contention. This strategy involves launching All-Reduce tasks as soon as they are ready to prevent delays, while also allowing All-to-All tasks to preemptively claim GPU resources upon initiation. However, implementing such precise stream scheduling is not feasible with highly optimized multi-GPU communication libraries like NCCL, which lock communication primitives into CUDA streams at the point of invocation. As a result, transmissions must be determined upfront, *precluding* any real-time adjustments in the use of core and bandwidth resources in conjunction with other operations.

To overcome these challenges, we propose decomposing both All-Reduce and All-to-All communications into micro-operations, which are executed in a pipelined fashion. In practice, expert prefetching leads to a reduced volume of All-to-All token transfers during the backward pass, diminishing their overlap with the computation of expert gradients. By strategically *interleaving* the micro-operations of All-Reduce and All-to-All communications, as vividly illustrated in Figure 9, we can fully capitalize on network idle periods when GPU workers are otherwise engaged.

7 Implementation

We have developed PopFetcher atop PyTorch, using Python, C++ and CUDA to construct the MoE training framework, which encompasses over 8,000 lines of code. The routing information collector, implemented using Python, aggregates runtime data via the All-Gather operator. Besides, the expert scheduling executor module utilizes the communication capabilities of torch.distributed, with the core logic for expert prefetching crafted in C++ and CUDA. Additionally, the executor facilitates parallel processing of computation and communication tasks through torch.cuda.Stream, and it manages a dedicated prefetching stream within the training system's prefetching interface.

For user convenience, PopFetcher is implemented as a PyTorch plugin that can function independently or be integrated into the Megatron-LM framework [34]. PopFetcher employs the torch.autograd.Function class, which allows for the customization of both forward and backward behaviors of the MoE operator, to ensuring its seamless integration into the MoE computational graph. All computation, communication, and prefetching activities are encapsulated within this custom MoE operator. Moreover, the pipeline scheduling of computation and communication streams is implemented in C++ and CUDA to optimize performance.

Table 3: Configuration of different MoE models.

Model	α	Hidden	Layer	Batch	Expert	Worker	Cluster
MoE-GPT	2	1024	12	32	32	8	*A*
				64	64	32	*B*
MoE-BERT	2	1024	12	32	32	8	*A*
				64	64	32	*B*

8 Evaluation

In this section, we evaluate the performance of PopFetcher in terms of token throughput and per-iteration time for different MoE models on real-world datasets.

8.1 Evaluation Setup

8.1.1 Hardware Setup

We evaluate PopFetcher on two GPU clusters.

- Cluster A. This GPU cluster comprises two machines, each outfitted with four NVIDIA RTX 4090 GPUs that have 24GB of memory per GPU. The GPU nodes are connected through a 100Gbps Mellanox ConnectX-5 InfiniBand adaptor for communication.

- Cluster B. The cluster includes eight machines, each equipped with four NVIDIA A10 GPUs, totaling 32 GPUs, with each GPU also featuring 24GB of memory. The inter-node communication operates over link with a maximum speed of 32Gbps bandwidth.

Besides, PyTorch version is 2.3 and CUDA version is 12.4. The communication backend is based on NCCL.

8.1.2 Datasets and Models

We test PopFetcher on two typical MoE models: (1) MoE-GPT [41], (2) MoE-BERT [16], which serve as representatives of PLMs that utilize Transformer decoder or encoder architecture. More details about model configurations are listed in Table 3. Both MoE-GPT and MoE-BERT are initially trained on the OpenWebText dataset [15]. Additionally, MoE-BERT undergoes further training on the significantly larger PILE dataset [14], which comprises approximately 600GB of data. We also conduct comparative experiments using the OSCAR-2201 dataset [1] to further assess the performance of PopFetcher under varying data conditions.

8.1.3 Baselines

We compare our PopFetcher with the following frameworks.

- DeepSpeed [30]: a high-performance system that supports massive scale MoE models.
- FasterMoE [16]: an easy-to-use and efficient MoE training system which simplifies the management of experts by shadowing them across GPU workers.
- Megablocks [13]: a lightweight library for MoE training, featuring a block-sparse GPU kernel that handles dynamic token routing and avoids token dropping without sacrificing the hardware efficiency.
- Tutel [17]: an optimized MoE system which achieves adaptive expert execution and adaptive pipelining for dispatch and combine operations in MoE layers.
- Janus [24]: a data-centric MoE training system which enables pulling experts to tokens. We replicated its functionality by prefetching all experts in our experiments, as the source code is not publicly available.

All baselines can be integrated into Megatron-LM [27, 34], and we conduct our comparisons using the same hardware and software environments to ensure fairness.

8.1.4 Metrics

For a comprehensive evaluation of performance, we employ two key metrics, i.e., token throughput and per-iteration time. In particular, token throughput characterizes the number of tokens processed by the training system in each iteration, reflecting the overall training efficiency. Per-iteration time quantifies the total time required to complete one forward and backward pass, with shorter iteration time indicating faster training speed and higher resource utilization.

8.2 Statistical Training Equivalence

PopFetcher significantly reduces the per-iteration time required for MoE training by prefetching popular experts, thereby accelerating the overall training process. To maintain training equivalence with traditional MoE methods, we conduct an additional reduction operation that synchronizes the gradient updates between the prefetched experts and the original experts. To substantiate this approach, we perform training sessions for MoE-GPT on Cluster A using both the conventional FasterMoE and our PopFetcher enhancement.

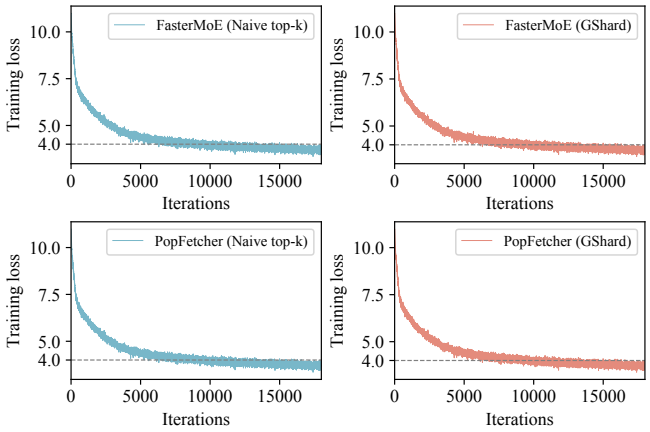

Figure 10: Loss value over training iterations.

The loss curves for both the naive top-k and GShard expert routing mechanisms are illustrated in Figure 10. The upper section of the figure depicts the original FasterMoE training scheme, whereas the lower section represents the enhancements made by PopFetcher. It is evident that regardless of the gating mechanism employed, be it naive or GShard, PopFetcher maintains the integrity of the expert selection process and does not introduce any additional steps in the convergence process. Consequently, all loss trajectories align perfectly across training iterations, demonstrating that PopFetcher achieves statistical equivalence with the standard training framework without compromising model accuracy.

8.3 Overall End-to-End Performance

Initially, we evaluate the end-to-end performance, focusing on the training time per iteration of our PopFetcher and various baselines. All results are obtained using GShard gating, given its broader application.

Figure 11 shows PopFetcher's overall speedup relative to baselines across different GPU clusters, calculated against the slowest system in each setup. We observe that PopFetcher boosts training speed by 1.28-2.4× and 1.18-18.3× in the two clusters, respectively. These gains stem from its expert prefetching design and network stream prioritization, which concurrently fetches popular expert parameters during non-MoE layer computations without blocking the backward pass. Since Janus employs a solution that pulls all expert parameters, it imposes extremely high demands on GPU memory capacity. Given the settings described, Janus often results in OOM errors and is therefore excluded from Figure 11.

PopFetcher consistently achieves robust training speeds, even in low inter-machine network bandwidth environments like Cluster B. In contrast, frameworks such as Megablocks,

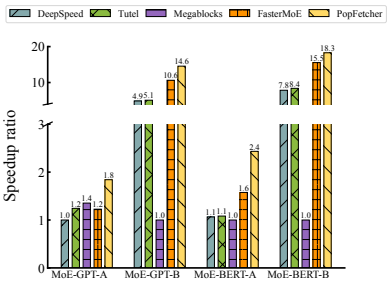

Figure 11: Speedups over baselines.

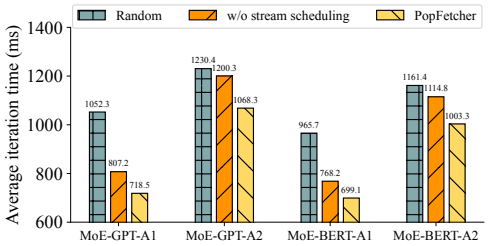

Figure 12: Expert and stream scheduling.

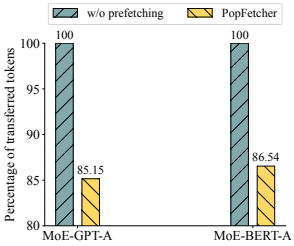

Figure 13: Token transfers.

heavily reliant on the inter-machine communication, can experience significant efficiency losses under similar conditions, resulting in slower training speeds. This contrast highlights PopFetcher's suitability for bandwidth-constrained hardware environments, such as those using consumer-grade GPUs. In these scenarios, with a high compute-to-bandwidth ratio ε, PopFetcher is able to effectively utilize the idle links during non-MoE layer computations.

8.4 Ablation Study

8.4.1 Expert Popularity and Stream Scheduling

We continue evaluating the benefits of expert popularity prediction and backward stream scheduling. We compare PopFetcher with baseline MoE training approaches that rely on random expert prefetching or built-in stream strategy, which ignore variations in expert selection or stream priorities, respectively. Our evaluations employ MoE-GPT and MoE-BERT models in Cluster A, varying the number of experts per layer for a comprehensive analysis: MoE-GPT-A1 includes 16 experts, MoE-GPT-A2 has 8, with similar setups for the MoE-BERT model.

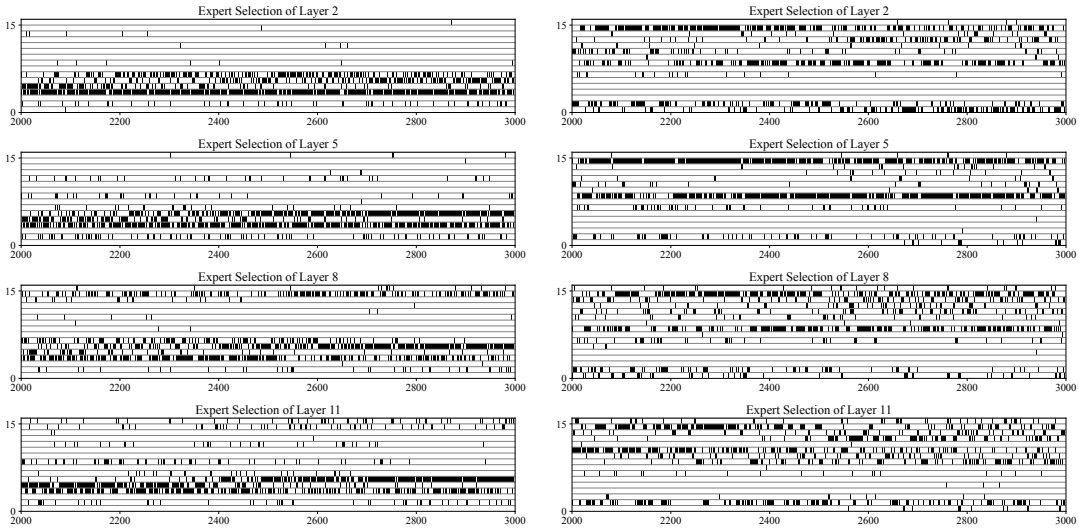
Figure 12 shows the average per-iteration time. In particular, our popularity-based expert scheduling yields significant speedup enhancements, achieving 1.30× and 1.26× faster training for MoE-GPT and MoE-BERT models, respectively, compared to random prefetching. Additionally, PopFetcher cuts the average iteration time by 10.9% for MoE-GPT and 10% for MoE-BERT, highlighting substantial efficiency gains from incorporating pipelined stream scheduling during the backward pass, thus avoiding network contention and removing computation blockage.

8.4.2 Token Transfer within Expert Prefetching

Expert prefetching in PopFetcher reduces token transfers in All-to-All communications, thus cutting the communication time. As shown in Figure 13, implementing our prefetching strategy globally decreases tokens transmitted by 14.85% for MoE-GPT and 13.46% for MoE-BERT in Cluster A.

Furthermore, we assess the prefetching status of experts in MoE-GPT and MoE-BERT models (16 experts per layer), as depicted in Figure 14. The vertical axis shows the global index of experts, and the horizontal axis represents iterations. Darker cell colors indicate more frequent prefetching. Results illustrate that strategic prefetching of certain experts can speed up training, with these experts consistently requested by multiple workers across consecutive training iterations. That is, expert popularity exhibits "locality" (discussed in Section 2.2), which is seen as long, dark bands in the figure. These popular experts vary per layer, but consistently, at least one such hot expert appears in every layer, highlighting a focused prefetching strategy to boost model performance.

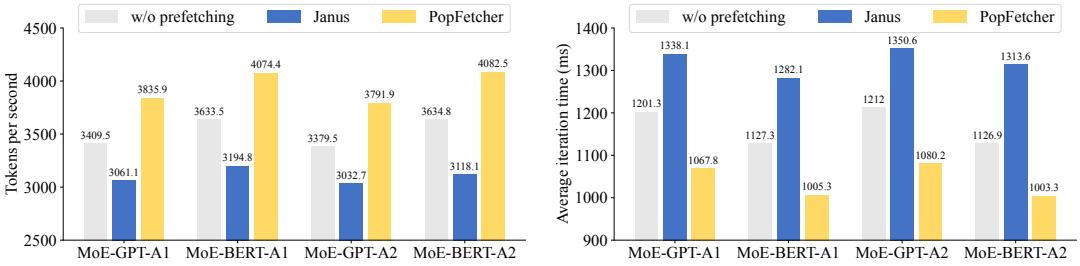
8.5 Hybrid Push-Pull Analysis



PopFetcher integrates the advantages of both traditional data-centric and expert-centric MoE training by adopting a hybrid approach that involves sending tokens and pulling experts. To demonstrate the superiority of PopFetcher, we compare its training throughput and per-iteration time with those of data-centric (Janus) and expert-centric systems (w/o prefetching).

As depicted in Figure 15, in experiments conducted on Cluster A using MoE-GPT and MoE-BERT models, PopFetcher surpasses both the expert-centric and data-centric paradigms in training throughput and per-iteration time. This outcome underscores the efficacy of our hybrid communication method which combines sending tokens and pulling experts, optimizing data transmission volumes in All-to-All communications. Our strategy fine-tunes the balance of load and addresses the granularity issues associated with load imbalances in All-to-All communications, thereby enhancing overall MoE training efficiency.

"Bad prefetching" arises when prefetched experts receive fewer tokens than alternatives, reducing All-to-All communication savings. However, PopFetcher effectively mitigates this issue by accurately prefetching popular experts using a sliding window and inter-layer correlation. Should "bad prefetching" occur, PopFetcher simply reverts to the conventional training mode without incurring additional overhead, as prefetch operations overlap with non-MoE computations.



8.6 Parameter Sensitivity Analysis

The performance of PopFetcher is closely linked to the prediction accuracy of expert popularity, which is influenced by the sliding window size s. A larger s does not necessarily lead to

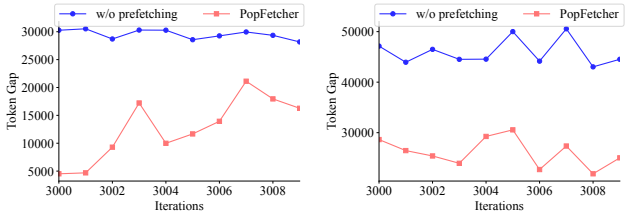
(a) MoE-GPT-A (b) MoE-BERT-A

Figure 14: Demonstrations of prefetched experts in PopFetcher over training iterations.

(a) Training throughput (b) Iteration time

Figure 15: Effect of PopFetcher's hybrid token send and expert pull.

Table 4: Prediction accuracy over sliding window size.



Acc. / Value / Gate	5	10	15	20	25	50	100
Naive top-k	77.46%	77.04%	76.77%	76.37%	76.25%	75.69%	75.31%
GShard	68.13%	69.62%	57.26%	53.66%	51.19%	46.49%	45.30%

better accuracy, but it does require maintaining an extensive history of past records, resulting in inefficient resource utilization without significant improvements in prediction accuracy.

Given the number of experts prefetched per layer is typically no more than four due to GPU memory constraint, we focus on measuring the accuracy of predicted top-5 popular experts against the actual top-5 hot experts. This evaluation is further averaged across all MoE layers. As depicted in Table 4, after assessing the prediction accuracy under various configurations, we select a sliding window size of 10 for runtime operations to achieve an optimal balance between prediction performance and memory consumption.

8.7 Balanced GPU Workload

By prefetching popular experts, PopFetcher ensures a more balanced workload distribution across workers, since the loads of hot experts are shared among multiple workers. As illustrated in Figure 16, it significantly reduces the disparity in token distribution between the least and most loaded workers: 43.1% for MoE-GPT and 57.1% for MoE-BERT. This uniform workload distribution during training prevents the communication blockages common in traditional MoE systems, where biased expert selections often cause workload imbalances and network congestion.

(a) MoE-GPT-A (b) MoE-BERT-A

Figure 16: Difference in received number of tokens between lightest and heaviest loaded workers (16 experts per layer).

8.8 GPU Memory Consumption

Through hybrid token dispatch and expert retrieval, PopFetcher achieves more efficient utilization of limited GPU memory. To illustrate, we compare the accommodated

Table 5: Maximum accommodated model size.

Size / Model / Method	MoE-GPT	MoE-BERT
FasterMoE	1.844B	1.884B
Janus	1.390B	1.430B
PopFetcher	**2.071B**	**2.262B**

parameter size of PopFetcher with those of FasterMoE and Janus by adjusting the number of experts in each MoE layer. Table 5 presents the maximum configurations and parameter scales that the MoE-GPT and MoE-BERT models can train on Cluster A. Compared to FasterMoE, PopFetcher demonstrates improvements of 12.3% and 20.1% in model size on the MoE-GPT and MoE-BERT models, respectively. Similarly, compared to Janus, PopFetcher achieves enhancements of 49.0% and 58.2% on the MoE-GPT and MoE-BERT models, respectively. These results underscore that the hybrid push-pull paradigm can effectively exploit GPU memory.

8.9 Runtime Overhead

PopFetcher introduces minimal runtime overhead, largely because the expert popularity prediction and the search for prefetching solutions are performed asynchronously on the CPU. These tasks run in the background without disrupting the main training process. Moreover, our pruning strategy significantly reduces the search space, rendering the computational cost negligible. In practical tests, the overhead for popularity prediction is less than 100ms, which is readily absorbed within the total training time. Given that the benefits of prefetching popular experts far outweigh this slight overhead, PopFetcher efficiently accelerates the training process while minimizing its negative impact.

9 Related Work

Sparse MoE model. Large-scale models have excelled in computer vision [39] and natural language processing [11], thanks to extensive parameters. MoE architectures, introduced in a 1991 paper [18], further boost parameter scales and capabilities while maintaining computational efficiency [26]. Shazeer *et al.* expands MoE to LSTMs with 137 billion parameters and 131,072 experts [31]. GShard adapts MoE for transformer models, achieving 12.5 to 600 billion parameters [21]. Switch Transformers enhances the T5 model by replacing Feed-Forward layers with MoE layers and optimizing routing strategy [12]. ST-MoE further develops an encoder-decoder MoE architecture with 269 billion parameters, 32 billion active at any time [43]. GLaM introduces a decoder-only model with a record 1.2 trillion size [10].

MoE model training. Switch Transformers pioneer EP by distributing individual experts across GPUs within the same MoE layer [12]. Tutel on the other hand emphasizes MoE's dynamic nature by optimizing token-expert allocation for data, model, and expert parallelism [17]. To enhance MoE training, Janus modifies the traditional All-to-All communication in EP by routing experts to where tokens are located [24]. Besides, Lina prioritizes All-to-All communication over typical All-Reduce operations while adoting data parallelism [23]. FasterMoE introduces dynamic load balancing through expert replication and a flexible pipeline scheduling strategy [16]. ScheMoE further develops a scheduling framework that manages communication and computation tasks, integrating an advanced All-to-All communication primitive to maximize bandwidth use [33]. These works significantly enhance the efficiency, scalability, and performance of MoE training systems through optimizing expert-token interactions and improving load balancing in large-scale distributed setups.

10 Conclusion

In this paper, we propose PopFetcher, an effective and scalable MoE training framework that incorporates popularity based expert-wise prefetching, to mitigate the All-to-All communication bottleneck in MoE training. PopFetcher identifies skewed and correlated patterns in expert selection and employs a sliding-window based prediction to determine the popularity of experts in upcoming layers. Building on this statistics, PopFetcher meticulously analyzes the end-to-end training latency of each MoE layer, and establishes an optimal mapping of prefetched experts to GPU workers. By doing so, PopFetcher not only minimizes communication time but also ensures a balanced workload distribution among workers. Additionally, PopFetcher exploits network idle periods to pipeline All-Reduce streams and non-MoE computation, thereby expediting the backward pass process. Experimental evaluations on real-world datasets show that PopFetcher outperforms state-of-the-art MoE training systems, as we can mitigate the training time by 15%-94.5%.

HYPERECA: Distributed Heterogeneous In-Memory Embedding Database for Training Recommender Models

Jiaao He Shengqi Chen Kezhao Huang Jidong Zhai

Tsinghua University

Abstract

Making high-quality recommendations is important in online applications. To improve user satisfaction and effectiveness of advertising, deep learning-based recommender models (DLRM) are widely studied and deployed. Training these models on massive data demands increasing computation power, commonly provided by a cluster of numerous GPUs. Meanwhile, the embedding tables of the models are huge, posing challenges on the memory. Existing systems exploit host memory and hashing techniques to accommodate them. However, the simple offloading design is hard to scale up to multiple nodes. The sparse access to the distributed embedding tables introduces high data management and all-to-all communication overhead.

We find that a distributed in-memory key-value database is the best abstraction to serve and maintain embedding vectors in DLRM training. To achieve high scalability, our system, *HypeReca*, utilizes both GPU and CPU memory. We improve the throughput of data management according to the batching pattern of DNN training, using a pipeline over decentralized indexing tables and a contention-avoiding schedule for data exchange. A two-fold parallel strategy is used to guarantee consistency of all embedding vectors. The communication overhead is reduced by replicating a few frequently accessed embedding vectors, exploiting the sparse pattern with a performance model. In our evaluation on 32 GPUs over real-world datasets, *HypeReca* achieves $2.16-16.8\times$ end-to-end speedup over HugeCTR, TorchRec and TFDE. The source code is available at https://github.com/thu-pacman/hypereca/.

1 Introduction

Making recommendations has always been one of the core components of the Internet. Users are served with blog posts and videos, products and advertisements as long as they are surfing online. Making more accurate recommendations is core of the business. In recent years, recommendation models based on deep learning (DLRMs) are showing superior model quality. They automatically learn from the enormous data generated by users' online behaviors. For instance, websites predict the click-through rate (CTR) of a video to decide whether to show it to a user. And then, actual click data is used to train the CTR-predicting model. This training cycle is processed every few minutes in real-world systems. To provide up-to-date recommendation, training performance of these models is critical. Training them demands a large amount of data processed by significant computational resources, e.g., up to hundreds of GPUs.

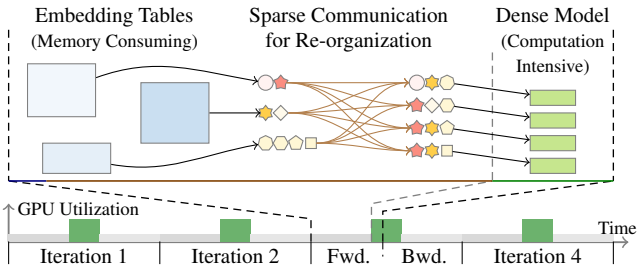

Figure 1: Sketch of a DLRM Training Process

As shown in Figure 1, the *sparse part* consists of embedding tables that contain the feature vectors of numerous items. To train the model, the related feature vectors of items in the training samples are gathered from the embedding tables via sparse inter-process communication. After receiving all the embedding vectors, the GPUs process them with the *dense part* of the model.

Typically, a hybrid parallel strategy is adopted to train the model. The memory-consuming embedding tables are partitioned across workers, and the host memory is commonly used to accommodate most of them. They may contain up to trillions of parameters [21, 25] in production. Rest layers of the model, the dense part, are replicated. They model is replicated on up to hundreds of GPUs, which provide the computation capability to train it.

Unfortunately, such parallel strategy fails to scale up, due

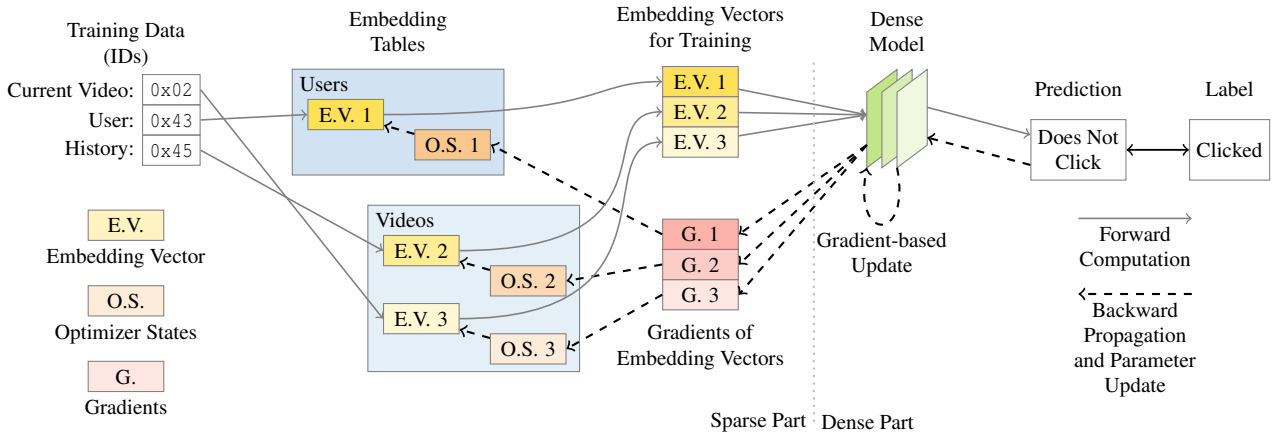

Figure 2: General Model Structure and Training Process of DLRMs

to the huge size and heterogeneity of the model parts. Every training sample is related to tens of embedding vectors that reside in several other workers, incurring significant overhead to exchange the embedding vectors among the hardware devices. From the ranklist of DLRM training benchmark [41] of MLPerf [23], we observe that the most advanced system from NVIDIA [39] only achieves 2.89× speed up using 13× more GPUs (from 8 to 112). We even find that using more GPUs may slow down the training in some cases.

A series of prior works introduce algorithms that change the training behavior to alleviate this problem, e.g., shuffling the training samples [2] or dropping certain embedding vectors [20]. Although higher throughput might be achieved, they pose uncertain influences on final model quality. Model developers thus usually appreciate systems that train the model without changing the algorithm to avoid any side effect. Therefore, we focus on improving the efficiency of the original synchronous training method.

We identify that existing model-transparent approaches fail to cope with the huge size and heterogeneity of the models due to the following two challenges.

High Data Management Cost Different from typical embedding tables in other models, embedding vectors of new items are constantly inserted to the tables, because there are always new items in the training data. Among the distributed embedding tables, overhead of the item-wise data management is high [43]. Current approaches maintain the embedding vectors differently at either table level [25, 33] or item level [3, 34] according to the access pattern. The system has to maintain locations of every embedding vector and guarantee the consistency. The GPUs consume up to millions of items every few milliseconds, posing high throughput requirement on the CPU-side embedding feeding and updating module.

High Communication Cost The communication overhead to gather the embedding vectors from remote nodes and sending the gradients back takes a significant amount of time, comparing with the neural computation on the GPUs. Uneven access pattern has been exploited by previous works [3, 25, 33, 34, 44] to accelerate the communication by replicating some frequently accessed items (e.g. items represented by stars in Figure 1) across all GPUs. However, this introduces additional overhead to synchronize the replicas, and the total commjjunication overhead can hardly be reduced. Selecting the items to replicate is critical but challenging.

We propose an in-memory embedding database, *HypeReca*, to address the challenges in the distributed DLRM training scenario. Behind a simple interface similar to a key-value database, it automatically utilizes both host and device memory in the cluster to store the embedding data, and serve it with different parallel strategies according to the specific pattern of DNN training and its data.

First, we design an efficient decentralized embedding vector management mechanism. The vectors are stored in chunks, and the locations are maintained by a distributed indexing table. As training data are fed to the model in batches during the training process, we utilize the multi-thread parallel processing capability for the throughput-critical indexing tasks. Furthermore, we introduce an intra-node pipeline to reduce the lock overhead over the tables.

Second, we adopt a two-fold parallel strategy for the embedding tables, namely ***2FP***. We apply communication-efficient data parallelism for a special chunk of frequently-accessed embedding vectors stored on GPUs. While slight redundancy is introduced, the synchronization operation is simplified, and thus better utilizes the network bandwidth. We build a performance model on the replication strategy that makes a trade-off when selecting the replicated items. The sparse embedding vector access pattern is exploited to reduce the overall communication latency.

We evaluate *HypeReca* on two different clusters with up to 32 GPUs. With identical model quality, our system achieves $2.16-16.8\times$ speedup over the baseline systems on different

models and training datasets with terabytes of data.

2 Background and Motivation

2.1 DLRM Model and Work Flow

DLRMs are commonly used to predict behaviors of users, e.g. click-through rate (CTR). It takes IDs of entities, including the user, the presented content, and any possibly related items, as input. Then, using a deep neural network, it conducts predictions to provide better recommendations. For example, when predicting CTR of a video shown to a user, the user's ID, together with the video's ID, and possibly IDs of past ten videos the user watched, are fed into the DLRM as one training sample. The fact that the user clicked it is used as a label, and the model is trained by supervised learning.

As shown in Figure 2, a DLRM model mainly consists of two parts. *Sparse Part* contains one or multiple embedding tables. *Dense Part* consists of various neural network models.

Sparse Part contains several embedding tables. They map discrete IDs of certain categories to embedding vectors, commonly consisting of tens or some hundreds of floating point numbers. Due to the numerous contents online, sparse parts of real DLRMs contain more than billions [20, 21, 25] of parameters. Despite consuming much memory, it is sparsely accessed, involving little computation. Optimizing the memory-intensive operators [28] is effective on a single GPU, but scaling it up requires special communication design.

Dense Part studies on the embedding vectors of input items and makes predictions. This part is being intensively studied by the model developing community. MLPs and CNNs, Transformers and MMoEs [5, 11, 27, 36], are introduced for better model quality. As recommendation tasks require low inference latency, these models are usually of moderate size, but much more computation-intensive.

To train the model, a batch of labeled training data, containing up to millions of IDs, is first fed into *Sparse Part*. The data is processed by the DLRM, and output of *Dense Part* is compared with the ground truth. Then, gradients produced by a loss function are propagated backward through both parts. Finally, a gradient-based optimizer, e.g. SGD [16] or Adam [18], is used to update the parameters.

It should be noticed that the embedding tables are part of the parameters of the model. They are updated every iteration when training. Maintaining the optimizer states of the embedding tables is a part of the parameter updating process. Although the gradients are sparse, the updated embedding vector may be immediately needed by the next training batch.

2.2 Existing Basic Parallel Strategy

Distributed training is the most promising way to increase training throughput. However, in DLRM, the dense part involves intensive computation, while the sparse part requires a lot of memory to store the embedding tables. The difference in workload leads to different selections of parallel strategy. A basic hybrid parallel strategy is commonly used in present DLRM training systems [15, 39, 43]. Figure 3 illustrates the hybrid parallelism that applies different parallel strategy to sparse part and dense part separately.

For *Sparse Part*, it is inevitable that the embedding tables are partitioned across multiple devices, as they may contain terabytes of parameters. For simplicity, we adopt *GSET* [43] technique that maps IDs of items in different categories into a unique global ID, which simplifies multiple embedding tables into one. To fit *Sparse Part* into distributed memory, embedding vectors of different items are placed on different workers. From the view of distributed deep learning, it adopts model parallelism, where rows of embedding vectors are stacked up to be a tall matrix, and split up horizontally. Host memory is commonly used to store these large embedding tables [25, 43]. Some GPU-centric systems put them on GPUs [12, 15, 39], but they still have to offload most embedding vectors elsewhere, due to the huge size of training datasets.

Rest parts of the model, including data loading and *Dense Part*, adopt data parallelism. A global batch of training data is split into multiple mini-batches by samples. Each worker is bound to one GPU. *Dense Part* is replicated across all GPUs, as it has fewer parameters and is more compute-intensive. To synchronize the replicas, `all-reduce` operation is performed over the gradients before updating the models. This approach can greatly scale up the throughput [19, 22, 31], but it is inefficient in utilizing memory.

Due to the different parallel strategies between the two parts, the embedding vectors are re-organized. For instance, a training sample on worker A includes items whose embedding vectors are on worker B and C. Then, B and C need to find them in local memory, and send them to A. Globally, for a batch of training samples, every worker gathers embedding vectors from local memory, and send them to other workers. This is commonly implemented by invoking `all-to-all`, a basic sparse collective communication operation [30]. It may be replaced by `all-reduce` over a tensor containing multiple rows of zeros, depending on the efficiency of the communication operation implementation [39].

The all-to-all communication pattern leads to significant scalability issues. Training time composition of several open-source distributed DLRMs [15, 39] is measured and presented in Figure 4. *Sparse Part*, which is dominated by the sparse all-to-all communication, makes up most of the training time, exceeding 90% in most occasions. Increasing network bandwidth is the only direct way to accelerate the inter-device communication. For example, previous works utilize high-bandwidth NV-Links among GPUs within a node [39, 47], or equip high-performance NICs for every GPUs [3, 25]. These hardware items are expensive and less scalable compared to clusters connected via commodity hardware (e.g. PCIe GPUs and Infiniband HCAs per node).

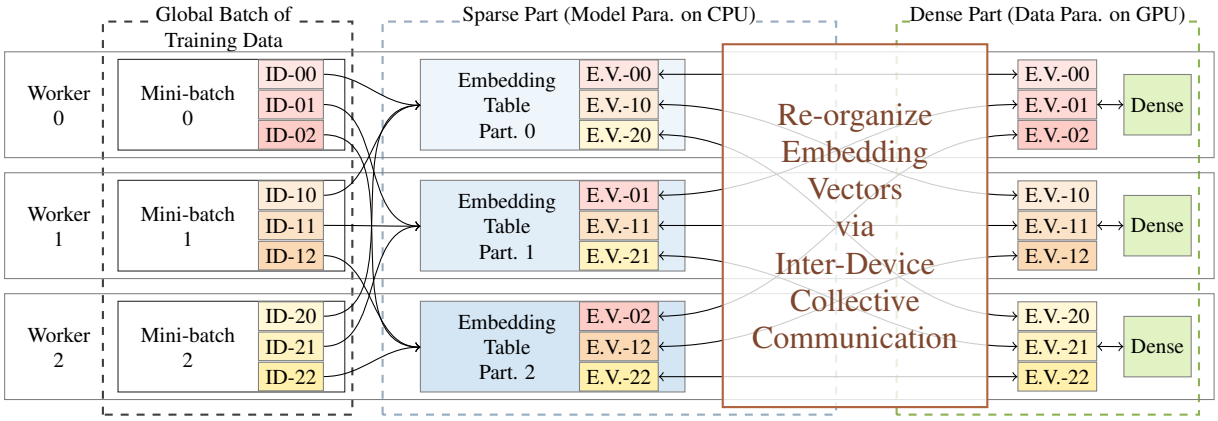

Figure 3: Existing Basic Hybrid Parallelism on Sparse Part and Dense Part

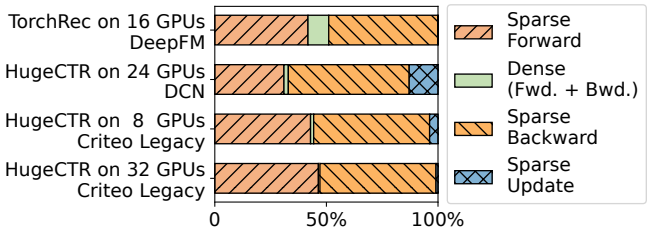

Figure 4: Iteration Time Break-down

In fact, the embedding vectors are created, read, and updated in the same way as a KV store system. Differently, the requests during DLRM training are served in large batches. The serving throughput is more important than the latency.

2.3 Throughput-Sensitive Data Management

While it is a widely known approach to handle hot and cold data separately, the presence of GPUs in DLRM training introduces unique challenges. Data management overhead of the training system is essential to overall performance. The system has to determine the items to replicate, indicate locations of all demanded items, and ensure synchronization of replicas within a short period of time.

When training a common DLRM, an NVIDIA V100 GPU consumes `159k` items in `10ms`. As there are commonly 8 GPUs in a node, the CPU has to provide the GPUs with embedding vectors of millions of items within a few milliseconds. The throughput of managing the embedding vectors should be as high as that of computation on GPUs, posing a strong efficiency demand.

The difficulty prevents prior works [2] from scaling up to multiple nodes. Expensive four-socket nodes [34] and even a dedicated CPU node equipped with Intel's most powerful Xeon Platium CPUs [3] are introduced to cope with the data management stress. As it is hard to change the hardware setup in many production cases, we focus on improving distributed DLRM training performance on the extensively deployed homogeneous clusters using commodity hardware.

2.4 Sparse Pattern of Training Data: Skewness

Intuitively, some items in DLRMs are much more frequently accessed than others, e.g., accounts of celebrities or spot news. Besides, embedding tables of some categories contain very few items, such as genders, which are always accessed. We refer to such uneven sparse access pattern as **skewness**.

It is easy to accelerate DLRM training by utilizing skewness across embedding tables. Applying different parallel strategies to different embedding tables [25, 33, 48] can reduce communication overhead with little modification of the training system. However, embedding tables are the smallest units of parallelism in these systems. Such granularity is so coarse that they miss many opportunities among items within embedding tables, and gain little improvement.

With a finer granularity, skew access pattern has been observed among embedding vectors within an embedding table [2,3,34]. We closely inspect such skewness in real datasets to find opportunities for improving the performance and scalability of distributed DLRM training.

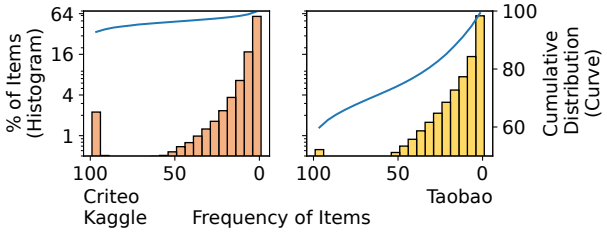

Figure 5: Observation on Skewed Distribution of Items

We inspect two public datasets, *Criteo Kaggle* [7] and *Taobao* [4]. We peek into 100 batches of training data in

each dataset. The histograms in Figure 5 aggregate the batch-frequency of items, i.e. the number of batches containing a certain item out of all 100 batches. In the *Criteo Kaggle* dataset, we find 2.2% items appear in more than 95 batches, indicated by the leftmost spiking bar of the histogram. We call them **frequent items** in our work. Similarly, we find that 0.6% items are frequent items in *Taobao* dataset. The rest items briefly follow an exponential distribution. Most of them appear in no more than 5 out of 100 batches.

We further inspect another batch to obtain the distribution of items over each bin, which indicates embedding vector access during training. Fewer than 1% items are not present in the previous 100 batches. As the cumulative curves in Figure 5 suggest, in *Criteo Kaggle* dataset, more than 90% accesses are directed to the 2.2% most frequently-accessed items. While in *Taobao*, 13% most frequent items can cover about 86% embedding vector accesses.

The skewness brings an opportunity for reducing communication. Suppose that we have a replica of the frequent items on each GPU, the `all-to-all` communication volume can be reduced by up to 90%. The end-to-end performance can be greatly improved since most time of distributed DLRM training is spent on the inter-device communication.

While the item-wise skewness pattern should be utilized, we keep in mind that the data management overhead should be minimized to achieve end-to-end speed up.

3 System Overview

HypeReca adopts the key-value store abstraction for the embedding vector database. As shown in Figure 6, the operations are integrated into the training process, while the stand-alone embedding database handles the requests.

Our system maintains the embedding vectors and the relevant optimizer states in chunks. The chunks may reside in host memory or device memory. As they occupy most of the storage space, *HypeReca* employs the following techniques to manage them. Decentralized Indexing Tables (**DIT**) are used to locate the embedding vectors in chunks on different processes, according to the input ID. It allows migrating the embedding vectors among chunks, and indexing the embedding vectors at high throughput. A special embedding chunk ($\mathcal{R}$ **chunk**) is placed in the device memory of GPUs to provide the dense part of the model with efficient direct device-local access to certain embedding vectors and utilize the skewness in the embedding vector access.

For a batch of IDs in the training dataset, the `Prefetch` operation first asynchronously locate or allocate the embedding vectors in the chunks. The `Pull` and `Push` operations work as the embedding computation in the forward and backward propagation. The `Update` operation commits the updates according to the gradients.

It takes negligible effort to use *HypeReca* with existing neural network training frameworks, such as PyTorch [29]

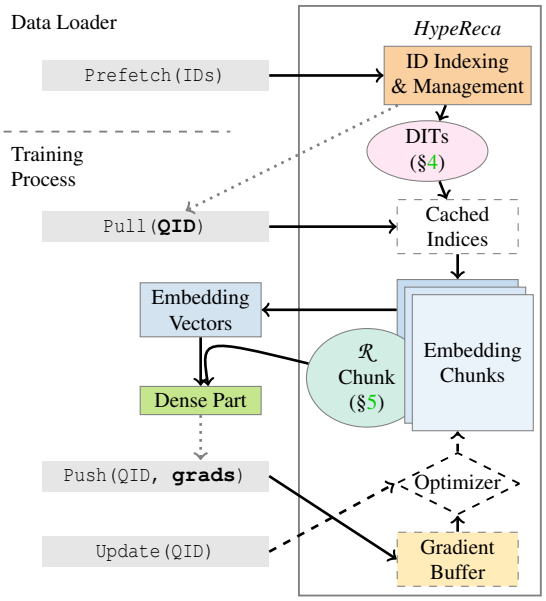

Figure 6: Overview of *HypeReca*

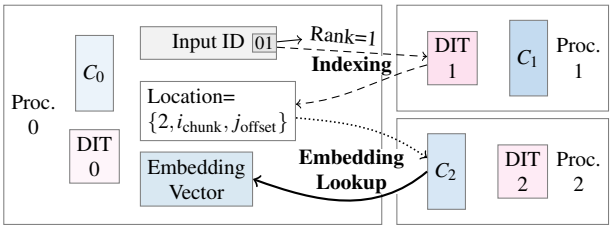
and HugeCTR [39]. While the `Prefetch` call may be inserted into the data loader or integrated with `Pull`, the operations can be simply used as a customized embedding layer.

4 Throughput-Oriented Data Management



Performance challenges of the sparse communication for embedding vector accesses come from complicated fine-grained data management. On the one hand, millions of items are consumed by the GPUs in milliseconds. On the other hand, the embedding vectors locate in various places to utilize the memory. For a batch of training data, the system goes through the management routine for each item separately, which results in fragmented memory access and inter-process communication. We mitigate these drawbacks with throughput-oriented designs for competitive end-to-end training performance.

4.1 Dynamic Decentralized Indexing

Most embedding vectors are maintained in distributed memory space across multiple processes. In existing systems, the input IDs are commonly directly mapped to partitions of the embedding table by simple hashing, e.g. using a few bits in the ID to indicate the index of the partition and offset within it. However, besides hash collision that may hurt model quality [43], it is less scalable. To extend the capacity of a partition, a significant amount of data has to be moved around in memory, leading to unpredictable access latency.

To efficiently manage memory, *HypeReca* allocates spaces for embedding vectors by chunks. Every process maintain several embedding chunks in the host memory. Also, we

place a special replicated chunk on each GPU. For a newly seen ID, it is assigned to a certain chunk. If there is no space left in the last chunk, a new chunk is allocated. By this design, *HypeReca* is able to avoid any collision, and keep allocated memory utilized. Besides, there is little overhead to maintain the chunks, because they are orders of magnitudes fewer than the embedding vectors.

Example embedding vector fetching process for an item in a mini-batch on process 0 whose location is maintained on process 1, and the embedding vector resides in chunk C_2 on process 2.

Figure 7: Workflow to Fetch an Embedding Vector

As Figure 7 shows, to fetch an embedding vector, there are two steps: (1) ID of the item is converted to location information in the distributed memory space, namely **indexing**; (2) the actual **embedding lookup** is performed, where the embedding vector is fetched from an embedding chunk.

The location information consists of rank of the process that holds the embedding vector, index of the chunk, and offset of the embedding vector within the chunk. This information is compactly packed into a few bytes.

HypeReca employs decentralized indexing hash tables (**DIT**) to maintain the locations of items, which is more scalable compared with a centralized indexing module. To guarantee consistency, each ID is exactly maintained by one certain hash table on a process. The last few bits of IDs are used to indicate the rank of the process. On each process, the DIT only maintains location information, which is much lighter than the embedding vectors.

In the embedding lookup step, the location information is used to retrieve the embedding vector from memory of processes *i*. Also, during backward propagation, the gradients are accordingly sent backward, and the embedding vectors are updated by the end of every iteration.

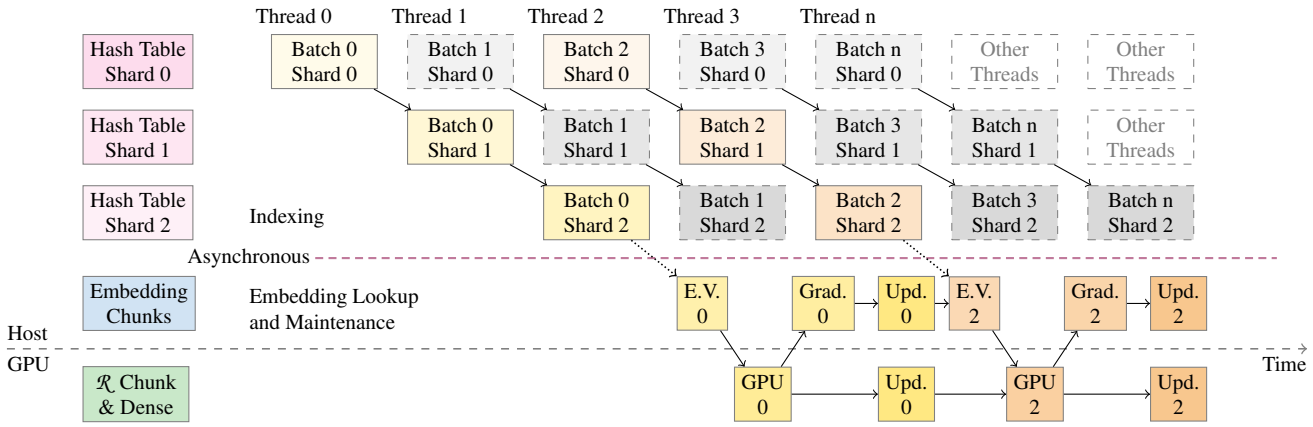
A notable detail is that simply accessing remote embedding vectors through RDMA is poorly efficient. In an experimental version of our system, we adopt one-sided RDMA put and get operations provided by UCX to directly fetch the embedding vectors from remote host memory. Unfortunately, because the embedding vectors are barely larger than 500 bytes, the overhead to send one-sided requests dominates. The actual communication bandwidth can hardly achieve more than 10% the theoretical peak bandwidth.

Instead, in our system, for a batch of embedding vector fetching requests from process *A* to process *B*, process *B* locally gathers embedding vectors from local chunks (and maybe perform some local pooling according to the model) into a temporary contiguous memory space before sending them to process *A*. This approach better utilizes the bandwidth of the network, and the RDMA network is managed by the high-level communication libraries, such as MPI and NCCL.

The decentralized indexing design provides *HypeReca* with high flexibility. ID of the items can be in any format, without the need to be preprocessed into contiguous indices, which is very useful for streaming training data.

4.2 Asynchronous Parallel Indexing Pipeline

We find an extra performance benefit from the indexing design. Performing indexing is not related to the actual data of embedding vectors, which is updated in every iteration. Therefore, indexing can be decoupled with embedding lookup, and moved to the thread for data loading. After the data loader reads IDs in a training sample from storage, *HypeReca* immediately convert these IDs into locations in *HypeReca*. The training thread then asynchronously reads them from a buffer, so the latency on the critical path is reduced.



Specifically, inter-process communication is conducted to perform indexing over remote DITs. When a process performs indexing for a batch of input IDs, it sends requests to all other processes. For each process, one thread handles one request from a remote process. The thread goes through the local DIT to find locations for each ID in the batch. New locations are assigned to embedding vectors of newly-seen IDs. Finally, after the allocation is finished, the thread responds to the request with a batch of locations.

The latency of the request-handling thread can be high, because even executed in batches, the latency to access hash tables is not that predictable. Fortunately, multiple threads are used to load multiple batches of data simultaneously ahead of training in most training systems, so indexing can also be performed in parallel to increase throughput.

To guarantee consistency of the DITs, read-write locks are used to support concurrent access. We observe that the lock is a performance bottleneck. Besides the overhead in its implementation, many other threads are blocked when one thread is trying to write new items. A naïve implementation can barely meet the throughput requirement.

We invent a parallel pipeline for the hash table operations, exploiting opportunities brought by the batch of queries. For better concurrency, we first slice the hash table into a few tens of shards. Multiple threads handling different indexing tasks go through the shards as a pipeline, as shown in Figure 8. Every thread only needs to lock a shard once, and all the IDs in this shard are processed. Such design eliminates most contention, because the threads are mostly operating on different shards in a pipeline manner.

This indexing pipeline is inspired by the commonly used

Batch 1 and 3 are trained on some remote processes. Thread 1 and 3 respond to the indexing request, and their further steps are not presented in this figure.

Figure 8: Indexing Pipeline and Computation in a Process

pipeline parallelism in training large neural networks. However, different from the inter-layer and inter-device pipeline parallelism, this pipeline works within the embedding layer and within a CPU. It utilizes independent data structures simultaneously for higher throughput.

Although this pipeline does not directly reduce indexing latency of one batch, the overall throughput of multiple threads is increased. As long as it can match the throughput on GPUs, the overall training process is not throttled by indexing, because it is processed by the data loading thread. In our practice, throughput of this indexing pipeline is high enough to match the throughput of 8 GPUs using 32 CPU threads.

5 Pattern-Aware Parallel Strategy

The chunk-based in-memory embedding database provides us with the flexibility to utilize skew access pattern by placing chunks on the GPU. The synchronization overhead of the chunks varies according to the placement strategy of the chunks and the related synchronization algorithm. Inspired by hybrid training algorithms of typical neural networks, we propose a hybrid chunk placement strategy, and build a performance model to guide the selection of the strategy. Over the ever-existing all-to-all communication for the sparse embedding vector access, we employ scheduling techniques to reduce its contention.

5.1 2-Fold Parallel Strategy

We partition the embedding vectors into two parts according to the access frequency. An item-wise two-fold parallel strategy (*2FP*) is applied to both parts of the embedding vectors. More specifically, we apply either of the following two strategies to the embedding vector related to an item: (a) data parallelism is used on a small portion of frequent items; (b) model parallelism handles the rest items.

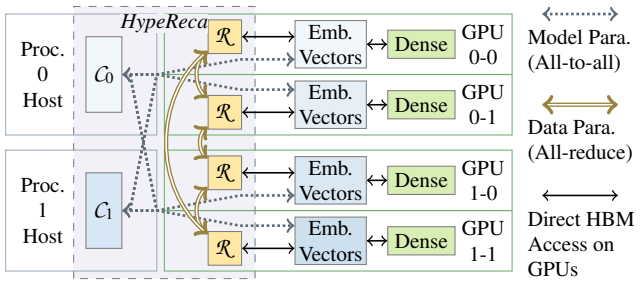


Figure 9: The Two-Fold Parallel Strategy (*2FP*)

Figure 9 illustrates the design of *2FP*. There are two exclusive types of partitions. Any embedding vector belongs to exactly one of them.

$\mathcal{R}$ is the replicated embedding chunk for high throughput GPU-local access of embedding vectors. There is a replica of $\mathcal{R}$ on each GPU, so accesses of embedding vectors in $\mathcal{R}$ are performed locally through the high-bandwidth device memory (HBM). Inter-device data movement is eliminated during forward and backward propagation, removing significant communication overhead. Synchronous data-parallel training algorithm is used over $\mathcal{R}$ to keep it consistent across GPUs. Gradients are synchronized in each iteration before updating the embedding vectors.

$\mathcal{C}_i (i \in [0, N_{\text{proc.}}))$ denotes the rest trivial chunks on process i. Host memory of the process is used to store embedding vectors in $\mathcal{C}_i$. This saves GPU memory to store $\mathcal{R}$ and the dense part. During training, processes fetch embedding vectors of samples in its local batch from all $\mathcal{C}_i$, excluding those in $\mathcal{R}$. Gradients are then pushed back, aggregated and used to update the embedding vectors. As the updates finish before the

pulling operation of the next iteration, the dense part always works on the latest version of embedding vectors. In other words, model parallelism is applied to $\mathcal{C}_i$. The embedding tables are row-wise partitioned.

HypeReca achieves model transparency via the two-fold strategy. The embedding vectors are kept in a fixed place throughout the training process. Without complicated strategies like prefetching or caching, we are able to guarantee strong consistency directly by parallel training algorithms.

Additionally, the *2FP* design removes the necessity to perform deduplication [46], which removes duplicated items before initiating all-to-all to reduce its volume, but introduces extra overhead. In *HypeReca*, the duplicated items are mostly frequent items in $\mathcal{R}$, which do not go through all-to-all.

In this section, we illustrate how to reduce the communication overhead with *2FP* by building a performance model. Speed up of *2FP* is achieved based on the efficient managing the data in end-to-end DLRM training processes.

5.2 Performance Modeling

To select proper items to put in $\mathcal{R}$ for optimal performance, there are two steps. First, we identify the frequency of items. Then, we pick a proper number of items.

For the first step, peeping at the dataset can provide adequate information to find out the most frequent items. As Figure 5 suggests, sampling of 100 training batches has already shown an obvious tendency of skewness. And 100 iterations are likely fewer than 1% of a training process that can be done in a few minutes. Due to the fact that more than $10k$ iterations are normally needed for training, and the data follows a similar skewed distribution, performing frequency counting of items in the first 100 iterations introduces only minor overhead. It is possible that the skewness changes during a training process that lasts much longer. We can always re-peep to keep $\mathcal{R}$ fresh, and this can be overlapped with other jobs that pause training, e.g. writing a checkpoint.

The second step is more challenging. The size of $\mathcal{R}$, denoted as $\mathbb{R}$, is significant to the performance. We find a trade-off between reducing the all-to-all volume and increasing the synchronization overhead of $\mathcal{R}$. Having more items in $\mathcal{R}$ can reduce the number of items that must be fetched across processes, i.e., all-to-all overhead. However, the whole $\mathcal{R}$ must be synchronized and updated as a dense parameter in every iteration, even if some items are not accessed at all, incurring overhead and losing the benefits of sparsity. Therefore, we need a proper $\mathbb{R}$ to minimize overall latency.

A performance model is built to help to determine $\mathbb{R}$. The overall communication latency L_{overall} consists of two parts:

$$L_{\text{overall}} = L_{\mathcal{R}} + L_{\mathcal{C}}$$

The latency to synchronize $\mathcal{R}$ is noted as $L_{\mathcal{R}}$ and the latency to fetch data in $\mathcal{C}_i$ is noted as $L_{\mathcal{C}}$. As both tasks are communication-intensive, there is little benefit from overlapping them, so we can add them up directly.

The first part, $L_{\mathcal{R}}$, is proportional to $\mathbb{R}$:

$$L_{\mathcal{R}} = \mathbb{R} C_{\text{ar}}$$

The latency comes with a coefficient C_{ar} that denotes the communication performance of all-reduce on given hardware and model setup, which can be calculated or measured by a micro-benchmark.

The second part, $L_{\mathcal{C}}$ is a little more complicated:

$$L_{\mathcal{C}} = N(1-\rho(\mathbb{R}))C_{\text{a2a}}$$

The latency of $\mathcal{C}_i$ is related to N, the number of items in a batch. Here, $1-\rho(\mathbb{R})$ denotes the portion of items that do not present in $\mathcal{R}$, and have to be fetched from $\mathcal{C}_i$. As communication for $\mathcal{C}_i$ is all-to-all, $L_{\mathcal{C}}$ is calculated with another coefficient, C_{a2a}, which can be obtained in a similar way to C_{ar} above.

Algorithm 1 Produce ρ from sampled training data

```
1:  function GetK(A sampled list of items D[N])
2:      C ← {0,0,...,0}   ▷ A map from item ID to counter
3:      for all Item ID i ∈ D do
4:          C_i ← C_i + 1
5:      end for
6:      U ← Unique IDs in C
7:      Descending sort U by C_{U_i}
8:      ρ_0 ← 0
9:      for i ← 1...|U| do
10:         ρ_i ← ρ_{i-1} + C_{U_i}/N
11:     end for
12:     return ρ
13: end function
```

$\rho(\mathbb{R})$ is a function that uses the sampled training data to estimate the portion of embedding vector accesses that are covered by $\mathcal{R}$. Algorithm 1 is used to determine $\rho(\mathbb{R})$ for any possible $\mathbb{R}$. Items are sorted according to their frequency, and the top $\mathbb{R}$ items are selected. Then, we calculate the expectations of items in $\mathcal{R}$ to appear in a training batch.

Finally, L_{overall} is expanded as follows:

$$L_{\text{overall}} = \mathbb{R} C_{\text{ar}} + N(1-\rho(\mathbb{R}))C_{\text{a2a}}$$

We observe that $L_{\mathcal{R}}$, the first part of L_{overall}, increases when $\mathbb{R}$ increases, while $L_{\mathcal{C}}$, the second part, decreases, corresponding to the aforementioned trade-off. Besides, $\rho(\mathbb{R})$ grows sharply with $\mathbb{R}$ when $\mathbb{R}$ is relatively small, e.g. a few thousands, and turns to a slow increase when $\mathbb{R}$ is larger. Therefore, L_{overall} is roughly a U-shaped curve over $\mathbb{R}$.

A ternary search algorithm can be used to quickly find an optimal range of $\mathbb{R}$, considering the memory limit as the maximum candidate value. Then, we employ bulk enumeration to get an optimal value of $\mathbb{R}$.

By further analyzing the equation, we can see that various batch sizes N lead to different optimal $\mathbb{R}$ values for minimum L_{overall}, as it only affects L_C. As N gets larger, $(1-\rho(\mathbb{R}))C_{\text{a2a}}$ becomes more significant in L_{overall}, and a larger $\mathbb{R}$ is more beneficial. This brings extra performance gain for *HypeReca* when scaling DLRM training up with larger batch size, if there is enough memory for a larger $\mathcal{R}$.

5.3 Analytical Effectiveness of *2FP*

Should the frequent items be removed from model parallelism, the communication volume of all-to-all can be significantly reduced. And as the they only make up a small portion of all items, they can be duplicated with little extra memory consumption, and synchronized with less communication overhead. This can be verified by applying the performance model to the real-world datasets that we observed.

First, we measure the performance of all-reduce for data parallelism and all-to-all for model parallelism on 32 GPUs across 4 nodes. Then, we calculate ρ from the datasets to estimate the reduction of communication.

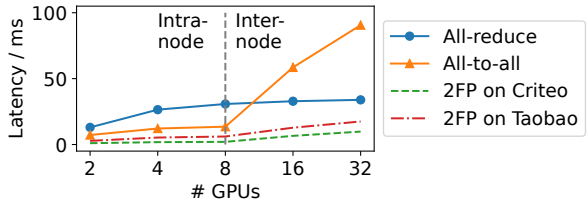

Figure 10: Communication Latency Modeling

For model parallelism using all-to-all, assume that there are `32MB` of embedding vectors to exchange on each GPU. Then, assume that the actual number of different items is about 6% the total number of samples. In this case, all-reduce is performed over `64MB` of embedding vectors on each GPU using data parallelism.

The solid lines in Figure 10 show the latency of both collective communication operations. The performance of all-to-all is better within a node, but its latency grows much larger than all-reduce when scaling up to more than 16 GPUs across multiple nodes, because it is unfriendly to the hierarchical connection topology. In contrast, all-reduce can scale up well across nodes, as the distributed reduction algorithms fit the hardware architecture and network topology better.

The dashed lines in Figure 10 show our estimation of communication latency of *2FP* on both datasets. When training over Kaggle dataset, we have $\rho(32,265) = 0.92$. This means about `32k` (2.2%) items are processed by all-reduce, and the all-to-all latency is reduced by 92%. Theoretically, the communication latency is reduced by 9.2×, compared to the original strategy that only applies model parallelism for the embedding vectors and performs all-to-all over all of them.

The case for Taobao is harder, but the opportunity is still significant. We use $\rho(227,058) = 0.86$, so having `227k` (13%) frequent items replicated removes 86% all-to-all overhead. As a result, the communication latency is reduced by 5.2×.

Even compared with data parallelism, there is $93\% - 245\%$ communication speed up. In fact, data parallelism is not practical because the actual memory footprint would be far more than that of all-to-all on the same number of items, because it duplicates instead of splitting data.

5.4 Contention-free Scheduling

Exchanging the embedding vector among processes is more complicated than a simple all-to-all collective communication operation. When the workers exchange the embedding vectors, they are first gathered into a temporary contiguous tensor from the chunks to utilize the network bandwidth. Similarly, during indexing, each worker iterates through its local DIT to respond to each indexing request.

We summarize the all-to-all request workload pattern as follow. Each process sends requests to all processes. To respond to the request, the remote process has to conduct computation locally before sending the results back. Basically, we employ a separate thread pool on each process to respond to the requests. Contention happens when multiple requests are sent to the same process simultaneously.

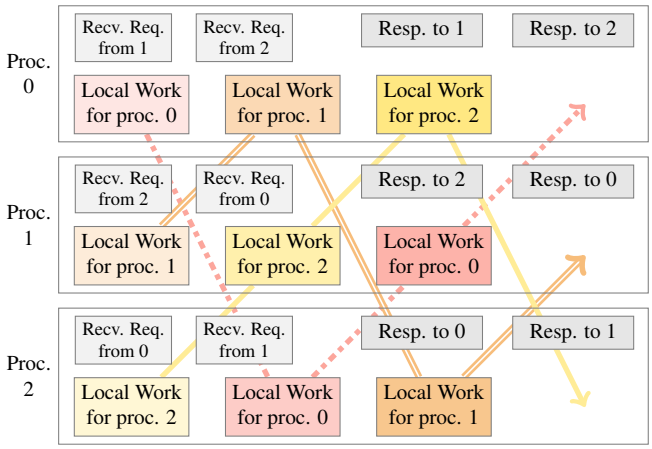

Figure 11: A 3-process Example of the Ring Schedule

HypeReca adopts a contention-free ring schedule to avoid the problem. Figure 11 instantiates the schedule with 3 processes. Formally, for a workload among n processes, n steps are performed. In step i, process r performs computation of request from process $((r+i) \mod n)$, and communication operations are executed accordingly.

For peak performance, the communication operations are all performed asynchronously to better overlap with computation. Computation for the request to the local process is

placed at the beginning of the schedule to minimize initialization overhead. Finally, at any point of time, each process has exactly one request to handle, so the demanded number of CPU cores remains stable through the training process, and the overall throughput is promising.

6 Evaluation

6.1 Setup and Methodology

We use two different clusters to evaluate *HypeReca*.

- *Antique*: Each node contains 8× `NVIDIA A100 SXM4` GPUs with `40GB` memory and dual `Infiniband HDR 200Gb/s` HCA cards. Due to limited quota, we are only able to compare scalability of *HypeReca* and HugeCTR over Terabytes dataset on this cluster.
- *Vintage*: Each node contains 8× `NVIDIA V100 PCIe` GPUs with `16GB` memory and an `Infiniband EDR 100Gb/s` HCA card. All experiments are conducted on this cluster unless otherwise stated.

Antique represents a high-end cluster setup for training large deep learning models, whereas *Vintage* has a more budget-friendly setting. The PCIe GPUs have similar communication bandwidth as consumer-grade GPUs, such as GTX 1080. As the DLRM training workload is communication-bound, we expect our system to achieve higher speedup on clusters with lower communication bandwidth, enabling DLRM training on these more economical hardware platforms.

We compare the performance of *HypeReca* with the following three open-source baselines.

TFDE [37] The name is short for TensorFlow Distributed Embeddings. It implements Parallax [17] for DLRMs using newer TensorFlow [1]. Compared with a bare data-parallel approach, this system maintains the sparse part by a distributed sparse parameter server. In fact, this is equivalent to the existing basic hybrid parallelism that applies model parallelism for the entire sparse part.

TorchRec [15] A coarse-grained hybrid parallel strategy [25, 33] is applied to utilize the skewness across embedding tables. It is easy to implement, yet missing opportunities within an embedding table. It also adopts CUDA unified memory technique for faster data transfer between host memory and GPU memory.

HugeCTR [39] This system is used by NVIDIA in the MLPerf DLRM benchmark, with a Caffe-like front end that supports a limited range of models. All the embedding tables are placed on GPUs, and it utilizes GPU-direct communication techniques to accelerate all-to-all.

We set up test cases using three public real-world datasets for three popular DLRMs, as shown in Table 1.

Taobao advertisement display and click dataset [4] is a public dataset of logs from *taobao.com*, one of the largest e-commerce websites in China. Sparse features of the dataset include IDs of products, customers, and campaigns. Criteo-Kaggle [7] dataset is a benchmark dataset for CTR prediction, with more masked sparse features per sample. Terabytes [6] is of similar data format, but much larger, used in MLPerf DLRM benchmark [41].

Table 1: Datasets and Models for Evaluation

Dataset Model	Taobao [4] DCN [27]	Criteo Kaggle [7] Legacy [39]	Terabytes [6] DLRM [41]
# Feat. (Den./Sp.)	4/4	1/39	14/26
# Samples	26M	36M	4.3B
Dataset Size	`1.17GB`	`4.3GB`	`671GB`
# Items	1.83M	1.60M	187M
Embedding Size	`117MB`	`411MB`	`96.1GB`

Deep and Cross Network (DCN) [27] uses a cross network layer, i.e. dot product of embedding vectors, to learn interactions between sparse features. The legacy model of HugeCTR [39] treats all features as sparse, and process them with a simple multi-layer perceptron (MLP) network. DLRM benchmark of MLPerf [41] uses an interaction layer with larger MLP, being a widely-used standard benchmark to evaluate DLRM training systems.

We first compare *HypeReca* with the baselines in end-to-end training. Each model is trained for 500 iterations, and the average trained samples per second is used as the metric of throughput. Then, we validate the performance model by testing different selection of $\mathbb{R}$. Also, we compare the indexing performance of *HypeReca* with a baseline implementation.

6.2 Scalability and End-to-end Results

We first measure both strong and weak scaling of *HypeReca*, i.e., keeping either global batch size or batch size per GPU the same, and use HugeCTR as a reference. We choose $\mathbb{R}$ of *HypeReca* for each setting according to the performance model, which is detailed in §6.5.

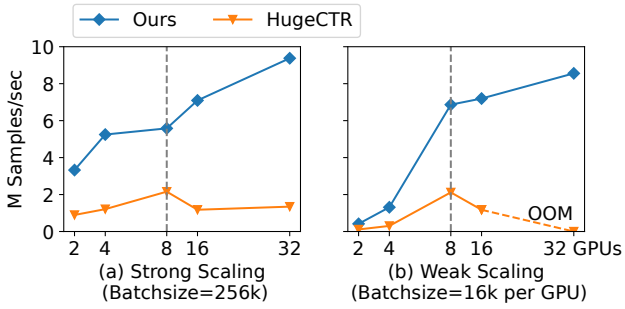

Figure 12: Intra- and Inter-Node Scalability on *Vintage*

The scalability on Criteo dataset is presented in Figure 12. Two systems show a similar tendency to scale up within a

node. However, when scaling to more than one node, *HypeReca* still speeds up as the number of GPUs increases, while HugeCTR becomes even slower. Notably, HugeCTR runs out of memory in the weak scaling experiment as the global batch size is too large, and it fails to utilize host memory. Meanwhile, *HypeReca* keeps most embedding vectors on the host side, using much less GPU memory, making it possible for larger batch sizes or more complicated dense parts.

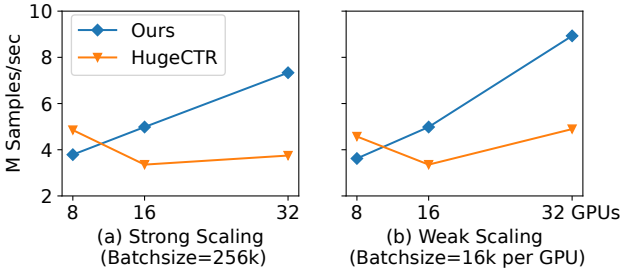

Figure 13: Inter-Node Scalability on *Antique* Cluster

Inter-node scalability on *Antique* over Terabytes dataset is shown in Figure 13. *HypeReca* is slower than HugeCTR on one node. HugeCTR benefits from the fast intra-node NVLink connection, while *HypeReca* has to copy embedding vectors in $\mathcal{C}_i$ from host memory via much slower PCIe connections. However, *HypeReca* outperforms HugeCTR on multiple nodes. Because the bandwidth of inter-node connection is lower (from `600 GB/s` per GPU to `400 Gbps` per node), HugeCTR is even slower on multiple nodes than on a single node. In contrast, *HypeReca* shows a better tendency to scale up to more nodes, even on a cluster with faster connections.

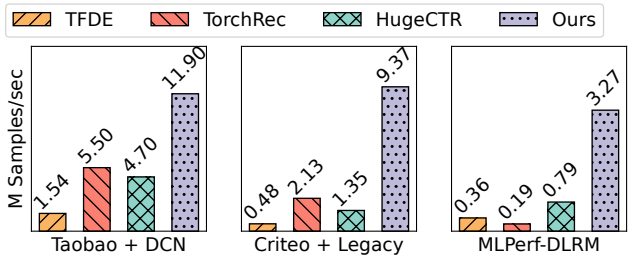

Figure 14: End-to-end Comparison on *Vintage* Cluster

Training throughput on 32 GPUs over different models and datasets are shown in Figure 14. TFDE achieves poor performance because of the high re-organization overhead. TorchRec outperforms HugeCTR in the first and second case, as it finds opportunities on certain embedding tables, while data transfer overhead between CPU and GPU slows it down on Terabytes dataset. *HypeReca* outperforms all baselines on all test cases, achieving 9.1×, 16.8×, and 4.2× speedup on the MLPerf benchmark, respectively.

Unfortunately, we are not able to compare *HypeReca* with other systems utilizing fine-grained skewness [2, 3, 34] due to issues on code availability or deployment feasibility. Meanwhile, they achieve less speed up over the same TorchRec baseline in test cases using similar models, datasets, and number of GPUs. As *HypeReca* outperforms TorchRec and HugeCTR on 32 GPUs, we believe that *HypeReca* achieves competitive performance and scalability.

6.3 Effectiveness of the Indexing Pipeline

We develop a micro-benchmark for the decentralized dynamic indexing module using different numbers of data-loading threads per process on each of 4 nodes. A node has 32 cores and 64 threads. As indexing is integrated into the data loader, the throughput of the data loader shall match the training throughput. We implement a baseline that uses hash tables without any schedule for the batches of queries. Another reference implementation is using a simple hash strategy for indexing without DITs, which involves the collision issue that degrades the model quality.

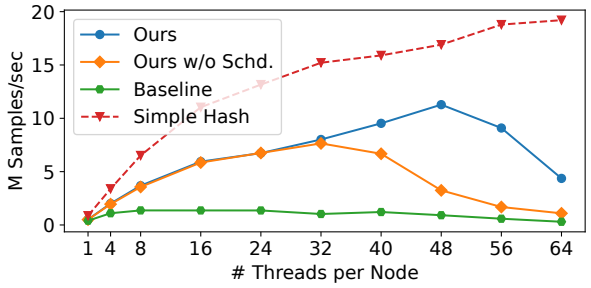

Figure 15: Multi-threaded Indexing Throughput

Figure 15 shows results of the micro-benchmark over Terabytes dataset. The baseline achieves a maximum throughput of 1.37M samples per second using 8 threads per node, much lower than the training throughput of *HypeReca*, 3.3M/s. Its throughput even decreases when using more threads, due to the high locking overhead of the DITs. In contrast, the indexing pipeline of *HypeReca* achieves more than 10M samples per second, 8.26× faster than the baseline. This matches the throughput of training the dense part on GPUs.

Because no communication is involved, the simple hash baseline is always faster than our system. Still, the optimally configured DITs achieve 50% the peak performance of such a performance-maximized implementation.

The *HypeReca w/o Schd.* curve shows the performance of *HypeReca* when we disable the contention-avoiding schedule of indexing. It is able to keep similar throughput with *HypeReca* using fewer than 32 threads. Because the CPU resource is relatively abundant, the requests can be handled quickly.

However, when having more threads that generate more requests simultaneously, contention severely slows down the indexing tasks, hence the whole system. Our schedule effectively reduces the contention, and is even able to improve the throughput when the CPU is oversubscribed. As there are other active threads, *HypeReca* achieves the peak performance when oversubscribing 50% CPU cores, which brings 40.8% extra throughput over the case using 32 cores.

6.4 Overhead for Changing Skewness

Regarding the change of skewness pattern during the training process, we first observe the Terabytes training data in an entire epoch. The data includes real online user access history across 24 days. We first get the $\mathcal{R}$ of different sizes according to the first 100 batches of the first day. Then, we inspect the coverage of access in the following iterations of the first day, and in some sampled batches of the next 23 days.

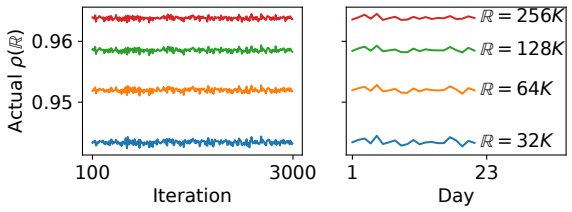

Figure 16: Variance of Skewness During Training

As shown in Figure 16, all of the actual $\mathcal{R}$ coverage rates are consistent, both within a day and across multiple days. Besides, shuffling of the dataset is a common practice for training on both offline and online training data. Therefore, this result is generalizable to other scenarios.

Second, we evaluate the overhead to update the $\mathcal{R}$ by writing all the embedding vectors back to the $\mathcal{C}_i$, and then pull new frequent embedding vectors into a new $\mathcal{R}$. The result of the micro-benchmark is shown in Figure 17.

Figure 17: Comparing the Latency of Re-sharding

As a reference, we include the latency of 10 training iterations of the MLPerf-DLRM model with different batch sizes. The overhead of such re-sharding operation increases with the size of $\mathcal{R}$. Meanwhile, even with the largest $\mathbb{R}$, it only takes about 1 second to complete the re-sharding tasks. The latency is at the same level of training for 10 iterations. Considering the above observations that the skewness pattern will likely remain stable, we can conclude that the overhead to update the $\mathcal{R}$ with the changing skewness pattern is minor in the whole training process.

6.5 Validating the Performance Model

We calculate $\rho(\mathbb{R})$ for all the datasets, as presented in Figure 18. When $\mathbb{R} = 64k$, $\rho(\mathbb{R})$ is 73.9% for Taobao, and around 96% for both Criteo and Terabytes. This contributes to the reduced communication volume of *HypeReca*, and explains the reason for *HypeReca* to perform better on the latter two.

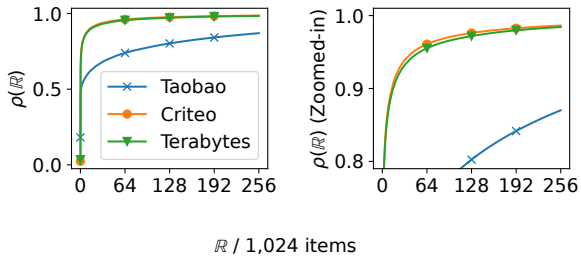

Figure 18: $\rho(\mathbb{R})$ for Used Datasets

The red dashed curve in Figure 19 indicates the latency predicted by our performance model using the above $\rho(\mathbb{R})$ in three setups on 32 GPUs. Except for a few outliers caused by performance disturbance, it matches the actual latency well. The average coefficient of determination, r^2, exceeds 0.9 when fitting parameters, C_{ar} and C_{a2a}, which validates the accuracy of our performance model.

The stacked areas of Figure 19 represent a break-down analysis of the latency over different $\mathbb{R}$. Latency of the dense part remains unchanged, because it only involves unchanged dense computation on GPUs. Overhead of data parallelism for $\mathcal{R}$ grows linearly with its size. The `all-to-all` overhead decreases in an L-shaped curve, in accordance with $(1 - \rho(\mathbb{R}))$. For Terabytes dataset, its latency reduces drastically when $\mathbb{R}$ increases from 0 to 1024, and then gradually gets smaller when increasing $\mathbb{R}$. As small $\mathcal{R}$ covers less items in Taobao dataset, the all-to-all latency decreases slower.

In all 3 different setups, the overall latency is a U-shaped curve over $\mathbb{R}$. An optimal $\mathbb{R}$ brings up to 7.80× speedup over Terabytes dataset, and 1.60× over Taobao, comparing with $\mathbb{R} = 0$, i.e., disabling *2FP*. This matches the speed-up over the baseline systems in Figure 14, and suggests that simply using host memory to store embedding vectors without *2FP* brings little speedup.

For Terabytes dataset, we conduct the ablation experiment over two different batch sizes. The optimal $\mathbb{R}$ gets larger as the batch size grows, which matches the observation from the equation of our performance model in §5.2.

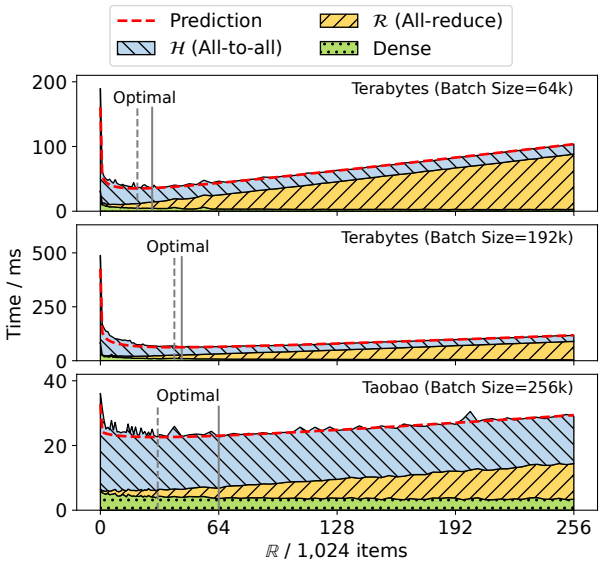

Figure 19: Iteration Time Prediction and Actual Breakdown

Meanwhile, the end-to-end latency varies little around the optimal $\mathbb{R}$ value. Estimating a brief range of $\mathbb{R}$ is enough to get near-optimal performance of *HypeReca*. In our experiments, the deviation of $\mathbb{R}$ estimations from real optimal values incurs no more than 1% overhead on actual latency.

As the optimal $\mathbb{R}$ ranges from 20k to 64k, the GPU memory of $\mathcal{R}$ ranges from `10MB` to `32MB` for the embedding vectors of 128 floating point numbers. Therefore the overhead to store and synchronize $\mathcal{R}$ is minor for GPUs.

7 Related Works and Discussion

General auto-parallel NN training systems. Recent works [26, 31, 32, 49] focus on partitioning typical dense models with a computation graph as input. These approaches fail to explore sparsity within layers, e.g. skewed data access pattern of embedding tables.

4-D parallelism for DLRM. A prior work [25] concludes all possible parallelism for DLRM into 4 types: column-wise and row-wise, table-wise and data parallelism. *2FP* generally contains the latter three ways of parallelism in a more flexible and high-performance way. While embedding vectors are mostly too short to be applied with column-wise parallelism in practice, *HypeReca* is also compatible with it.

Using GPU memory as cache. GPU memory is treated as a cache of CPU memory in many other works [9, 24, 42], and they achieve speedup on single GPUs. However, they select frequent items separately on each worker, and do not change the `all-to-all` communication pattern. Therefore, they do not scale up to multiple GPUs better than HugeCTR [39], which puts all data on GPUs, Furthermore, our work is orthogonal to these works, and can directly apply their techniques on $\mathcal{C}_i$ in *HypeReca*.

Distributed replicated cache [3] is partly equivalent to *2FP*, but online addition and eviction make its control flow too complicated to achieve competitive scalability.

Hardware-dependent systems. Introducing specific hardware can alleviate the communication bottleneck, e.g. utilizing fast NVLinks within a node [48] or pairing every GPU [25, 34] with high-performance NICs. Compared with these systems that require expensive hardware, *HypeReca* is more general and applicable to various setups with more affordable commodity hardware.

Changing the training algorithm. Embedding vector decomposition [35, 38, 40] and compression [10] reduce the memory footprint of the sparse part. Asynchronous training [21, 24, 43] and dropping some unimportant embedding vectors [20] are proved effective in certain cases. Model developers have to be aware of the deviation of algorithms which may affect model quality. *HypeReca* does not bring such concern, while being compatible with them.

DLRM as a graph. The training samples of DLRMs may be treated as edges in a hypergraph. Using graph-based methods to train the model may improve its efficiency [45]. However, it is hard for current graph-based training systems [13, 14] to meet the throughput demand of DLRMs and keep model-transparency at the same time.

Typical KV store systems. Cold/hot partitioning is employed by typical key-value store systems [8]. Meanwhile, applying such technique to the DLRM training workload demands extra dedicated design in synchronization policy and throughput-centric data management mechanism.

8 Conclusion

Scalability of DLRM training is important, while sparse communication of re-organizing data between its two parts introduces huge communication cost. We design an in-memory distributed embedding database, *HypeReca*, to reduce the cost. The throughput-centric data management module allows us to utilize GPU memory with the sparse access pattern of the workload. The two-fold parallel strategy effectively boosts the overall performance of the distributed DLRM training.

CrossPipe: Towards Optimal Pipeline Schedules for Cross-Datacenter Training

Tiancheng Chen[1], Ales Kubicek[1], Langwen Huang[1] and Torsten Hoefler[1]

[1]Department of Computer Science, ETH Zürich

Abstract

Training large language models (LLMs) now requires resources that exceed a single datacenter, making cross-datacenter strategies increasingly crucial. We present CrossPipe, a framework designed to optimize model training across geographically distributed datacenters by explicitly modeling and mitigating the impact of network latency and limited bandwidth. It enables unified analysis and optimization incorporating both pipeline parallelism (PP) and opportunities for overlapping data parallelism (DP) communication. CrossPipe generates optimized pipeline schedules using either solver-based optimal or fast near-optimal greedy algorithms, built upon a flexible execution engine that separates scheduling logic from communication details. Our evaluation shows that CrossPipe reduces training time by up to 33.6% compared to traditional pipeline schedules under identical memory constraints. When memory constraints are relaxed, CrossPipe maintains strong performance despite communication delays, approaching the efficiency of idealized schedules without delays. CrossPipe offers improved scalability and resource utilization, particularly in environments with high network latency or limited bandwidth.

1 Introduction

Large language models (LLMs) have revolutionized natural language processing, demonstrating remarkable capabilities in tasks such as text generation, translation, and question answering. These models, trained on massive datasets, exhibit sophisticated context understanding and generate human-like responses. Their applications span scientific research [59], content generation [29], and personal assistants [31]. LLM training consists of three stages: pre-training, fine-tuning, and alignment, with pre-training consuming the majority of computational resources [11, 15, 66].

As LLM performance scales with model size and data volume, computational demands have increased exponentially. Recent studies estimate that training compute for state-of-the-art models quadruples annually [48], necessitating both vertical scaling (faster accelerators) and horizontal scaling (distributed computation). While GPU performance and energy efficiency continue to improve steadily [16], the power and infrastructure required to support LLM training is growing even faster. If current trends hold, GPU counts must nearly triple each year, with power consumption rising accordingly.

The escalating computational demands of LLMs are straining existing infrastructure, particularly power supply systems. To address these energy requirements, companies like Microsoft, Google, and Amazon are turning to nuclear energy sources to power their new AI datacenters [7, 36, 46], emphasizing the need for reliable and high-capacity power sources. Scaling a single datacenter introduces challenges including local power limitations and increased vulnerability to outages. Report suggests that deploying multiple smaller facilities is more practical than scaling a single massive one [5].

As LLM scale grows, multi-datacenter training is becoming essential [1], distributing both compute and energy loads. However, geographic distribution introduces significant communication inefficiencies that must be addressed to support this shift. In the context of cloud-based training, allocating large blocks of GPUs in one region is often infeasible [54], making cross-regional GPU acquisition a practical alternative. The high cross-region communication cost poses challenges to the efficiency of existing training methods. This work attempts to assess the impact of network inefficiencies to synchronous training tasks and improve the performance to reduce the cost and energy consumption.

This paper introduces CrossPipe[1], a framework that improves the efficiency of cross-datacenter (cross-DC) LLM training through the following contributions:

- **Analysis:** We present a comprehensive analysis of cross-DC training methodologies and show that pipeline parallelism is the most feasible approach in this setting.
- **Performance Model and Algorithm:** We present a latency

[1]The code is available at https://github.com/spcl/crosspipe.

and bandwidth-aware performance model specifically designed for the cross-DC environment. This model enables the co-optimization of pipeline schedules with potential data parallelism (DP) communication overlap, unifying the modeling of cross-DC PP and cross-DC DP. Next, we introduce a system-aware pipeline schedule generation algorithm: CrossPipe. The algorithm leverages either constraint optimization techniques to generate *optimal* cross-DC pipeline schedules (Section 4.1) or fast greedy algorithm to generate efficient and *near-optimal* schedules (Section 4.2).

- **Framework:** Finally, we propose and implement a flexible and easily extensible pipeline execution engine featuring a two-layer abstraction that decouples block scheduling from communication arrangement (detailed in Section 6.3). This design enables efficient deployment of different pipeline schedules, including those generated by CrossPipe.

2 Cross-DC Training

2.1 Parallelism Strategies

Distributed LLM pre-training [4] employs a combination of different parallelism strategies (termed *hybrid parallelism*) to partition the workload across GPU clusters. Table 1 lists symbols and notations used in this paper.

Tensor Parallelism (TP) [2]: Splits each model layer across multiple GPUs [27,53], requiring extensive collective communication (e.g., Reduce-Scatter and Allgather [37]) during both forward and backward passes. Due to limited opportunities for overlap [64] and high communication costs, TP is typically restricted to high-bandwidth domains (e.g., NVLink [40]), making it unsuitable for spanning geo-distributed DCs.

Pipeline Parallelism (PP): Divides the model layers into n_{PP} *stages*, with each stage assigned to a different GPU. Communication occurs only at stage boundaries via point-to-point send/receive of activations and gradients.

Data Parallelism (DP): Replicates the full model on each GPU, where distinct batches are processed independently and gradients are synchronized across replicas. DP is usually applied with ZeRO [45] to reduce memory redundancy. This work assumes DP with ZeRO stage 1, partitioning optimizer states without increasing communication overhead compared to vanilla DP. Higher ZeRO stages introduce extra communication with diminishing memory savings.

Sequence Parallelism (SP) [3]: Scales sequence dimension [21,33] and is typically applied at the end of pre-training to increase model context window [12].

Expert Parallelism (EP): Distributes the expert MLPs in Mixture of Experts (MoE) [20, 51] models. The per-layer, high-volume, and dynamic Alltoall communication in EP makes it challenging to deploy on cross-DC links.

[2]Also known as Operator Parallelism.
[3]Also known as Context Parallelism.

Notation	Description
n_{DC}	# of datacenters
$n_{\{TP,PP,DP\}}$	TP, PP, DP size
$T_{\{F,B,W\}}$	Runtime of F, B, W block
$M_{\{F,B,W,L\}}$	Net memory change in F, B, W block and memory budget
M_L	Memory limit per device
α, β	Communication latency and inverse of bandwidth
T_α, T_β	Communication cost matrix
b, $\hat{B}$	Microbatch size and global batch size
n_{mb}, ε	Number of microbatches per DP rank, and ratio n_{mb}/n_{PP}
s, d	Model sequence length and hidden dimension
n_{sub}	Number of parts in a sub-block schedule (Section 4.2)

Table 1: List of symbols and notations.

Key Insight: TP, SP, and EP introduce layer-wise communication with high frequency and/or volume, making them highly sensitive to the latency and limited bandwidth typical of cross-DC links. Therefore, PP and DP emerge as the primary candidates for cross-DC traffic, due to their less frequent (PP, DP) or point-to-point (PP) communication patterns.

2.2 Communication Model

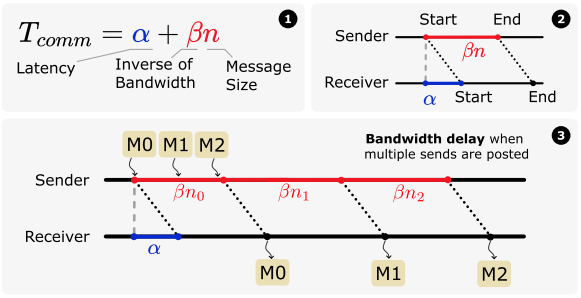

Figure 1: Alpha-Beta communication model ❶ sending a single message ❷. When multiple pending messages are to be sent, the latter messages need to wait for the previous ones to be placed on the transmission link first. This results in an extra bandwidth delay ❸.

In this work, we assume a small number of DCs (e.g., $n_{DC} \leq 4$). For modeling the communication time T_{comm}, we adopt the Alpha-Beta model, accounting for both latency (α) and bandwidth limitations (β). Multiple concurrent messages incur additional queuing delays, illustrated in Figure 1.

2.3 Distributed Training Infrastructure

Cross-DC infrastructure setups can be categorized into four primary types, as shown in Figure 2. We differentiate between high-performance clusters and public cloud environments, further classified by geographic proximity: either nearby (same-campus, same-region) or distant (cross-campus, cross-region).

- **Same-Campus Clusters** ❶ setup represents tightly interconnected DCs on the same campus, typically connected via frontend network or additional switch layer. This setup features low latency (up to 10 us [4]) and high bandwidth (800 Gb/s [4] per port), making communication overhead negligible, but still slightly higher than a single cluster.
- **Cross-Campus Clusters** ❷ setup represents geographically distributed DCs (typically up to 40 km apart, using public products like NVIDIA MetroX) interconnected with high-bandwidth links (200 Gb/s [4] per port). Network latency is bounded by the physical distance (10-200 us [4]).
- **Same-Region Cloud** ❸ setup represents closely allocated instances within the same cloud region. This setup features low bandwidth (around 11.3 Gb/s [5]) [55] and higher latency (around 1 ms [5]) [55] compared to the setups discussed above due to the usage of less specialized networking hardware.
- **Cross-Region Cloud** ❹ setup represents instances allocated across cloud regions or even continents. This setup inherits the same properties as a same-region cloud but with significantly higher latency (30-100 ms [5]) [55] and even lower bandwidth (1.4-5.0 Gb/s [5]) [55] due to distance.

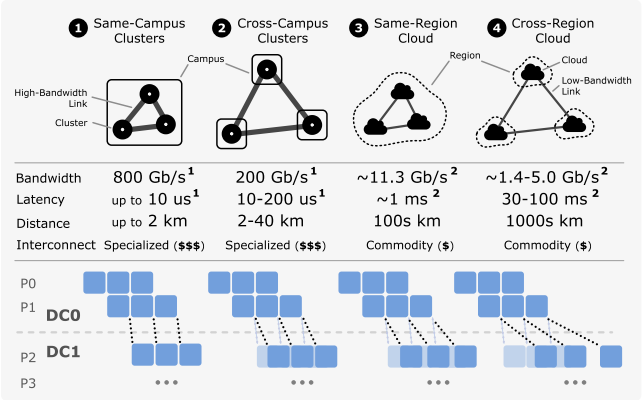

Figure 2: Cross-DC infrastructure setup types and their impact on the PP communication at DC boundaries.

Table 2: The hidden dimension d, number of parameters N of LLMs. D and E refer to dense and MoE models respectively.

Model	d	N (10^9)	N/d (10^6)
Mistral 7B (D) [23]	4096	7.24	1.77
Mixtral 8x7B (E) [24]	4096	46.7	11.4
Qwen2.5 32B (D) [44]	5120	32.8	6.41
DeepSeek V3 (E) [9]	7168	685	95.6
Llama 3 405B (D) [12]	16384	406	24.8

These infrastructure variations drastically affect communication characteristics. To analyze their impact independent of specific hardware or model configurations, we normalize the communication time components (T_{lat} and T_{bw}) by the max per-microbatch forward computation time per stage (T_F), see Section 3.3). This yields dimensionless ratios, T_{lat}/T_F and T_{bw}/T_F, which capture the relative cost of communication.

2.4 Cross-DC Parallel Dimension Selection

Hybrid parallelism exhibits structured communication patterns, with over 99% of GPU pairs having no direct traffic [65]. The choice of parallelism strategy across DCs significantly influences training efficiency. Figure 3 compares two viable options identified in Section 2.1: cross-DC PP and cross-DC DP. Cross-DC PP communication volume is characterized by $sd * n_{DP}$ while cross-DC DP communication volume is characterized by model parameters N. The key hyperparameters of some LLMs are shown in Table 2. We analyzed both cross-DC PP and cross-DC DP for Llama 3 405B in Section 5.2, demonstrating that cross-DC PP is generally the better choice. The increased popularity of MoE models further shifts the preference towards cross-DC PP [6], since experts in MoE models introduce extra DP communication volume compared to dense models with similar width d.

3 Pipeline Model

3.1 Computation Blocks

PP partitions model chunks across n_{PP} stages, processing input microbatches in sequence. During the backward pass, gradients propagate in reverse, from the last model chunk back to the initial one. Periods when devices remain idle while awaiting required data are termed pipeline bubbles. To evaluate pipeline efficiency, we define the bubble ratio as the fraction of idle time over total time per device.

We denote the Forward computation for each chunk as the F block, and the Backward computation as the B block. Each B block can be further split into an input data gradient computation block (DGrad, or D) and a weight gradient computation block (WGrad, or W) [43]. An illustration of this decomposition is provided in Appendix B. This finer granularity facilitates the construction of more efficient pipeline schedules with reduced bubble ratios.

3.2 System Parameters

Although our focus is on training Transformer-based [61] LLMs in cross-DC environments, our approach applies to large models structured as a sequence of layers. Relevant

[4] Calculation based on the best commercially available hardware (NVIDIA LinkX / MetroX), assuming 5 ns/m.

[5] Measured.

[6] Llama 3 405B is trained with $s = 8192$, $n_{DP} = 128$, yielding $N/sdn_{DP} \approx 23.6$. DeepSeek-V3 is trained with $s = 4096$, $n_{DP} = 128$, yielding $N/sdn_{DP} \approx 182$. Notice that Llama 3 405B is wider in d and therefore can be viewed as the basis of a MoE model much larger than DeepSeek-V3.

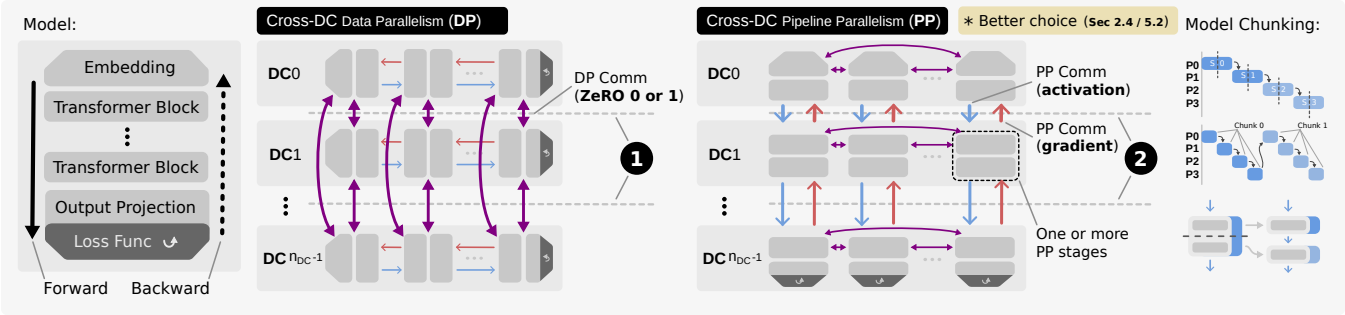

Figure 3: Typical LLM architecture (left). **Cross-DC DP:** Each DC maintains independent model copies. ❶ Collective operations (Allgather and Reduce-Scatter, or Allreduce) synchronize gradients and update parameters (ZeRO stage 0 or 1). **Cross-DC PP:** The model is partitioned among DCs at layer boundaries. Each DC holds one or more pipeline *stages*. DP communication happens internally within each DC to synchronize gradients of stages each holds. ❷ Inter-DC communication employs point-to-point send/receive operations for exchanging activations and gradients. Stages can further split into finer *chunks* to enhance scheduling efficiency (Section 3.3).

system parameters include memory usage, per-chunk computation time, and inter-stage communication latency and bandwidth delays. Memory consumption encompasses static elements (parameters, gradients, optimizer states) and dynamic allocations (activations cached during F blocks and released after D and W).

3.3 Pipeline Schedules

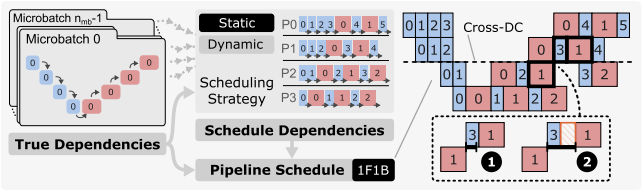

Figure 4: Construction of a 1F1B static schedule. True dependencies guide the creation of schedule dependencies. The resulting acyclic dependency graph governs execution and is used for runtime estimation (Section 3.5). Highlighted parts (right) show the timing of activation/gradient arrival either ❶ enables immediate scheduling or ❷ causes delays (bubbles).

Pipeline schedules are represented as acyclic dependency graphs, with vertices as pipeline blocks and edges representing two types of dependencies: true dependencies (data dependencies within each microbatch) and schedule dependencies (execution order within each pipeline stage). The construction of a 1F1B schedule is illustrated in Figure 4.

True dependencies reflect actual data flow across blocks (forward for activations, backward for gradients). Figure 5 shows key traversal (data flow) patterns: Unidirectional (UD), Bidirectional (BD), Loop, and Wave.

Schedule dependencies define the execution order of pipeline blocks within each stage. These dependencies are determined using either a static or dynamic scheduling strategy. Static strategies predetermine block placements (usually hand-optimized), while dynamic strategies adapt based on system parameters. CrossPipe schedules (Section 4) fall under dynamic scheduling.

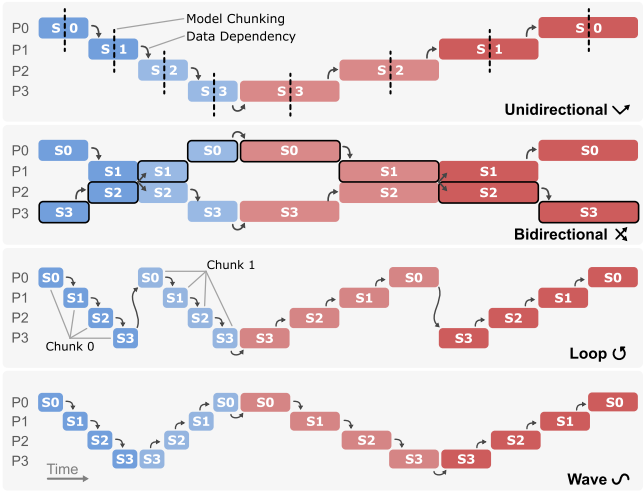

Figure 5: Traversal patterns for a single microbatch (two microbatches shown in the Bidirectional pattern). Loop and Wave patterns leverage model chunking to refine granularity.

3.4 Problems of Static Scheduling

In the presence of communication delays, we identify two major limitations that reduce the efficiency of static schedules in cross-DC PP: static execution order (scheduling-level) and static communication arrangement (implementation-level).

Static Execution Order: Static schedules are optimized under the assumption of negligible communication cost, as in single-DC settings. When directly applied to cross-DC training, they fail to adapt to higher communication delays, resulting in pipeline inefficiencies visualized as *bubble strides* (illustrated in ❷ Figure 6 and Appendix C). **Schedule** ❷ in

Figure 6 depicts a critical path in a 1F1B schedule across 2 DCs involving 8 cross-DC PP communications. Since the path consists solely of true and schedule dependencies (Section 3.3), its length imposes a lower bound on overall runtime. For a 1F1B schedule of n_{mb} microbatches, there exists a path containing $O(n_{mb})$ cross-DC communications. As a result, communication delays are amplified proportionally, significantly degrading training throughput. A detailed analysis of this amplification effect is presented in Section 5. CrossPipe addresses this limitation via dynamic scheduling strategies, detailed in Section 4. **Schedule ❸** in Figure 6 illustrates that reordering pipeline blocks can improve efficiency while maintaining the same peak activation memory if needed.

Static Communication Arrangement: Existing frameworks such as Megatron-LM often group pipeline communication operations (e.g., GPU 0 sending to GPU 1 while receiving from GPU 1) for simplicity and hardware efficiency, which introduces implicit synchronization. Moreover, even if this grouping is avoided, the two-sided communication pattern introduces synchronization between the sender and receiver in each send/recv operation. Due to variations in stage execution time, the receiver may fail to post the corresponding receive in time, causing the sender to wait. These delays disrupt stage alignment, which many hand-optimized schedules assume, and propagate bubbles across the pipeline. The interleaved 1F1B schedule [39] overlaps communication with one computation block to mitigate this synchronization cost. However, its static design is only effective under small delays. To address this, CrossPipe decouples scheduling logic from communication orchestration, allowing more fine-grained and adaptive execution, as elaborated in Section 6.3.

3.5 Pipeline Performance Model

We develop a performance model to estimate the runtime of a pipeline by leveraging the topological ordering of its dependency graph (Section 3.3). This model assumes that scheduling and communication orchestration are decoupled, thereby excluding delays caused by synchronization overhead (see Section 3.4). The start time of each block is determined by the maximum of two values: (1) the completion time of the preceding block on the same stage (❶ in Figure 4), and (2) the completion time of the dependent block plus the communication delay (❷ in Figure 4). The communication delay consists of a fixed latency component and a bandwidth-related component, which depends on both link bandwidth and current occupancy (Section 2.2).

4 CrossPipe Schedules

4.1 Optimal Schedule

The optimal pipeline schedule depends on the system parameters and can be framed as a job scheduling problem. Prior

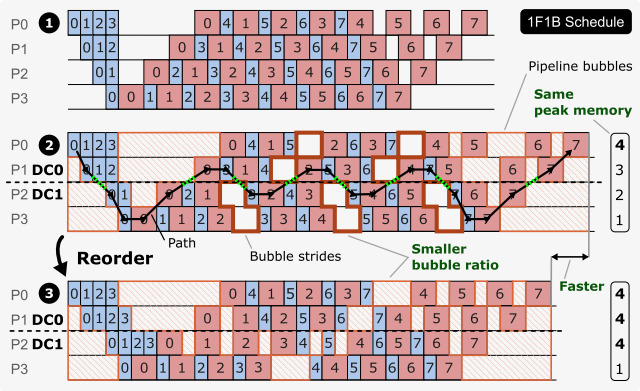

Figure 6: ❶ Original 1F1B schedule. ❷ 1F1B schedule with Cross-DC PP communication which leads to *bubble strides*. A *Path* is depicted (→) including cross-DC boundary crossings (⇢). ❸ The schedule after reordering is more efficient while maintaining the same peak memory. More microbatches or memory budget can help to further reduce runtime.

work [43] formulates this using mixed integer linear programming. Building on this, we elevate communication operations to first-class citizens alongside computation, incorporating both latency and bandwidth delays into the formulation, and generalize this to traversal patterns (Figure 5). This leads us to define the problem as a constraint optimization (CO) task. In addition to yielding start and end times for all operations, the solution inherently determines the execution order of communication operations that share the same cross-DC link, thereby handling link contention and scheduling order of cross-DC communications implicitly.

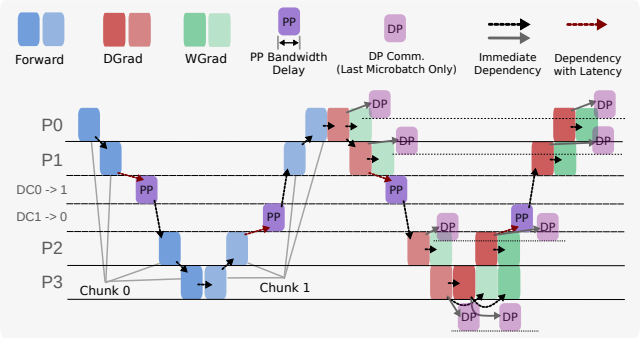

Figure 7: The data dependency in a Wave schedule with modeling of both computation and communication. For each model chunk, the DP communication only depends on the W block of last microbatch. The modeling of vanilla DP is shown in the figure. For DP with ZeRO stage 1, an Allgather block should precede the F block of the first microbatch in each model chunk.

Sets and Indices Every *compute* operation is uniquely identified by the triple $(s,k,t,m) \in \mathcal{S} \times \mathcal{K} \times \mathcal{T} \times \mathcal{M}$. Each communication operation $c \in \mathcal{C}$ transfers the data produced by a

compute operation on stage $\text{src}(c)$ to stage $\text{dst}(c)$.

- $\mathcal{M}$: Microbatches, indexed by $mb = 1, \ldots, n_{mb}$
- $\mathcal{S}$: Devices (pipeline stages), indexed by $s = 1, \ldots, n_{PP}$
- $\mathcal{T}$: Operation types, $\mathcal{T} = \{F, D, W\}$
- $\mathcal{K}$: Model chunks
- $\mathcal{P}$: Compute operations (indexed by (s, k, t, m))
- $\mathcal{C}$: Communication operations
- $\mathcal{O} = \mathcal{P} \cup \mathcal{C}$: All operations

Inputs The input variables are closely related to system parameters in Section 3.2.

- d_o: Duration of $o \in \mathcal{O}$ (bandwidth time for $c \in \mathcal{C}$, computation time otherwise)
- ℓ_c: Latency delay for $c \in \mathcal{C}$
- m_p: Net memory change after compute $p \in \mathcal{P}$ completes
- $M_s^{\max}$: Memory limit of device s
- $\text{Pred}(o)$: Immediate predecessor of o in data dependency

Decision Variables

- $t_o \in \mathbb{R}_{\geq 0}$: Start time of operation $o \in \mathcal{O}$
- $x_{o,o'} \in \{0, 1\}$: Order for operations sharing a device/link

Constraints

- **Data Dependencies** An example of data dependency of Wave schedules is shown in Figure 7.

$$\forall o \in \mathcal{O},\ \forall p \in \text{Pred}(o): \quad t_o \geq t_p + d_p + \begin{cases} \ell_p & \text{if } p \in \mathcal{C} \\ 0 & \text{if } p \in \mathcal{P} \end{cases}$$

- **Resource Non-overlap** For any $o, o' \in \mathcal{O}$ sharing a device or link, overlapping is not allowed:

$$t_o + d_o \leq t_{o'} + H(1 - x_{o,o'})$$
$$t_{o'} + d_{o'} \leq t_o + H x_{o,o'}$$

  H is a large constant bounding the scheduling horizon.
- **On-device Memory Capacity** Let $u_{p,q} = 1$ iff compute p completes before q starts. Then for all $s \in \mathcal{S}$ and $q \in \mathcal{P}$ assigned to s:

$$\sum_{\substack{p \in \mathcal{P} \\ \text{device}(p) = s}} m_p u_{p,q} \leq M_s^{\max}$$

- **Microbatch Order within Stage and Type** For any $o, o' \in \mathcal{P}$ on same device s and type $t \in \mathcal{T}$, if microbatch index $mb(o) < mb(o')$, then:

$$t_o + d_o \leq t_{o'}$$

  This constraint reduces the search space.

Objective We minimize the makespan, defined as the time from the earliest start to the latest finish on the first device:

$$\min \left(t_{\text{last}(0)} + d_{\text{last}(0)} - t_{\text{first}(0)} \right)$$

DP Overlap Modeling DP communication can be modeled as distinct operations triggered after the completion of the W block for the final microbatch of the current model chunk. In the case of ZeRO stage 1, the corresponding weight All-gather operations are scheduled before the first F block of each model chunk. An illustrative example is shown in Figure 7. The objective is then extended to account for the added communication.

Solver Scalability We evaluate the runtime performance of both MILP and CO solvers on identical pipeline scheduling problems, as detailed in Appendix D.1. It demonstrates the feasibility of using solver-based methods in production environments. However, the search space expands rapidly with the number of pipeline stages, which can lead to prohibitive computation time for extremely large-scale scenarios or dynamically changing system parameters. In such cases, solver-based scheduling becomes less practical, motivating the need for alternative approaches (Section 4.2).

4.2 Greedy Schedule

To address the scalability limitations of solver-based approaches, we introduce a greedy schedule generation algorithm. This method is designed to rapidly generate near-optimal pipeline schedules while adapting to potentially dynamic system conditions.

4.2.1 Greedy Sub-block Scheduling

The greedy algorithm operates using *local* information, only considering scheduled blocks and those ready for scheduling. To counter the suboptimal decisions typical of greedy methods, we employ block-splitting: each computation block is divided into n_{sub} sub-blocks. This finer granularity enhances the ability to reduce pipeline bubbles with negligible scheduling overhead compared to training iteration time.

Algorithm Inputs The inputs to the greedy algorithm include: Per-stage runtimes of F, D, and W blocks: T_F, T_D, T_W; corresponding memory usage: M_F, M_D, and M_W; per-stage memory limit: M_L; communication delay matrices: α and β, where $\alpha[i, j]$ and $\beta[i, j]$ represent latency and bandwidth inverse of communication from device i to device j. The scheduling procedure for the *CrossUDSub* schedule is outlined in Algorithm 1.

4.2.2 Scheduling Loop

The scheduling loop consists of three core steps:

Stage Selection The `next_stage_to_schedule` method identifies the stage with the earliest schedulable time, which is defined as the maximum between the end time of the last scheduled operation and the earliest available time of schedulable operations.

Algorithm 1 Greedy Generation for *CrossUDSub* Schedule

Output: Per-stage schedule $S_d, \forall d \in [n_{PP}]$
for i in $[n_{mb}]$ **do**
  Add F_i operation for stage 0 to S_0's schedulable operations.
end for
while True **do** *Scheduling Loop (Sec 4.2.2)*
  $cur \leftarrow$ `next_stage_to_schedule()`
  if no stage is schedulable **then**
    break
  end if
  $p_{cur} \leftarrow$ schedulable operation of highest priority on stage cur
  Schedule next sub-block of p_{cur}
  if $p_{cur}.type$ = D **and** no remaining sub-blocks of p_{cur} **then**
    Add W operation to schedulable operations of current stage
  end if
  Let p_{next} be the operation dependent on p_{cur}
  if p_{next} exists **and** no remaining sub-blocks of p_{cur} **then**
    $T_{lat} \leftarrow \alpha[cur, next]$
    $T_{bw} \leftarrow \beta[cur, next] * \text{Msg_Size}$
    $E_{bw} \leftarrow$ `bw_model`$(p_{cur}.T_{end}, cur, next, T_{bw})$
    $p_{next}.T_{avail} \leftarrow E_{bw} + T_{lat}$
    Add p_{next} to S_{next}'s schedulable operations.
  end if
end while

Operation Selection The scheduler selects operations available at or after the end of the last scheduled operation on the chosen stage. When multiple options exist, it applies a heuristic priority across three phases:

- **Warm-up phase**: prioritizes F blocks
- **Steady phase**: interleaves F and D full blocks
- **Tear-down phase**: prioritizes D over W blocks

When memory constraints prevent scheduling F or D blocks, a W sub-block is scheduled.

Operation Scheduling The selected operation is scheduled on its stage. If it is the last sub-block of a D block, the corresponding W is added to the schedulable operations of the stage. The dependent blocks are then made schedulable on the receiving stage with the earliest start time calculated using the communication model.

4.2.3 Bandwidth Occupancy Model

To model bandwidth contention, we use a simple range-based bandwidth occupancy model. Communication is assumed to begin immediately upon completion of the relevant computation block. The `BW_model`$(T_{ready}, src, dst, T_{bw})$ function determines the earliest available transmission window of length T_{bw}, starting at or after T_{ready}, and returns its end time.

4.2.4 Performance Characteristics

While greedy algorithms do not guarantee global optimality, our approach demonstrates strong empirical performance. As detailed in Section 5&7, the CrossUDSub schedule achieves:

- Equivalent performance to ZB-H1 [43] under negligible communication delays and same memory constraints.
- Faster than static schedules under non-negligible communication delays by filling sub-block size bubbles.
- Further improvements when memory constraints are relaxed, allowing greater scheduling flexibility.

4.2.5 Time Complexity

The main loop executes $3n_{mb}n_{sub}n_{PP}$ iterations, with each iteration scheduling one sub-block. Identifying the next stage and highest priority operation incurs $O(n_{mb}n_{sub}\log(n_{mb}n_{sub}))$ cost. Hence, the overall complexity is $O(n_{mb}^2 n_{sub}^2 n_{PP}\log(n_{mb}n_{sub}))$. In practice, since the number of schedulable operations per stage remains small, the runtime approximates $O(c \cdot n_{mb}n_{sub}n_{PP})$ for a small constant c.

5 Analysis

In this section, we use simulation experiments based on the performance model described in Section 3.5 to investigate two key questions: (1) How do different pipeline schedules respond to latency and bandwidth delays? (2) Between cross-DC PP and cross-DC DP, which is more efficient for training in cross-DC settings?

5.1 Schedule Efficiency

Schedule	Type	WGrad	Bubble Ratio	Memory	DP Overlap
1F1B [38]	UD	Combined	High	Medium	Medium
IV1F1B [39]	Loop	Combined	Medium	Medium+	Medium+
ZBH1 [43]	UD	Split	Medium	Medium	Low
ZBV [43]	Wave	Split	Low	Medium	Low

Table 3: Static pipeline schedules used in the analysis. UD and BD stands for unidirectional and bidirectional. IV1F1B is the abbreviation for the interleaved 1F1B schedule.

We compare various pipeline schedules under increasing communication delay in a cross-DC PP setting. Bidirectional (BD) schedules are excluded as they involve both PP and DP cross-DC communication. The main static schedules that we focus on are summarized in Table 8. We use $n_{PP} = 4, n_{mb} = 8$, and simulate 2 DCs with 2 stages each. Dynamic schedules are generated with the same memory limits as their static counterparts (e.g., CrossUD mirrors 1F1B). Delay sensitivity is measured as slowdown relative to the ZBV schedule under no communication delay. Delay is varied using T_{lat}/T_F (latency delay) and T_{bw}/T_F (bandwidth delay), where T_F is the per-stage forward computation time. Key observations from Figure 8 include:

- WGrad-split schedules consistently outperform unified-backward ones due to finer scheduling granularity.
- Wave schedules are more efficient in low-delay settings, while UD schedules become superior as delays grow.
- Loop schedules show the highest sensitivity to delays, due to more frequent cross-DC communication (6 per micro-batch, compared to 4 for Wave and 2 for UD).

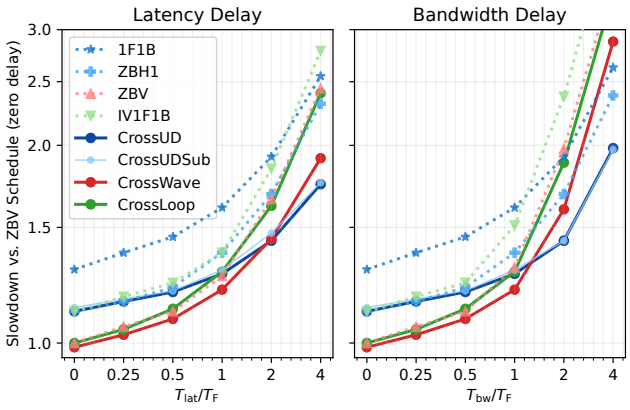

Figure 8: Impact of latency and bandwidth delay on runtime across different pipeline schedules. Static (····) and dynamic (—) schedules are compared. Setup: 4 stages, 8 microbatches (2 DCs, 2 stages per DC). *Cross*-prefixed schedules are generated by the CO solver (Section 4.1). Slowdown is measured relative to the ZBV schedule at zero delay.

- The greedy CrossUDSub schedule matches the solver-based CrossUD in most delay regimes, highlighting its efficacy as a lightweight alternative.
- When delays are small, latency and bandwidth contribute equally to runtime. However, once bandwidth delay exceeds the forward time per chunk, it induces additional pipeline bubbles from queuing (Section 2.2).

5.2 Cross-DC PP vs. Cross-DC DP

We simulate iteration times for cross-DC PP and cross-DC DP approaches using the Llama 3 405B model [12] under various latency and bandwidth conditions (detailed in Appendix E).

Results in Figure 9 show that latency (ranging from 4–128 ms) has little impact on runtime in this scenario, as the per-stage forward time ($T_F \approx 109$ms) keeps the delay ratio low. However, bandwidth significantly affects performance. Cross-DC PP outperforms cross-DC DP by up to 3.05x when the cross-DC link bandwidth is limited to 4 GB/s. This gap narrows as bandwidth increases, becoming negligible beyond 1024 GB/s. Compared to the ideal single-DC case, cross-DC PP sees only a 1.3× slowdown at 64 GB/s. These results suggest that for large models with long per-stage computation time (T_F), bandwidth is the primary bottleneck in cross-DC communication. Under such conditions, cross-DC PP offers superior efficiency relative to DP, particularly when network resources are constrained.

6 CrossPipe Implementation

Schedules generated by CrossPipe can adapt to configuration changes, including PP size, hybrid parallelism setups,

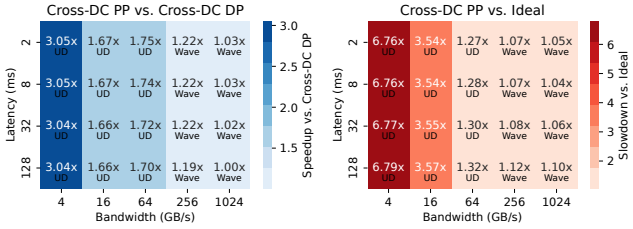

Figure 9: Simulation results comparing cross-DC PP and DP for Llama 3 405B training across two DCs. Left: Speedup of cross-DC PP over cross-DC DP. Right: Slowdown of cross-DC PP compared to an ideal single-DC setup. Labels indicate exact values and optimal schedule types per configuration.

and system parameters. In contrast, static PP modules in existing frameworks support only a limited, hard-coded range of schedules, making them difficult to adapt to and extend. Our implementation addresses these limitations through the CrossPipe module, which integrates seamlessly with the existing training framework. We use Megatron-LM as our base framework. The CrossPipe module is primarily implemented in Python, with components in C++ to enable latency and bandwidth injection (Section 6.4) for emulating cross-DC network conditions on a homogeneous cluster.

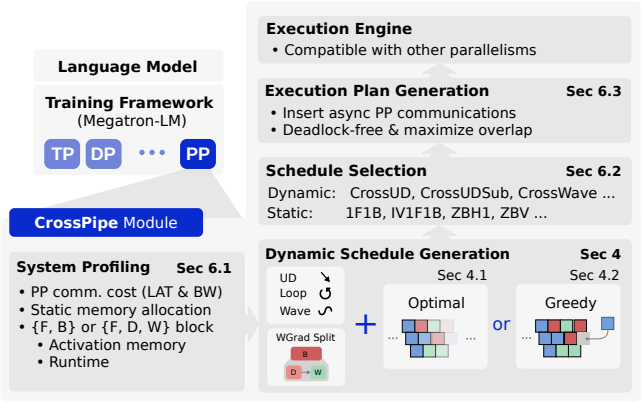

Figure 10: Components of the CrossPipe module.

An overview of our implementation is shown in Figure 10 . The module begins by collecting system parameters via lightweight benchmarks (Section 6.1). It then generates dynamic pipeline schedules (defining the order and timing of computation blocks) using either the constraint optimization solver (Section 4.1) or the greedy algorithm (Section 4.2). A schedule with the best simulation performance is selected (Section 6.2). Next, CrossPipe lowers it to a concrete execution plan by inserting and optimizing communication operations (Section 6.3). This decouples high-level scheduling logic from low-level execution, enabling dynamic, fine-grained control. The selected schedule can also be hot-swapped during training if better options are found.

6.1 System Profiling

CrossPipe collects critical metrics in a single iteration using lightweight profiling. These include runtime and memory usage of F, D, and W blocks, as well as communication delay parameters (α, β). We follow the model partitioning strategy of Llama 3 [12], treating embedding and output layers as transformer layers to ensure load balance across stages.

6.2 Schedule Selection

CrossPipe selects the schedule with the best estimated performance and supports hot-switching to adapt to changes during training.

- **Static schedules** are well-suited for single-DC training.
- **Dynamic schedules** are more suitable in cross-DC settings with high or varying communication costs. They also adapt better to available memory. Under rich memory budgets, dynamic schedules may increase the number of in-flight F blocks to improve efficiency.

6.3 Execution Plan

In this step, CrossPipe converts the selected pipeline schedule into an execution plan by inserting non-blocking communication operations. This plan is executed by the CrossPipe engine integrated into the training framework.

Communication Orchestration We use NCCL as the communication backend to leverage high-bandwidth intra-node interconnects and reduce inter-node data movement overheads. To decouple point-to-point communications in PP, we dedicate four GPU streams for each direction and role ({Send, Recv} × {Next, Prev}), avoiding interference and deadlocks. In both directions, Recv operations are reordered to align with the corresponding Sends, avoiding NCCL deadlocks. NCCL implements a rendezvous protocol for point-to-point communication, requiring both the sender and the receiver to synchronize before the transfer begins. To maximize communication overlap, we post Recv operations ahead of their corresponding Sends based on profiling estimates. This delay-aware arrangement improves overlap and is applied to both static and dynamic schedules (evaluated in Section 7).

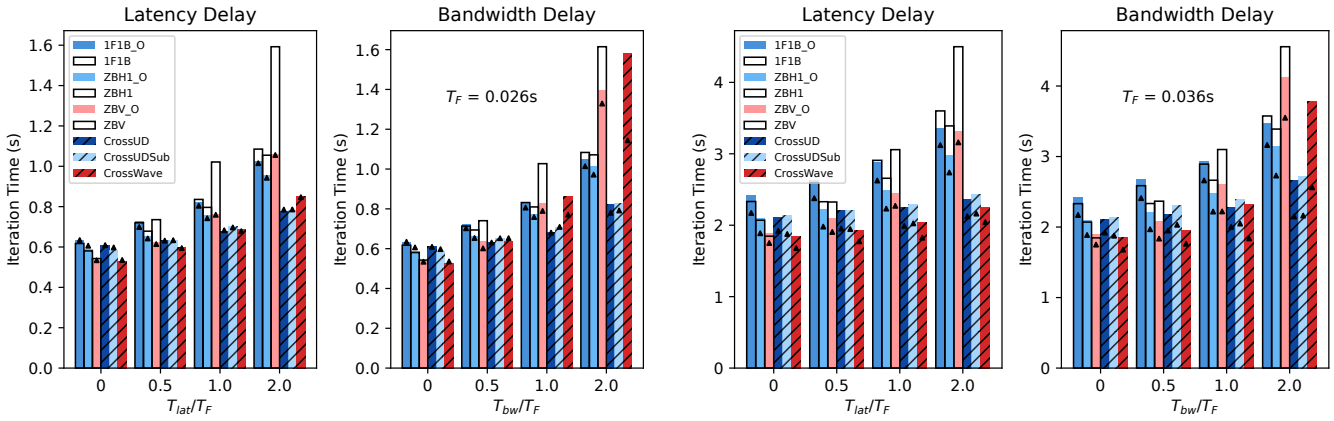
6.4 Latency and Bandwidth Injection

We extend the PyTorch `ProcessGroupNCCL` C++ backend to inject latency and bandwidth delays in specific Send/Recv operations. This allows us to emulate various cross-DC network conditions (as described in Section 2.3) within a single cluster. Latency is injected on the receiver side of cross-DC communication, while bandwidth is throttled by running spinning kernels on the communication streams of both sender and receiver. Implementation details are provided in Appendix F.1, and validation results in Appendix F.2.

Name	Hidden Dim.	Int. Dim.	Att. Heads	KV Heads	Layers
M8	4096	14336	32	8	30+2
M70	8192	28672	64	8	62+2

Table 4: Hyperparameters of models used in the evaluation. Example: M70 is a model with Transformers layers of the same size as the ones in the Llama 3 70B model. The number of layers is reported as number of transformer layers + embedding & output layers.

7 Evaluation



We conducted comprehensive evaluations on the Alps supercomputer to validate CrossPipe's performance and scalability. Each compute node is equipped with four GH200 Grace Hopper Superchips [41]. Each GH200 features 96 GB HBM3 memory integrated with the Hopper GPU die and 120 GB LPDDRX5 memory connected to the Grace CPU. The chips utilize a fully-connected topology with six NVLink 4.0 links between each GH200 pair, providing 200 Gb/s bandwidth per link per direction. Network connectivity is provided by HPE Cray Cassini-1 200 Gb/s NICs in a Dragonfly [25] topology using HPE Cray Slingshot-11 [8, 49] interconnect.

We use LLMs built up from the Llama-style Transformer layers, the hyperparameters of which are listed in Table 4. Each model configuration follows the naming convention `M{model_size}`, where the model_size indicates the size of Transformer layers it contains. For example, M70 uses the Transformer block of the same size as the one in the Llama 3 70B model. The models are then constructed by replicating and stacking identical Transformer layers, along with the vocabulary embedding layer and the output layer. We evaluate the following schedules: 1F1B, IV1F1B, ZBH1, ZBV, CrossUD, CrossUDSub, and CrossWave. The reason to exclude bidirectional (BD) and Loop schedules is explained in Section 5. By default, we set the microbatch size $b = 1$ and sequence length $s = 4096$. In these configurations, the message size for pipeline communication (activations/gradients) is approximately $32n_{DP}$ MB for M8 and $64n_{DP}$ MB for M70. FlashAttention [50] is enabled for higher throughput and less peak memory consumption. For each schedule, we measure 64 iterations and report the minimum value to minimize the network noise effects [17].

7.1 Impact of Latency and Bandwidth Delay

We evaluate the performance of schedules on the cluster with various emulated latency delay T_{lat} or bandwidth delay T_{bw} for each PP communication crossing the DC boundary, using the injection mechanism from Section 6.4. We conduct the experiments on both M8 and M70 models in a two-DC setting. The parallelism configurations are:

- **M8:** $n_{TP} = 2$, $n_{PP} = 4$, $n_{DP} = 1$, $GBS = 2n_{PP}n_{DP} = 8$.
- **M70:** $n_{TP} = 4$, $n_{PP} = 8$, $n_{DP} = 1$, $GBS = 2n_{PP}n_{DP} = 16$.

(a) Model M8

(b) Model M70

Figure 11: Evaluation of static and CrossPipe schedules under various emulated latency and bandwidth delay ratios. The runs of static schedules with communication arrangement optimization (Section 6.3) is marked with the suffix _O. The runtime prediction from the performance model (Section 3.5) is represented as (▲). Schedules are compared using the iteration time in seconds (lower is better). Dynamic schedules (Cross*) use the same peak memory budget as their corresponding static base schedule (e.g., CrossUD matches 1F1B).

We vary delay ratios $T_{lat}/T_F, T_{bw}/T_F \in \{0.0, 0.5, 1.0, 2.0\}$. T_F is defined as the maximum runtime of the per-microbatch forward computation among stages. The results are shown in Figure 11. For the static schedules, we vary two settings: with or without the delay-aware communication orchestration (Section 6.3). Runs with this optimization are marked with the suffix _O. This optimization reduces the impact of delayed receivers, aligning closely with the assumptions of our performance model (Section 3.5). This model accurately predicts the runtime of tested schedules in most configurations. Overall, the CrossPipe schedules show superior performance compared to static schedules, with a reduction in runtime of up to 33.6% (vs. original) or 21.9% (vs. optimized), achieved by the M70 model at $T_{bw}/T_F = 2$.

To ground these delay ratios in realistic scenarios, we take the M70 model as an example. We assume a practical DP size of $n_{DP} = 16$, with intra-DC DP communication fully overlapped. Under this setting, the message size per PP communication is calculated by $bsdn_{DP} * 2 = 1$ GB. Given a forward time of $T_F = 0.038$ s (Figure 11.b), the resulting injected latency delays range from 19 ms to 76 ms, and simulated bandwidth from 105 Gbps to 421 Gbps.

7.2 Further Bubble Reduction

Section 7.1 shows that block reordering helps to reduce PP runtime when the memory budget and global batch size (GBS) are strictly constrained. However, substantial bubble ratios persist under high communication costs. This observation necessitates examination of trade-offs among runtime, GBS and memory budget. Also, we take layer-wise activation recomputation [6] into consideration. Since the GBS varies among the settings, we use runtime per microbatch to compare schedules. We conduct the experiments on the M70 model in a 2-DC setting, with $n_{TP} = 4, n_{PP} = 8, n_{DP} = 1$, under delay combinations: $(T_{lat}/T_F, T_{bw}/T_F) \in \{(0,0), (0.25,2), (2,0.25), (2,2)\}$, across three configurations:

- **Case 1:** $GBS = 2n_{PP}n_{DP} = 16$, activation memory budget 1.0× (same as 1F1B), no recomputation.
- **Case 2:** $GBS = 32$, activation memory budget 1.0×, layer-wise recomputation.
- **Case 3:** $GBS = 32$, activation memory budget 2.0×, no recomputation.

The result is shown in Table 5. Static schedules cannot leverage extra memory budget to further reduce pipeline bubbles ('-' in case 3). Without delay, where $(T_{lat}/T_F, T_{bw}/T_F) = (0,0)$, the efficiency of the CrossPipe schedules is comparable to manually optimized static schedules. Increasing GBS amortizes bubbles in the warm-up and tear-down phases by extending the length of the steady phase which contains fewer bubbles. Under high latency (e.g.,$(2,0.25)$), increasing GBS and memory budget helps the CrossWave schedule to achieve pipeline efficiency (0.115 s per microbatch), matching the no delay case (0.118 s per microbatch). When the bandwidth delay dominates (e.g., $(2,0.25)$ or $(2,2)$), increasing both GBS and memory budget improves schedule efficiency by up to 1.33× (0.196 s to 0.147 s per microbatch for CrossUD). In general, the bandwidth delay is harder to mitigate than the latency delay under the same settings of GBS and memory budget. Layer-wise recomputation generally does not improve the runtime of dynamic schedules, as the recomputation during the backward pass negates its low memory benefits.

$\frac{T_{lat}}{T_F}$	$\frac{T_{bw}}{T_F}$	Case	Static			Dynamic (This Work)

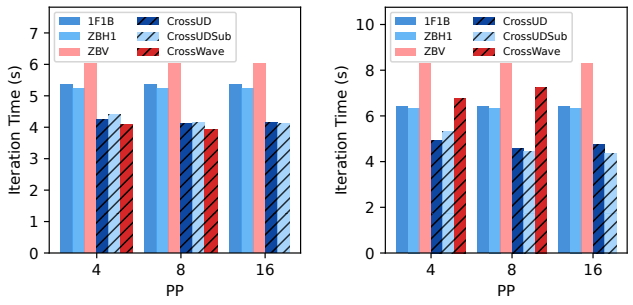
Table 5: M70 model, 2-DC training. Runtime per microbatch of cross-DC PP solutions under various configurations (case 1-3) and communication delay. The best result of each configuration is shown in bold (lower is better). CrossUDSub, CrossUD and CrossWave schedules are abbreviated as UDSub, UD and Wave, respectively.

7.3 Scale to More DCs

We extend our analysis to 4 homogeneous interconnected DCs with uniform cross-DC link characteristics, using the same setup as the previous section (M70, $n_{TP} = 4$, $n_{PP} = 8$, $n_{DP} = 1$, now with 2 stages per DC). Table 6 confirms previous findings: CrossPipe is competitive without delay and outperforms static schedules in cross-DC scenarios. CrossWave excels CrossUD(Sub) at low delays but suffers under higher delays, especially under high bandwidth delays. With extra memory budget and GBS (Case 3), CrossUD schedule achieves 0.178 s per microbatch, only 22.8% slower than the corresponding 2-DC scenario at $(T_{lat}/T_F, T_{bw}/T_F) = (2,2)$. The larger bubble size in 4-DC training makes recomputation more effective here. Layer-wise recomputation with increased GBS (Case 2) is comparable to or outperforms the baseline without recomputation (Case 1) in most delay settings.



7.4 Trade-off of PP and DP

We analyze the choice of large PP size vs. large DP size in a 2-DC homogeneous training scenario. With a fixed number of compute nodes per DC and setting n_{TP} to the number of GPUs within each compute node, the product $n_{PP} \times n_{DP}$ equals the total node count of 2 DCs. Given the number of microbatches $n_{mb} = \varepsilon n_{PP}$, the global batch size $GBS = \varepsilon n_{PP} n_{DP}$ depends solely on the ratio ε. Then the GBS remains the same with various combinations of PP and DP.

We evaluated the trade-off on the M70 model across three PP configurations ($n_{PP} \in \{4, 8, 16\}$) with four combinations

Table 6: M70 model, 4-DC training. Runtime per microbatch of each PP schedule is listed. The rest of the configurations remain the same as Table 5.

(a) $T_{lat}/T_F = 1, T_{bw}/T_F = 0.25$; Static Mem. ($n_{PP} = 4$): 25%

(b) $T_{lat}/T_F = 0.125, T_{bw}/T_F = 2$; Static Mem. ($n_{PP} = 4$): 25%

(c) $T_{lat}/T_F = 1, T_{bw}/T_F = 0.25$; Static Mem. ($n_{PP} = 4$): 50%

(d) $T_{lat}/T_F = 0.125, T_{bw}/T_F = 2$; Static Mem. ($n_{PP} = 4$): 50%

Figure 12: Trade-off between PP and DP ($n_{PP} \times n_{DP}$ is fixed) in a 2-DC training. Using M70 with 16 nodes ($n_{TP} = 4$ fixed) and a fixed GBS. Each subplot shows iteration time vs. n_{PP}. Labels indicate delay ratios (T_{lat}/T_F, T_{bw}/T_F) and static memory usage. Memory in percentage shows the consumption of static memory at $n_{PP} = 4$ w.r.t. device limit.

of communication delay and memory settings. For communication delay $(T_{lat}/T_F, T_{bw}/T_F)$, we test high latency, low bandwidth $(1, 0.25)$ and low latency, high bandwidth $(0.125, 2)$ settings, with a static memory budget of 25% and 50%. This percentage is defined as the allocation of static memory (parameters, gradients, and optimizer states) at $n_{PP} = 4$ w.r.t. the device memory limit. Larger n_{PP} reduces the static memory per stage and the activation memory size per microbatch, so that it increases the activation memory budget and allows for more in-flight forward blocks. Also with larger n_{PP}, the communication volume is lower due to smaller DP, but at a higher frequency. While the absolute latency remains constant when increasing n_{PP}, the latency delay ratio T_{lat}/T_F increases due to reduced T_F as n_{PP} grows (less work per stage). $\varepsilon = 4$ to enable more in-flight blocks in each schedule to benefit from available memory. Since the GBS (total workload) and the number of compute nodes (total GPUs) are fixed, we use runtime to compare different configurations. As shown in Figure 12, these factors balance out. The schedule efficiency remains largely invariant to PP/DP configurations across scenarios. This balance likely stems from the flexibility of CrossPipe to fully utilize the available memory with sufficient GBS.

8 Discussion

8.1 Heterogeneous DCs

In this work, we primarily evaluated homogeneous GPUs and nodes across DCs due to cluster constraints. However, our approach can be extended to heterogeneous environments. If compute resources (e.g., GPU, network) differ significantly between DCs, our generated schedules may be suboptimal because faster nodes will finish computation earlier and create bubbles in the pipeline, and slower nodes may run out of memory since their device memory is usually more limited. A practical solution is to maintain homogeneity within each pipeline stage, which aligns with current DC practices where nodes within the same cabinet tend to be identical. The compute nodes with faster GPUs can be assigned more layers to balance the computation time across stages. Our formulation (Section 4.1) and greedy algorithm (Section 4.2) already support stage-specific parameters, naturally supporting this adjustment.

8.2 Network Dynamics and Fault Tolerance

Real-world cross-DC networks exhibit variability and are prone to failures. CrossPipe can employ several strategies to enhance robustness:

- Short-Term Variations (seconds or less): Section 7.2 shows that CrossPipe schedules can trade system resources (e.g., device memory, by allowing more in-flight microbatches) for efficiency. Conservative (higher) latency and/or (lower) bandwidth estimations can be used to generate schedules that tolerate small spikes in communication delay.
- Longer-Term Variations (minutes or more): Network conditions can shift due to traffic or routing. CrossPipe's flexible execution engine (Section 6) supports hot-switching of pipeline schedules. The system with CrossPipe enabled can periodically re-profile network conditions (Section 6.1) and generate new, tailored greedy schedules (Section 4.2) to adapt without interrupting training.
- Packet Loss/Link Errors: Transient network errors such as packet drops can be handled by mechanisms like Forward Error Correction (FEC) [14] or Selective Repeat [2], leading to spikes in communication delay as mentioned above.
- Node Failures: The failure of a compute node requires higher-level mechanisms beyond pipeline scheduling. Efficient checkpointing, such as asynchronous methods [35] and in-memory approaches [67], is necessary to save training state efficiently and recover from the last checkpoint with minimal progress loss.

10 Conclusion

In this work, we first introduced a validated pipeline performance model that explicitly accounts for latency and bandwidth delays in cross-datacenter links. Using this model, we demonstrated that pipeline parallelism is often the superior approach for the parallelism dimension spanning across dat-

acenters, especially under constrained network conditions. Next, we leveraged the model to develop optimal and near-optimal algorithms for generating pipeline schedules that minimize cross-datacenter communication delays while adhering to memory constraints. Finally, we integrated these methods into a flexible execution engine featuring a two-layer abstraction (block scheduling and communication arrangement) that works seamlessly with existing training systems, such as Megatron-LM.

Our evaluation shows that CrossPipe effectively overcomes the challenges of cross-datacenter training. It reduces the training time by up to 33.6% compared to traditional pipeline schedules in a cross-DC setup, all while maintaining the same memory constraints. When memory constraints are relaxed, CrossPipe in a cross-DC setup is able to achieve a similar training time as a static ZBV schedule in a single-DC setup where there is almost no communication delay. CrossPipe thus offers improved scalability and resource utilization, making large-scale distributed training more feasible and efficient.

Acknowledgments

We are grateful to our shepherd and the anonymous reviewers for their insightful comments and constructive feedback. We thank the CSCS team for providing access to the Ault and Alps machines, as well as for their outstanding technical support. We are grateful to Siyuan Shen and Mikhail Khalilov for their valuable advice, and to Timo Schneider for his assistance with infrastructure at SPCL. We also acknowledge the Polish high-performance computing infrastructure PLGrid (HPC Center: ACK Cyfronet AGH) for providing computational resources and support.

A Runtime Definition

In cross-DC training, due to the relatively high communication cost, the stage 0 usually finishes last among all the stages. So we adopt the most used definition of pipeline runtime as the following: the duration from the start of the first forward block on PP stage 0 till the completion of the last block on any PP rank (or the final DP communication on any rank). This definition aligns with frameworks that apply additional synchronization for global gradient norm computation (for clipping) and numerical anomaly detection (NANs/INFs) in mixed-precision training.

B Weight Gradient Separation

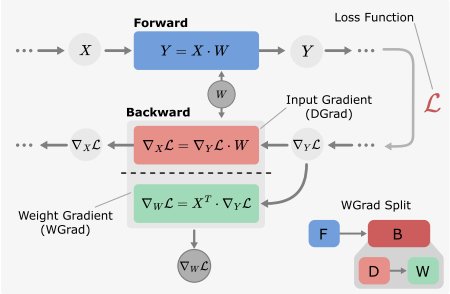

Figure 13: Separating input gradient computation (DGrad, or D) and weight gradient computation (WGrad, or W) in a linear layer.

Figure 13 illustrates how each B block can be further divided into two parts: input data gradient computation (DGrad, or D) and weight gradient computation (WGrad, or W) [43].

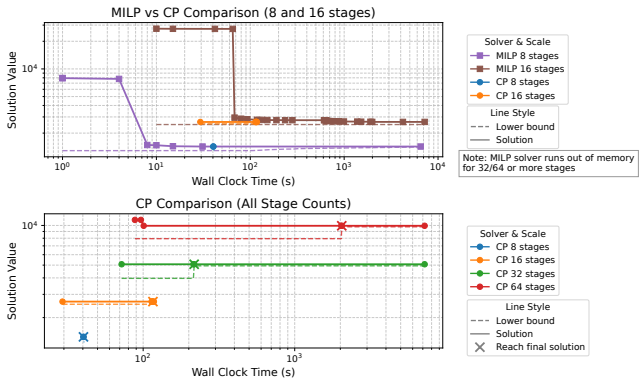

Figure 14: Scalability of MILP and CP solvers finding optimal pipeline schedules. Results show time-to-solution for varying pipeline stage counts (n_{PP}) with a fixed microbatch factor ($n_{mb} = 2n_{PP}$). Markers indicate the moments when the solver discovers an improved solution.

C Bubble Strides in Schedules

Figure 15 further illustrates the existence of *bubble strides*. We show schedules with 16 stages and 2 DCs for the static schedules that we compared in our work (1F1B, IV1F1B, ZBH1, and ZBV). The latency delay on the cross-DC link is set to $1.5 \cdot T_F$. Despite this relatively small latency (compared to the size of the pipeline blocks), the delay accumulates throughout the schedule rather than being absorbed or mitigated. This accumulation underscores the need for adaptive scheduling.

D Optimal Scheduling

D.1 Scalability of MILP and CO Solvers

We compare the scalability of both MILP and CO solvers, Gurobi (12.0.0) and CPLEX (22.1.1) respectively, both among the best solvers in their fields. The MILP formulation is from [43] and the CO formulation from Section 4.1. We conduct the experiments on a machine with AMD EPYC 7742 @ 2.25GHz CPU (128 physical cores), 256GB RAM. Each solver is configured to 256 worker threads, with a time limit of 7200 seconds. We use Gurobi Optimizer with the `NodefileStart=0.5` parameter to handle potential memory limitations.The solver is early-terminated if the relative gap between the objective value of the best integer solution found so far (ObjVal) and the best objective bound (ObjBound) is below 1%, defined as $\frac{|ObjBound - ObjVal|}{|ObjVal|} \leq 0.01$. The time to solution of both solvers are shown in Figure 14. The CO solver scales better than the MILP solver for pipeline schedule generation, ideally because of its specialized optimization w.r.t. job scheduling problems. The MILP solver runs out of memory even for runs of 32/64 stages and converges slower than CO solver. On the other hand, CO solver shows tractable performance when problem size scales up, and is able to find a good feasible solution in a reasonable amount of time while spending most of the time searching for a tighter bound.

E Comparing Cross-DC PP and Cross-DC DP

We use a 2 DC setup for the Llama 3 405B model training. The training configuration is taken from Llama 3 [12]: $n_{TP} = 8$, $n_{PP} = 16$, $n_{DP} = 64$, $seq_len = 8192$, $GBS = 2n_{PP}n_{DP}$.

We estimate the computation time of each layer by the following equation:

$$T_{layer} = \frac{C_{layer}}{P_{GPU} \times n_{TP}}$$

where C_{layer} is the FLOPs count of a transformer layer in the 405B model, P_{GPU} is the practical BF16 performance of GPU (500 TFLOPs per second is used in the analysis, considering the TP communication overhead). Assuming the GPUs

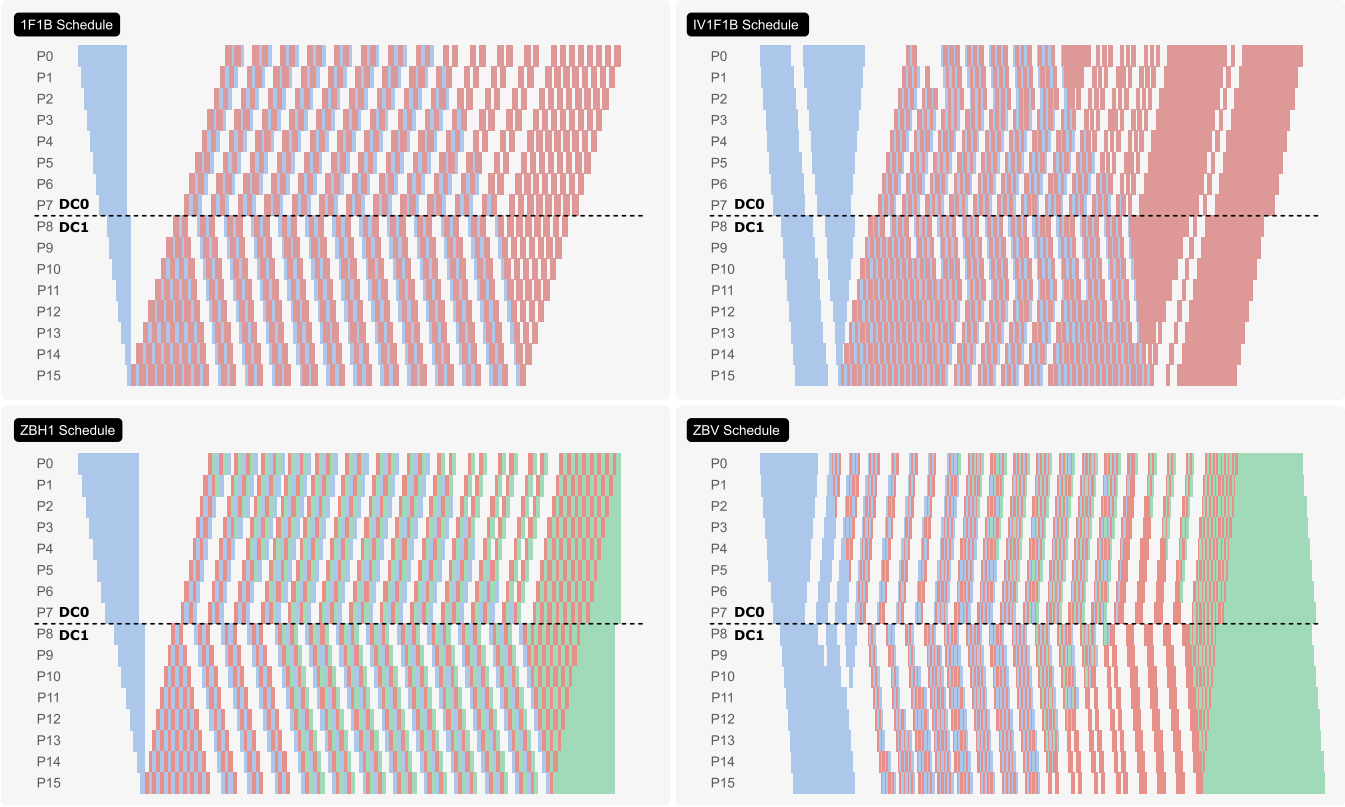

Figure 15: Illustration of bubble strides in various static pipeline schedules (1F1B, IV1F1B, ZBH1, and ZBV). Setup: 16 stages, 2DCs (8 stages per DC), $n_{mb} = 32$.

are equally distributed in 2 DCs. In cross-DC PP, we apply solver-based schedules (CrossUD or CrossWave, whichever is better for the given delay). In cross-DC DP, we use the ZBV schedule and assume that the extra cross-DC communication is not overlapped. For Allreduce (or Reduce-Scatter + Allgather) DP communications, we apply the bandwidth-optimal Ring-algorithm. The cross-DC DP communication cost can be estimated as $2 \times (\alpha + 2 \times \frac{N}{2} \times \beta) = 2\alpha + 2N\beta$ which accounts for two rounds of communication between two DCs and half of the parameters/gradients are sent/received. N is the number of model parameters, the extra factor 2 in the bandwidth term comes from the size of the BF16 datatype (2 bytes/param).

F Latency and Bandwidth Delay Injection

F.1 Implementation Details

Figure 16 illustrates our mechanism for injecting latency and bandwidth delay, used to emulate cross-DC network behavior in a controlled setting, without modifying core NCCL behavior or requiring network hardware manipulation. GPU kernel execution, including that of NCCL communication kernels, is asynchronous to the host CPU, making precise delay injection non-trivial.

- **Bandwidth Delay**: To simulate limited bandwidth, we inject additional delay into the communication path by occupying the communication stream after each NCCL send/receive. Specifically, a spin kernel is posted to the same stream immediately after the NCCL call, both on the sender and receiver sides. The spin kernel duration is computed to match the target delay. This effectively stalls further communication or computation that shares the stream, emulating a fully utilized link.
- **Latency Delay**: We extend PyTorch NCCL backend by adding a new method, `handle.wait_with_lat_delay()`, which is invoked on the receiver side during each blocking wait on NCCL communication. It is similar to the original `wait()` method but adds a controlled amount of host-side spinning to delay the launch of subsequent computation kernels.

The injection process contains the following steps: ❶ Sender and receiver post matching asynchronous point-to-point operations.❷ Optional compute kernels may be posted to overlap with communication. ❸ The receiver calls `wait_with_lat_delay` to synchronize the computation stream with the communication stream. ❹ A CUDA event measures the elapsed time from the completion of the communication kernel to the current time on the computation stream. ❺ The host then synchronizes with the computation stream

to retrieve the elapsed time and calculates the remaining delay (if any) to inject. ❻ A spinning kernel is posted to the computation stream for the remaining delay. This mechanism ensures that delay is not introduced when communication has already completed, and only partially injected when communication is partially complete (e.g., due to overlap with computation), thereby preserving the correct performance behavior of latency-hiding schedules.

This injection method is specifically designed for the CrossPipe implementation, where communication in four directions is split across four concurrent streams. Injecting delays into collective communications is more complex. While latency delays can be introduced within communication libraries [52], simulating bandwidth delays may require additional configurations at the network switch level.

In our communication model, we account only for latency and bandwidth delays along the critical path. We assume that the transmission of control messages, such as "ready to send" signals in a rendezvous protocol, is removed from the critical path. This assumption is crucial for maintaining performance, especially under high-latency conditions.

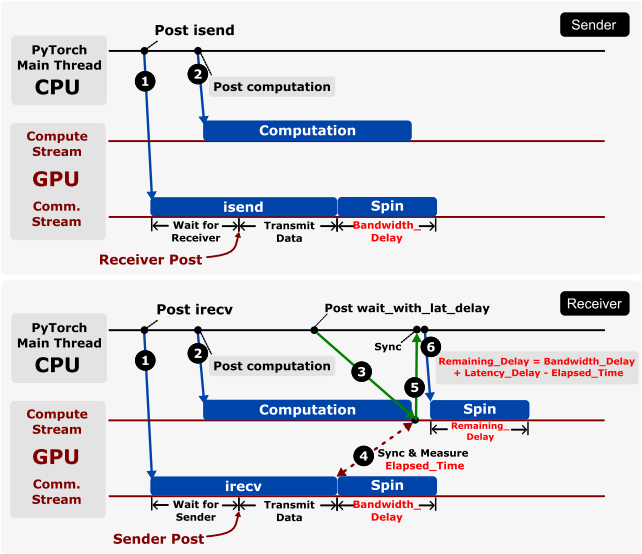

Figure 16: Mechanism for latency and bandwidth delay injection. Top: sender side. Bottom: receiver side.

F.2 Validation

To validate the accuracy of our delay injection methods (Section 6.4), we conduct experiments on a single GH200 node using 4 GB messages.

For latency tests, we use ping-pong communication between two processes: each round consists of a sender transmitting a message, waiting for a reply, and measuring the round-trip time. We divide the round-trip latency by two and compare it against the baseline (no injection). For bandwidth

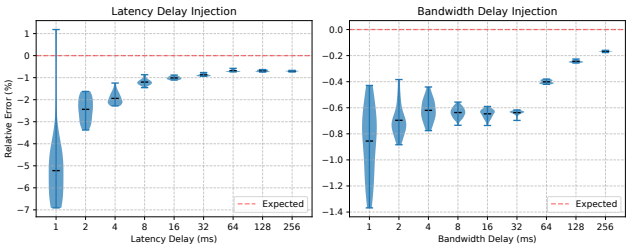

Figure 17: Validation of latency and bandwidth delay injection methods described in Section 6.4.

tests, the sender transmits multiple large messages back-to-back, while the receiver posts matching receives. We compute the average time per message and compare it to the baseline.

For each delay setting, we compute the relative error between the observed and expected delays. Specifically, we perform multiple iterations per setting, discard outliers, and report the percentage deviation from the expected delay. These measurements are then visualized using violin plots.

Results in Figure 17 demonstrate that our injection methods accurately reflect the communication model described in Section 2.2. Minor deviations primarily stem from host CPU synchronization and slight underestimation of GPU clock rate by `cudaGetDeviceProperties` in the spinning kernel. The validation shows the injected delay closely matches the target delay, confirming the mechanism's suitability for emulating cross-DC network conditions.

Unveiling Compiler Faults via Attribute-Guided Compilation Space Exploration

Jiangchang Wu, Yibiao Yang*, Maolin Sun, Yuming Zhou
State Key Laboratory for Novel Software Technology, Nanjing University, Nanjing, China

Abstract

Compiler testing is critically important, as compilers serve as the foundational infrastructure in system software development. A comprehensive exploration of the compilation space is essential for uncovering bugs in compilers. Existing methods primarily involve the utilization of various compilation options alongside test programs as inputs for stress-testing compilers. However, these compilation options are typically applied uniformly across all program elements-such as functions and variables–by default, limiting the ability to thoroughly explore the compilation space. In programming languages like C and C++, attributes such as the `__attribute__((always_inline))` directive provide a mechanism for programmers to specify additional information for specific code elements to the compiler. These attributes allow for precise control over the compilation process, such as enforcing constraints and customizing optimization passes for particular elements. This flexibility in specifying attributes offers opportunities to investigate previously unexamined areas within compilers. Unfortunately, few studies have leveraged attributes for compiler testing. To this end, we propose ATLAS, an attribute-guided approach that strategically inserts attributes into test programs to facilitate a more thorough exploration of the compilation space. Our key insight is that attributes specified for individual program elements can provide a more flexible means of exploring the compilation space. Our extensive experiments on GCC and LLVM demonstrate the superiority of ATLAS over baseline testing techniques that do not employ attributes, particularly in terms of bug detection and code coverage. Furthermore, ATLAS has led to the discovery of 73 unique bugs in GCC and LLVM, 58 of which have already been confirmed or fixed, showcasing its practical utility.

*Corresponding author

1 Introduction

Compilers are fundamental to the development of system software, as nearly all system software relies on them for construction [2]. However, the complexity and extensive scope of compilers make them prone to errors. Bugs hidden within compilers can have far-reaching consequences, affecting system correctness, security, reliability, performance, and maintenance. Therefore, ensuring the reliability and correctness of compilers is of critical importance.

To ensure the quality of compilers, various compiler testing methods have been proposed [5]. Csmith [52], a notable tool in this domain, randomly generates diverse test programs based on predefined rules or grammar. More recently, YARPGen [32] and its successor YARPGen v.2 [33] have been proposed, focusing on generating test programs specific to the compiler's loop optimization strategies. Both Csmith and YARPGen are capable of generating a large number of test programs to stress test compilers. During the testing process, different combinations of compilation options are employed which aim to explore the compilation space, thereby exposing potential bugs in compilers. EMI [25], a representative metamorphic testing technique [9], mutates existing programs by removing or inserting random code while preserving the original input/output behaviors. EMI also applies various compilation options to compile the mutated programs which also intend to trigger unexplored behaviors of compilers. This line of research has yielded significant results, uncovering a considerable number of bugs in mature and well-established compilers [26, 46].

However, existing compiler testing methods primarily depend on the use of different compilation options to explore compilation space. These options are typically applied to the entire program, which limits their capabilities to explore the deeper states of compilers. In practice, **attributes** in programming languages such as C and C++ provide a valuable mechanism for programmers to specify additional information to the compiler to enforce constraints, optimize specific sections of code, or facilitate targeted code generation. The additional

information can include the intended use and behavior of variables, functions, and types [13, 19, 20], which can influence various stages of the compilation process, from optimization to code generation, and even runtime behavior. For instance, the `noinline` attribute instructs the compiler not to inline a function during optimization [13]. The `aligned` attribute specifies the necessary alignment for data structures during code generation [20]. Similarly, the `noreturn` attribute indicates that a function does not return, allowing the compiler to optimize control flow and potentially eliminate unnecessary cleanup code [13].

Approach In this paper, we propose ATLAS [1], an attribute-guided comprehensive compiler testing technique. The key insight underlying ATLAS is that attributes provide flexible control over the compilation process for individual elements within test programs, thereby facilitating a more thorough exploration of compiler behavior. Specifically, for a given test program, ATLAS first identifies the program elements, i.e., the functions, variables, and statements, that potential attributes can be specified. Subsequently, ATLAS randomly inserts appropriate attributes for those elements, resulting in mutated test programs with the inserted attributes. These mutated test programs will be then fed to compilers for subsequent testing. By strategically combining various compilation options with the attributes inserted programs, ATLAS can thoroughly explore the functionalities of the compiler, thereby improving the effectiveness in exposing compiler faults.

To evaluate the performance of ATLAS, we conduct an extensive study based on GCC and LLVM. In the study, we compared ATLAS with those baseline techniques without inserting any attributes. Our experimental results show that ATLAS outperforms these methods in terms of the number of bugs found within the same testing period. In particular, ATLAS can detect 109.1% more bugs than the baseline approaches on average. Moreover, ATLAS achieves higher code coverage of GCC and LLVM triggered by the mutated test programs than the baseline approaches. Furthermore, we applied ATLAS to test the trunk version of both GCC and LLVM. In total, ATLAS has successfully detected 73 unique bugs, 58 of which have been confirmed or fixed by developers, demonstrating the effectiveness of ATLAS.

Contributions. We make the following major contributions:

- **Novelty:** We introduce an attribute-guided compilation space exploration approach for comprehensive compiler testing. Specifically, we propose to strategically insert appropriate attributes for program elements to systematically explore the compilation space for testing compilers.
- **Prototype:** We have developed a prototype implementation of our proposed approach, named ATLAS, which leverages various attributes to more effectively explore the compilation space of compilers.
- **Usefulness:** We conduct an extensive study to evaluate ATLAS on two most widely used C compilers (i.e., GCC and LLVM), demonstrating its effectiveness. In particular, ATLAS has led to 73 unique bugs for GCC and LLVM, 58 of which have been confirmed or fixed by developers.

[1] ATLAS: **At**tribute-Guided Compi**la**tion **S**pace Exploration

Paper Organization. The rest of this paper is structured as follows. Section 2 describes the background and our motivation. Section 3 illustrates our proposed approach, ATLAS. Section 4 presents our extensive evaluation of ATLAS. Section 5 is the discussion. Section 6 is the related works. Section 7 is our conclusion.

2 Background and Motivation

This section first presents a brief introduction to compiler optimizations and compiler attributes. Then, we motivate our technique using a real bug example.

2.1 Compiler Optimizations

Modern compilers, such as GCC and Clang, use optimization techniques to reduce compilation time, minimize binary size, and improve runtime performance [23]. These compilers typically provide multiple standard optimization levels, such as -O1, -O2, -Os, and -O3, each comprising a set of optimization options. For example, the -O1 optimization level in GCC includes options like `-fdce`, which eliminates unreachable code within the programs, and `-fmerge-constants`, which consolidates duplicate constants within the programs. These optimization options can be applied as part of optimization levels or individually specified in the compilation setting [18]. Regardless of whether they are enabled by default within a compilation level or specified individually, these strategies usually apply to the entire program rather than to specific code elements (e.g., a single function).

Over the past two decades, substantial research efforts have been devoted to the field of compiler testing [6, 12, 25, 27, 30, 32, 33, 46, 53]. Various techniques have been proposed that primarily focus on generating diverse test programs and then utilizing different optimization levels or employing various combinations of optimization options to perform differential testing of compilers. However, these approaches overlook the application of attributes, which allow for the flexible specification of different compilation strategies for individual code elements. As a result, they miss the opportunity to explore the extensive compilation space thoroughly.

2.2 Compiler Attributes

Attributes provide a mechanism for passing additional details about code generation and code optimization to the compiler [1]. For instance, attributes can control inlining decisions, specify memory alignment requirements, or impose specific

constraints on variable usage [13, 20]. Unlike compiler options, attributes operate at a finer granularity, allowing precise control over specific program elements, such as individual functions or variables. Common types of attributes include function attributes [13], variable attributes [20], and type attributes [19], covering functionalities such as optimization control, memory alignment, warning suppression, and specifying function characteristics. For instance, the `noreturn` attribute indicates that a function does not return, while the `pure` attribute specifies that a function has no side effects [13]. Such fine-grained functionality cannot be achieved through compilation options alone.

During compilation, the compiler identifies and parses these attributes in the syntax analysis phase. In the semantic analysis phase, it adjusts its behavior based on the information provided by the attributes. For instance, recognizing a `noreturn` attribute allows the compiler to handle functions that do not return appropriately. In the optimization phase, attributes can guide the compiler to perform specific optimizations or disable certain optimizations. Ultimately, in the code generation phase, the compiler produces the target code following these attributes. By applying different attributes to finer-grained program elements, such as functions or variables, the compiler can trigger additional behaviors, maybe further exploring previously unexamined areas within compilers.

```
struct S {
  int i;
};
inline struct S bar() {
  struct S s = { 0 };
  return s;
}
__attribute__((optimize("-ftree-loop-distribution")))
void foo() {
  bar();
}
```

Figure 1: GCC bug 43234. The optimization attribute `optimize("-ftree-loop-distribution")` specified for the function `foo()` triggers a GCC bug.

As depicted in Figure 1, the highlighted code snippet demonstrates the use of an optimization attribute applied to the `foo()` function. The `-ftree-loop-distribution` optimization option, which can improve cache performance on big loop bodies and allow further loop optimizations [18], is typically enabled at the `-O3` optimization level. When used in conjunction with `attribute`, this optimization can be selectively applied to individual functions. In this case, when GCC compiled the program with the optimization attribute applied to the `foo()` function, a crash occurred. Interestingly, the original program does not have an optimization attribute on `foo()`, and compiling the original program with the optimization option directly did not result in a compiler crash. This approach allows for finer-grained compilation control over individual functions within the program.

Proper use of attributes is a vital strategy for improving both code quality and compiler efficiency. Through the judicious application of attributes, programmers can achieve substantial gains in performance, and clarity of code intent, making attributes an essential tool for enhancing the quality of code and the performance of the compiler.

```
int **a;
__attribute__((always_inline)) int *foo(void) {
  int b[1];
  (void) b;
}
__attribute__((no_sanitize_address)) static char
bar(void) {
  *a = foo();
}
void baz(void) {
  bar();
}
```

Figure 2: GCC bug 114956, which is triggered by a test program generated by ATLAS. When this generated program is compiled with the flags `-O2 -fsanitize=address,null`, it results in a crash.

2.3 Motivation

To illustrate the motivation behind our work, consider the compilable program shown in Figure 2. It is generated by our tool, ATLAS, which triggered an internal compiler error (ICE) when GCC-15 compiled it with `-O2 -fsanitize=address,null`. The `-fsanitize=address` uses AddressSanitizer (ASan) [44] to detect memory-related bugs in programs and the option `-fsanitize=null` is used to detect null pointer in programs. The highlighted code of the figure denotes the attribute segments inserted by ATLAS. While the original program compiled normally, the introduction of these attributes caused the compiler to crash during the compilation of the modified program. The `always_inline` attribute is used to force the compiler to inline a function, even if the compiler's optimization heuristics would normally choose not to do so. The `no_sanitize_address` attribute is used to instruct the compiler not to instrument a particular function with ASan marks, even if ASan is enabled globally.

In this case, the `always_inline` function `foo()` is inlined into the `no_sanitize_address` function `bar()`, ASan marks (like `.ASAN_MARK` calls) are still left in the code during compiler optimization (`O2`). These leftover marks cause issues during later compilation stages, resulting in an internal compiler error (ICE). The compiler does not correctly remove the ASan instrumentation calls when inlining functions into a caller with sanitization disabled, leading to this bug. When attempting to inline the `foo()` function via the command line, the program must be compiled with the `-finline-functions` option. However, this would apply inlining to all functions within the program. Additionally, compiling the program with the `-finline-functions` and `-fsanitize=address` options, without applying the `always_inline` attribute to `foo()`,

does not trigger a compiler crash. The crash is only triggered when the `always_inline` and the `no_sanitize_address` attributes are applied separately to the `foo()` and `bar()` functions, respectively.

The example demonstrates that the combination of optimizations and attributes can result in uncommon scenarios and expose bugs within the compiler. The occurrence of such situations would not have been possible without the use of attributes. This also serves as evidence for the feasibility of utilizing attributes to achieve fine-grained control over the exploration of the compilation space for compiler testing.

3 Approach

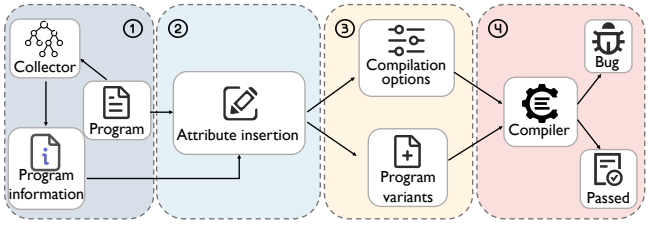

Figure 3: The workflow of ATLAS.

The fundamental workflow of our proposed approach is illustrated in Figure 3. Initially, in step ①, the program $\mathcal{P}$ is parsed to identify potential candidates that attribute could be inserted, forming the candidate set $\mathcal{S}$. Subsequently, in step ②, compiler attributes are randomly inserted into program $\mathcal{P}$ based on $\mathcal{S}$, creating a set of mutated program variants $\mathcal{S}_p$. Each variant $\mathcal{P}'$ in $\mathcal{S}_p$ explores a broader range of code paths within the compiler compared to $\mathcal{P}$. As discussed in Section 2.2, some attributes only take effect when specific compilation options are used. To ensure the inserted attributes are effective, we not only insert the attributes but also select the relevant compilation options. To enhance the complexity of the compilation options, a carefully designed strategy for combining compilation options is applied in step ③. This strategy involves selecting more diverse compilation options for each $\mathcal{P}'$, aiming to generate a more intricate combination of compilation options. In step ④, the compilation options selected in step ③ are combined with optimization options to compile the mutated program variants. If the compiler encounters any crashes during the compilation process, the bugs are found.

This section details our approach to combining compilation options and attributes to explore the compilation space for validating compiler reliability. Our strategy attempts to maximize the diversity of compilation option combinations with a wide range of attributes. This approach not only broadens the exploration of the compilation space but also increases the chances of uncovering potential compiler bugs.

3.1 Collecting Information

The initial step of our approach involves gathering essential information about functions, variables, and statements present in the test programs. Test programs typically comprise multiple functions and assorted variables. During the front-end parsing phase, the compiler analyzes different code fragments and variables individually and then performs targeted optimizations tailored to their specific requirements. As an illustration, LLVM follows a multistep process for program compilation. Initially, the program undergoes translation into an Intermediate Representation (IR). The compiler then traverses the IR, identifies specific structural patterns, and applies customized optimizations for those patterns [24, 34]. For instance, the `Instcombine` pass is responsible for identifying duplicate instructions and merging redundant ones through the execution of the pass [39]. Due to the different structure of functions, the compiler can perform different optimizations on them.

ATLAS collects function information, variable information, and statement information within the programs. We define the collector $\widehat{Collect}$ as follows:

Definition 1 (Collection). Given a program $\mathcal{P}$ and the function set $\mathcal{S}_f$, variable set $\mathcal{S}_v$, and statement set $\mathcal{S}_s$, the collector $\widehat{Collect}$ records the property tuple $\mathcal{A}$ for each function, variable, and statement in $\mathcal{P}$.

To provide a more detailed explanation, we define the following tuples to depict information from $\widehat{Collect}$:

- $\mathcal{A}_{\langle n,t,pos\rangle}$ contains the following information in $\mathcal{S}_f$: the function name n, the function return type t, and the function definition locations pos.
- $\mathcal{A}_{\langle t,pos\rangle}$ contains the following information in $\mathcal{S}_v$: the variable type t, and the variable declaration locations pos.
- $\mathcal{A}_{\langle vl,pos\rangle}$ contains the following information in $\mathcal{S}_s$: the variables vl in statement, and the statement locations pos.

To acquire insights into the program's structure, ATLAS initially extracts the Abstract Syntax Tree (AST) of the program. In our implementation, given a new seed program $\mathcal{P}$, we first utilize the $\widehat{Collect}$ collecting method to obtain $\mathcal{S}_f$, $\mathcal{S}_v$, and $\mathcal{S}_s$. Afterward, we generate program variant set $\mathcal{S}_p$ based on $\mathcal{S}_f$, $\mathcal{S}_v$, and $\mathcal{S}_s$.

3.2 Inserting Attributes

As detailed in Section 2.2, attributes allow developers to finely tune their code's behavior and performance, granting them better control over the compilation process. For instance, we can use `__attribute__((optimize(1))) int f();` to instruct the compiler to optimize the function `f()` at the O1 level. In light of this, we propose a method for fine-grained

control of compilation by leveraging compiler function attributes. More specifically, we utilize these attributes to explicitly influence the decisions made by the compiler. Algorithm 1 lists the primary procedure used in ATLAS to achieve fine-grained control of compilation by randomly inserting attributes into the program.

Algorithm 1: Insert Attributes

Input: $\mathcal{P}$, original program
$\mathcal{S}_{fa}$, function attribute set
$\mathcal{S}_{va}$, variable attribute set
$\mathcal{S}_{sa}$, statement attribute set
$\mathcal{S}_f$, function set of the original program
$\mathcal{S}_v$, variable set of the original program
$\mathcal{S}_s$, statement set of the original program
$\mathcal{N}$, the number of mutated programs
Output: $\mathcal{S}_p$, the set of programs with attributes inserted

1 $\mathcal{S}_p \leftarrow [\,]$;
2 $\mathcal{P}' \leftarrow \mathcal{P}$;
3 $n \leftarrow 0$;
4 **while** *true* **do**
5 **foreach** $\mathcal{A}_{\langle n,t,pos\rangle} \in \mathcal{S}_f$ **do**
6 **if** *FlipCoin()* **then**
7 $attr \leftarrow formFuncAttr(\mathcal{S}_{fa}, \mathcal{A}_{\langle n,t,pos\rangle})$;
8 $pos \leftarrow \mathcal{A}_{\langle n,t,pos\rangle}.getPos()$;
9 $\mathcal{P}' \leftarrow insertAttr(\mathcal{P}', attr, pos)$;
10 **foreach** $\mathcal{A}_{\langle t,pos\rangle} \in \mathcal{S}_v$ **do**
11 **if** *FlipCoin()* **then**
12 $attr \leftarrow selectVarAttr(\mathcal{S}_{va}, \mathcal{A}_{\langle t,pos\rangle})$;
13 $pos \leftarrow \mathcal{A}_{\langle t,pos\rangle}.getPos()$;
14 $\mathcal{P}' \leftarrow insertAttr(\mathcal{P}', attr, pos)$;
15 **foreach** $\mathcal{A}_{\langle vl,pos\rangle} \in \mathcal{S}_s$ **do**
16 **if** *FlipCoin()* **then**
17 $attr \leftarrow formStmtAttr(\mathcal{S}_{sa}, \mathcal{A}_{\langle vl,pos\rangle})$;
18 $pos \leftarrow \mathcal{A}_{\langle vl,pos\rangle}.getPos()$;
19 $\mathcal{P}' \leftarrow insertAttr(\mathcal{P}', attr, pos)$;
20 $\mathcal{S}_p.add(\mathcal{P}')$;
21 n++;
22 **if** $n >= \mathcal{N}$ **then**
23 **break**
24 **return** $\mathcal{S}_p$

Function Attribute Insertion. For each function within program $\mathcal{P}$, ATLAS employs $FlipCoin()$ to probabilistically determine the inclusion of each attribute from the attribute set $\mathcal{S}_{fa}$ (Line 5-9 in Algorithm 1). The $formFuncAttr()$ method selects one or more attributes and ATLAS inserts them into each function (Line 7 in Algorithm 1). Figure 4 illustrates an example of how ATLAS inserts function attributes. First, ATLAS identifies the location of function definitions based on position information *pos* from $\mathcal{A}_{\langle n,t,pos\rangle}$ marking these locations with <func>. After marking the locations, ATLAS selects appropriate function attributes based on the function return type t and inserts them at the specified positions. For instance, the return type of `c()` is `int`, we cannot apply `noreturn` attribute to it. Since $\mathcal{P}_1$ contains two function definitions, two corresponding marked locations are created. The mutated program $\mathcal{P}_f$ shown in Figure 4-(b), is derived from $\mathcal{P}_1$, with the highlighted code segments representing the function attributes inserted by ATLAS.

Variable Attribute Insertion. For each variable within program $\mathcal{P}$, the method *selectVarAttr*() picks appropriate variable attributes through type checking (Line 12 in Algorithm 1). For example, the `packed` attribute, which instructs the compiler to pack structure members tightly together without inserting padding [20], cannot be applied to variables of type `int`. As such, the method *selectVarAttr*() will only apply `packed` attribute to member variables within a structure. In the case of program $\mathcal{P}_2$ shown in Figure 5-(a), ATLAS identifies the positions of all variables and marks them with <var> using the position information *pos* from $\mathcal{A}_{\langle t,pos\rangle}$. The mutated program $\mathcal{P}_v$ in Figure 5-(b) is derived from $\mathcal{P}_2$, where ATLAS inserts the `vector_size` attribute into a member variable of the structure `d`. Since there are two <var> marks in $\mathcal{P}_2$, ATLAS selects the one within the structure `d` based on the outcome of the $FlipCoin()$ decision.

```
int a;
int b(int);
<func> int c() {
  a = 1;
  while (a)
    a = 2;
  return a;
}
<func> int e(void) {
  int d = c();
  b(d);
}
```

(a) Original Program $\mathcal{P}_1$.

```
int a;
int b(int);
__attribute__((pure,
  returns_twice))
int c() {
  a = 1;
  while (a)
    a = 2;
  return a;
}
int e(void) {
  int d = c();
  b(d);
}
```

(b) Mutated Program $\mathcal{P}_f$.

Figure 4: Illustration examples of function attributes insertion. $\mathcal{P}_f$ was mutated from $\mathcal{P}_1$ by inserted function attribute. This program triggers the GCC bug 114687 when compiled with -fsanitize=address -O1.

```
<var> int a;
void b();
int e(int *c, struct d {
<var> char an[*c]} *) {
  sizeof(struct d);
}
void f() {
  if (e(&a, 0))
    b();
}
```

(a) Original Program $\mathcal{P}_2$.

```
int a;
void b();
int e(int *c, struct d {
__attribute__((
  vector_size(4)))
  char an[*c]} *) {
  sizeof(struct d);
}
void f() {
  if (e(&a, 0))
    b();
}
```

(b) Mutated Program $\mathcal{P}_v$.

Figure 5: Illustration examples of variable attributes insertion. $\mathcal{P}_v$ was mutated from $\mathcal{P}_2$ by inserted variable attribute. $\mathcal{P}_v$ triggers the GCC bug 117145 when compiled with -O1.

Statement Attribute Insertion. The process of statement attribute insertion is outlined in Algorithm 2. This process begins with the use of the function $FlipCoin()$ to determine which attributes from the set $\mathcal{S}_{sa}$ will be utilized in subsequent steps (Line 4). The method *isEmpty*() is employed to verify the presence of variables within the statement (Line 6). If variables are indeed present, the *Construct*() method gener-

ates a simple expression based on the identified variable list *vl* to accomplish the corresponding attribute. Notably, each statement is associated with only a single attribute. To provide a clearer understanding, consider program $\mathcal{P}_3$ as depicted in Figure 6-(a), where ATLAS annotates the loop statement with `<stmt>`. The variables `x` and `y` are included in the variable list; consequently, the *Construct*() method selects a `linear` modifier and produces simple expression `(uval (x): y + 1)`. The highlighted code in Figure 6-(b) illustrates the attribute generated by $formStmtAttr()$. `#pragma` is also a form of attribute. For clarity, this line of code has been folded to enhance readability.

```
void a (int &x, int &y) {
  <stmt>
  for (i=0; i<10; i++) {
    x += y + 1;
  }
}
```

(a) Original Program $\mathcal{P}_3$.

```
void a (int &x, int &y) {
  #pragma omp simd
    linear(uval (x): y+1)
  for (i=0; i<10; i++) {
    x += y + 1;
  }
}
```

(b) Mutated Program $\mathcal{P}_s$.

Figure 6: Illustration examples of statement attributes insertion. $\mathcal{P}_s$ was mutated from from $\mathcal{P}_3$ by inserted statement attribute. This program triggers the LLVM bug 108166.

Algorithm 2: Form Statement Attributes

```
1  Function formStmtAttr(S_sa, A_⟨vl,pos⟩):
2      a ← " ";
3      foreach attr ∈ S_sa do
4          if FlipCoin() then
5              var_list ← A_⟨vl,pos⟩.getVarList();
6              if !var_list.isEmpty() then
7                  a ← Construct(var_list);
8                  break
9              else
10                 a ← attr;
11     return a
```

3.3 Selecting Options

In practical use, certain attributes become effective only when specific compilation options are applied. As illustrated in Figure 2, we utilize the `no_sanitize_address` attribute to disable the instrumentation of `bar()` function. Such attribute will only exert its influence during the compilation process if the `-fsanitize=address` option is specified. Following the insertion of attributes in Section 3.2, ATLAS selects the appropriate compilation options based on the attributes inserted to ensure their effectiveness.

The procedure for this selection is outlined in Algorithm 3. In the map $\mathcal{M}_o$, each attribute (key) corresponds to the compilation options (value) that activate it. The *getInsertedAttr*() method retrieves all attributes that have been inserted into the program $\mathcal{P}$ (Line 2). By iterating the attributes in the list $\mathcal{L}_{attr}$,

Algorithm 3: Select Compilation Options

```
Input: P, the programs with attributes inserted
       M_o, the map of attributes and their options
Output: O, the compilation option of P
1  select ← set();
2  L_attr ← getInsertedAttr(P);
3  foreach attr ∈ L_attr do
4      if attr ∈ M_o.keys() then
5          select.add(M_o.getValues(attr));
6  O ← FormOpt(select);
7  return O
```

the corresponding compilation options are retrieved (Line 3-5). These options are then consolidated to form the final compilation options O for the program $\mathcal{P}$ (Line 6).

3.4 Validating Compiler

Once the program variants are generated, the testing process becomes straightforward. The modifications made by ATLAS, such as attribute insertion, do not compromise the overall structure of the programs. For each variant, a stochastic selection process is employed to randomly choose a sequence of optimization options from a set of options O_{all}. O_{all} contains all optimization options for the compiler. The number of selected optimization options does not exceed five, as previous research investigations have indicated that the average number of optimization options leading to bugs is five [6]. These selected options are then combined with the options in O determined by Algorithm 3 for compilation along with the program variant. We define the validation process as follows.

Definition 2 (Validation). Program $\mathcal{P}_i$ is a variant of program $\mathcal{P}$ and the option O_i is carefully designed. The compiler under test is denoted as $\mathcal{C}omp$, which can receive compilation options and test programs as inputs. If $\mathcal{C}omp(\mathcal{P}_i, O_i)$ crashed, a compiler bug is identified.

Our key insight is that when considering a valid program $\mathcal{P}$, the compiler should exhibit stability without encountering any crashes throughout the compilation process with a specific compilation option, denoted as O_p. Figure 2 illustrates the final results of our tool. In the case of the attribute-inserted variant, detecting the bug requires both the selection of appropriate compiler options (`-fsanitize=address,null`) and the application of suitable optimization settings (`-O2`). The results illustrated in Figures 4 and 5 further substantiate the importance of selecting the appropriate optimization options in the identification of compiler bugs.

4 Evaluation

This section presents our extensive evaluation of ATLAS to find bugs in compilers. Our evaluation is based on the follow-

ing research questions:

- **RQ1 (Effectiveness):** How many compiler bugs have been found by ATLAS?
- **RQ2 (Efficiency):** How efficient is ATLAS in uncovering compiler bugs?
- **RQ3 (Capability):** Can ATLAS improve code coverage?

4.1 Implementation and Evaluation Setup

Implementation. ATLAS is designed to run in a fully automated way, including program information collection, attribute-guided mutation, and validation stages. ATLAS utilizes LLVM's LibTooling library [36] to facilitate the program information collection task as described in Section 3.1. Once launched, ATLAS will automatically generate programs and feed them into the compilers under test.

Target Compilers. We used ATLAS to continuously test the trunk version of two widely used compilers: GCC and LLVM. Specifically, we obtained daily builds of GCC from its repositories and utilized nightly packages of LLVM [37]. Testing on the latest development versions of software offers several advantages:

- By testing these trunk versions, developers can immediately identify and address these bugs.
- This approach can avoid duplicate bug reports as much as possible because once bugs are found in the trunk version, developers tend to quickly fix them [25, 52].

Test programs. In our testing, we have drawn from two sources of programs to generate test programs:

- *Compiler Test Suites*: Each of GCC and LLVM has an already sizable and expanding regression test suite [17, 35], which we can use for generating various test programs. We chose GCC test suite and LLVM test suite because: (1) they are open source which can be easily obtained; (2) they are typically used for compiler regression testing, covering a wide range of C semantics; and (3) many of these test programs can be compiled and executed independently, as they do not rely on external libraries and have fixed inputs.
- *Generated Code*: We choose Csmith [52] and YARPGen [32, 33] as the random program generators to generate C programs to test compilers for the following main reasons: (1) they are extensively used in the literature of C compiler testing [6, 26, 46]; (2) they are effective in finding bugs as thousands of bugs have been exposed and reported for the most widely-used C compilers; (3) each test case generated by Csmith and YARPGen is valid and does not require external inputs; and (4) they are efficient as a test program with tens of thousands of lines can be generated quickly.

Attributes. All the attributes we used are from the GCC and LLVM documentation [10, 15]. The attributes and options map $\mathcal{M}_o$ described in Algorithm 3 was also formed from the documentation. We chose attributes for the following main standard: (1) Programming Language Compatibility: The attribute must be compatible with the C programming language. (2) Exclusions: Attributes that are specifically designed for GPU support are not considered. The attribute sets utilized for GCC and LLVM in our experiments were distinct.

Hardware. Our evaluation was conducted on a workstation with an Intel 48-core 2.30GHz CPU, 120GiB RAM, and Ubuntu 22.04.2 LTS operating system.

Testing process. Our testing process is fully automated and runs continuously. ATLAS first inserts attributes into programs for the test program to get the program variants set, then chooses a proper compilation option for each variant. The program variant with a range of compilation options is used to test GCC and LLVM. Once a program triggers a compiler bug, we use C-Reduce [43] to reduce the program. If the program triggers a new compiler bug, we report the bug to the developers. The only manual step in the testing is analyzing and reporting bugs.

4.2 RQ1: Bug-finding

Table 1 summarizes the bugs we discovered during our testing period. Overall, we reported 73 bugs in total: 44 for GCC and 29 for LLVM. The developers have confirmed 58 of them. This highlights the bug-finding capability of ATLAS. Of all these bugs, 17 of them have been fixed of which 13 fixed bugs are in GCC and 4 fixed bugs are in LLVM[2]. We also experienced that the LLVM developers were less responsive than GCC and mostly only labelled our reports as bugs without further diagnosis. The results presented in the "Options" column indicate whether the triggering of a bug requires compilation options. If such options are necessary, the bug is marked with ✓; if not, it is marked with ✗. A total of 49 bugs require compilation options for triggering, while only 24 bugs can be triggered solely through the insertion of attributes. In the Table 1, the "Priority" is priority of a bug report. The field priority of a bug report is determined by developers for prioritizing bugs, expressing the order in which bugs should be fixed [47]. P1 is the most urgent level and bugs of this level should be fixed soon, and P3 is the default priority level. LLVM developers do not prioritize bugs explicitly in the bug repository, so we only present the priority on GCC.

Note that the bug management guidelines of GCC and LLVM are not exactly similar. Specifically, a reported bug in GCC Bugzilla will be initially labelled as "UNCONFIRMED", and the status will turn to "NEW" if developers confirm it. However, in LLVM issue tracker, a reported bug

[2]For one GCC bug (ID: 116687), developers commented it as "Confirmed", unless they marked them as "NEW", we still regard it as unconfirmed.

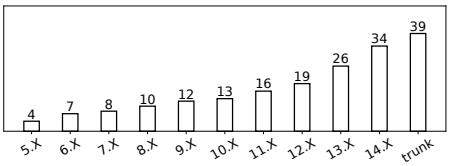

Table 1: The bugs reported by ATLAS.

ID	Priority	Status	Options	Attributes	ID	Priority	Status	Options	Attributes

will be labelled as “new issue" by default, and if the developers confirm it, they will remove the “new issue" label and add other labels. For example, if the bug is related to link time optimization, it will be labelled as “LTO". In addition, if the status of a bug is “Assigned" means the bug is confirmed and is assigned to a certain developer to deal with it. If a bug is fixed by developers in LLVM issue tracker, the corresponding issue report will be closed. If the bug has the same root cause with the bug reported by other developers previously, we categorize it as “Duplicate".

Priority of bugs. To analyze the importance of the bugs, we present the priority levels of GCC bugs in the Table 1. One bug (ID:114687) has been marked as P1 priority by the developers, and 14 bugs have been marked as P2 priority. The higher priority assigned to these bugs indicates the developers' attention to the bugs. Developers have to fix all P1 bugs before making the next release [30].

Influence of bugs. To further understand the influence of our reported bugs, we investigate the official release versions of compilers affected by the reported bugs. Here, we select GCC-5 (released in 2015) and LLVM-5 (released in 2017) as the earliest versions of the subjects because they are the first stable versions that support sanitizers [29] and our compilation options include sanitize options. The results indicate that

(a) Affected GCC versions

(b) Affected LLVM versions

Figure 7: Compiler versions affected by the reported bugs.

ATLAS is capable of identifying critical bugs. As illustrated in Figure 7, four enduring bugs spanning eight years are evident within the GCC-5, signifying its persistence over a considerable period. Similarly, in LLVM, four bugs have persisted within the compiler for a duration of six years. Most bugs affect at least two compiler versions. These findings demonstrate the capability of ATLAS in uncovering long-standing bugs, further emphasizing the significance and impact of our

bug-finding results.

Severity of the bugs. Some of the identified bugs have impact on compiler correctness and reliability. For example, GCC Bug 112709 leads to an ICE during sanitizer instrumentation on function return values, which directly causes the compiler to crash. GCC Bug 114687 reflects an overly aggressive constraint in handling the function call during instrumentation, which may result in incorrect control-flow or optimization behavior. These issues demonstrate fragility in the compiler's Static Single Assignment (SSA) and Control Flow Graph (CFG) transformation logic, especially under instrumentation. Other bugs affect semantic correctness or type handling. For instance, GCC Bug 117145 occurs when a vector_size attribute is applied to a struct, and the compiler fails to treat it as a Variable Modified Type (VMT), leading to type analysis errors. GCC Bug 117230 misuses type precision on vector types, potentially resulting in incorrect code generation or undefined behavior when vector types are involved. Bugs related to SIMD support can result in broken vectorization or compilation failure. GCC Bug 115847 misinterprets the simd attribute on functions with vector return types, breaking code generation. LLVM Bugs 96383 and 108166 show the compiler's inability to handle loop-level SIMD attributes properly, which causes compilation errors when auto-vectorization is attempted. These examples represent only a subset of the bugs we identified. Many other issues were found across different components of the compiler. Overall, these bugs impact the reliability of compilers in real-world scenarios.

Table 2: The number of affected compiler components.

Component	GCC	LLVM	Total
Front-End	17	6	23
Middle-End	13	8	21
Optimization	11	5	16
Back-End	3	10	13

Affected Compiler Components. As shown in Table 2, the 73 identified bugs span a wide range of compiler components, with the front-end being the most affected, accounting for 31.5% of the total. Additionally, 28.8% of the bugs occur in the middle-end, suggesting that attributes have a significant impact on the generation and manipulation of intermediate representations (IR), a critical phase where high-level code is transformed into an optimized, lower-level form. Furthermore, 16 bugs were found within the optimization components. This finding highlights that attribute insertion can influence the compiler's optimization processes, triggering rarely exercised code paths. The presence of such bugs underscores the importance of thoroughly testing the interaction between attributes and optimization routines, particularly in complex or highly optimized code scenarios.

Valuable attributes. The attribute combination of each bug is listed in Table 1 tables. Since some attributes can be applied to both functions and variables, we explicitly annotate their usage: "func" represents function attribute, "var" represents variable attribute, "stmt" represents statement attribute. To ascertain the effectiveness of various attributes in bug detection, we analyzed the 73 test cases that trigger bugs. Specifically, we find that each test case contained at least one attribute, indicating that attribute insertion is essential. Delving deeper, we find that certain attributes are more frequently involved in bug-triggering test cases. Table 3 presents the number and types of attributes involved in the test cases. The attributes of GCC and LLVM displayed in the table reveal differences. For example, in the context of optimization-related attributes, LLVM and GCC have distinct approaches to applying optimization settings to functions. LLVM typically disables optimization for a function by specifying the `optnone` attribute on the function. Notably, the largest number of function attributes is `return_twice` in GCC (7). A variety of optimization-related attributes were also identified. Additionally, the attributes `always_inline`, `noipa` and `noinline` are utilized to control function-level optimizations, influencing how specific functions are treated during the optimization process. These findings highlight the effectiveness of our approach in uncovering bugs by fine-tuning function optimization through attribute manipulation. The `vector_size` attribute, which can be applied to both variables and functions, requires careful distinction based on its usage context. This attribute proves effective in detecting bugs in both GCC and LLVM, as compilers often struggle with optimizing code when `vector_size` is used, particularly in complex expressions or with multiple vectorized operations. Furthermore, the

Table 3: The distribution of the valuable attributes. "#" denotes the number of bugs detected by ATLAS.

Attribute	Type	#	Attribute	Type	#

`simd` attribute uncovered several bugs in both compilers due to its role in generating SIMD instructions for loops. Automatically transforming scalar operations into vectorized forms is a complex process; the compiler must analyze dependencies and ensure that operations can be executed in parallel without introducing errors. Such observations suggest that compiler developers should pay more attention to these attributes to ensure the compiler's correctness.

Commonly Used Attributes. The attributes that triggered bugs found by ATLAS are not rarely used; rather, they are commonly found in real-world software systems. For instance: the `optimize` and `optnone` attributes are used to enforce or disable optimization on specific functions, which is common in debugging, benchmarking, and embedded systems; The `simd` attribute is prevalent in high-performance computing (HPC), multimedia processing, and numerical libraries where loop vectorization is critical; The `malloc` attribute is frequently applied to memory allocation routines to improve alias analysis and enable optimizations; The `aligned` attribute is widely used in performance-critical software to ensure proper memory alignment for data structures, particularly in low-level systems code and signal processing; The `vector_size` attribute is common in SIMD programming and is used in many numerical and graphics applications. These attributes appear regularly in system libraries, graphics engines, deep learning frameworks, HPC software, and performance-tuned applications. As a result, the bugs associated with them are likely to be triggered in real-world development.

4.3 RQ2: ATLAS Efficiency

Baseline approaches. We compared ATLAS with the most direct and the state-of-the-art approach for compiler testing:

- **Random Option (RO):** To isolate and understand the contribution of ATLAS, we evaluate ATLAS without incorporating attributes into the programs. The **RO** approach represents the conventional approach, where programs are generated randomly and paired with randomly selected optimization flags. This method aims to explore the compilation space without any guided mechanism, thereby serving as a fundamental baseline for assessing the efficacy of our proposed method.
- **Attribute Only (AO):** Since ATLAS also compiles programs with compilation options, it is necessary to investigate the contribution of this part. Therefore, we evaluate ATLAS without compilation options compiled with programs. In this scenario, attributes that depend on specific options to be effective are excluded from insertion into the program. **AO** helps in quantifying the extent to which compilation options enhance the exploration of the compilation space. The approach **AO** ensures broad coverage of the compilation space by using attributes, albeit without specific direction.
- **Equivalence Modulo Inputs (EMI):** We also compared ATLAS against Hermes [46], which is the most recent and powerful EMI-based compiler testing tool.

These comparative analyses provide a comprehensive understanding of the strengths and weaknesses of ATLAS in relation to both the **EMI**, **RO** and **AO**, a method devoid of its core attribute-based exploration strategy. We use Csmith and YARPGen as the generators to generate the test programs.

Measurements. Following the existing work [6, 7, 51], we used the number of detected bugs within the same testing period to measure the performance of ATLAS. Same as the existing study [6, 7, 51], we tested each subject using each approach for 10 days , and adopted Correcting Commits [4], a method commonly used in existing studies [6, 8, 51], to identify the number of detected bugs from a set of failing test programs. More specifically, for any test program that triggers a bug of a compiler C whose commit version is x, the Correcting Commits method checks subsequent commits of the compiler and determines which commits fix the bug. If two failing test programs have the same correcting commit, they are regarded as triggering the same bug. The number of correcting commits is approximately regarded as the number of detected bugs. In fact, the accuracy of this method is quite substantial as existing studies [4, 8] demonstrate. This method may be a threat to our study. However, it is the only automatic method to measure the number of detected bugs and its accuracy has been demonstrated by the existing study, and thus this threat may be not serious. We applied **RO**, **AO**, **EMI**, and ATLAS to test GCC-5.1 and LLVM-5.0.0. We choose these old releases rather than the latest release since: 1) they are the stable versions that support sanitizers [29] and the compilation options includes sanitizer options; 2) they released for a long time, and thus most bugs have been exposed; 3) most bugs have been fixed as they have been maintained for a long period, thus we will have enough correcting commits to evaluate different strategies.

Table 4: The number of detected bugs and generated compilable programs within 10 Days.

Generators	Techniques	GCC Bugs(#)	LLVM Bugs(#)	Total Bugs(#)	Compilable Programs(#)	Total Programs(#)
Csmith	RO	13	5	18	53,458	53,481
	AO	19	11	30	32,043	47,825
	EMI	17	11	28	48,765	49,279
	ATLAS	32	17	49	30,170	46,416
YARPGen	RO	8	6	14	123,087	123,192
	AO	12	10	22	70,361	108,085
	EMI	10	9	19	101,734	103,628
	ATLAS	25	13	38	62,142	99,439

Number of detected bugs. Table 4 shows the number of detected bugs within 10 days. For programs generated by Csmith, the total number of bugs identified by ATLAS, **AO**, **RO** and **EMI** is 49, 30, 18 and 28, respectively. For programs

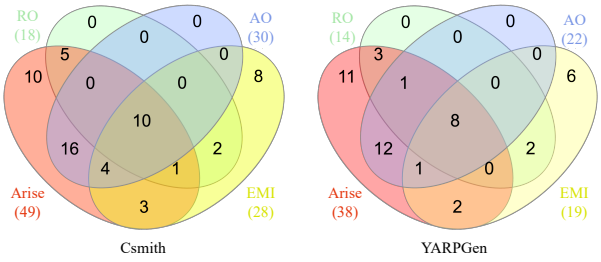

Figure 8: Unique bugs found by different techniques.

generated by YARPGen, the corresponding numbers are 38, 22, 12, and 19. A comparative analysis indicates that ATLAS consistently outperforms **AO**, **RO** and **EMI** across both generators, demonstrating the effectiveness of ATLAS.

Number of unique bugs. We further analyzed the number of unique bugs detected by each approach, whose results are shown in Figure 8. More specifically, these Venn diagrams show various relations among the bugs detected by the four approaches, including the unique bugs and the common bugs. For programs generated by Csmith, ATLAS detects 10 unique bugs, accounting for approximately 20.4% of its total findings. This result demonstrates the distinct bug-finding capability of ATLAS. Moreover, ATLAS can detect most (18) of the bugs detected by **EMI**. **AO** identifies more bugs than **RO** and `EMI`, highlighting the effectiveness of using attribute insertion for compiler testing. Furthermore, ATLAS is able to detect all the bugs identified by method **AO**. In the case of YARPGen-generated programs, ATLAS again detected all bugs identified by **AO** and uncovered 11 unique bugs.

Although ATLAS is superior in detecting compiler bugs compared with **RO** and **AO**, **EMI** can also detect some unique bugs. We further analyze the reason for this phenomenon. Regarding **EMI**, it modifies the program's structure and enhances its diversity by adding and removing code. Additionally, it compiled and executed more test programs than ATLAS during the same testing period. As demonstrated by the existing study [7], the number of test programs indeed affects the performance of compiler testing to some degree, and thus this may result in the unique bugs detected by **EMI**.

There is a different performance between LLVM and GCC in Table 4. We summarize the reasons as follows: (1) The release time of the LLVM subjects is about two years later than the GCC subjects. Thus, these LLVM subjects should have fewer bugs than those GCC subjects. The chosen LLVM subjects are LLVM-5.0.0 released on 9/7/2017 [38]. While GCC-5.1 were released in 4/22/2015 [16]. There is a two-year gap between the LLVM subjects and the GCC subjects. In addition, Csmith was released in 2011. At that time, Csmith found 203 bugs for LLVM and 79 for GCC [52]. In other words, most bugs found by Csmith have been fixed in those LLVM subjects as they were released two years later after Csmith. (2) Each LLVM version is maintained for a shorter period than the three subject GCC versions. LLVM-5.0.0 was only maintained for ten months [40]. While the GCC-5.1 are respectively maintained for 30 months [14]. Since the GCC subjects were maintained for much longer than the LLVM subjects, the GCC subjects should have much more bug-fixing commits than LLVM during the maintenance period.

Compilable Programs. As shown in Table 4, **RO** and **EMI** generated the highest proportion of compilable programs among these approaches. This outcome is expected, as the programs generated by Csmith and YARPGen strictly adhere to the C language standard, whereas **EMI** performs equivalent mutations on these programs. The total number of test programs generated by **AO** and ATLAS is smaller than those produced by **RO** and **EMI**. This is because the program generation phase in **AO** and ATLAS involves both modifying the original program and selecting attributes, resulting in slightly higher overhead compared to **EMI**. Additionally, the proportion of programs successfully compiled by **AO** and ATLAS is lower than that of **RO** and **EMI**. This is primarily due to the insertion of certain attributes—particularly those related to variables, such as `vector_size`—which may conflict with the program's requirements for variable usage.

Time Trends. Figure 9 illustrates the time trends in the number of unique bugs discovered for both GCC and Clang, with the top two subplots corresponding to programs generated by Csmith, and the bottom two to those generated by YARPGen. For the Csmith generated programs, **RO** reached a saturation point after approximately 40 hours, making it challenging to identify additional bugs in GCC and LLVM. **EMI** approached saturation after more than 200 hours. Meanwhile, **AO** and ATLAS continued to uncover bugs over a period of 10 days. For programs generated by YARPGen, all four techniques were able to detect bugs continuously. However, as the number of discovered unique bugs increased, the time required for **AO**, **RO**, and **EMI** to find additional bugs also grew significantly. In comparison, ATLAS maintained a more consistent discovery rate, further demonstrating its efficiency and robustness in uncovering compiler bugs over time.

Table 5: Code coverage of GCC and LLVM.

Compiler	Techniques	Line	Function	Branch
GCC	**RO**	33.5%	35.2%	21.1%
	AO	34.7%(+13,080)	36.9%(+419)	22.0%(+10,697)
	EMI	35.3%(+19,619)	36.8%(+314)	22.4%(15,450)
	ATLAS	36.3%(+30,519)	37.6%(+1,152)	23.2%(+24,958)
LLVM	**RO**	34.4%	25.6%	20.0%
	AO	35.6%(+20,324)	26.5%(+849)	20.9%(+6,472)
	EMI	35.1%(+12,435)	26.9%(+1,307)	21.3%(+9,592)
	ATLAS	36.8%(+41,806)	27.6%(+1,953)	21.7%(+12,954)

4.4 RQ3: Code Coverage

To evaluate the effectiveness of ATLAS, we analyzed the coverage achieved while testing the compiler using this approach.

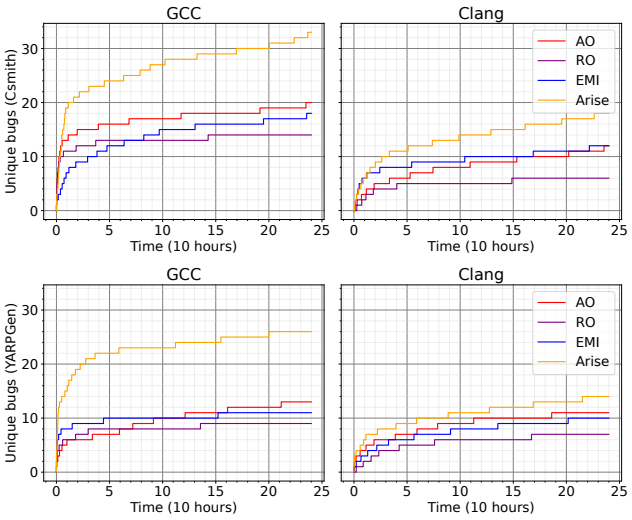

Figure 9: The earliest time each unique bug was discovered.

We randomly generated 10,000 seed programs by Csmith following the methodology outlined in previous work [30] and inserted attributes into these programs. These test programs were distinct from those generated in Section 4.3. For each set of seed programs and their corresponding variants, we utilized the most recent releases of compilers, such as LLVM-19.0.0 and GCC-15.0.0. The compilation of each program was constrained to a maximum of 10 seconds, and we measured the code coverage achieved during these compilations. The primary aim was to determine if the variants produced by ATLAS could improve code coverage compared to the original seed programs. An improvement in code coverage would suggest that our transformations effectively explore additional code paths within the compilers, thereby increasing the likelihood of triggering compiler bugs.

The results of these experiments are summarized in Table 5 (the best results are marked in gray), which displays the code coverage metrics for line, branch, and function coverage achieved by four techniques: **RO** and **AO**, **EMI** and ATLAS. Although the coverage percentages are relatively similar, a detailed analysis of the specific values reveals an improvement of tens of thousands in the number of covered lines and branches. These results indicate that ATLAS improves code coverage across all metrics of the compilers under test. By triggering more code paths in the compilers, ATLAS not only enhances the thoroughness of compiler testing but also increases the potential for uncovering hidden bugs. This demonstrates the practical value and efficacy of ATLAS.

5 Discussion

5.1 Threats to Validity

We have identified the following main threats to validity:

Impact of subjects. One potential threat to the validity of our results is the representativeness of the compiler versions used in our experiments. In Section 4.3, we acknowledge that using a single version of a compiler may not adequately reflect the diversity of compilation scenarios encountered in practice. To mitigate this threat, we selected the two most widely used C compilers, GCC and LLVM, and evaluated multiple versions of each. This approach is consistent with existing studies [3, 4, 6, 21, 22, 26, 27, 41, 45, 47, 52], which have demonstrated the importance of considering a variety of compiler versions to ensure a comprehensive evaluation. By incorporating different versions, we aimed to enhance the generalizability and robustness of our findings regarding the effectiveness of ATLAS.

Impact of metrics. The accuracy of our bug detection metrics is another critical aspect that could affect the validity of our study. We employed the Correcting Commit approach, as used in prior research [4, 6–8], to estimate the number of bugs in our test programs that trigger errors. Although this method may not achieve perfect precision, it is currently the only automated approach available for estimating bug counts. Previous research [4] has demonstrated the reliability of this method, suggesting that its limitations do not pose significant concerns. Furthermore, we took measures to mitigate the occurrence of duplicate false positives by carefully analyzing crash messages. False positives were rare in our study, and we did not encounter any instances of false positives when testing with GCC and LLVM.

Test programs. To reduce the threat posed by the test programs, we used the most widely used C test program generation tools, Csmith and YARPGen, following many existing compiler-testing studies [11, 25–27, 48]. Additionally, many other test program generation tools are also adapted from Csmith and YARPGen [24, 29]. We also incorporated test suites from both GCC and LLVM for testing.

5.2 Integration with Other Techniques

ATLAS can be easily integrated with other compiler testing techniques. Specifically, ATLAS can take test programs generated by tools such as Csmith [52], YARPGen [32, 33], and EMI [25] as seed inputs. For each seed program, ATLAS parses its AST and identifies locations where attributes can be meaningfully inserted. By systematically injecting attributes at these locations, ATLAS enables exploration of additional compiler compilation space, such as those involving optimization, code generation for special attributes, or attribute-sensitive transformations. Take EMI [25] as an example. EMI generates program variants that are semantically equivalent on a given input. After these variants are created, ATLAS can further process each of them by analyzing their ASTs and inserting attributes at appropriate positions. This layered approach enables the discovery of bugs that only manifest under specific combinations of program structure and attributes. A similar integration can be achieved with

Creal [30], which generates test cases by inserting real-world functions. ATLAS can apply attribute insertion to these programs as well. In summary, ATLAS is highly compatible with existing compiler testing frameworks and can be seamlessly integrated to explore a broader compilation space.

6 Related Work

This section introduces the related work on compiler testing techniques and compilation space exploration.

6.1 Compiler Testing Techniques

The identification of compiler bugs has been the subject of extensive research, with significant efforts dedicated to testing various functionalities of compilers. Notable contributions in this area include the widely-used Csmith [52], a program generator specifically designed for C, which has successfully uncovered numerous compiler crashes and correctness bugs. It is worth noting that programs generated by Csmith are guaranteed to be devoid of undefined behavior. Another approach, Equivalent Modulo Input (EMI) [25], has been proposed for mutating or transforming seed programs while preserving their semantics under the same input. EMI can be implemented through techniques such as deleting dead statements [25], inserting new code in inactive regions [26], or synthesizing equivalent code in active regions [46]. When combined with Csmith, EMI has proven effective in uncovering thousands of compiler optimization bugs. YARPGen [32, 33] is another program generator for C/C++ that specifically focuses on testing scalar optimizations in compilers. SPE focuses on enumerating variable usage patterns in skeleton-based test synthesis [55]. GrayC designs five semantic-aware mutators specifically for creating more compilable programs [11]. Recent researchers have leveraged large language models (LLMs) in compiler testing: Ou et al. [42] proposed using LLMs to generate mutators, and Gao et al. [12] introduced a bracket-based masking strategy driven by historical Rust compiler bugs to synthesize valid test inputs, leading to the discovery of multiple confirmed bugs. Li et al. [30] use real-world code snippets to construct semantics-preserving programs for testing optimizing compilers.

In addition to optimization correctness,other aspects of compiler reliability such as incorrect debug information [31, 50], debugger toolchain bugs [54], and missed optimizations [48, 49], have also been extensively studied.

6.2 Compilation Space Exploration

Li et al. [28] introduced the concept of the compilation space exploration(CSE), which encompasses a comprehensive collection of Just-In-Time (JIT) compilation options. These options can be cross-validated to ensure the correctness of JIT compilation. To systematically explore the compilation space, Li et al. employed strategic mutations in the code structure of test programs. These mutations were thoughtfully designed to preserve the code's semantics while effectively triggering a wide range of JIT compilation choices. Chen et al. [6] conducted an empirical study on GCC and LLVM, highlighting the distinctive value of exploring the space of compiler optimizations. They proposed the COTest by considering both optimization settings and test cases to boost compiler testing.

Different from these approaches, our approach integrates not only the optimization options but also compilation options with the attributes to facilitate the exploration of the compilation space. Additionally, we introduce the insertion of attributes into the program, enabling a fine-grained and in-depth exploration of the compilation space. This integration of attributes with compilation options represents a novel approach, providing a more detailed and comprehensive examination of compiler behavior and reliability.

7 Conclusion

This study introduces a novel approach that utilizes attributes to guide the exploration of compilation space for compiler testing. To achieve this, we strategically incorporate attributes into existing test programs to generate mutated versions. Since attributes enable precise control over the compilation strategies applied to individual code segments, the mutated versions can be utilized to explore previously unexamined areas of compilers. We implement this concept as a prototype called ATLAS. Through extensive evaluation, we demonstrate the practical value of ATLAS, as it successfully detected a total of 73 bugs for GCC and LLVM. Notably, 58 of these bugs have been confirmed, and 17 have been resolved by the developers, underscoring the significant impact and efficacy of ATLAS in identifying compiler bugs.

Acknowledgments

We are grateful to the anonymous reviewers and our shepherd, Aravind Machiry, for their valuable and constructive feedback on this work. We are also indebted to the GCC and LLVM developers, particularly Jakub Jelinek, Richard Biener, Marek Polacek, and Martin Jambor for inspecting and fixing our reported bugs. This work is partially supported by the National Natural Science Foundation of China (Grants 62072194, 624B2067, 62172205, 62272214), the Jiangsu Natural Science Foundation under Grant BK20231402, the Collaborative Innovation Center of Novel Software Technology and Industrialization, and the Fundamental Research Funds for the Central Universities (XJ2024003301, XJ2025000601).

A Artifact Appendix

Abstract

The artifact contains the code and datasets we used for our experiments, as well as scripts to generate the numbers and tables of our evaluation. Specifically, it includes (a) links and bug-triggering test cases of each reported bug and (b) detailed instruction documentation for using ATLAS. Everything is packaged and pre-built as a docker image.

Scope

The artifact allows validation of the identified bugs shown in Table 1. Additionally, Table 2, Table 3, and Figure 7 are based on a manual analysis of the identified bugs.

Contents

This artifact consists of the following items:

- **The AST Parsing Tool.** This artifact provides the tool to parse the seed programs.
- **Attribute Insertion Tool.** This artifact provides scripts that can be used to insert attributes into the seed programs

- **Documentation.** This artifact provides step-by-step instructions on setting up and using the Docker image, along with usage guidance for the tools above.

Hosting

The artifact is archived on Zenodo and can be downloaded at the following DOI: https://doi.org/10.5281/zenodo.15375789

Requirements

For optimal performance, we recommend running the full evaluation on a machine with the following specifications:

- **CPU:** 16 cores or more
- **Memory:** At least 32 GB
- **Disk Space:** 20 GB free

A.1 Installation

The Docker image is provided in a pre-configured format, obviating the need for any installation. The following commands can be employed to extract the artifact archive and import it into Docker:

```
$ gunzip -c atlas.tar.gz > atlas.tar
$ docker load -i atlas.tar
$ docker run -it -name atlas
compiler_testing:atlas /bin/bash
```

Understanding and Detecting Fail-Slow Hardware Failure Bugs in Cloud Systems

Abstract

Fail-slow hardwares are still running and functional, but in a degraded mode, thus slower than their expected performance. Bugs triggered by fail-slow hardwares cause severe cloud system failures. Existing testing tools fail to efficiently detect these bugs due to overlooking their characteristics. In order to address this problem, this paper provides a bug study that analyzes 48 real-world fail-slow hardware failures from typical cloud systems. We observe that (1) fail-slow hardwares make high-level software components vulnerable, including synchronized and timeout mechanisms; (2) the fine granularity of fail-slow hardwares is necessary to trigger these bugs. Based on these two observations, we propose Sieve, a fault injection testing framework for detecting fail-slow hardware failure bugs. Sieve statically analyzes target system codes to identify synchronized and timeout-protected I/O operations as candidate fault points and instruments hooks before candidate fault points to enable fail-slow hardware injection. To efficiently explore candidate fault points, Sieve adopts grouping and context-sensitive injection strategies. We have applied Sieve to three widely deployed cloud systems, i.e., ZooKeeper, Kafka, and HDFS. Sieve has detected six unknown bugs, two of which have been confirmed.

1 Introduction

Cloud systems have become the backbone of numerous modern applications [29, 57, 61, 65]. However, fault-triggered failures in cloud systems cause severe loss of customer satisfaction and revenues for service providers [9, 19, 53]. To achieve high reliability, cloud systems need to correctly handle various faults [1, 10, 37, 42]. Based on the scope of faults, we classify them into two categories: **coarse-grained** and **fine-grained** faults. Specifically, when only considering I/O operations in a cloud system, let D=$\{D_1,D_2,...,D_n\}$ represent the set of disk I/O operations and N=$\{N_1,N_2,...,N_m\}$ represent the set of network I/O operations. Coarse-grained faults affect all associated I/O operations, e.g., the I/O operations in D fail in fail-stop disks [46] and those in $D \cup N$ fail in node crashes [16, 42]. Fine-grained faults affect a subset of associated I/O operations, e.g., fail-slow Network Interface Cards (NICs) [22] slow down N_{sub} ($N_{sub} \subset N$). Coarse-grained faults have been well studied and handled by existing well-designed fault tolerance mechanisms [5, 18, 52, 56]. However, emerging fine-grained faults propose new challenges to the reliability of cloud systems.

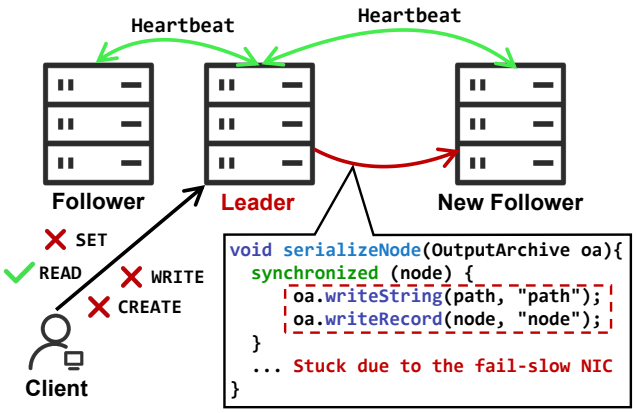

Figure 1: A production ZooKeeper failure due to the fail-slow NIC [11]. The writeRecord operation becomes slow within the synchronized block. The update-type requests are blocked. Developers fixed the bug by copying the node object and serializing the copy out of the synchronization.

Recently, fail-slow hardwares [22, 44] received an increasing amount of attention, which deliver lower-than-expected performance and cause fine-grained faults. For example, the throughput of a 1-Gbps NIC might suddenly drop by several orders of magnitude to 1 Kbps due to partial buffer corruption and retransmission [12], which slows down partial network I/O operations. Lu et al. [44] indicate that the fail-slow NVMe SSD has become a widespread and severe problem. On average, 1.41% of NVMe SSDs (over one million NVMe SSDs) are infected within four months of monitoring. Moreover,

fail-slow hardware incidents always consume hours or even months to detect. Only 1% of the cases are detected in minutes [22]. As a consequence, once fail-slow hardwares bring cloud systems down, it requires large human efforts to detect the root cause. For example, several AWS services become unavailable due to unexpected high network latency [53], which takes developers nine hours to detect the root cause. Figure 1 presents another real-world fail-slow hardware failure from ZooKeeper [11] which is a widely used distributed coordination to tolerate leader and follower crashes. Specifically, an entire cluster becomes a near-freeze status. `write()` and `create()` requests fail, but `read()` requests can be successfully processed. The developers at PagerDuty [50] spend five months to diagnose this failure. In this paper, we refer to the fault caused by the fail-slow hardware as the **FSH fault** and the bug triggered by the FSH fault as the **FSH bug**. We define ***fail-slow hardware failures*** as the failures caused by FSH bugs and refer to these failures as **FSH failures**.

To prevent the FSH fault from breaking cloud systems at runtime, it is essential to develop an FSH fault injection testing framework. Fault injection testing [1, 6, 14, 16, 21, 31, 32, 42, 48] is a commonly used technique for detecting fault-triggered bugs. There are enormous efforts in developing various fault injection testing frameworks. However, existing schemes fail to efficiently detect FSH bugs due to overlooking the characteristics of FSH failures. To address this problem, we conduct a study of 48 real-world FSH failure cases from five large-scale and open-source systems. Furthermore, we observe that there are two key characteristics in efficiently detecting FSH failures like the example in Figure 1.

1) The vulnerable synchronized and timeout mechanisms cause all studied FSH failures. For example, synchronized tasks slowed down by fail-slow hardwares block other tasks for an uncertain time; data race can occur between the timeout task caused by the fail-slow hardware and the corresponding timeout handler with simple timing constraints. This characteristic can significantly prune the huge fault injection space. However, existing bug studies overlook this characteristic since they focus on either the fail-slow software or hardware. Unlike them, our bug study comprehensively analyzes how the fail-slow hardware affects the software.

2) The fine granularity of FSH faults is necessary to trigger FSH failures. One of the main reasons is that fine-grained FSH faults are relatively easy to escape the detection of internal checkers. For example, as shown in Figure 1, there are two network I/O operations, i.e., `serializeNode` and `Heartbeat`. The fail-slow NIC only slows down `serializeNode` so that the heartbeat thread in the leader can maintain the liveness of the cluster. Hence, the entire cluster becomes a *near-freeze status*. In this scenario, the fail-slow NIC escapes the detection of the heartbeat threads in the followers. The fine-grained fault injection is necessary to trigger such failure. Specifically, if a fail-stop NIC is injected in the leader, these two network I/O operations are affected. Subsequently, the heartbeat threads in the followers will detect this coarse-grained fault and start a new leader election, which drives the cluster into a healthy status. Most existing fault injection testing frameworks focus on coarse-grained faults. Although these schemes are enough to detect crash recovery bugs or distributed protocol bugs, they cannot effectively detect FSH bugs.

Inspired by these two key characteristics, we propose Sieve, a fault injection testing framework designed to detect FSH bugs in cloud systems. Sieve treats synchronized and timeout-protected I/O operations as candidate fault points. To identify candidate fault points, we investigate various synchronized and timeout mechanisms in cloud systems and conclude four general patterns from them. Based on these four patterns, Sieve identifies I/O operations in synchronized and timeout-protected domains through lightweight static analysis at the code instruction level. Besides, Sieve automatically instruments hooks before candidate fault points to precisely control the fine-grained FSH fault injection.

To efficiently explore these candidate fault points, Sieve adopts grouping and context-sensitive injection strategies. Specifically, Sieve groups fault points within the same basic block[1]. Because fault points within the same basic block are always under the same high-level system states (e.g., leader election and snapshot synchronization) and protected by the same fault-tolerance handler, which indicates these fault points trigger similar scenarios. Besides, Sieve leverages the context-sensitive injection strategy to (1) avoid exploring the same contexts of fault points and (2) find buggy contexts of the same fault points. During testing, the hook sends the fault injection query to the injection controller. The controller checks the runtime context of the fault point, e.g., call stack and thread ID, and decides whether to inject the fault.

We have implemented a prototype of Sieve and evaluated it on three large-scale cloud systems, i.e., ZooKeeper [70], Kafka [33], and HDFS [2]. Moreover, Sieve has detected six unknown bugs in these systems. Besides, we have released Sieve (including bug study, scripts for reproducibility, and source codes) for public use at https://github.com/RabbitDong-on/Sieve.

In summary, this paper makes the following contributions:

- We conduct a study of 48 real-world FSH failure cases from five cloud systems. Our bug study helps developers to comprehensively understand the characteristics of FSH failures.
- We propose Sieve, a novel approach that enables fine-grained FSH fault injection for detecting FSH bugs. Based on our bug study, Sieve analyzes synchronized and timeout-protected I/O operations as candidate fault points. To efficiently explore these candidate fault points, Sieve adopts grouping and context-sensitive injection strategies.

Table 1: The numbers of FSH Failures.

ZooKeeper	HDFS	HBase	MapReduce	Cassandra
11	18	10	4	5

- We implement a prototype of Sieve and evaluate it on three large-scale real-world cloud systems. Sieve has detected six unknown bugs, two of which have been confirmed.

2 Methodology

To understand the FSH failure, we studied 48 real-world failures in five popular cloud systems shown in Table 1. We leverage the search tool in JIRA [54] to identify reports related to fail-slow hardwares. First, we search reports using the following keywords: "slow disk", "slow storage", "slow network", "slow NIC", and "slow switch". Second, we exclude the issues that have priority of "Minor", "Trivial" and "Low". Third, we identify the issues that are indeed related to fail-slow hardwares. Specifically, for each issue, we carefully read the failure report to obtain an overview of the failure. If the unit test is provided, we run the unit test to reproduce the failure. The unit test provides simplified buggy logic, which is an important guideline for us to read source codes. If the unit test is absent, we directly read source codes based on conversations between the bug reporter and project maintainers. We can identify the root cause in both scenarios. If the root cause is related to the delay and the issue report explicitly mentions the delay is caused by the fail-slow hardware, we preserve this issue.

Threats to Validity. Like all characteristic studies, the results of our study should be interpreted with the following limitations.

Representativeness of the selected systems. The selected systems are diverse, widely-used and open-source: ZooKeeper [70] is a distributed coordination service; MapReduce [58], HDFS [2], and HBase [23] are the cores of the dominant Hadoop data analytics platforms; Cassandra [4] is a highly available peer-to-peer NoSQL database. However, without accurate market information, it is difficult to conclude whether we have chosen the most widely-used cloud systems. Besides, closed-source cloud systems could have different characteristics.

Limitations of the filtering criteria. We clarify that this paper focuses on two types of fail-slow hardwares including the fail-slow storage and network devices. The main reason is that it is relatively easy for developers to confirm the impact of the fail-slow storage and network devices, i.e., slow I/O operations. It is still possible to miss the FSH failures whose issue reports do not contain the selected keywords. The fail-slow hardware is difficult to identify [22]. Developers may not be sure whether the delay is caused by the fail-slow hardware. Hence, the issue report possibly misses the selected keywords. We did try other keywords like "slow", and found that the resulting issue reports contain too many false positives, i.e., non-FSH failures. It is impractical to reduce false positives one by one.

Observer errors. To minimize the possibility of observer errors, each failure is investigated by two inspectors with the same criteria. Any disagreement is discussed in the end to reach a consensus.

Table 2: FSH Failure Symptoms.

Symptom	**%**
Node service unavailable	58.3
Data unavailability	10.4
Data inconsistency	10.4
Job failure	8.3
Performance degradation	6.3
Client stuck	4.2
Node crash	2.1

3 Understanding FSH Failures

In this section, we present some findings and implications by analyzing collected FSH failures.

3.1 Findings

Finding 1: *Over half (58.3%) of FSH failures cause node service to be unavailable.*

Table 2 shows that FSH failures exhibit various failure symptoms. Over half of FSH failures cause certain software functionality or the entire node to be unavailability. In some cases, even a normal node is removed from the cluster. For example, in HDFS-9178 [27], the upstream datanode is stuck in the fail-slow disk. Hence, the downstream node timeouts when reading the packet from the upstream datanode. Then, the upstream datanode sends an ACK to the client and sets the downstream datanode status to `ERROR`. Finally, the client excludes the downstream datanode from the pipeline, even though the upstream datanode is the abnormal one.

Finding 2: *20.8% of FSH failures are silent (including data unavailability and inconsistency).*

These failures are difficult to detect without the correctness specification. For example, in HBase-26195 [24], synchronizing Hlog to HDFS timeouts due to the fail-slow hardware. The client receives an exception and rolls back the data protected by the Hlog. However, this procedure only rolls back the data in the primary node leading to data inconsistency between the primary and replicated nodes. Besides, internal checkers in HBase do not raise any explicit alarms in system

Table 3: FSH Failure Root Causes.

Root cause		%
Non-concurrency		81.2
◇ Indefinite blocking	41.6	
◇ Buggy internal checker	35.4	
○ Buggy error checking	20.8	
○ Buggy error handling	14.6	
◇ Infinite loop	2.1	
◇ Logic error	2.1	
Concurrency		18.8
◇ Data race	16.7	
◇ Deadlock	2.1	

logs or immediately stop the system, which makes this failure detection difficult.

Finding 3: *The root causes of studied failures are diverse. The top three (total 93.7%) root causes are indefinite blocking, buggy internal checker, and data race.*

Indefinite blocking means that synchronized tasks slowed down by fail-slow hardwares block other tasks for an uncertain time. In Figure 1, `writeRecord` within the `synchronized` block becomes extremely slow due to the fail-slow NIC. This synchronized `writeRecord` blocks all following write requests from clients. The fine-grained fail-slow NIC escapes the detection of `Heartbeat`, which is critical to trigger this failure. Buggy internal checker incorrectly handles timeout tasks caused by fail-slow hardwares. For example, in HDFS-5522 [26], the delay caused by the fail-slow disk is treated as a network error. Hence, `checkDiskError` is not invoked, which fails a lot of client requests. Data race occurs between timeout tasks caused by fail-slow hardwares and timeout handlers. Other root causes include infinite loop, logic error, and deadlock.

Finding 4: *Buggy internal checker fails to correctly handle timeout tasks.*

Buggy internal checker includes buggy error checking and error handling [67], which are confused by the impact of fine-grained FSH faults. Specifically, buggy error checking fails to figure out sources of FSH faults, such as fail-slow disks in HDFS-5522 [26]. Even though error checking is correct, error handling may also incorrectly handle FSH faults. For example, in MapReduce-1800 [47], the reducer fails to fetch the mapper's output due to the reducer-side fail-slow NIC. However, the reducer can still talk to the job tracker(JT). When a sufficient number of reducers fail, the normal mapper is blacklisted by the JT. In this example, although error checking finds the slow network, error handling incorrectly handles this fault. The fine-grained FSH fault is key to trigger this failure. Specifically, if a network partition occurs, the reducer cannot talk to the JT. Hence, the normal mapper is not blacklisted.

Table 4: The percentage of each involved event.

Event type	%
Client/Server connection	12.5
Client request	83.7
One fail-slow hardware	89.6
Multiple fail-slow hardwares	10.4
Node reboot/join cluster	4.2

Finding 5: *Data race can occur between the timeout task caused by the fail-slow hardware and the corresponding timeout handler with simple timing constraints.*

The task slowed down by the fail-slow hardware triggers the timeout mechanism. Moreover, the invoked timeout handler does not end the slow task. Therefore, if the timeout handler finishes before the slow task, this task will corrupt the data written by the timeout handler. For example, in ZooKeeper-710 [72], the client connects with the follower that encounters the fail-slow NIC. This connection request triggers the timeout mechanism. The invoked timeout handler sends another connection request to the leader. After successfully connecting with the leader, the former connection request is processed by the follower and the renewal request is sent to the leader. The renewal request overwrites the metadata of the current connection. As a result, the leader still connects with the client, but cannot process the client request. This data race occurs without the complex thread interleaving control. Besides, the fine granularity of the fail-slow hardware is necessary to trigger data race. Specifically, if coarse-grained faults, e.g., node crashes and network partitions, occur in the follower, the renewal request will not be sent to the leader. Hence, data race does not happen in this scenario. Additionally, our bug study shows that the buggy timeout mechanism is a new root cause for concurrency bugs.

Finding 6: *Most (89.6%) of FSH failures are caused by one fail-slow hardware.*

As shown in Table 4, the triggering conditions of most FSH failures do not require multiple fail-slow hardwares and complex inputs. For example, in HDFS-5341 [25], `DirectoryScanner` encounters a fail-slow disk when scanning the dataset with a lock. As a result, `DirectoryScanner` blocks the heartbeat and all DataXceiver threads that acquire the lock. This example only requires simple client requests as inputs.

3.2 Implications

Overall, our bug study reveals that the FSH failure is a severe problem in cloud systems (Table 2). Most (73.5%) of studied failures were reported in the last decade. Moreover, over half (58.3%) of FSH failures cause node service to be unavailable (Finding 1). Even though existing in-production

detectors [28, 39, 43, 51] can detect part of FSH failures, the detected failures already cause damages, e.g., node unavailability and data inconsistency [28, 39, 43, 51]. Hence, it is necessary to design an FSH fault injection testing framework to detect FSH bugs before releasing production. The fault injection space explosion is a notorious problem in fault injection techniques [1, 6, 14, 16, 21, 31, 32, 42, 48]. However, our bug study reveals that synchronized and timeout-protected I/O operations are error-prone, which significantly reduces the fault injection space. Besides, most FSH failures are caused by one fail-slow hardware (Finding 6). Hence, the fault injection space does not increase exponentially due to the combinations of different fault points, which indicates that the fault injection testing framework can efficiently explore the fault injection space without complex fault injection strategies.

There are four points to avoid most FSH failures:

- Do not perform I/O operations within synchronization structures. For example, the solution of the example in Figure 1 is to copy and serialize data out of the `synchronized` block.
- Use the fine-grained lock to accurately synchronize I/O operations.
- Collect more information from other components of cloud systems to figure out sources of FSH faults, e.g., the delay from upstream datanode in HDFS-9178 [27], and take suitable actions.
- Avoid data race between the timeout task and timeout handler. Developers can use timestamps to avoid buggy execution order.

4 The Sieve Design

In this section, we first discuss Sieve's fault model (§ 4.1) and then describe the workflow (§ 4.2) and main components: Fault Point Analysis (§ 4.3), Injection Controller (§ 4.4), Workload Driver (§ 4.5), and Failure Checkers (§ 4.6).

4.1 Fault Model

Fail-slow hardwares exhibit two types of fine-grained faults. The first type slows down partial I/O operations. The second type incurs exceptions from partial I/O operations. In this paper, we only focus on the first type and leave the second type as future work.

Cloud systems are designed to tolerate various faults, but their fault-tolerance levels are limited. If we inject multiple faults, the accumulated side effects possibly break cloud systems as expected. Moreover, one fault is enough to trigger most FSH failures (Finding 6). Hence, Sieve simulates the first type by injecting one delay for each test run.

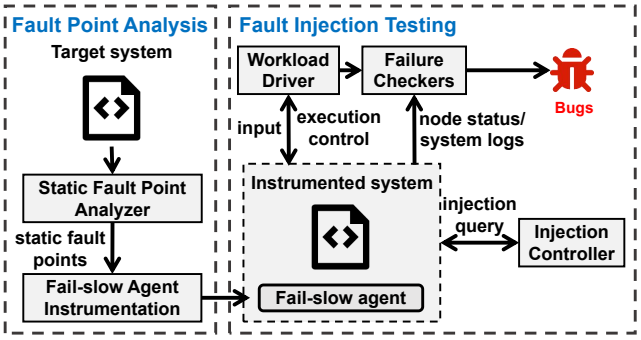

Figure 2: The workflow of Sieve.

4.2 Workflow

In a nutshell, Sieve identifies all fault points and then performs fault injection testing at each fault point. Figure 2 presents the workflow of Sieve, which consists of two phases. The first phase (left half of Figure 2) leverages the static analysis to identify fault points and instruments fail-slow agents within the cloud system to query fault injection decisions. The second phase (right half of Figure 2) treats the fault injection testing as a series of test runs. For each test run, Sieve leverages the workload driver to exercise the cloud system. When a fail-slow agent is executed, it sends an RPC query to the injection controller. The controller decides whether to inject the fault based on the history injection record. If the fail-slow agent receives a positive reply, it injects a delay into the cloud system. During this test run, failure checkers detect abnormal system behaviors, e.g., system crashes.

4.3 Fault Point Analysis

Cloud systems contain a large number of fault points affected by fail-slow hardwares. Moreover, most fault points can be tolerated by cloud systems [6, 16, 39, 42]. Therefore, it is impractical to exhaustively explore all fault points. Based on our bug study, we observe that synchronized and timeout-protected I/O operations are error-prone. Hence, our fault point analysis focuses on these two types of fault points, which can reduce the fault injection space.

Identify the Synchronized I/O Operation. In general, synchronized mechanisms have two effects: (1) avoid multiple threads to simultaneously access critical data; (2) control different tasks to execute in a certain order. There are two corresponding patterns of synchronized mechanisms. The first pattern creates a critical region, e.g., Lines 2-10 in Figure 3. I/O operations (I/O_{1-3}) in the critical region are considered to be synchronized. To identify these synchronized I/O operations, Sieve needs to find the critical region. The critical region is wrapped by entry and exit points at the instruction level. It is non-trivial to identify the critical region by matching the entry point to the correct exit point, since branch and return instructions introduce more than one exit point. For

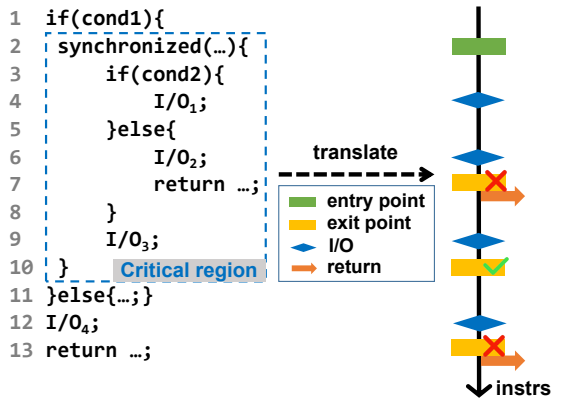

Figure 3: The left part shows an example of creating a critical region (Lines 2-10). The right part shows low-level instructions, which only preserve I/O, return, entry and exit points.

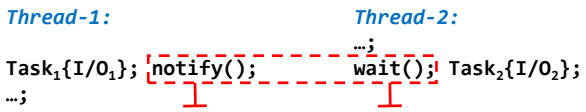

Figure 4: An example of controlling the execution order of $Task_{1,2}$ via the barrier.

example, in Figure 3, there are three exit points. If Sieve matches the entry point to the first or last exit points, it will miss a synchronized I/O operation (I/O_3) or incorrectly treat a non-synchronized I/O operation (I/O_4) to be synchronized.

To match the correct exit point, the intuitive method is to (1) understand how the programming language designs the interaction among the critical region, branch, and return instructions (2) and design a search algorithm that leverages former understanding. However, the first step is difficult and requires large human efforts. Hence, we try another practical method. Specifically, we analyze different combinations of the critical region, branch, and return instructions case by case. In this process, we observe that the correct exit point is the last not followed by the return instruction, i.e., the second exit point in Figure 3. Based on this observation, Sieve can correctly identify the critical region and synchronized I/O operations in practice. Specifically, Sieve traverses the call graph[2] twice. (1) If encountering an entry point, Sieve pushes this entry point into a stack. Subsequently, if encountering an exit point not followed by the return instruction, Sieve pops the top non-entry point from the stack and pushes this entry point into the stack. If the encountered exit point is followed by the return instruction, Sieve just ignores this exit point. Finally, all entry and matched exit points stored in the stack confirm all critical regions. (2) Sieve identifies I/O operations in critical regions.

[2]A directed acyclic graph. Its vertex represents a function and its edge means a function call relation

The second pattern creates a hard barrier that makes sure one task is executed before the other, e.g., `notify()` and `wait()` create a barrier in Figure 4. I/O operations (I/O_1) before the barrier are considered to be synchronized. Identifying these synchronized I/O operations is trivial. Sieve traverses the call graph, finds barriers, and identifies I/O operations before these barriers. Timeout mechanisms also have this pattern that creates a soft barrier (using `notify()` and `wait(timeout value)`) that means the latter task ($Task_2$) can timeout and invoke timeout handler to process the former task ($Task_1$). Sieve uses the same method to deal with this pattern of timeout mechanisms.

Identify the Timeout-protected I/O Operation. Timeout mechanisms are commonly used to handle unexpected faults in cloud systems. After investigating several cloud systems, we conclude two general patterns of timeout mechanisms. One has been discussed in § 4.3.

The other is related to get-time functions, e.g., `nanoTime` and `currentTimeMillis` in Java. Specifically, cloud systems record **startTime** and **endTime** assigned by get-time functions and calculate **elapsedTime = endTime - startTime** to obtain the execution time of the task. If elapsedTime exceeds the predefined timeout value, the timeout handler is invoked to process this abnormal task. We define the timeout scope as the scope between assignments of startTime and endTime. I/O operations in the timeout scope are considered to be timeout-protected. To identify these timeout-protected I/O operations, Sieve needs to match startTime to the corresponding endTime, which is non-trivial. In real-world cloud systems, there are many {**startTime**,**endTime**} pairs interleaving with each other, e.g., $\{startTime_1, endTime_1\}$ interleaves with $\{startTime_2, endTime_2\}$ in Figure 5. Moreover, most {startTime, endTime} pairs usually have irregular variable names. Hence, we cannot distinguish which endTime ($endTime_{1,2}$) is matched to $startTime_1$. When reviewing this pattern, we note that startTime and the matched endTime must appear in the same formula: **elapsedTime = endTime - startTime**. Based on this observation, Sieve can correctly identify timeout-protected I/O operations. Specifically, Sieve (1) collects all variables ($startTime_{1,2}$ and $endTime_{1,2}$) assigned by get-time functions as a get-time set. (2) then checks all expressions whose forms are **A=B-C**. If two operators in the expression are in the get-time set and the result of this expression is used in `If` expression, this expression is the target formula ($elapsedTime_1 = endTime_1 - startTime_1$). The two operators ($startTime_1$ and $endTime_1$) in this expression correctly confirm a timeout scope ($timeoutscope_1$). (3) finally identifies all I/O operations in the timeout scope.

Instrument the Fail-Slow Agent. To enable fine-grained fault injection, Sieve instruments fail-slow agents before candidate fault points, i.e., synchronized and timeout-protected I/O operations. When the fail-slow agent is reached at runtime, it sends a query to the injection controller, which includes the current call stack, instrumented function information, instru-

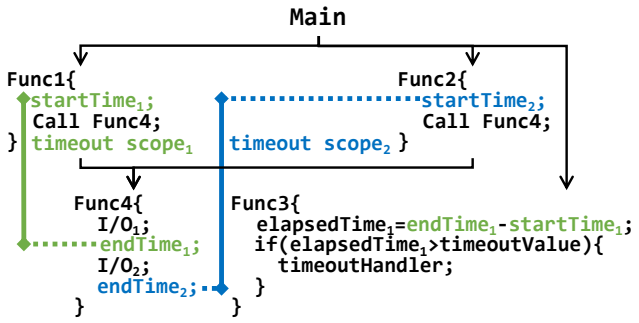

Figure 5: An example of identifying timeout-protected I/O operations.

mented position, and thread ID. If the reply is positive, the fail-slow agent invokes `Thread.sleep`. Additionally, Sieve instruments some hooks to obtain timeout values.

4.4 Injection Controller

In the fault injection phase, Sieve injects one fault for each test run. In each test run, the injection controller receives many injection requests from fail-slow agents, collects the information from injection requests, and decides on the fault injection. Finally, only one of the agents obtains a positive reply. To efficiently explore candidate fault points, Sieve implements grouping and context-sensitive injection strategies.

Grouping Injection Strategy. Through the fault point analysis, Sieve has pruned many fault points with a low possibility of triggering FSH bugs. However, there are still a large number of fault injection choices. It is inefficient to exhaustively explore all choices. We note many fault injections explore similar scenarios when these fault points are within the same basic block. Because different I/O operations within the same basic block are always under the same high-level system states (e.g., leader election and snapshot synchronization) and protected by the same fault-tolerance handler. To further reduce the fault injection space, Sieve groups fault points within the same basic block and selects the last fault point as the representative of the group. The fault point analyzer implements this grouping strategy by instrumenting the fail-slow agent before the last fault point within the same basic block.

Context-sensitive Injection Strategy. In addition to grouping fault points, Sieve implements a context-sensitive strategy (listed in Algorithm 1) to (1) find the buggy context of the fault point (2) and avoid repeatedly injecting faults at the same point under the same context. Specifically, Sieve collects the call stack of the fault point carried by the injection request (Line 20). When an injection request is received, Sieve checks whether the corresponding fault point has already been explored. If the fault point is not explored, Sieve grants this fault injection. Otherwise, Sieve compares call stacks of previous fault injections with that of current fault injection (Lines 15-19). If the current call stack is unique, Sieve injects one fault at this point.

Algorithm 1: Fault injection strategy

```
1  Function scheduleFaultInjection(request):
2      if !checkRequest(request) then
3          return false;
4      end
5      fault ← getFault(request);
6      if fault.type=SYNC then
           delayTime ← 5 * 60 * 1000 ;
7      else
           delayTime ← 3 * getTimeOutValue(fault)/2 ;
8      grant(request,delayTime);
9  Function checkRequest(request):
10     if isInjected then
11         return false;
12     end
13     curContext ← getContext(request);
14     curFault ← getFault(request);
15     foreach preContext ∈ historyInfo.contexts() and
           preFault ∈ historyInfo.faults() do
16         if preFault=curFault and
               preContext.contain(curContext) then
17             return false;
18         end
19     end
20     record(historyInfo,curContext,curFault);
21     return true;
```

Fault Impact. Except for injection strategies, Sieve needs to determine how long the delay lasts. Specifically, Sieve checks the type of the fault point after receiving the injection request (Line 5). If the injection request comes from the synchronized I/O operation, Sieve uses 5 minutes as the default delay which is enough to cause indefinite blocking (Line 6). Hence, the gray failure checker in Sieve can detect this bug. Meanwhile, this delay duration does not significantly extend the evaluation time.

For the timeout-protected I/O operation, the delay duration is two-thirds of the timeout value (Line 7). In this way, Sieve not only triggers timeout mechanisms to mislead internal checkers but also reorders timeout tasks and timeout handlers. Sieve obtains timeout values by analyzing two general patterns shown in § 4.3 and instrumenting hooks. When hooks are reached at runtime, they send timeout values to the injection controller.

4.5 Workload Driver

Sieve leverages the workload driver to exercise a target cloud system. The workload driver can use various sources ranging from simple unit tests to carefully-crafted test cases as workloads. For each cloud system, we either implement several common workloads or select several existing test cases as

workloads shown in Table 5.

The workflow of the workload driver is as follows. First, the workload driver creates multiple clients and each client connects with one system node. Hence, if the client encounters an exception, it can send an RPC request to failure checkers reporting the corresponding system node is suspicious. Second, the client executes the workload. If the client finishes the workload, it sends an RPC request to failure checkers reporting the workload progress. Finally, the workload driver restarts the target system for each test run to avoid the impact of previous injected faults.

4.6 Failure Checkers

To determine whether a bug occurs in cloud systems, Sieve provides two checkers:

- **Log error checker.** It scans the execution log of each system node to check whether there are FATAL, ERROR, and WARN entries or uncommon exceptions.
- **Gray failure checker.** It is a simplified version of Panorama [28] to identify whether differential observability exists. This checker marks the test run suspicious if (1) the system's internal checker indicates a node is healthy, but the node's client reports errors. Specifically, this checker receives an RPC request that reports errors from the client, while obtaining a healthy status of the corresponding node by existing tools, e.g., `./zkServer.sh status` in ZooKeeper. (2) a subset of clients do not finish their workloads. Specifically, this checker does not receive RPC requests that report the workload progress from a subset of clients.

As a testing framework, developers can flexibly add specific checkers to assert system properties they care about, such as performance bug [35] and inconsistency [40].

5 Implementation

We have implemented Sieve in Java with around 8,100 SLOC for core components. The fault point analyzer is built on top of Soot, a Java program analysis framework [59]. Sieve instruments cloud systems using Javassist, a Java bytecode instrumentation toolkit [30]. The injection controller is designed in a client-server architecture via Java RMI for RPCs.

I/O Operation Identification. Sieve identifies all I/O operations by statically analyzing cloud systems. If the function is implemented by general I/O packages, it is treated as an I/O operation. Sieve analyzes five general I/O packages, including `java.io`, `java.nio`, `java.net`, `javax.net` and `io.netty`. Additionally, some cloud systems implement their customized I/O operations, e.g., serialize/deserialize APIs in class Record of ZooKeeper. Sieve also identifies such I/O operations.

Timeout Value Collection. Sieve analyzes two general patterns of timeout mechanisms presented in § 4.3. For the first pattern, Sieve instruments hooks before soft barriers, e.g., `wait` in Java. The hooks intercept barriers and capture their parameters. For the second pattern, Sieve finds elapsedTime through the taint analysis. Sieve instruments a hook before `CMP` instruction that contains elapsedTime. The hook captures the other operator of `CMP` instruction. The captured parameters and operators are timeout values. Finally, the hooks send timeout values to the injection controller.

Table 5: The evaluated systems.

System	Release	Workload
ZooKeeper (ZK)	3.9.0	Create/read/update/delete znode
Kafka (KA)	3.6.0	Producer/consumer performance test
HDFS	3.3.6	Read/write/move/put file

6 Evaluation

Our evaluation aims to answer two questions: (1) How effective is Sieve in detecting bugs? (2) How does Sieve compare with state-of-the-art fault injection approaches?

Evaluated Systems. We evaluated Sieve by using three widely used and open-source cloud systems in Table 5. Note that Kafka [33] is not included in our bug study, which is a popular stream-processing service. To prove that Sieve is not specific to the five studied systems, we selected Kafka as a benchmark. All target systems are the latest versions during the experiments.

Setup. We apply default configurations to all cloud systems and deploy a cluster of cloud systems on a single physical machine using dockers. The physical machine contains two Intel Xeon Gold 6230R CPUs, which include 52 cores, and 192GB DRAM running Ubuntu18.04. In the evaluation, the cluster consists of either three nodes for ZooKeeper and Kafka or four nodes for HDFS. The fault injection experiment for each system consists of 2000 test runs. The time of each test run varies depending on how the system reacts to the injected faults and whether it fails early or not. The experiment time for the three systems is 20.9 hrs, 24.9 hrs, and 29 hrs respectively.

6.1 Effectiveness of FSH Bug Detection

6.1.1 Methodology

We apply Sieve to the target systems and check whether Sieve can detect unknown bugs and reproduce studied bugs.

6.1.2 Detecting Unknown Bugs

As shown in Table 6, Sieve has detected seven FSH bugs, including six unknown bugs and one known bug (HDFS-15869). Moreover, ZK-4836 and KAFKA-16412 have been confirmed by developers. Although HDFS-15869 was reported by developers, it has not been fixed yet. Hence, Sieve can detect

Table 6: Bugs detected by Sieve. The last five columns show whether the bugs are detected by different approaches shown in Table 7.

	Bug ID	Failure Symptoms	Random	FATE	Legolas	Chronos	Sieve-I	Sieve-S	Sieve
Unknown Bugs	ZK-4816	A follower cannot follow the leader for a long time (more than 30 seconds)	✗	✗	✗	✗	✗	✓	✓
	ZK-4817	CancelledKeyException cannot catch the client disconnection exception	✗	✗	✗	✓	✗	✓	✓
	ZK-4844	Fail-slow disk while executing writeLongToFile causes the follower to hang	✗	✗	✗	✗	✗	✓	✓
	ZK-4836	Inconsistent ACL index leads to MarshallingError	✗	✗	✗	✗	✗	✓	✓
	KAFKA-16401	One request consumes all request handler threads	✗	✓	✓	✗	✓	✓	✓
	KAFKA-16412	An uncreated topic is considered as a created one	✗	✗	✓	✓	✗	✓	✓
Known Bugs	HDFS-15869	Namenode hangs due to the slow sendResponse	✗	✓	✓	✗	✓	✓	✓

HDFS-15869. Moreover, we did not know about HDFS-15869 before. These bugs cause node hang, uncaught exceptions, node crash, and semantic violation.

ZK-4816. A follower cannot join the cluster for a long time (more than 30 seconds). Specifically, the cluster consists of three nodes. The first node becomes the leader after the election. The leader is stuck in serializing the snapshot to the local fail-slow disk. The followers disconnect from the leader, since their sync operations are blocked by the snapshot serialization in the leader. These two followers start a new leader election. The second node becomes the new leader. However, the old leader does not change the node status. There have been two leaders in the cluster for a long time. The third node is confused and cannot follow any leader for a long time.

ZK-4817. `CancelledKeyException` cannot catch the client disconnection exception in some cases. Specifically, NIOServerCxn throws `CancelledKeyException` if the client disconnects from the server abnormally. When NIOServerCxn executes `doIO`, the disk becomes fail-slow. The client cannot receive heartbeats and disconnects from the server. If `doIO` is blocked for 30 seconds, NIOServerCxn throws `CancelledKeyException`. However, when `doIO` is stuck for more than 30 seconds, `CancelledKeyException` disappears in system logs. Although the clients disconnect from the server abnormally in two scenarios, `CancelledKeyException` does not work in the latter scenario.

ZK-4844. Fail-slow disk while executing writeLongToFile causes the follower to hang. Specifically, the follower executes `writeLongToFile` slowed down by the fail-slow disk. The internal checker is blocked by `writeLongToFile`. The leader excludes the follower from the cluster, but the follower believes that it still acts as a follower. As a result, all requests sent to the follower cannot be processed. This bug is similar to Zookeeper-4074 [71]. Zookeeper-4074 can be solved by adding `-Dlearner.asyncSending=true`. However, this method cannot solve ZK-4844.

ZK-4836. An inconsistent ACL index leads to MarshallingError. Specifically, when a leader creates a node (N0) with an ACL entry (ACL_0) and deletes it due to the node deletion (assume the current aclindex is 0). A follower starts to synchronize the snapshot (including the ACL table and datatree) with the leader. When synchronizing the ACL table to the follower, the NIC becomes fail-slow, which slows down the ACL table transmission. Meanwhile, a client sends a request that creates a node (N1) with a new ACL entry (ACL_1) to the leader. In the leader, the datatree contains N1->1 (indicates that N1 points to the second slot of the ACL table) and the ACL table contains 1->ACL_1 (indicates that ACL_1 is stored in the second slot of the ACL table). The leader synchronizes the updated datatree to the follower. When the follower deserializes the new datatree, the aclindex is set to the number of elements in the ACL table. The follower contains the old ACL table (aclindex=0) and the new datatree (N1->1). The ZAB protocol synchronizes the client creation request from the leader to the follower. When replaying the client creation request in the follower, ACL_1 will be added into the first slot of the ACL table (0->ACL_1). However, the node N1 still points to the second slot of the ACL table (N1->1). Finally, when executing getAcl N1, MarshallingError arises, which leads to the follower crash.

KAFKA-16401. One request consumes all request handler threads. Specifically, a consumer request is stuck in `storeOffsets` slowed down by the fail-slow disk. The thread response for this request is blocked and holds a group lock. Due to timeouts, the consumer resends requests to the broker. All request handler threads are quickly occupied by these requests and stuck in acquiring the group lock. As a result, new requests cannot be processed.

KAFKA-16412. An uncreated topic is considered as a created one. Specifically, a client sends the request for topic creation to the broker. Another client also sends the same request to the broker. When the first request is not finished, the second one fails and returns `TopicExistsException` to the second client. However, subsequent requests that operate on this unestablished topic from the second client fail, which confuses the second client.

HDFS-15869. Namenode hangs due to the slow `sendResponse`. Specifically, a client sends a write request. When the namenode handles this request and writes the editlog to the disk, the disk becomes fail-slow. The thread response for writing the editlog is stuck, so that it does not process the following write requests from clients.

Except for five detected bugs in ZooKeeper and HDFS, Sieve also detects two bugs in Kafka that are out of the five studied systems. Because (1) Sieve is designed to detect FSH bugs for most cloud systems that contain synchronized and timeout mechanisms, not just the studied systems. (2) There

are buggy synchronized and timeout mechanisms in Kafka.

6.1.3 Reproducing Studied Bugs

To further evaluate Sieve's effectiveness, we try to reproduce all studied bugs. For each bug, we first check whether Sieve can correctly identify its corresponding fault point. If successful, we further modify Sieve and only inject the FSH fault at the corresponding point to detect the bug. If the failure report provides workloads, Sieve directly uses them. Otherwise, the workloads shown in Table 5 are used. When the checkers mark test runs suspicious, we manually check whether their symptoms and system logs are consistent with the original failure report in JIRA. If consistent, the corresponding bug is successfully reproduced.

Sieve successfully reproduces 34 of 48 studied bugs. There are 14 bugs not reproduced. For the five bugs (HBase-11536, HDFS-3493, HDFS-11755, HDFS-16659, and MapReduce-1800), multiple fault injections within one test run are necessary. However, Sieve currently focuses on a single fault injection. To reproduce these five bugs, we need to provide multiple buggy fault points and the correct fault injection order. Moreover, for the first four bugs, we need to provide additional checkers due to their silent symptoms (Finding 2). For the remaining six silent bugs (ZK-417, HDFS-7065, HDFS-10301, HDFS-13111, HBase-26195, and HBase-13430), Sieve fails to reproduce them due to the absence of accurate checkers. For the bug (ZK-4293), the complex thread interleaving causes deadlock. However, Sieve is designed to detect concurrency bugs with simple timing constraints (Finding 5). Although Sieve fails to reproduce the above twelve bugs, it can identify buggy fault points. However, Sieve fails to reproduce the remaining bugs (HBase-12270 and HBase-27947), since the static analysis in Sieve cannot analyze the synchronized data structures, i.e., the FIFO queue in these two bugs. To reproduce these two bugs, we need to extend the static analysis in Sieve to analyze the FIFO queue.

6.2 Comparison with Alternative Fault Injection Approaches

6.2.1 Methodology

We compare Sieve with six alternative fault injection approaches shown in Table 7. These approaches include coarse-grained (FATE) and fine-grained (Random, Legolas, Chronos, and two variants of Sieve) tools.

Random is implemented as the baseline of the fault injection strategy. We reuse the client-server architecture of Sieve and instrument the fail-slow agent before each I/O operation. When the fail-slow agent is reached at runtime, the injection controller randomly grants an injection request.

FATE [21] focuses on node-level faults, making it not directly comparable to Sieve. We re-implement its fault injection strategy in Sieve to attempt meaningful comparisons.

Table 7: Settings for Alternative Approaches. S/T I/O operations represent synchronized and timeout-protected I/O operations.

Approach	Fault Point	Injection Strategy
Random	All I/O operations	Random
FATE [21]	All I/O operations	Context-sensitive
Legolas [62]	All I/O operations	Abstract state and bsrr
Chronos [8]	T I/O operations	Deep-priority
Sieve-I	S/T I/O operations	Context-insensitive
Sieve-S	S/T I/O operations	Context-sensitive
Sieve	S/T I/O operations	Grouping and context-sensitive

Specifically, we define the failure ID like FATE, which comprises the class name, function name, line number, and call stack of the I/O operation. The injection controller can receive injection requests from all I/O operations and grant an injection request whose failure ID is unique.

Legolas [62] is a state-of-the-art fine-grained fault injection tool. Legolas infers abstract states of cloud systems and stores fault points in queues. The fault injection strategy of Legolas is called budgeted-state-round-robin (bsrr). Specifically, Legolas selects a queue in the round-robin way and dequeues a fault point to test.

Chronos [8] is a state-of-the-art fine-grained delay injection tool and adopts the deep-priority guided algorithm to detect timeout bugs. However, its core components are not available. Hence, we re-implement its fault injection strategy in Sieve. Specifically, the injection controller records timeout-protected I/O points, randomly selects six fault points to explore and records new fault points that only appear after injecting delays. If the depths of new fault points are larger than the average depth of selected fault points, Sieve injects delays at new fault points and selected fault points in the next test run. The depth of a fault point means the number of preceding fault points that include tested and untested fault points in the execution path. If there is not a new fault point, the injection controller randomly selects six fault points again.

Sieve-I adopts the context-insensitive injection strategy which means that all identified fault points are explored once. Except for the injection strategy, other components of Sieve-I are the same as Sieve.

Sieve-S is built on top of Sieve-I. Sieve-S explores identified fault points multiple times. We evaluate the effectiveness of grouping and context-sensitive strategies by comparing Sieve-S with Sieve and Sieve-I respectively.

All the above six approaches are performed with the same settings as Sieve, i.e., cluster configurations, failure checkers, workload driver, and 2000 test runs that consume more than 20 hours. Additionally, Chronos injects multiple faults since its strategy is designed to explore the combinations of different delays. Except for Chronos, the remaining five approaches inject one fault for each test run. Legolas uses its fault point configuration, which injects a one-minute delay for each test

Table 8: # Dynamic/Static fault points indicate the number of injected and candidate faults. S/T indicates that Sieve identifies all synchronized and timeout-protected fault points. S/T+Gr indicates that Sieve applies the grouping strategy to S/T fault points.

	# Dynamic fault points							# Static fault points		
	Random	FATE	Legolas	Chronos	Sieve-I	Sieve-S	Sieve	All	S/T	S/T+Gr
ZooKeeper	2000	2000	2000	2000	423	1291	705	1905	1266	856
Kafka	2000	2000	2000	2000	267	1968	967	1953	1090	780
HDFS	2000	2000	2000	2000	383	883	658	4216	1974	1568

run. Random and FATE also inject a one-minute delay for each test run like Legolas.

6.2.2 Comparison Result Analysis

Compared with alternative approaches, we aim to answer one question: is Sieve more effective and efficient in detecting FSH bugs? We answer this question from two aspects: the number of detected bugs and explored fault points.

The Number of Detected Bugs. Table 6 shows that Sieve is more effective in detecting FSH bugs. Random does not detect any bugs since it misses buggy fault points in deeper system states due to injecting faults at the beginning of workloads.

Compared with FATE and Legolas, four out of seven FSH bugs can only be detected by Sieve. FATE exhaustively explores the huge fault injection space, which is impractical and inefficient. Hence, FATE misses the buggy points of ZK-4816, ZK-4844, and KAFKA-16401 within 2000 test runs. Although we can add more test runs, FATE will generate more reports which require large human efforts to confirm true bugs. Legolas fails to detect ZK-4816 and ZK-4844 due to the same reason. For ZK-4817, to observe different behaviors in system logs, injecting fault twice with different delay durations at the buggy fault point is necessary for the checkers. Although FATE and Legolas may explore this point multiple times, the duration of the injected delay does not change. Hence, FATE and Legolas fail to detect ZK-4817. ZK-4836 is a concurrency bug and requires a suitable timing constraint. However, the long delay (1min) injected by FATE and Legolas causes the client creation request to timeout, so that the updated datatree will not be synchronized to the follower. As a result, ZK-4836 does not occur. Therefore, FATE and Legolas fail to detect ZK-4836.

Compared with Chronos, Sieve detects five more bugs. ZK-4816, ZK-4844, and HDFS-15869 are out of the scope of Chronos since these bugs are not related to timeout mechanisms. Chronos fails to detect ZK-4836 since multiple delay injections cause the client creation request to timeout, like a single long delay injection in FATE and Legolas. For KAFKA-16401, Sieve injects a delay before the synchronized I/O point on the server side, which causes the client to frequently retry the timeout request. If Chronos wants to detect KAFKA-16401, it needs to repeatedly inject a delay before the same I/O point on the client side. However, this scenario contradicts the deep-priority guided algorithm of Chronos, which aims to explore the combinations of different delays. Chronos can detect ZK-4817 and KAFKA-16412 thanks to our broad log error checker. The original failure checkers of Chronos described in its paper detect two symptoms: server crash and service hang. However, ZK-4817 and KAFKA-16412 do not cause these two symptoms. Therefore, Chronos should have failed to detect the two bugs.

The Number of Explored Fault Points. We record the number of dynamic and static fault points in Table 8. The number of dynamic fault points is less than 2000, which indicates all fault points exposed under current workloads are explored. Tables 6 and 8 show that Sieve can explore fewer fault points, while detecting more bugs. However, Random, FATE, and Legolas explore too many useless fault points to detect some FSH bugs. In some worse cases, Random even repeatedly explores the same fault under the same runtime context. Compared with FATE, Sieve-S can efficiently detect more FSH bugs, since our bug study reveals that synchronized and timeout-protected I/O operations are error-prone, which significantly prunes the fault injection space. Besides, thanks to the effective context-sensitive strategy, Sieve-S explores more useful contexts of fault points and further detects more FSH bugs than Sieve-I. Moreover, compared with Sieve-S, Sieve explores fewer fault points without compromising the number of detected bugs, which indicates that the grouping strategy is effective. In summary, Sieve is more efficient in detecting FSH bugs thanks to its effective design.

Chronos aims to explore the combinations of different delays, which cause the fault injection space to increase in an exponential manner. Therefore, Chronos implements a deep-priority guided algorithm to efficiently explore such huge fault injection space. However, Sieve focuses on the practical and common scenario, i.e., one delay injection (Finding 6). Chronos and Sieve have different target scenarios. Hence, we do not compare with Chronos in this aspect.

6.3 False Positive

Threats of false positives come from two sources. The first source is injected faults. If the injected fault is not realistic, a false positive arises. Specifically, injecting delays before non-blocking I/O operations causes false positives. To eliminate these false positives, Sieve simulates a 10s delay for the

fail-slow disk and NIC using the device mapper (DM) and traffic control (TC) in Linux (a 10s delay is suitable since it exceeds the time consumed by normal I/O operations and does not break cloud systems). As a result, the consumed time of the non-blocking I/O operation is less than 10 seconds. Because the non-blocking mechanisms are implemented above the layer that simulates the fault using DM and TC in Linux, which indicates the non-blocking I/O operation returns before reaching the simulated fault. Based on this feature, Sieve re-executes the suspicious test run marked by failure checkers and calculates the time consumed by the explored I/O operation. If the consumed time is less than 10 seconds, Sieve abandons the report of the suspicious test run. Overall, the faults injected by Sieve do not cause any false positives. In addition, the fault simulated by DM and TC slows down all I/O operations, which cannot enable fine-grained fault injection.

The second source is failure checkers. The gray failure checker is a simplified version of Panorama [28], so it cannot obtain comprehensive information of components in cloud systems. For example, in Zookeeper, if Sieve injects a delay on the client side when the client connects to the server, the gray failure checker will obtain an error report from the client. Meanwhile, the gray failure checker obtains a healthy status of the server by using `./zkServer.sh status` provided by Zookeeper. Based on different server statuses observed by the client and server, the gray failure checker reports a bug. In fact, the reported bug is a false positive. The log error checker also makes mistakes. For example, our checkers mark a test run suspicious when a fault is injected in `LearnerHandler` since ERROR entries appear in system logs. However, such ERROR entries are expected behaviors in ZooKeeper. To eliminate these false positives, for each suspicious test run, we (1) read system logs to understand system behaviors; (2) check whether system behaviors are consistent with design documentation. (3) report this bug to developers and discuss it with them. In the near future, we plan to enhance our checkers by using more accurate rules. However, our core contribution focuses on our bug study and fault injection methodology.

6.4 Overhead Analysis

Table 9 shows the runtime overhead of Sieve. The **Baseline** column shows the original workload run time without any instrumentation. The **Info Collection** column shows the average fault-free run time of the instrumented system. The **Average Test Time** column shows the average run time with one fault injection.

The results show that Sieve introduces 1.1× to 4.9× baseline time for runtime information collection. On average, testing a fault point consumes around 1.9× to 6.3× baseline time. Each test run includes a series of operations such as initializing the execution environment, executing the workload, collecting runtime information, deciding the fault injection, and checking failure symptoms. Additionally, the static analysis completes in three minutes and consumes at most 8GB memory for each cloud system.

Table 9: Runtime Overhead (in seconds).

System	Baseline	Info Collection	Average Test Time
ZooKeeper	9.41	13.17	37.64
Kafka	7.12	34.89	44.86
HDFS	24.87	27.36	52.23

7 Discussions

Fault Model. Sieve currently injects one delay to simulate the fail-slow hardware. However, the fail-slow hardware may incur other subtle faults such as exceptions and multiple delays. Hence, Sieve misses some bugs caused by these subtle faults. For example, in § 6.1.3, Sieve fails to detect five bugs caused by other subtle faults. Extending Sieve to support more fault models becomes our future work.

Fault Point Analysis. The keywords, e.g., `synchronized`, used in synchronized and timeout mechanisms are necessary for the fault point analysis in § 4.3. Sieve has analyzed several most common keywords: `synchronized`, `lock`, `wait`, `await`, `tryacquire`, `join`, `nanoTime` and `currentTimeMillis`. Our implementation is modular, which makes it convenient for developers to add more keywords and patterns completing the fault point analysis in Sieve.

Workload Driver. Table 8 indicates current workload drivers cannot trigger all candidate fault points since the used workloads are simple, which limit the code coverage. Fuzzing is an automatic input generation technique [3, 7, 13, 20, 49, 60, 63, 64, 69] that can improve the code coverage. Developers can integrate fuzzing tools into Sieve to explore more candidate fault points.

8 Related Work

Fault Injection. In recent years, various fault injection techniques [1, 6, 15–17, 21, 31, 32, 42, 48] have been proposed to detect bugs triggered by various faults in cloud systems. Many existing schemes focus on coarse-grained faults and adopt various fault injection strategies. For example, CrashTuner [42] injects node crashes when meta-info variables are accessed; NEAT [1] provides simple APIs for developers to inject network partitions. Unlike them, Sieve instruments fail-slow agents before I/O operations to enable fine-grained FSH fault injection. Recent fine-grained delay injection tools [8,62] fail to efficiently explore the FSH fault injection space due to overlooking the characteristics of FSH failures. Our work provides a bug study to analyze FSH failures and concludes some findings shown in § 3 Inspired by our bug study, Sieve is proposed to efficiently explore the FSH fault injection space.

CORDS [14] and WASABI [55] inject expections into cloud systems to detect error handling bugs. However, Sieve injects delays to detect FSH bugs. Sieve is orthogonal to CORDS and WASABI.

Distributed System Model Checker. Distributed system model checkers [34, 45, 66] intercept non-deterministic distributed events and permute their ordering. These schemes detect protocol bugs caused by complex interleaving of node-level events, such as message and node crash/reboot, while Sieve aims to detect implementation-level bugs triggered by fine-grained FSH faults. Sieve is complementary to existing schemes.

Distributed Concurrency Bug Detection. Several schemes [36, 38, 41, 68] have been proposed to detect concurrency bugs in cloud systems. For example, DCatch [36] uses specific happen-before rules to identify conflicting operations and reorders them. Sieve is an FSH fault injection framework that aims to detect diverse bugs including concurrency bugs.

Bug Studies on Fail-Slow Incidents. Guanwai et al. [22] present a study of fail-slow hardwares and analyze how fail-slow hardwares occur. Several works [39, 43, 51] provide studies of fail-slow failures at the software level and analyze how to accurately detect fail-slow failures by in-production monitoring. However, unlike them, our bug study aims to study how fail-slow hardwares affect the software so that we can design an effective and efficient fault injection tool to detect FSH bugs before releasing production. Besides, our bug study shows that FSH failures caused by fail-slow hardwares include fail-slow and fail-stop failures. Our bug study is complementary to existing bug studies.

Fail-Slow Failure Detection. Several works [28, 39, 43, 51] develop advanced detectors for fail-slow failures. Panorama [28] detects fail-slow failures by enhancing the observability of different system components. IASO [51] detects fail-slow nodes based on timeout signals and peer evaluation. OmegaGen [39] generates customized watchdogs for detecting and localizing fail-slow failures. PERSEUS [43] leverages machine learning techniques to detect fail-slow failures. These detectors focus on in-production monitoring and require a significantly long time to detect failures, which are not suitable for testing before releasing production. For example, ISAO has been deployed for more than 1.5 years to catch fail-slow failures. However, Sieve focuses on detecting FSH bugs before releasing production by injecting FSH faults.

9 Conclusion

Fail-slow hardwares cause severe failures in cloud systems. This work presents a study of 48 real-world FSH failures in cloud systems to analyze their characteristics. We propose Sieve, a novel fault injection testing framework that enables fine-grained FSH fault injection for detecting FSH bugs. Sieve treats synchronized and timeout-protected I/O operations as candidate fault points that are likely to trigger FSH bugs. Sieve implements grouping and context-sensitive injection strategies to efficiently explore candidate fault points. Our evaluation shows that Sieve is effective and efficient in detecting FSH bugs in real-world cloud system.

CONVEROS: Practical Model Checking for Verifying Rust OS Kernel Concurrency

Abstract

ASTERINAS is an open-source, general-purpose operating system written in Rust, compatible with the Linux ABI, and designed with a focus on reliability and security.

We developed a practical model-checking methodology, CONVEROS, to verify the correctness of ASTERINAS concurrency modules such as synchronization primitives and critical thread-safety components. CONVEROS leverages the rigor of formal specifications and introduces a multi-layered, multi-grained specification approach to make writing scalable specifications practical, demonstrated in our case by writing PlusCal specifications for Rust code. It also makes conformance checking incremental and more automated to detect specification-code discrepancies. While many formal methods are challenging to apply due to complexity and the expertise required, CONVEROS makes model checking cost-effective, accessible, and adaptable to evolving specifications and code. We applied CONVEROS to 12 critical concurrency modules, uncovering 20 bugs that led to issues such as data races, deadlocks, livelocks, and kernel panics. With a specification-to-code ratio ranging from 0.3 to 2.3 and a verification effort of only four person-months, our results demonstrate the practicality and effectiveness of CONVEROS.

1 Introduction

ASTERINAS [2, 64] is a new general-purpose OS kernel written in Rust, compatible with the Linux ABI and designed for improved reliability and security. It is being developed with the goal of supporting future deployment within Ant Group. Although still in its early stages, ASTERINAS has a substantial codebase of 100K lines of Rust, supports 200 commonly used Linux syscalls, and can run large-scale applications such as the JVM and MySQL. ASTERINAS is open-source and has built an active community, attracting many contributors.

While ASTERINAS is rapidly evolving, we have encountered numerous low-level concurrency bugs that tests cannot reliably rule out. Although Rust greatly enhances memory safety and prevents data races in safe code, OS kernel development inevitably requires `unsafe`, which may still introduce concurrency-related undefined behaviors such as data races. Logical errors and flawed designs can lead to deadlocks, livelocks, and functional violations. These concurrency bugs are notoriously difficult to detect, reproduce, and fix correctly.

We decide to apply formal methods by model checking the ASTERINAS implementation because we want to verify the correctness of complex concurrency code to prevent severe bugs from reaching production, inspired by recent successful industrial experiences [31, 38, 47, 61] and efforts to enhance the practicality of model checking [31, 34, 38, 63].

However, applying model checking to complex OS implementations is hard. First, writing specifications can be challenging, as it requires domain knowledge with formal methods and poor specifications can hinder model checking scalability. Second, discrepancies between specifications and implementations–caused by modeling errors or the rapid evolution of code–can compromise verification results, leading to both false positives and false negatives.

Contributions. To address these challenges, we present CONVEROS, a practical methodology for model checking OS concurrency modules. CONVEROS consists of three steps: (1) writing formal specifications (§4), (2) checking conformance between implementation traces and specifications (§5), and (3) model checking the refined specifications. We focus on steps (1) and (2), which make model checking results effectively reflect code correctness. To make CONVEROS practical, each step is small, incremental and provides rapid feedback.

For writing specifications, we introduce a multi-layered, multi-grained specification approach (§4), which divides each module into manageable components for incremental modeling at different granularities. The multi-layered specifications consist of high-level and low-level specifications (§4.1). The high-level specifications represent the correct design, abstracting away implementation details. The low-level specifications reflect code details and incorporate potential code bugs. This ensures model checking can identify those bugs effectively.

*Work done during an internship at Ant Group.
†Corresponding author.

We use a multi-grained specification approach [63] for low-level specifications (§4.2), enabling incremental verification by verifying modules separately and coarsening actions if the modules do not interact. To make writing specifications more accessible, CONVEROS adopts the imperative-like language PlusCal[54], which is compiled into TLA$^+$[53]. PlusCal offers a syntax similar to C, making it familiar to programmers. Writing PlusCal specifications is applicable across programming languages; in our case, we model Rust code.

For conformance checking, we employ trace validation [34] to check specification-code conformance (§5). Trace validation executes the implementation to generate traces and checks whether these traces are allowed in the specification's state space (§5.1 and §5.2). We enhanced trace validation to improve automation and usability by introducing a new algorithm that automatically infers missing events (§5.3). This improvement addresses issues such as inaccurate timestamps where recorded event times do not precisely reflect actual occurrences and enables quick and incremental establishment of specification-code conformance, even when logging is incomplete for all actions, significantly reducing logging effort. Checking high-level specification conformance helps identify code bugs. Checking low-level specification conformance increases confidence that the specifications accurately reflect the code's behavior. When model checking low-level specifications reveals violations, we write test cases to confirm the bugs and often uncover by-product bugs during testing.

Key Results. We have applied CONVEROS to ASTERINAS by verifying 12 critical concurrency modules including spinlocks, mutexes, file locks, futex, SysV semaphore IPC, a lock-free ring buffer, a locking protocol for page tables, and lock usage in TTY. We have detected 20 new bugs in ASTERINAS: 9 were automatically detected by CONVEROS, and 11 were manually found when diagnosing bugs reported by CONVEROS. All bugs have been confirmed, and 14 have been fixed. The effort required for writing specifications and checking conformance has proven to be manageable and cost-effective. The specification-to-code ratio ranges from 0.3 to 2.3, with approximately 43.5 person-days spent writing all specifications and 21.5 person-days on conformance checks–amounting to a total of about four person-months.

Summary. This paper presents four main contributions:

- We designed a practical model checking methodology, CONVEROS, for verifying safety and liveness of OS concurrency modules, featuring a structured, incremental process for specification, trace validation, and model checking.
- We developed a multi-layered, multi-grained specification approach that improves practicality and enables incremental modeling and scalable verification by composing modules at different granularities.
- We proposed a novel algorithm to enhance trace validation for spec-code conformance by automatically searching for missing events, and improved automation and usability for granularity alignment and discrepancy debugging.
- We applied CONVEROS to ASTERINAS, modeling and verifying 12 concurrency modules. CONVEROS revealed 20 bugs and helped improve code correctness, demonstrating its practicality for real-world OS verification.

2 Background and Motivation

2.1 ASTERINAS

ASTERINAS [2, 64] is an open-source collaborative project between academic researchers and industry practitioners aimed at creating a production-grade operating system entirely in Rust. It aims to support general-purpose usage scenarios such as data centers and trusted execution environments, where thread safety is essential. Although still in the early stages, ASTERINAS is positioned as a serious industry effort intended to serve as a drop-in replacement for Linux, providing Linux-compatible system call interfaces and replicating key Linux features. To date, it currently comprises approximately 100K lines of code, has implemented 200 of the 336 most commonly used Linux system calls and is capable of running large-scale applications such as JVM and MySQL.

Rust's ownership model and strict borrowing rules prevent memory safety issues like dangling pointers and use-after-free errors. An example of Rust ownership and concurrency is shown in Figure 1, illustrating the use of Mutex for concurrently updating shared data. Line 6 is detailed in Figure 9, while line 7 involves dereferencing mutable data, which internally uses `unsafe` as shown in Figure 14. Rust's ownership model ensures proper resource management, such as automatically unlocking the mutex when the guard goes out of scope. However, these features do not eliminate all concurrency issues. They can still occur in unsafe code or result from design flaws and improper use of low-level synchronization primitives [66]. Concurrency issues are still frequently reported [3], particularly in custom synchronization primitives designed specifically for the OS. This motivates the adoption of formal methods to rigorously verify the concurrency correctness of these modules and increase confidence in their reliability.

```
1 // Arc shares ownership across threads via atomic ref counting
2 let m = Arc::new(Mutex::new(0));
3 for _ in 0..10 {
4   let c = Arc::clone(&m); // refcount++; `c` owns a reference
5   thread::spawn(move || { // Ownership of `c` moves in
6     let mut guard = c.lock(); // Blocks until lock acquired
7     *guard += 1; // Critical section: mutable access
8     // `guard` dropped: lock released; `c` dropped: refcount--
9   });} // `m` dropped: refcount goes to zero, Mutex is dropped
```

Figure 1: Rust ownership and concurrency example

2.2 TLA$^+$ and PlusCal

TLA$^+$. TLA$^+$ [53] is a formal specification language widely used in both academia and industry to verify concurrent and distributed systems [32, 34, 38, 47, 61, 63].

  \/ cs(p)
```

Figure 2: A simple lock specification. The PlusCal specification (left) includes two procedures (e.g., `acquire_lock`) and four atomic actions/labels (e.g., `lock`) with `PS` processes executing the `process` statement concurrently. The `lock` action can be executed only when the `await` condition is true. In the compiled TLA$^+$ specification (right), `pc` is a generated variable that stores the next labels to execute for each process. "`\E`" and "`\A`" represent existential and universal quantifiers.

```
1  struct RangeLockItem {lock: RangeLock, waitqueue: Arc<WaitQueue>}
2  struct RangeLockList {inner: RwMutex<Vec<RangeLockItem>>}
3  impl RangeLockList {
4  fn set_lock(&self, req_lock: &RangeLockItem) -> Result<()> {
5    loop { // Loop until `req_lock` is inserted
6      let conflict_lock;
7      { let mut list=self.inner.write();// Access `list` for write
8        if let Some(existing_lock) = list
9          .iter().find(|l| req_lock.conflict_with(l))
10       { // Find a conflict lock, clone for waiting
11         conflict_lock = existing_lock.clone();
12       } else { // No conflict lock, insert and return
13         Self::insert_lock_into_list(&mut list, req_lock);
14         Ok(()) } // Implicit return
15     } // `list` (write guard) is dropped at the end of the scope
16     conflict_lock.waitqueue.wait_until(|| {// Wait: no conflicts
17       let list = self.inner.read(); // Access `list` for read
18       if list.iter().any(|l| req_lock.conflict_with(l)) {
19         None // Continue waiting
20       } else { Some(()) } // Condition satisfied, break waiting
21     }); // `conflict_lock` is dropped at the end of loop
22   }}}
```

Figure 3: Buggy range lock code causing lost wakeup. When a waiter (line 16) is woken up, it checks for conflicts, and if found, it continues waiting (highlighted code) on `conflict_lock.waitqueue`, which is shared with `existing_lock`'s (line 11). When `existing_lock` is removed from `list` by another thread, that thread wakes waiters on `existing_lock.waitqueue`–the only opportunity for them to be woken up. If a waiter rechecks and waits again, no thread can wake it, resulting in lost wakeup.

TLA$^+$ models a system as a state machine comprising variables, initial states, and state transitions. A typical specification follows the form `Init /\ [Next]_vars /\ L`. "/\" and "\/" represent conjunction and disjunction. `Init` specifies the initial state by assigning values to all variables. `Next` specifies state transitions as a disjunction of actions, modeling nondeterminism by allowing multiple possible next steps. `vars` contains all variables in the specification. `[Next]_vars` expands to `Next \/ vars' = vars`, representing that either `Next` holds or all variables remain unchanged (i.e., stuttering), where primed variables represent their next state. `L` is a temporal formula used to assert liveness and fairness assumptions.

To ensure correctness, safety properties (asserting that nothing bad ever happens) and liveness properties (asserting that something good eventually happens) must also be specified.

PlusCal. PlusCal is a formal specification language designed to describe algorithms using imperative-like structures, with simple syntax and constructs similar to widely-used programming languages (e.g., `while` loops and `procedure` calls), making it more accessible to programmers. PlusCal specifications are compiled into TLA$^+$ and verified using TLC [1].

A PlusCal specification consists of one or more processes, declared with the `process` keyword. Each process executes sequentially, while multiple processes run concurrently and can interleave. In the `process` and `procedure` bodies, labels are defined to mark atomic actions. Figure 2 illustrates a simple lock specification in PlusCal and its compiled TLA$^+$.

Industrial experiences show that programmers find PlusCal more productive to start with than TLA$^+$ [61]. Since low-level specifications need to closely reflect the code's structure. PlusCal offers an imperative style that is more intuitive for programmers, making writing, maintaining, and incrementally improving specifications significantly easier.

2.3 Motivation Example

Concurrency bugs, especially in OS kernels, are difficult to detect, reproduce and fix. Addressing concurrency bugs through expert reviews and CI testing is unreliable and may overlook corner cases. Formal methods provide rigorous verification of safety and liveness properties, helping identify bugs, generate violation traces, and ensure the correctness of fixed code.

We demonstrate the effectiveness of CONVEROS in identifying a hard-to-find, difficult-to-fix concurrency bug in range lock implementation [8] (Figure 3). This bug was introduced by a bug fix, but the fix was still incorrect [28]. We fixed it correctly after multiple failed fix attempts.

Range locks (i.e., file record locks) allow processes to place multiple read and write locks on different regions of the same file via the `fcntl` system call. This involves complex semantics for merging and splitting locks when new locks overlap with existing regions. The implementation maintains a list (i.e., `RangeLockList`) of active locks for the file inode associated with the file descriptor. When a requested lock conflicts with an existing one (i.e., their ranges overlap and at least one is a write lock), the process waits for the conflict to be resolved (lines 16–21) before inserting the new lock.

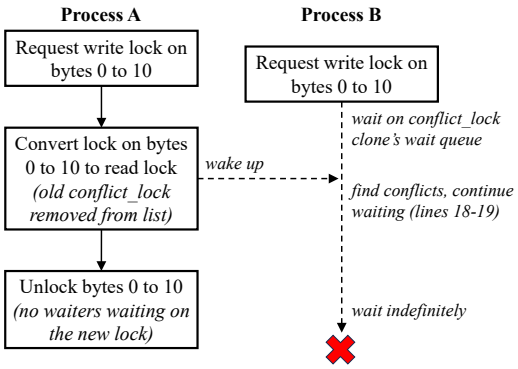

Figure 4: Range lock bug trace. Process A requests a write lock, blocking Process B's conflicting write lock request. Process A then converts its lock type to read atomically, replacing the old write lock with a new read lock in `list` and waking up the waiters on the old write lock. Process B is woken up but finds conflicts with the new read lock and re-enters waiting. Process A unlocks the read lock but wakes no process because no waiters are on the read lock's `waitqueue`.

The model checker revealed a deadlock bug cause by lost wakeup of the waiting process. The root cause lies in how the code manages wait queues for conflicting locks. When a requested lock `req_lock` conflicts with an existing one (lines 8–9), the thread clones `existing_lock` into `conflict_lock` (line 11), also cloning its `Arc`-wrapped `waitqueue` (line 1). This creates a shared `waitqueue` between threads. The thread then blocks on this `waitqueue` (line 16), expecting another thread operating on the same queue to wake it up when the conflict may have been resolved. However, if all locks associated with that `waitqueue` are removed from the list while some threads are still waiting on it, those threads will block indefinitely. Figure 4 shows how the bug can occur. Several attempts to fix the bug in the specification were identified as incorrect through model checking, highlighting the challenge of correctly fixing concurrency bugs.

- **First fix attempt.** The fix transferred the `wait_queue` to the new lock when replacing the old lock (scenario in Figure 4). However, the model checker revealed another lost wakeup scenario: when a `conflict_lock` is removed by `unlock`, it wakes up the waiting process. But before the waiter checks for conflicts, another process inserts a conflicting lock, causing the waiter to re-enter the wait state even when the old `conflict_lock` has been removed from `list`.
- **Second fix attempt.** The previous attempt demonstrated the need to ensure the `conflict_lock` remains in the list before entering the wait state. To avoid a costly loop check, we tried optimizing by checking if the reference count of the `conflict_lock.waitqueue` would reach 0. However, the model checker revealed that multiple processes could be waiting on the same `conflict_lock`, causing multiple clones and a non-zero reference count even when the lock was no longer in the list.

```
1  fn set_lock(&self, req_lock: &RangeLockItem) -> Result<()> {
2    loop {
3      let (waiter, waker); // Dedicated waiter/waker pair
4      { let mut list=self.inner.write();// Access `list` for write
5        if let Some(existing_lock) = list
6          .iter().find(|l| req_lock.conflict_with(l))
7        { (waiter, waker) = Waiter::new_pair();
8          existing_lock.waitqueue.enqueue(waker);
9        } else {
10         Self::insert_lock_into_list(&mut list, req_lock);
11         Ok(()) }
12     } // `list` (write guard) is dropped at the end of the scope
13     waiter.wait(); // Upon wakeup, enter the next iteration
14   }}
```

Figure 5: Correct bug fix code for range lock. Uses a dedicated waiter/waker pair instead of cloning `existing_lock` (lines 7–8), and upon wakeup, enters the next loop iteration to recheck for conflicts (line 13).

- **Third fix attempt.** We then attempted to wait on an empty condition; once woken up, the process would start the next loop for conflict detection. The model checker identified a livelock scenario: at the end of each loop, the `conflict_lock` clone would be dropped, waking up all waiting processes. These processes would then drop their `conflict_lock` clones, re-check for conflicts, and re-enter the wait state, potentially being awakened by a slower drop of `conflict_lock` clones. This resulted in an infinite loop under specific timing conditions, which became increasingly likely under high contention, causing the exclusive write access to `list` to be held almost continuously.
- **Final fix.** Finally, we abandoned cloning `existing_lock` to `conflict_lock` and instead directly enqueued the waiter upon detecting a conflict (Figure 5). Similar to the third fix attempt, the process starts the next loop upon waking up, but this time it waits directly on a dedicated waiter/waker pair, which won't wake up other processes on drop.

All fix attempts were conducted using model checking, which quickly verified each method and provided counterexamples for incorrect fixes. Once the bug was correctly fixed in the specification, we applied the corresponding fixes to the code and verified specification-code conformance.

3 CONVEROS Overview

We present CONVEROS, a practical methodology for model checking OS concurrency modules. CONVEROS draws inspiration from recent advancements in TLA$^+$ for writing multi-grained specs [63] and validating traces for conformance [34].

The effectiveness of CONVEROS lies in addressing spec-code discrepancies through conformance checking, which enables model checking to detect real code bugs. Applying CONVEROS involves three main steps: (1) formal specification (§4), (2) conformance checking (§5), and (3) model checking. Figure 6 illustrates the overall workflow for verifying a concurrency module using CONVEROS. For step (1), developers write a PlusCal specification derived from

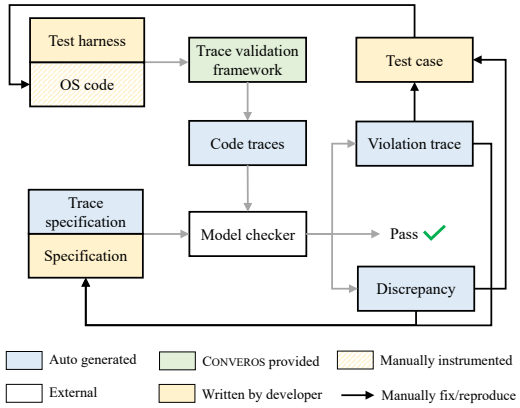

Figure 6: An overview of CONVEROS's workflow

the code (e.g., Figure 2). For step (2), They manually instrument the module and create a test harness to run it for trace collection (e.g., Figure 7). When discrepancies are found during conformance checking, developers manually revise the specification or code. Step (3) involves model checking the revised specification and manually writing test cases to reproduce any reported violations. We automated the generation of trace specifications, code traces, and discrepancy traces for conformance checking, while writing specifications, test harnesses, and test cases, and fixing bugs remain manual tasks. We summarize the overall developer burden in §6.2.

CONVEROS is designed to be practical by making each step small, incremental, and quick to execute, ensuring rapid feedback throughout the process. Consider a lock module that provides `lock` and `unlock` public APIs. The process begins with writing a simple specification that models the public APIs while abstracting away code details (Figure 2). Next, a corresponding test harness is written to use the lock's public APIs in a loop, recording logs for each action[1] (Figure 7). Each log corresponds to a specification's action.

CONVEROS's trace validation framework then automatically runs the test harness to generate code traces. Each trace line represents a code action, recording the action name, process ID and (partial) variable updates. CONVEROS automatically generates a trace specification that constrains the model-checking state transitions by the trace's action name and variable updates. For example, as logged on line 7 in Figure 7, the `start` action constrains the next value of `pc` to `lock`; if it evaluates to a different value, the state is pruned.

CONVEROS subsequently runs the model checker for trace validation (step 2) and property verification (step 3). If the model checker finds discrepancies, developers address the issue in the code or specification, based on whether the specification reflects the intended design (as in this simple example) or detailed code logic. For property violations, both the spec and code must be fixed if the bug is confirmed in the code.

[1]In the code, we use "action" and "event" interchangeably, while in PlusCal specifications, "action" and "label" are used interchangeably.

```
1  pub struct MutexModel;
2  impl TlaModel for MutexModel {
3    fn run(&self, procs: usize, loops: usize) {
4      let mutexlock = Arc::new(Mutex::new(0));
5      let proc_func = move || {
6        for _i in 0..loops {
7          TlaLogger::new("start").next_pc("lock").record();
8          let guard = mutexlock.lock();
9          TlaLogger::new("lock").next_pc("cs").record();
10         TlaLogger::new("cs").next_pc("unlock").record();
11         drop(guard);
12         TlaLogger::new("unlock").record();
13       }
14     };
15     run_procs(procs, proc_func); // Provided by trace framework
16   }}
```

Figure 7: Simplified test harness for a mutex lock model. It implements the `run` method of the `TlaModel` trait, defines a closure using Mutex's public APIs, and logs each action corresponding to a specification's action. `run_procs` executes the closure in parallel and post-processes the log output.

To ensure practicality, CONVEROS addresses two key challenges. First, it makes specifications incremental and scalable through a multi-layered, multi-grained specification approach (§4). Second, it improves automation of trace validation by introducing a new algorithm that allows missing events (§5).

4 Formal Specification

We design multi-layered and multi-grained specifications to make them easy to write, incremental, and scalable for model checking. Additionally, we define correctness properties to verify whether the system behaves as required.

4.1 Multi-Layered Specifications

Multi-layered specifications serve distinct purposes at each layer. High-level specifications capture the design intent (primarily for basic synchronization primitives) and are straightforward to write and verify (e.g., Figure 2). Low-level specifications are developed from the code and reflect implementation details (e.g., Figure 8 corresponds to the Mutex module shown in Figure 9). We do not construct formal refinement mappings [5] between high-level and low-level specifications, as this imposes substantial burdens on developers. Instead, we directly check the properties on the low-level specification.

High-Level Specifications. High-level specifications capture design requirements and are straightforward to write for their public APIs. These specifications are primarily used for basic synchronization primitives like spin and mutex locks, which are simple to write and easy to verify. For example, the PlusCal specification for an abstract lock, shown in Figure 2, models two public APIs: `acquire_lock` and `release_lock`, written in a style resembling imperative procedural code. These specifications ensure the APIs satisfy common locking properties, such as mutual exclusion, and absence of deadlocks and livelocks (as discussed in §4.3).

```
1  variables locked = FALSE, has_woken_of_wakers = <<>>,
2    num_wakers = 0, wakers_lock = FALSE, wakers = <<>>;
3  procedure acquire_lock()
4  variable waiter_ref; (* Local variable *) {
5  fast_path:
6    if (locked = FALSE) { locked := TRUE; return; };
7  slow_path:
8    has_woken_of_wakers := Append(has_woken_of_wakers, FALSE);
9    waiter_ref := Len(has_woken_of_wakers);
10 loop:
11   while (TRUE) {
12 \*enqueue: skip;
13     acquire_wakers_lock:
14       await wakers_lock = FALSE; wakers_lock := TRUE;
15     enqueue_waker:
16       wakers := Append(wakers, waiter_ref);
17     inc_num_wakers:
18       num_wakers := num_wakers + 1;
19     release_wakers_lock:
20       wakers_lock := FALSE;
21   try_lock:
22     if (locked = FALSE) { locked := TRUE; goto drop_waiter; };
23   do_wait:
24     await has_woken_of_wakers[waiter_ref] = TRUE;
25     has_woken_of_wakers[waiter_ref] := FALSE;
26   };
27 drop_waiter:
28   has_woken_of_wakers[waiter_ref] := TRUE; return; }
```

Figure 8: A low-level Mutex PlusCal specification

```
1  pub struct Waker { has_woken: AtomicBool } // has_woken_of_wakers
2  pub struct Waiter { waker: Arc<Waker> }
3  pub struct WaitQueue { num_wakers: AtomicU32, // num_wakers
4    wakers: SpinLock<VecDeque<Arc<Waker>>>} // wakers_lock, wakers
5  pub struct Mutex<T> {lock: AtomicBool, queue: WaitQueue, val: T}
6  impl<T> Mutex<T> {
7    pub fn lock(&self) -> MutexGuard<T> { // acquire_lock in spec
8      self.queue.wait_until(|| self.try_lock())
9    }}
10 impl WaitQueue {
11   pub fn wait_until(&self, cond: ...) -> ... {
12     if let Some(res) = cond() { return res; }     // fast_path
13     let (waiter, _) = Waiter::new_pair();         // slow_path
14     let cond = || { self.enqueue(waiter.waker()); // enqueue
15                     cond() };                     // try_lock
16     loop {                                       // loop
17       if let Some(res)=cond() {/* drop(waiter); */ return res;};
18       waiter.waker.do_wait();                     // do_wait
19     }
20   }
21   pub fn enqueue(&self, waker: Arc<Waker>) {
22     let mut wakers = self.wakers.lock(); // acquire_wakers_lock
23     wakers.push_back(waker);             // enqueue_waker
24     self.num_wakers.fetch_add(1);        // inc_num_wakers
25     /* drop(wakers); */                  // release_wakers_lock
26   }}
27 impl Drop for Waiter {                   // drop_waiter
28   fn drop(&mut self) { self.waker.has_woken.swap(true); }}
```

Figure 9: Simplified Mutex code in ASTERINAS. `try_lock` performs `compare_exchange` and returns a guard on success. `do_wait` blocks until `has_woken.swap(false)` returns true. Comments in yellow correspond to labels in Figure 8's spec.

High-level specifications are designed to provide a quick startup for our approach, enabling incremental development of more detailed low-level specifications based on them. They also support early conformance checking (§5), facilitating efficient application of CONVEROS (§3). Since our focus is on identifying real code bugs in specifications, high-level specifications may be omitted if they are difficult to define (e.g., for modules with complex lock usage).

Low-Level Specifications. Unlike high-level specifications aiming to represent a correct design specification, low-level specifications should closely reflect the code implementation. When bugs exist, the low-level specification enables detection through model checking against correctness properties.

A low-level specification can build on its high-level specification and model code details within the public APIs. For example, Figure 8 presents the `lock` procedure of a mutex's specification, while Figure 9 shows the corresponding code.

Translating Rust code into a PlusCal specification is relatively straightforward because PlusCal supports many programming constructs and concepts, such as `while` loops and procedure calls. However, some Rust-specific characteristics require special handling: (1) Rust automatically invokes `drop` when a variable's goes out of scope, which must be explicitly modeled in PlusCal (e.g., line 27 in Figure 8). (2) Closures in Rust do not have direct support in PlusCal and must be expanded into explicit steps (e.g., the closure on line 8 in Figure 9 is expanded in PlusCal to lines 6 and 22 in Figure 8).

4.2 Multi-Grained Specifications

A key challenge in specifying low-level code is determining the appropriate level of granularity. Fine-grained specifications can lead to state-space explosion, while coarse-grained ones risk missing concurrency bugs. To address this, we adopt the methodology of multi-grained specifications from Remix [63]. Multi-grained specifications use different levels of granularity for composable modules [6, 7, 35, 50]. They include fine-grained modules for detailed code-level behavior and coarse-grained modules that preserve interactions while omitting internal details to reduce state space.

A mixed-grained specification combines fine-grained and coarse-grained modules and aims to mitigate state explosion by verifying selective concurrency interleavings without compromising the ability to detect bugs. This is achieved through the interaction-preserving principle [63], i.e., for each module, only the internal part can be omitted while the interactions with other modules must be preserved. It enables verifying the complex concurrency code module by module and abstract fine-grained actions in verified modules to coarse-grained actions. For example, the `acquire_lock()` procedure in the Mutex module (Figure 8) uses five variables. When the Mutex is integrated into another module, only the `locked` variable, which represents the lock guard, interacts externally and is preserved, while other internal variables are abstracted. Similarly, the SpinLock module is coarsened by preserving only the `wakers_lock` variable (Figure 8), which interacts with the Mutex module, while omitting internal details.

Following the mixed-grained specification approach, we analyze dependencies for each module and adopt a stepwise, modularized process. We first specify and verify basic synchronization primitives, such as SpinLock and RwLock, using fine-grained specifications. For modules built on top of these verified primitives, we coarsen their specifications to abstract

away internal details, while continuing to specify and verify the module's own logic with fine-grained actions.

Fine-grained specifications are written based on high-level specifications, capturing the low-level code logic. A key challenge is determining atomic actions. In PlusCal, labels define atomic actions and can be placed in any statement. In our case, the guiding principle is that each modification to a shared variable should be treated as an atomic action because such modifications may be immediately observed by other threads, and lead to interleavings. For example, in Figure 8, we insert labels such as `enqueue_waker` and `inc_num_wakers`, corresponding to the operations at lines 23 and 24 in Figure 9. Additionally, we abstract unrelated low-level scheduling mechanisms. For instance, the `do_wait` code that parks the kernel thread (line 18 in Figure 9) is assumed correct and modeled as a single atomic action (line 23 in Figure 8).

Once fine-grained specifications are verified, their actions can be composed into coarse-grained actions. This typically requires minimal rewriting compared to Remix [63], as high-level specification actions can often be reused if they follow the interface-preserving principle. PlusCal and TLA$^+$ natively support action composition, allowing multiple fine-grained actions to be composed into a single coarse-grained action. For example, in PlusCal, removing labels merges consecutive actions into one atomic action, while TLA$^+$'s action composition [53] composes multiple actions in a single step.

By employing multi-grained specifications, we can achieve incremental modeling and scalable verification, without missing bugs thanks to the interaction-preserving principle.

4.3 Correctness Properties

We define correctness properties to verify whether the system behaves as required. These properties are classified into two categories: *safety* and *liveness*. Safety properties specify that the system never reaches undesirable states (i.e., "something bad never happens"), and liveness properties specify that the system eventually reaches desirable states (i.e., "something good eventually happens").

For concurrency modules, several correctness properties are commonly checked, as demonstrated in Figure 10. Safety properties include mutual exclusion for locks, which asserts that no two processes are in the critical section simultaneously. Liveness properties include absence of deadlock, livelock, and starvation. Deadlock/livelock freedom specifies whenever a process is in the code attempting to acquire a lock, some process must eventually enter the critical section. Starvation freedom specifies that any process attempting to acquire a lock will eventually succeed in entering the critical section.

In addition to common properties, many modules require domain-specific correctness properties. For example, semaphores must ensure that the semaphore count never drops below zero. These specific properties are typically functional safety properties that require domain knowledge.

```
1 MutualExclusion     == \* Safety
2   \A i, j \in Procs: (i /= j) => ~(pc[i] = "cs" /\ pc[j]="cs")
3 DeadAndLiveLockFree == \* Liveness
4   \E i \in Procs: pc[i]="lock" ~> (\E j \in Procs: pc[j]="cs")
5 StarvationFree      == \* Liveness
6   \A i \in Procs: pc[i]="lock" ~> (pc[i]="cs")
```

Figure 10: Common safety and liveness properties

5 Conformance Checking

Verifying conformance between high- and low-level specifications and code increases confidence in verification correctness. In TLA$^+$, conformance checking can be performed using two approaches: top-down [38, 63, 68] and bottom-up [34, 38, 47]. The top-down approach generates specification traces with the model checker and replays them in the code, requiring deterministic control over event interleaving. In contrast, the bottom-up approach captures code execution traces and verifies whether these traces are allowed by the specification. Controlling thread interleavings in OS kernels is challenging, so we adopt and extend the bottom-up trace validation method outlined in §3. This section describes the trace validation technique used to increase confidence that implementation traces conform to specifications with different granularities.

5.1 Trace Validation

To increase confidence that the implementation's behavior conforms to the spec, we build on trace validation [34] by collecting trace logs and creating a trace specification that reuses actions from the high-level or low-level specification to match trace logs. Unlike CCF [47], which checks properties during trace validation, we focus on conformance at this stage, with property checking as optional. Figure 11 shows an example trace log and the trace specification. Trace logs are generated by instrumenting the code to log each specified action, with each log recording a timestamp, event name, process ID, and optional variable updates. To validate traces, the trace specifications execute the corresponding actions (`SpecActions`) under constraints set by the trace log and enforced by `IsEvent`. `IsEvent` advances the trace line number `l`, enforces event constraints, and applies variable update constraints. A trace is valid once `l` exceeds the trace length.

5.2 Trace Collection

To collect traces for concurrency modules, we execute the modules with logging inserted after each code region corresponding to a labeled action. The executions align with the `process` blocks defined in the specification (e.g., lines 15–23 in Figure 2). Since existing unit tests generally do not meet these requirements, we develop lightweight test harnesses (similar to unit tests) to run concurrency modules. One example test harness is shown in Figure 7. The `run_procs` function launches a specified number of kernel threads, each pinned

TlaLogger::new_missing().cur_pc("lock").record();
TlaLogger::new("cs").next_pc("unlock").record();
TlaLogger::new_missing().cur_pc("unlock").record();
drop(guard);
TlaLogger::new_missing().cur_pc("unlock").record();
```

Figure 13: Logging for missing events

to a specific CPU core, executing the defined closure functions. After generation, logs are sorted by timestamps, post-processed (e.g., adding common constraints; improvements such as merging consecutive missing events are discussed in §5.3), and then output. Finally, the configuration (e.g., process set) and trace files required by the trace specification are automatically produced based on the generated logs.

5.3 Our Improvements

Allow Missing Events. The success of trace validation relies on two key assumptions. First, the order of concurrent events is either strictly logged or does not impact the results. Second, the trace length precisely matches the length of an accepted behavior inferred by the model checker, as in the trace validation method proposed by Cirstea et al. [34], which advances the trace line number `l` after matching an event.

However, the first assumption poses challenges in synchronization with shared memory. Modifications to shared variables become immediately visible to other threads, but timestamps may not accurately reflect the actual event timings. This misalignment can cause the incorrect reordering of concurrent events. For instance, in a spinlock scenario, if thread A unlocks and thread B immediately locks the spinlock, the correct trace should show thread A unlocking before thread B locks. Due to timestamp inaccuracies, the order might be reversed in the logs, making the trace invalid. Introducing a global lock to serialize events has been shown to cause problems [38], as it changes system behavior and is prone to deadlock. For example, if thread A holds the global lock and executes the `acquire_wakers_lock` (Figure 8, line 13), which attempts to lock `wakers_lock`, while thread B already holds `wakers_lock` and attempts to acquire the global lock in `inc_num_wakers` (line 17), the two threads can deadlock.

The second assumption requires users to align granularity by composing actions in the trace specification and logging every corresponding specification label. This is burdensome, particularly for low-level specifications with numerous labels (e.g., the `RwMutex` specification contains 47 labels).

We addressed these issues by introducing a new algorithm for inferring missing events, as illustrated in Figure 12, with usage shown in Figure 13. During the instrumentation process for logging, missing events are inserted before and after specific code regions, representing a time window during which some events might have occurred. These missing events can also set constraints, such as allowed events or expected variable updates to guide state exploration. In log post-processing, consecutive missing events are merged into a single event. This ensures that the next event after a missing event is either a normal event (i.e., non-missing) or EOF. When a missing event is encountered, state exploration diverges:

- One branch attempts to match the next (normal) event following the missing event, advancing `l` by two (skipping the missing event and consuming the matched event).
- The other branch explores any enabled actions allowed by the missing event without advancing `l`, so that the missing event remains active in the next step, enabling exploration of additional paths.

As a result, a missing event can correspond to zero or more inferred actions. Figure 13 shows how missing events address timestamp inaccuracies by replacing lines 8–12 in the test harness of Figure 7. To illustrate how missing events reduce logging burden for low-level specifications, one can omit the `cur_pc` constraint that limits the allowed events based on the current `pc`. This allows users to avoid logging all labels at once and instead log them incrementally, as discussed in §5.4.

While this approach allows for greater flexibility, it significantly increases the state space to search, as missing events introduce additional nondeterminism during exploration. To address this, we introduced two pruning constraints:

- **Maximum exploration depth.** A per-event constraint that limits exploration depth for inferred missing events.
- **Convergence points.** A subsequent trace line is marked as a convergence point during post-processing, instructing the model checker to stop exploring states for the corresponding missing event (implemented by storing a constraint globally via `TLCSet`). Between the divergence (the missing event) and the convergence point, all processes allowed by the missing event must match at least one normal event.

These constraints can lead to false positives by prematurely pruning valid paths. To mitigate this risk, We set the maximum exploration depth slightly above the estimated limit. For convergence points, adding more detailed constraints (e.g., more variable updates) for the normal event following the missing event, helps improve the accuracy of convergence points. This prevents overly relaxed conditions from creating false convergence points that prune valid traces.

Cirstea et al. [34] implemented depth-first search (DFS) for trace validation in TLC, which is orders of magnitude faster than breadth-first search (BFS). DFS prioritizes deepening paths that advance `l`, backtracking only when no successors are enabled. Consequently, convergence pruning offers no performance gain in DFS mode, as DFS does not backtrack on genuinely converged paths. However, incorrect pruning at false convergence points may discard valid states and cause false positives. To avoid this, we disable convergence pruning in DFS mode. Conversely, convergence pruning is beneficial for BFS when inferring minimal traces. Without it, BFS becomes impractical, even with a few missing events.

Constrain Variable's Current State. In Cirstea et al. [34], the `UpdateVariables` operator only sets constraints for variables' next states. To constrain the current state of a variable, users previously had to manually modify the trace specification by adding conjunctions in `IsEvent`, as demonstrated in [47]. We simplify this by incorporating support for current state constraints directly into the logging mechanism and the TLA$^+$ trace library. These constraints can check not only equality but also other conditions, such as inequality, greater-than, or subset relationships. Our test framework automatically generates methods to set these constraints, such as `cur_pc` in Figure 13, which constrains the current `pc` state.

Automatic Generating Trace Specifications. CONVEROS automatically generates trace specifications by parsing TLA$^+$ specifications compiled from PlusCal. These specifications follow a standardized format where each action includes an event name stored in `pc` and a single argument representing the process, and each variable is defined using consistent keywords. These elements are easily extracted and incorporated into the trace specification (e.g., lines 13 and 18 in Figure 11). By using missing events for aligning granularities (§5.4) and setting current-state constraints during the logging process, we eliminate the need to manually modify trace specifications, enabling fully automatic generation.

Automatic Generating Debugging Trace for Discrepancies. Incorrect logging, unsound pruning, or genuine discrepancies can cause trace rejection, necessitating debugging to identify the issues. The work [34, 47] leverages the TLA$^+$ debugger to debug discrepancies by allowing users to step through formula evaluations and generate all unsatisfied states for trace comparison, but it still needs manual intervention when running batches of trace validations that frequently fail.

CONVEROS automates discrepancy trace generation by performing a second run with the longest unmatched trace line number. When the first run fails, the line number is set as a breakpoint in the improved trace specification for the next run. We use the `ENABLED` operator in TLA$^+$ to determine if an event can be matched under constraints before applying undiscardable constraints (which assign the variable's next state). If an event cannot be matched and the trace line number reaches or exceeds the breakpoint, the trace specification searches for a possible missing event without applying trace line constraints and triggers an assertion failure. This causes TLC to produce a counterexample consisting of the longest inferred trace with the unsatisfied state as the final state. Additionally, we periodically print the longest matched trace line number and automatically visualize the failed trace validation state space graph when it is small (e.g., fewer than 100 states).

Although we can construct multiple unsatisfied states after the longest matched trace line, a single constructed unsatisfied state is typically sufficient for debugging. This is because the missing event limits the exploration to the process specified in the trace line, and within a single process, execution is usually deterministic with no multiple successor states.

5.4 Granularity Alignment

Our specification approach is multi-layered and multi-grained, producing specifications with varying granularities. Users must ensure that each label corresponds to a specific code location during development. Trace validation requires adding logging for all these code locations, which supports all granularities. However, logging for low-level specifications with numerous labels can be burdensome and error-prone. To address this, we adopted an iterative and incremental process.

High-level specifications model public APIs and abstract internal implementations, allowing logging in the test harness without instrumenting the APIs themselves (Figure 7). Due to timestamp inaccuracies, events involving atomic variables and concurrent updates are marked as missing to let TLC infer a valid execution order (Figure 13).

For low-level specifications, we can reuse the high-level test harness for preliminary conformance checks by marking public API events as missing in logging. For example, in Figure 7, the `lock` and `unlock` (i.e., `drop(guard)`) events need to be marked as missing without constraining the event (i.e., the current `pc`), enabling trace validation without instrumenting these APIs. This helps detect major discrepancies early, such

as missing implicit logic like drop in the specification. We then iteratively log internal API labels, using missing events as placeholders for labels that are not yet fully logged. As more labels are logged, trace validation can uncover increasingly subtle discrepancies, such as incorrect condition checks, as illustrated in Figure 16 and discussed in §6.3.

After logging, we aggregate trace logs to assess event coverage. For uncovered labels, we analyze why the corresponding code paths are not triggered and add assertions to the specification so that if those paths are reached, TLC generates traces that help diagnose and resolve the issues.

5.5 Bug Confirmation

After trace validation, we conduct model checking to detect property violations. When violations are identified, we create test cases to reproduce the bugs. The violation trace provides serialized sequence and event timing, making test case development straightforward. Typically, this involves adding delays to events to reconstruct the violation path in the code.

If a test case fails to reproduce the bug, it indicates a discrepancy that requires further specification adjustments. Conversely, successfully reproducing the bug confirms its existence. We then fix the specification, verify it, apply the fix to the code, and rerun trace validation to check conformance.

Additionally, running test cases may uncover by-product bugs. Each test is executed repeatedly in a debugging environment to confirm the fix, which can occasionally reveal additional issues such as kernel panics and hangs. When such by-product bugs are identified, they are addressed to enhance overall system robustness.

6 Evaluation

To demonstrate CONVEROS's practicality, we applied it to 12 concurrency modules in ASTERINAS, evaluating bugs discovered, verification effort, and discrepancy detection. We dedicated 4 person-months to model checking about 4,000 lines of ASTERINAS code and identified 20 bugs. This includes 9 bugs discovered automatically through model checking and 11 by-product bugs discovered during diagnosis, and they were all confirmed by the developers. Among these, 8 model-checking bugs and 6 by-product bugs were fixed, with the remaining unfixed due to low priority. All bugs were detected under a model checking configuration with 2-5 processes, and each one was detected within 3 minutes on a laptop equipped with a 16-core CPU, 32GB of RAM, and 22 parallel threads.

6.1 Case Study

Table 1 summarizes the bugs we found. We examine two case studies to demonstrate how we apply CONVEROS to identify and fix these bugs. Analyses of the other bugs are provided in Appendix A.

Case Study 1: Mutex. We found a mutual exclusion bug in the Mutex module that caused severe data races, allowing multiple threads to enter the critical section and obtain multiple mutable references through unsafe. Figure 14 shows the buggy code. The root cause was an eagerly evaluated MutexGuard in the then_some argument, which was unintentionally dropped when the lock was not acquired (line 3). The drop method for MutexGuard then unlocks the mutex (line 7). It was introduced following a compiler linter suggestion to replace then with then_some. Trace validation using the high-level specification successfully found this bug. We fixed it by restoring then and wrapping the MutexGuard construction using a new method inside a lazily evaluated closure (line 4).

```
1  impl<T> Mutex<T> {
2    pub fn try_lock(&self) -> Option<MutexGuard<T>> {
3  -   self.acquire_lock().then_some(MutexGuard { mutex: self })
4  +   self.acquire_lock().then(|| MutexGuard::new(self))
5    }}
6  impl<T> Drop for MutexGuard<T> {
7    fn drop(&mut self) { self.mutex.unlock(); }}
8  impl<T> DerefMut for MutexGuard<T> {
9    fn deref_mut(&mut self) -> &mut T {
10     unsafe { &mut *self.mutex.val.get() }
11   }}
12 impl bool {
13   pub fn then_some<T>(self, t: T) -> Option<T> {
14     if self { Some(t) } else { None }
15   }}
```

Figure 14: Mutex mutual exclusion bug and fix. MutexGuard is incorrectly dropped when acquire_lock fails.

Case Study 2: RwLock. We found a livelock/starvation bug in the RwLock module that can cause temporary kernel hangs under high contention (Figure 15). The RwLock is a spinning lock with its state represented by an AtomicUsize, encoding readers, an upgradable reader, and a writer. A writer can downgrade to an upgradable reader, or vice versa. The root cause was that the try_read method for acquiring a read lock was non-atomic. This method uses fetch_add (line 2) to increase the reader count, and if failed to acquire the read lock, it reverts with fetch_sub (line 6). The try_downgrade method fails at the intermediate state created by try_read, as it requires the lock state to match exactly that of a writer.

```
1  pub fn try_read(&self) -> Option<RwLockReadGuard<T>> {
2    let lock = self.lock.fetch_add(READER);
3    if lock & WRITER == 0 {
4      Some(RwLockReadGuard { inner: self })
5    } else {
6      self.lock.fetch_sub(READER);
7      None
8    }}
9  fn try_downgrade(mut self)->Result<RwLockUpReadGuard<T>,Self> {
10   let inner = self.inner.clone();
11   let res = self.inner.lock
12     .compare_exchange(WRITER, UPREADER);
13   if res.is_ok() {
14     drop(self);
15     Ok(RwLockUpReadGuard { inner })
16   } else {
17     Err(self)
18   }}
```

Figure 15: RwLock livelock/starvation bug

ID	Module	Violation/Manifestation	Description
Found by CONVEROS			
#1	RangeLock [8]	Deadlock-free	Lost wakeup due to waiting on an outdated wait queue
#2	Mutex [9]	Mutual exclusion	Incorrect guard construction in `lock` causing unintended `unlock` on `drop`
#3	RwLock [10]	Livelock/Starvation-free	Non-atomic `read()` operation racing with `downgrade()`
#4	RwMutex [11]	Deadlock-free	Wrong wakeup condition causing a dropped upreader to never wake up a waiter
#5	Semaphore [12]	Semaphore count ≥ 0	Semaphore count decreases below 0 due to unhandled multi-operation `semop()`
#6	Futex [13]	Deadlock-free	Signal or timeout leaving outdated futex item uncleared, causing lost wakeup
#7	Flock [14]	Deadlock-free	Incorrect wait condition causing permanent wait
#8	Pipe [15]	Write atomicity	Writes smaller than `PIPE_BUF` size are not guaranteed to be atomic
#9	TTY [16]	Deadlock-free	Circular dependencies from incorrect locking order causing TTY hang
By-product bugs			
#10	Semaphore [17]	(Found during modeling)	Incorrect initialization of the waiter count, leading to wrong lookup results
#11	Futex [18]	(Found during modeling)	Poor hash algorithm leads to uneven key distribution, overloading a few buckets
#12	Atomic mode [19]	Kernel panic	Misuse of spinlock/mutex breaks atomic mode
#13	IRQ [20]	Stack overflow	Improper IRQ enabling during the bottom half leads to nested IRQs
#14	TLB [21]	Kernel hang	Deadlock caused by a spinlock used in IRQ without disabling IRQ outside it
#15	Trap [22]	Kernel panic and hang	Uncleared direction flag (`rflags.DF`) leads to memory corruption on traps
#16	Task switch [23]	User process crash	Missing FPU state save/restore causes memory corruption on task switch
#17	Sendfile syscall [24]	User data truncation	Short writes cause data truncation when input is read but not fully written
#18	Kernel tests [25]	Kernel test hang	Assertion in kernel test threads leads to infinite error message unwraps
#19	Kernel threads [26]	Kernel panic	A new scheduler feature breaks CPU affinity setting
#20	Logging [27]	Kernel hang	Logging allocating memory during low-memory rescue triggers recursive rescues

Table 1: Bugs found. "Violation" indicates violated properties, while "Manifestation" indicates by-product bug manifestations.

Both `try_read` and `try_downgrade` are repeatedly invoked in surrounding loops, resulting in a livelock where neither operation succeeds. Under high contention, the probability of encountering this issue rises sharply. In our test case, the `downgrade` method took 26 seconds to complete with 30 readers. This type of liveness bug is challenging to detect through testing but can be effectively identified by CONVEROS.

6.2 Verification Effort

Table 2 summarizes key verification effort metrics for the modeled concurrency modules, including lines of code, specification size, number of variables and actions, and the estimated effort in person-days based on Git history.

Our multi-grained specification approach allows coarsening of verified components, and non-essential code such as logging is excluded as well, resulting in a low specification-to-code ratio ranging from 0.3 to 2.3 across 12 modules. Meanwhile, PlusCal effectively supports fine-grained modeling in an imperative style. These factors make modeling each module cost-effective and relatively straightforward, averaging 330 lines of code and 3.6 person-days per module. Variations in effort are mainly due to module complexity and required domain knowledge; for example, the SysV semaphore module took 9 person-days because of its intricate semantics.

Trace validation efforts benefited from improvements to our validation framework, including automation and usability enhancements such as allowing missing events. Developing the trace validation framework took 12 person-days, which included 681 lines of Rust and 396 lines of Python code. On average, trace validation took 2 days per module. Early efforts required more time (e.g., SpinLock took 5 days), as we debugged and refined the framework. Refining the approach into manageable steps significantly sped up later validations.

Writing test cases for confirming and fixing bugs typically took less than a day. Overall, one developer with TLA$^+$ expertise contributed four full-time person-months to writing specifications, developing the trace validation framework, performing trace validation and model checking, and debugging, demonstrating CONVEROS's cost-effectiveness.

6.3 Discrepancies

We identified around 15 modeling errors that caused discrepancies throughout the workflow, especially during trace validation. Trace validation proved effective in uncovering subtle issues that did not trigger obvious property violations. Other discrepancies were easier to detect, as they caused violations during early model checking in specification development.

For example, a discrepancy in RwMutex is illustrated in Figure 16. The `try_upread` method uses `fetch_or` to set the `UPREADER` bit and returns the previous lock value, retaining only the `WRITER` and `UPREADER` bits. In our low-level specification, the lock state was divided into variables like `upreader_lock` and `writer_lock`. We incorrectly modeled the returned lock to retain only the previous `upreader_lock` state (line 4) and mistakenly checked the current `writer_lock` state (line 8) to determine the success condition.

Trace validation identified this discrepancy in a trace where another process released the write lock between the `fetch_or` and `check` actions. In this trace, the `check` action reported unsuccessful lock acquisition because the `WRITER` bit was set in the previous lock value. However, the last unmatched state in the discrepancy trace indicated that the upread lock was successfully acquired, revealing the modeling error.

Code		Specification			Est. Effort	
Module	**#LOC**	**#LOC**	**#Var.**	**#Act.**	**Spec.**	**Conf.**
SpinLock	147	49	1	5	1.5	5
Mutex	113	89	4	14	4	3
RwLock	404	261	5	19	5	2.5
RwMutex	202	460	9	47	3.5	2.5
CondVar	238	199	6	25	3.5	1.5
Semaphore	622	490	10	37	9	2
PageCursor	468	297	10	21	5	-
Pipe	392	143	7	17	1.5	1
RangeLock	457	529	9	24	4	2
Flock	144	176	7	12	1.5	0.5
Futex	469	201	5	21	4	1
TTY	309	138	4	20	1	0.5
Total	3965	3032	77	262	43.5	21.5

Table 2: Verification effort. "#Var." and "#Act." denote the number of variables and actions respectively. "Spec." and "Conf." represent specification and conformance efforts (in person-days). Conformance checking was skipped for PageCursor as the module is undergoing refactoring.

```rust
pub fn try_upread(&self) -> Option<RwMutexUpReadGuard<T>> {
  let lock = self.lock.fetch_or(UPREADER) & (WRITER | UPREADER);
  if lock == 0 {
    Some(RwMutexUpReadGuard { inner: self })
  }
```

(a) RwMutex code

```
 procedure try_upread()
 variable prev_lock; {
 fetch_or:
-  prev_lock := upreader_lock;
+  prev_lock := <<upreader_lock, writer_lock>>;
    upreader_lock := TRUE;
 check:
-  if (~prev_lock /\ ~writer_lock) {
+  if (~prev_lock[1] /\ ~prev_lock[2]) {
    success:
      role[self] := UPREADER;
      return;
    }
```

(b) Discrepancy and fix in the RwMutex specification

Figure 16: RwMutex discrepancy: code and specification

7 Discussions

Assurance. CONVEROS provides assurance that, within the explored state space, the model-checked code satisfies specified safety and liveness properties, assuming it conforms to its low-level specification. To improve this conformance, CONVEROS performs trace validation between code and specification. In addition, high-level specifications help scale to larger systems by enabling compositional verification in mix-grained specifications, where each component can be verified assuming the correctness of the components it interacts with.

False Positives and False Negatives. The final bugs reported by CONVEROS's model checking stage did not include false positives, all detected bugs were reproduced in the bug confirmation. However, the trace validation stage can report false positives, mainly due to incorrect logging (e.g., incorrect logging of a variable's value) and unsound pruning (e.g., stopping exploration prematurely due to a maximum depth constraint). To ease diagnosis, discrepancy traces are automatically generated (§5.3). False negatives may result from unmodeled components or incomplete exploration of the state space, which are inherent limitations of model checking. In addition, CONVEROS may miss bugs, as trace validation does not prove refinement and may accept traces that do not conform to the specification. CONVEROS mitigates these issues through multi-layered and multi-grained specifications. Writing specifications also enforces clear thinking, precise designs, and unambiguous documentation, increasing confidence in correctness. To further reduce the risk of undetected discrepancies, we compute trace event coverage (§5.4).

Generalizability. The design of CONVEROS, including its formal specification approach and trace validation techniques, is generic and can be extended beyond OS concurrency modules. It is suitable for verifying systems with clear correctness properties, such as crash safety in file systems or fault tolerance in distributed systems. For example, applying CONVEROS to a distributed system follows a similar workflow as shown in Figure 6. Core components can be reused, including the multi-layered, multi-grained specification approach, incremental trace validation with support for missing events, and automatic generation of trace specifications and discrepancy traces. In contrast, system-specific elements must be developed anew, including domain-specific specifications (e.g., modeling both intra-node and inter-node concurrency such as faults and messages as separate `processes` in PlusCal), logging instrumentation, and test harness.

8 Related Work

CONVEROS model-checks ASTERINAS's concurrency modules using multi-layered, multi-grained specifications, building on recent advances in specification development [63] and trace validation [34, 38, 47]. Remix [63] model-checks distributed systems using multi-grained specifications and checks conformance by replaying specification traces against the implementation. In contrast, CONVEROS targets shared-memory OS concurrency, employs both high-level and low-level specifications, and validates code traces within the specification. It further improves coarse-grained specification construction by leveraging TLA$^+$'s action composition. We discuss related work on conformance checking in TLA$^+$, and on model checking, deductive verification, and testing for OS.

Conformance Checking. Prior work has explored conformance checking in TLA$^+$ using trace validation [34, 38, 41, 47, 65, 69] and test case generation [38, 63, 68, 70]. Tasiran et al. [69] first validated execution traces against TLA$^+$ specifications. Pressler [65] formalized trace validation as a refinement check, and Davis et al. [38] applied it to MongoDB (MBTC). However, they found MBTC impractical for conformance, as refinement requires complete state logging and a strict mapping between code and specification actions–both

are often infeasible. Cirstea et al. [34] improved trace validation by leveraging TLA$^+$'s nondeterminism to infer missing states and implementing action composition to align granularity, proving effective in CCF [47]. Building on these techniques, CONVEROS introduces a new missing-event algorithm that enables three key improvements. First, it allows inference of event ordering in shared-memory concurrency, where exact timings are hard to trace. Second, it adopts an iterative and incremental workflow for aligning granularity, and improving usability and automation. Unlike prior work requiring manual trace specifications, CONVEROS automatically generates them and only requires incremental code logging. Finally, it enhances discrepancy debugging by automatically reconstructing traces leading to the next unmatched event.

Davis et al. [38] also check conformance by generating test cases from the TLC state space, and attribute its success to the specification being written close to the implementation, namely a low-level specification in our terms. This observation is further supported by SandTable [68] and Remix [63], which check conformance in distributed systems using low-level specifications. Mocket [70], by contrast, uses a high-level specification for conformance but encounters challenges aligning granularities. They report two conformance issues caused by generalizations in common TLA$^+$ modeling patterns, which led them to revise the specification to more closely reflect the implementation. These works suggest that high-level specifications may not always be sufficient to fully guide concrete executions. CONVEROS instead uses trace validation to check code traces against the specification, supporting logging missing events for flexible granularity alignment, which works for both high-level and low-level specifications.

OS Model Checking. Model checking has been extensively studied for detecting bugs in various OS components [4, 29, 30, 39, 42, 52, 58–60, 62, 73, 74]. The most closely related work is C2TLA+[58], which statically translates concurrent C code to TLA$^+$ for property checking, and uses refinement checking to ensure the correctness of a manually written abstraction that helps reduce the state space. In contrast, CONVEROS dynamically checks conformance through trace validation, which additionally can uncover by-product bugs in the process. Moreover, CONVEROS uses multi-layered specifications to ease the writing burden and multi-grained specifications to reduce the model checking search space.

CMC [60] is an explicit-state model checker capable of verifying code extracted from OS kernels. It was later extended to support running the Linux kernel directly within its environment [59, 73], effectively detecting numerous bugs in network protocol implementations and file systems. EXPLODE [74] applies in-situ model checking to validate file systems by running their implementations as-is, reducing both the effort needed to adapt code for verification and false positives introduced by modifications. VSync[62] extends stateless model checking with await-checking to verify OS synchronization primitives under weak memory models. Kani [4] is a bounded model checker for Rust programs, effective in verifying unsafe code and memory safety, but it lacks support for concurrency and functional verification. Compared to previous approaches that directly model check the system implementations, CONVEROS improves the efficiency of model checking by first model checking multi-layered, multi-grained specifications and then confirming bugs at the implementation level. To make it practical, CONVEROS provides an approach for writing high-quality specifications using trace validation.

OS Deductive Verification. Recent work has made great progress in formally verifying OS components using deductive verification [33, 36, 37, 44–46, 51, 55–57, 67, 71, 75]. These approaches offer very strong correctness guarantees but often require significant manual proof effort–commonly 5X to 20X the size of the implementation. CONVEROS takes a different approach: it uses model checking to verify an existing, concurrent OS without requiring any manual proofs. While CertiKOS also adopts a multi-layered strategy, it uses refinement proofs to ensure that low-level code meets top-level specifications. In contrast, CONVEROS uses multi-layered specifications to reduce specification effort by modeling top-down, and multi-grained specifications to reduce the search space of model checking.

OS Testing. Recent research has proposed systematic testing techniques for OS concurrency by exploring different interleavings of kernel events [40, 43, 48, 49, 72]. Despite being effective in detecting concurrency bugs, it is hard for testing to exhaustively explore the (bounded) space of system states. CONVEROS provides a systematic and efficient way to explore the system state space using model checking.

9 Conclusion

This work presented CONVEROS, a practical methodology for verifying OS concurrency modules using model checking. CONVEROS employs a multi-layered, multi-grained specification approach and enhanced trace validation to improve usability and automation, enable incremental conformance checking, and scale verification. We show that CONVEROS is both practical and effective: in just four person months, we verified 12 concurrency modules and uncovered 20 bugs, including some that were difficult to detect and fix. We hope that CONVEROS leads to a practical step toward more accessible and efficient verification of real-world systems.

A Descriptions of Bugs Found by CONVEROS

RwMutex. One deadlock bug was found in the RwMutex module that caused kernel hangs. The RwMutex is a blocking version of RwLock, designed with wakeup mechanisms triggered when a lock holder drops. The root cause of the bug was that the wakeup condition for dropping an upgradable reader as the last reader was incorrectly checked. It assumed that the `fetch_sub` method's return value represented the state after the change, whereas it actually represented the state before the change. As a result, the condition indicating the last reader was never satisfied.

Semaphore. One safety bug was found in the SysV semaphore IPC. The bug was related to the complex design of SysV semaphores, which allows a single `semop` syscall to operate on multiple semaphore numbers with multiple operations. The root cause was the failure to handle cases where multiple operations affected the same semaphore number within a single `semop` call. In these cases, each operation could proceed (e.g., decreasing the count by 1 when the semaphore count was 1), but the overall result required waiting. The precheck to determine if the syscall could proceed failed to detect this case, causing it to proceed without waiting, which led to the semaphore count dropping below zero.

Futex. One deadlock bug was found in the Futex system call, a critical component for constructing user-space synchronization mechanisms like `pthread_mutex_lock`. The bug caused user process hangs due to lost wakeups. When a process waiting on a futex system call was interrupted by a timeout or signal, the futex item was not properly removed from the wait queue. As a result, a subsequent wake operation targeted the leftover futex item instead of a legitimately waiting one, leading to lost wakeups and user process hangs.

Flock. One deadlock bug was found in the Flock module. Similar to RangeLock, which locks specific file regions, Flock locks the entire file. The root cause of the bug was the incorrect use of the `WaitQueue` API to wait for an invalid condition. Specifically, the locking method attempted to wait on a `None` condition when encountering conflicts, intending to resume execution once woken up. However, the `WaitQueue` API does not support such conditions, resulting in an infinite wait.

Pipe. One safety bug was found in the Pipe module, which is implemented using a lock-free ring buffer. While verifying the ring buffer, we found no issues. To ensure correctness, we also wrote test cases to simulate real-world usage. However, a short write issue was identified in the `sendfile` system call, causing user data truncation. Although short writes are allowed in the ring buffer, the POSIX standard requires that pipe writes of sizes up to `PIPE_BUF` be atomic. After learning about this atomicity requirement, we verified it and, unsurprisingly, found it violated. We then implemented a fix and confirmed its correctness through model checking.

TTY. One deadlock bug was found in the TTY driver, which handles input from the keyboard and outputs to the terminal. During testing, we observed that the TTY occasionally became unresponsive or hung completely. Debugging revealed a circular dependency in the spinlock usage. The TTY driver employed four spinlocks, and the circular dependency led to deadlocks. To ensure the correctness of our fix, we modeled the spinlock usage, reproduced the circular dependency issue, and verified the fix.

BIN2WRONG: a Unified Fuzzing Framework for Uncovering Semantic Errors in Binary-to-C Decompilers

Zao Yang
University of Utah

Stefan Nagy
University of Utah

Abstract

Binary *decompilation* is central to many systems tasks that rely on analyzing or modifying closed-source software, such as debugging, performance tuning, and security hardening. Decompilers translate executables into C code with the goal of reconstructing a semantically-equivalent form of the original program's source. Unfortunately, when challenged by intricate program logic, data structures, and diverse executable layouts, decompilers often produce semantically-*wrong* code. Proactively detecting such decompilation defects is critical for ensuring the success of downstream tasks that depend on precise binary analysis. Yet, current methods for assessing decompiler correctness only narrowly explore the variety of source constructs, compilers, optimization levels, executable formats, and *combinations thereof* that influence binary code. Fully guaranteeing decompilation precision—and, by extension, supporting all tasks that hinge on accurate binary-to-source recovery—demands a testing approach that unifies *all* factors affecting binary code, extending practical, systematic correctness testing to all decompilers today.

To accelerate discovery of decompilation defects, this paper introduces BIN2WRONG: a general-purpose decompiler fuzzer combining systematic binary mutation with practical, decompiler-agnostic support. Our approach coalesces *all* factors of binary generation—source, compiler, optimization, and executable format—into a novel, unified testcase structure for mutation. Beyond enabling deeper exploration along these individual dimensions, BIN2WRONG finds unique *combinations* exposing complex, multi-dimensional errors that elude prior decompiler testing approaches. In evaluating BIN2WRONG alongside state-of-the-art decompiler fuzzers Cornucopia and DecFuzzer across seven free and commercial decompilers, BIN2WRONG achieves upwards of **10.39**× and **17.18**× higher binary diversity and **1.16**× and **1.32**× more decompiler code coverage, respectively, whilst uncovering **the most** decompilation bugs. Beyond finding **48 *new* bugs**, **with 30 confirmed**, BIN2WRONG spurred a major redesign of the commercial decompiler Binary Ninja—showing its utility in **uncovering critical defects in mainstream decompilers**.

1 Introduction

Binary *decompilers* are crucial for analyzing, maintaining, and modifying modern systems software, translating raw machine code into more human-readable higher-level representations, most commonly C. By bridging this gap, decompilers become indispensable for tasks that must proceed without a program's original source, such as performance tuning of closed-source components [37], malware analysis [136], security assessment of proprietary kernels [34], and third-party patching of production systems [40]. Popular decompilers today include Binary Ninja [108], Angr [132], Ghidra [78], and RetDec [6].

Decompilers' ultimate goal is recovering code identical or semantically-equivalent to the program's original source. Recent advancements are vastly improving decompilation accuracy through neural networks [30, 141], LLMs [5, 135], and heuristic code restructuring [15, 33]. Yet in practice, decompilers face steep challenges due to the lossy nature of compilation, which strips source-level semantics like type information, function and variable names, and high-level program structures. Moreover, diverse executable formats (e.g., ELF, PE, Mach-O), compiler-specific code layout patterns (e.g. variable arrangement, function ordering), and optimizations (e.g., inlining, loop jamming, dead code elimination) further impede precise decompilation, requiring significant specialized handling. As even subtle mistakes (e.g., a misrecovered branch condition) cause trickle-down failures (e.g., incorrect control flow) in downstream binary analysis tasks, **vetting decompilers' correctness is critical to the success of many systems engineering and reliability efforts today**.

Inspired by the success of automated testing—namely fuzzing—in other software domains, recent works propose testing strategies specially tailored to finding semantic errors in decompilers [20, 54, 89, 142]. While such approaches have historically uncovered bugs, they are overwhelmingly ineffective at finding the vast majority of decompiler defects today. Executables are influenced by four key dimensions: (1) *source*, the fundamental blueprint behind binary generation; (2) *compilers*, which emit and structure the bi-

nary's code; (3) *optimizations*, which restructure, expand, or trim the binary accordingly; and (4) the *executable format*, which encapsulates platform-specific code layout and calling conventions. Yet, despite the equal importance of each of these aspects, current decompiler fuzzers fail to explore them comprehensively—hardcoding themselves to only specific, narrow subsets that ultimately highly overlap with those already-covered by past testing efforts. Worse yet, these restrictive approaches cannot reveal the many decompiler bugs caused by specific source and compilation parameter *combinations*—leaving these edge-case errors unlikely to be found until they inevitably confront decompilers' own users. Thus, preventing the failure of critical efforts reliant on precise decompilation demands **a systematic correctness-testing approach spanning *all* aspects of binary generation—whilst supporting all of today's diverse decompiler ecosystem**.

To accelerate discovery of decompiler errors producing semantically-wrong code, this paper introduces BIN2WRONG: a general-purpose fuzzer that explores *all* aspects of binary generation—source, compiler, optimizations, and executable formats—in a synergistic *and* decompiler-agnostic manner. Unlike prior decompiler fuzzers that view these dimensions individually, BIN2WRONG unifies and mutates them *altogether*, facilitating more flexible and thorough exploration of diverse binary semantics as well as the unique interplay arising from distinct *combinations* of all four factors. When applied to state-of-the-art decompilers, **BIN2WRONG reveals many more decompilation errors** than prior overly-restrictive approaches, assisting decompiler developers in strengthening their tools against complex edge-cases that otherwise derail their users with real-world inaccuracies.

We evaluate BIN2WRONG alongside the state-of-the-art decompiler fuzzers DecFuzzer [54] and Cornucopia [89] on seven free and industrial x86 decompilers: Binary Ninja, Angr, Radare2/Ghidra, Reko, Relyze, RetDec, and Rev.Ng. Overall, BIN2WRONG's holistic, binary-centric mutation strategy vastly outperforms DecFuzzer and Cornucopia in generated binary diversity by upwards of **10.39**× and **17.18**×, respectively. When used to test decompilers, BIN2WRONG's higher-diversity binaries achieve a mean **1.16**× and **1.32**× decompiler code coverage relative to DecFuzzer and Cornucopia—while uncovering **38** and **48** more decompilation semantic errors, respectively. After analyzing BIN2WRONG's **48 newly-found bugs** and reporting them to their decompilers' developers, **30 are so far confirmed or fixed**. Importantly, BIN2WRONG *uniquely* discovered many critical bugs, including one that prompted **a total overhaul** of the industrial decompiler Binary Ninja's core code structuring techniques.

In summary, our paper makes the following contributions:

- **Insights:** We analyze and categorize 64 publicly-reported decompiler semantic defects; and are the first to shed light on the importance of *all four* factors behind binary generation—source, compiler, optimization, and executable format—in facilitating decompiler defect discovery.
- **Challenges:** We weigh the limitations of prior decompiler testing efforts in considering our aforementioned four factors of binary generation; as well as their capability of supporting *all* of today's diverse decompiler ecosystem spanning both free and industrial decompilers.
- **Solutions:** We design BIN2WRONG: the first general-purpose decompiler fuzzer to balance automated, large-scale exploration of diverse binary semantics stemming from distinct source code and compilation parameter combinations—in a fully decompiler-agnostic manner. Beyond supporting virtually all of C's control and data constructs (e.g., floating-point and string literals, `switch-case` statements, `goto` branches, etc.), BIN2WRONG integrates six different C compilers, three binary executable formats, and 5,183 distinct compiler optimizations.
- **Results:** In an evaluation of BIN2WRONG versus state-of-the-art decompiler fuzzers Cornucopia and DecFuzzer, we show that BIN2WRONG achieves the highest-overall binary diversity, code coverage, and semantic bug discovery across seven mainstream binary-to-C decompilers: Binary Ninja, Angr, Radare2/Ghidra, Reko, Relyze, RetDec, and Rev.Ng. Moreover, while prior decompiler testing works explore only limited sets of compilers and optimizations, we present the *first* comprehensive study of the distinct impacts of varying source code—combined with the largest-ever tested set of compilers, executable formats, optimizations, and *their combinations*—on the discovery of semantic errors within contemporary binary decompilers.
- **Impacts:** We report all discovered bugs to their respective decompiler developers. So far, **30** of **48** BIN2WRONG-found bugs are confirmed, with many since fixed. Several BIN2WRONG-uncovered bugs motivated significant changes to mainstream decompilers, including a major restructuring of the commercial decompiler Binary Ninja.

We will publicly release BIN2WRONG, as well as all evaluation artifacts and uncovered bugs at the following URL: `https://github.com/FuturesLab/Bin2Wrong`.

2 Background

This section provides a brief overview of the process of binary decompilation, as well as the most common classes of correctness defects affecting today's various binary decompilers.

2.1 An Overview of Binary Decompilation

Decompilers' goal is *inverting* program compilation: consuming a pre-built executable and recovering its source code [22]. For systems, decompilers critically facilitate human understanding and reasoning about software whose source is unavailable, such as legacy or proprietary components, and obfuscated malware. In the following, we outline and discuss the four main steps central to virtually all decompilers today: **(1) Control Flow Recovery**, **(2) Control Flow Analysis**, **(3) Data Flow Analysis**, and **(4) Code Generation**.

1. **Control Flow Recovery.** Control Flow Recovery aims to understand programs' underlying flow of execution. Instruction disassemblers (e.g., Capstone [3], Intel XED [39]) are used to translate raw binary code into machine instructions—and further—group them into *basic blocks*: sequences of consecutive instructions both targeted-by and terminating-in a *control-flow transfer* (i.e., branches, fall-throughs, calls, or returns). Additional analyses are performed to group basic blocks into functions, culminating in the overall program Control-flow Graph (CFG), where nodes and edges denote basic blocks and control-flow transfers between them, respectively.
2. **Control Flow Analysis.** With the CFG in-hand, decompilers begin abstracting basic block groupings into higher-level *control structures* like loops, switch-cases, and dispatch tables. Critical to CFG analysis is recognizing high-level structures via known patterns: for example, standard techniques for loop identification leverage control-flow dominance between basic blocks to determine the loop's overarching header [90]. Ultimately, recovery of higher-level control structures offers a richer understanding of program semantics, forming the backbone of decompilers' subsequent data flow recovery and code generation steps.
3. **Data Flow Analysis.** Following control structure recovery, decompilers shift focus to examining how *data* is read, written, and propagated throughout program execution. Primary goals of these analyses include identifying distinct data objects, such as function arguments, return values, and both local and global variables, along with determining their associated data *types*. These elements are critical to decompilers' final code generation phase as they directly impact virtually all aspects of program semantics: control-flow logic, data expressions, and more.
4. **Code Generation.** Decompilers' final stage leverages all collected control- and data-flow artifacts to generate the program's final *source* representation. Yet, as all prior steps are inherently undecidable, decompilers' generated code is unlikely to be identical to the program's original source. To this end, decompilers still aim to yield semantically-equivalent source representations which—while visually different from the original—*behaves* the same.

2.2 Semantics-affecting Decompilation Defects

Decompiler defects range from cosmetic inconsistencies affecting human readability of decompiled code—for example, haphazard ordering of `switch-case` labels (Binary Ninja issue [113])—to **insidious *semantics-affecting* errors that completely misrepresent program behavior**. Semantics-affecting defects uniquely burden decompiler users with *incorrect* results, thus impeding the success of downstream systems-oriented binary analysis tasks. To better understand these obstacles, we review public issue trackers of mainstream decompilers and distill reported bugs into four high-level categories of semantics-affecting defects shown in Table 1: **(1) Data Expressions**, **(2) Control-flow Logic & Structures**, **(3) Data Objects, Types, & Values**, and **(4) Compilation-specific Defects**. We briefly discuss these below.

Category	Origin(s)	Decompilers and Examples of Relevant Defects
Data Expression	Instructions	**Ghidra** [75], **Radare2** [82], **Reko** [48], **RetDec** [7, 13]
	Refinement	**Angr** [95, 106], **Binary Ninja** [120, 121, 125], **RetDec** [12]
Control Logic, Structures	If / Else	**Binary Ninja** [114, 126, 130], **Ghidra** [65], **RetDec** [8, 9]
	Loops	**Angr** [94, 99, 103], **Binary Ninja** [112, 116], **Reko** [47]
	Goto	**Angr** [104, 105], **Binary Ninja** [122], **Reko** [44], **RetDec** [11]
	Switches	**Binary Ninja** [111, 115, 116], **Radare2** [84], **RetDec** [10]
Objects, Types, Values	Arguments	**Angr** [93, 101, 102], **Binary Ninja** [117, 123, 127, 129]
	Variables	**Angr** [97, 100], **Binary Ninja** [124], **Ghidra** [72–74]
	Literals	**Angr** [92], **Binary Ninja** [119], **Ghidra** [66, 77], **Reko** [46]
Compile Configs	Code Opts	**Angr** [91, 93, 98], **Binary Ninja** [110], **Ghidra** [71, 76]
	Format	**Angr** [96], **Binary Ninja** [118, 128, 131], **Ghidra** [68, 70]

Table 1: Reported semantic bugs in mainstream decompilers.

- **Defects in Recovering Data Expressions.** Errors in instruction disassembly or handling of instruction semantics often lead to data inconsistencies in decompilers' higher-level code generation. For example, in Ghidra [75], incorrect handling of x86's `FCOMP` (floating-point comparison) results in comparison operands being *swapped*; and as this comparison governs a conditional branch, the code guarded by this branch ends up only being reachable under conditions totally different from the original program's. Additionally, decompilers often refine data expressions using techniques such as constant folding and propagation to enhance code readability [33], conciseness [137], or better align with real-world source code patterns [15]. However, subtle errors in these optimizations also lead to incorrect data. For example, in Binary Ninja [121], constant propagation for x86's `ROL` (rotate-left) and `SHL` (shift-left) instructions inaccurately simulates 32-bit registers, yielding divergent expression results when analyzed on 64-bit systems.
- **Defects in Recovering Control Logic & Structures.** In addition to data expressions, we identify numerous instances of semantics-affecting defects in decompilers related to the recovery of control logic and structures. These include missing bodies for conditional branches (e.g., RetDec [9]); incorrect recovery of loop starting conditions (e.g., Reko [47]); and missing, spurious, or misdirected `goto` branches (e.g., Angr [105]). Handling of `gotos` is particularly contentious—and error-prone—in decompilation research and design, with current decompilers employing vastly different strategies for their recovery and structuring (e.g., [15, 137]). Furthermore, we see that `switch-case` statements remain one of the most universally-challenging control structures across all decompilers, leading to downstream errors that result in unrecoverable code blocks (e.g., Radare2 [84], RetDec [10]), or complicating recovery of other intermingled control logic (e.g., Binary Ninja [116]).
- **Defects in Recovering Data Objects, Types, & Values.**

While recovery and refinement of data expressions pose challenges for decompilers, even identifying and reconstructing their underlying *data objects* (e.g., string, integer, and floating-point variables and literals)—along with their corresponding types and values—presents significant difficulties that directly impact the accuracy of decompiled code semantics. We observe many instances of functions missing arguments (e.g., Angr [101], Binary Ninja [127]) or return values (e.g., Angr [100]), as well as general type incompatibilities on local variables (e.g., Binary Ninja [124], Ghidra [74]). Strings and floating-point literals also present distinct challenges for decompilers, which commonly miss (e.g., Binary Ninja [119]), truncate (e.g., Ghidra [77]), or otherwise erroneously perturb them (e.g., Reko [45]).

- **Defects from Specific Compilation Configurations.** Lastly, we see many issues stemming from *compilation* diversity, such as function recovery defects specific to MacOS Mach-O (e.g., Angr [96], Ghidra [68]) and Windows PE binaries (e.g., Binary Ninja [128]). Additional challenges arise under certain compiler optimizations; for instance, Ghidra [71] and Angr [93] face difficulties with calling convention recovery under MSVC's `/LTCG` (link-time code generation) and GCC's `-Ofast` optimizations, respectively. Furthermore, we see source constructs present unique semantic recovery challenges depending on the executable format they are compiled into, as demonstrated by Binary Ninja's and Ghidra's errors on floating-point function arguments from PE binaries ([69] and [70], respectively).

As binary-oriented systems tasks such as malware analysis, vulnerability discovery, and security hardening all depend on *accurate* decompilation, decompiler developers are working aggressively to fix errors and prevent misleading their users with inaccuracies or failures. However, the lack of a systematic testing approach leaves today's decompiler developers overwhelmingly relying on *manual* bug discovery (e.g., Table 1), limiting their ability to proactively identify critical, semantics-affecting defects. Enhancing the reliability of decompilers thus demands moving beyond cumbersome manual bug-finding and adopting **automated, *practical* testing techniques that thoroughly explore the complex interplay between source *and* compilation diversity** in binary code.

3 Challenges of Testing Decompilers

To automate discovery of semantics-affecting decompiler defects, a handful of decompiler testing efforts have emerged over the years (Table 2): Cornucopia [89], DecFuzzer [54], D-Helix [142], and DSmith [20]. Unfortunately, as we show below, these approaches are fundamentally limited in achieving systematic, practical decompiler defect discovery. In the following, we weigh their trade-offs with respect to addressing the three main challenges of automated decompiler defect discovery: **(1) source construct diversity**, **(2) compilation diversity**, and **(3) supporting *all* decompilers**.

Approach	Source Diversity			Compilation Diversity					Decomp.
	Exprs	Ctrl	Data	Comp	Opts	ELF	PE	Mach-O	Agnostic
DecFuzzer	✔	👎	👎	1	✗	✔	✗	✗	✔
Cornucopia	✔	✔	✔	2	✔	✔	✗	✗	✔
D-Helix	✔	✔	👎	2	👎	✔	✗	✗	✗
DSmith	✔	👎	👎	1	👎	✔	✗	✗	✔
BIN2WRONG	✔	✔	✔	6	✔	✔	✔	✔	✔

Table 2: Survey of state-of-the-art decompiler testing works. ✔ = full support; ✗ = no support; 👎 = limited or poor support.

3.1 Challenge 1: Source Construct Diversity

Varying source constructs pose unique hurdles for decompilation, complicating reconstruction of high-level program logic and structure. For example, both `switch-case` and `if-else` statements are often compiled-down into jump tables [80], challenging decompilers' differentiation of the two. To this end, modern decompilers devote significant analyses and heuristics to recovery and refinement of distinct source constructs [50]. Moreover, decompilers frequently differ in handling specific constructs (e.g., `gotos` [15]), meaning that the same source often produces disagreeing results among decompilers. Thus, maximizing diversity of input source code is crucial to scrutinizing decompilers' underlying capabilities and accuracy in handling real-world binaries.

Limitations: In examining today's leading automated decompiler testing efforts (Table 2), we observe varying support for many of today's most common source code constructs. Although each considers control-flow like loops, conditional branches, function calls and returns, and `gotos`, both DSmith and DecFuzzer entirely omit `switch-case` statements, limiting their ability to thoroughly evaluate decompilers' control-flow recovery. Further, almost all exhibit limitations in supporting various types of literals: DecFuzzer, DSmith, and D-Helix all fail to support floating-point literals; while DecFuzzer and DSmith additionally exclude string literals because their underlying source code generation tooling does not yet support them [139]. Omitting common source constructs drastically reduces the scope of previous methods, **leaving them unable to catch many critical decompiler defects likely to emerge in practice**.

3.2 Challenge 2: Compilation Diversity

Modern compilers have unique code generation strategies and internal algorithms, creating vast differences in their resulting binary code. For example, virtual dispatch tables take on fundamentally disparate forms when compiled by MSVC versus GCC [14]. As a result, identical source overwhelmingly yields *different* binaries when compiled by multiple compilers. This entropy is further increased by compiler *optimizations*, which additionally obscure precise disambiguation of control and data constructs; for example, MSVC's aggressive data and code inlining [60]. Furthermore, platform-specific executable file formats—Windows' PE, Linux's ELF, and MacOS's Mach-O—have fundamentally unique binary layouts,

necessitating decompilers' specialized handling of each [25]. Because reverse engineering—and thus, decompilers—targets *every* software ecosystem, it is thus crucial to identify and characterize the kinds of errors that decompilers encounter across the vast space of possible compilation configurations.

Limitations: While prior decompiler testing works vary in the diversity of the source constructs they examine, they are even more restricted in their exploration of binary compilation parameters—**hardcoding themselves specific, hand-chosen compilation configurations, making them unable to automatically explore *others***. All four cover no more than *two* compilers: D-Helix and Cornucopia focus exclusively on GCC and Clang, while DSmith and DecFuzzer limit themselves to only GCC. In terms of optimizations, Cornucopia examines nearly all possible GCC and Clang optimization levels, whereas the others are more constrained: D-Helix is limited to `O0` and `O2-O3`, D-Smith explores `O0-O3` and `Os`, and DecFuzzer omits optimizations altogether. Additionally, these approaches consider only the Linux ELF executable format, entirely neglecting PE and Mach-O binaries. Moreover, their designs are rigid and hardcoded to specific compilation parameters, **preventing them from automatically exploring the diversity of binaries generated from a single input source code**—and the decompilation defects these variations might introduce—without additional effort and re-engineering.

3.3 Challenge 3: Broad Decompiler Support

Modern binary decompilers exhibit considerable diversity in their implementations, encompassing different programming languages, internal code representations, and degrees of transparency. While many are open-source (e.g., Angr [132], Ghidra [78], and Rev.Ng [24]), some of today's most widely-used decompilers are commercial products and hence remain fully or partially closed-source, limiting insight into their underlying internals (e.g., Binary Ninja [108], IDA Pro [36], and JEB3 [81]). Therefore, a comprehensive vetting approach is required that is supportive of *all* decompilers—regardless of their architectural design variations or transparency.

Limitations: Most previous approaches prioritize scalability by treating decompilers as black-box systems, analyzing only their output C code. In contrast, D-Helix operates directly on the *non-C* Intermediate Representations (IRs) used internally by decompilers prior to final code generation. Yet, such approach requires costly, *per-instruction semantic modeling*—further burdened by the vast differences between decompiler-specific IRs (e.g., Angr's `VEX` vs. Binary Ninja's `LLIL`, `MLIL`, and `HLIL` IRs). Currently, D-Helix only supports Ghidra's `P-code` and Angr's `VEX` IRs, leaving others (e.g., Rev.Ng's LLVM IR [24]) **beyond its reach**. According to its developers [142], extending D-Helix to *other* decompilers' IRs—which often differ significantly in semantics [42]—demands considerable manual effort and domain expertise on the order of **40 days' time per unique decompiler integration**.

Motivation: Thoroughly vetting binary decompilers requires a multifaceted testing approach that accommodates ***all* decompilers** whilst accounting for every factor influencing executable code generation. We propose a holistic view of binary mutation—**integrating diverse source code, multiple compilers, and varying optimizations and executable formats *simultaneously***—to maximize the detection of semantic decompilation defects across *different* decompiler platforms, irrespective of their internal differences or level of transparency.

4 BIN2WRONG: Systematic, Practical Fuzzing for Binary Decompilers

To tackle the limitations of prior decompiler testing approaches, we present BIN2WRONG (Figure 1): a general-purpose fuzzer for uncovering decompilation semantic bugs whilst supporting *any* decompiler—irrespective of internals or transparency. We detail our high-level design of BIN2WRONG's key components below.

4.1 Mutation of Binary-affecting Dimensions

Recent work shows [57, 133] fuzzing is most effective when mutation is *maximized*—randomly distributing mutations across a target program's *entire* input space rather than only along a small portion. Yet, while binaries are distinctly influenced by source, compilers, optimizations, and executable formats, **current decompiler testing approaches limit exploration to only a *small* part of this vast input space**. DecFuzzer [54] focuses on source alone, eluding optimizations entirely; and similarly, prior approaches [20, 89, 142] consider only GCC and/or Clang, excluding other compilers—and consequently—other binary formats like PE and Mach-O.

To overcome these limitations, we propose a holistic approach to decompiler-oriented fuzzing, where source code and compilation parameters are treated and mutated as a *single, unified* testcase. Below, we describe BIN2WRONG's overarching **unified binary testcase construction** (Figure 2), and explain how its components work together to enable a deeper exploration of more diverse binary semantics—and more effective decompiler fuzzing—than previously possible.

4.1.1 Unifying Source and Compilation Mutation

With AFL++ [29] came new possibilities in implementing domain-specific mutators through its versatile *custom mutator API* (e.g., [86, 140]). Building on these capabilities, we develop BIN2WRONG's decompiler-oriented binary mutation via a suite of custom AFL++ mutators targeting both source- and compilation-level modifications, detailed below.

4.1.2 Mutating Compilation

As § 3.2 shows, different compilers, formats, and optimizations produce unique binaries even from identical source, chal-

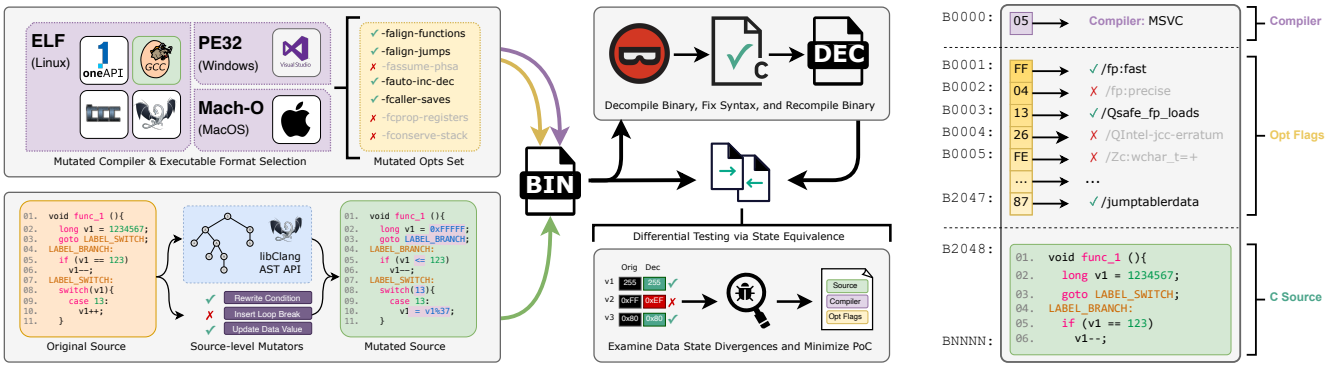

Figure 1: BIN2WRONG's high-level fuzzing workflow in a setup targeting Binary Ninja.

Figure 2: Our unified testcase design.

lenging decompilers' recovery of higher-level code from varied binary structures (Table 1). Rather than restrictively *hard-code* compilation parameters like prior approaches (Table 2), BIN2WRONG reshapes compilation diversity as a fuzzing *mutation* technique: randomly selecting the compiler—and further—randomly toggling-on its available optimizations. Accordingly, BIN2WRONG's unified testcase construction (Figure 2) dedicates **the first 2048 bytes** to encode the fuzzer-mutated compilation parameters: byte `0` specifies the compiler, while bytes `1-2047` are each mapped to individual optimization flags specific to the chosen compiler. Upon selecting a testcase from its queue, BIN2WRONG modifies the compiler byte to one of its six supported compilers; while mutating optimization bytes to either *odd* or *even* numbers, denoting whether that optimization is enabled or disabled, respectively.

Compiler and Executable Format: Since BIN2WRONG is built atop the Linux-based fuzzer AFL++ v4.09c [29], it naturally supports Linux-native compilers such as GCC and Clang. In further maximizing compilation diversity across Linux's ELF binary format, we incorporate several mainstream Linux ELF compilers **unexplored by prior decompiler testing approaches**: Tiny C (TCC) [17], which aims to speeds-up compilation performance; as well as Intel's oneAPI DPC++ (ICX) [38], which uses advanced x86-specific optimizations.

Unfortunately, no Linux-based compilers support *non-*Linux formats MacOS's Mach-O and Windows' PE, leaving such approach unable to find their related bugs (e.g., Angr [96], Ghidra [71]). Yet, we see opportunities in cross-platform compatibility layers that run non-Linux code *on Linux* (e.g., WINE [2], Darling [26]). We leverage these tools to extend BIN2WRONG to non-ELF compilers—Apple's Xcode compiler (AppleClang) [4] for Mach-O, and Microsoft's Visual Studio Compiler (MSVC) [61] for PE—making BIN2WRONG **the first decompiler fuzzer spanning ELF *and* non-ELF formats *altogether***.

Optimization Selection: After selecting a compiler for the eventual binary, BIN2WRONG mutates its choice of the optimization options specific to that compiler, spanning a total of **1,029** total options for GCC v11.4.0, **1,378** for Clang v18.0.0, **7** for TCC v0.9.27, **1,174** for ICX v2024.0.2, **217** for MSVC v19.38.33134, and **1,378** for AppleClang v18.0.0. Should BIN2WRONG's compilation mutation later select a *different* compiler (e.g., MSVC→ ICX), BIN2WRONG remaps its 2,047 optimization bytes to the corresponding set for the *new* compiler. If incompatible optimizations result that prevent compilation, BIN2WRONG defaults to one of the compiler's standard optimizations (e.g., `-O1` to `-O3` for ICX), thus resolving 100% of optimization-related compile issues.

While BIN2WRONG's high-level optimization mutation is inspired by Cornucopia's [89], Cornucopia is built to explore only a single compiler's optimization suite at a time, and therefore cannot generalize across different compilers and formats in any one campaign. Comparatively, BIN2WRONG's ability to explore *multiple* compilers' optimizations simultaneously enables it to encompass **5,183** optimizations in total versus Cornucopia's 892 explored Clang-based optimizations—resulting in a far greater binary diversity from **BIN2WRONG's inclusion of both ELF and non-ELF compilers *and* their optimizations**.

Our Approach: Framing compilation diversity as a fuzzing mutation allows for **dynamic exploration of varied, compilation-dependent binary semantics**—enabling broader exploration than prior decompiler testing approaches that rely on hardcoded compilation parameters.

4.1.3 Mutating Source Code

Following compilation mutation, BIN2WRONG explores varied code semantics through its source-level mutators. We model BIN2WRONG's testcases after those in prior compiler [139] and decompiler fuzzers [54], each consisting of a single function targeted for source mutation. To minimize risk of syntax-breaking mutations, we use the LLVM [52] framework's libClang abstract syntax tree (AST) API [56] alongside our own suite of AFL++ custom mutators.

Informed by our survey of real-world semantic bugs (Table 1), we implement the following *expression*-level mutators to probe decompilers' recovery of complex data-affecting instruction sequences (e.g., Ghidra [75], Binary Ninja [121]):

- **Expressions:** Deleting an entire expression; or duplicating it immediately after the original one:
  e.g., `v0 = v1++;` → `v0 = v1++; v0 = v1++;`
- **Sub-expressions:** Deleting or duplicating sub-expressions; or expanding with an existing one:
  e.g., `v1/v4;` → `v1/v4 + (v1%v2);`
- **Operators:** Randomly replacing arithmetic/bitwise operators; or flipping increments/decrements:
  e.g., `(v1*v2)-(v3++);` → `(v1/v2)*(v3-);`

To test decompilers' recovery of complex control-flow logic (e.g., RetDec [9], Angr [105]), we additionally implement the following *control structure* mutators:

- **Loops:** Inserting a conditional `break` or `continue` with a random threshold at a random location:
  e.g., `for (i=0){}` → `for (i=0){ if(i>37) break; }`
- **Conditional Branches:** Replacing the condition with a always-`true` or always-`false` condition:
  e.g., `if(v2/v3 == 0){}` → `if(1){}`
- **Unconditional Branches:** Replacing a `goto` destination with a randomly-chosen existing label:
  e.g., `goto LABEL_BRANCH;` → `goto LABEL_SWITCH;`
- **Switch-Cases:** Replacing the `switch`'s expression with a randomly-selected existing case value:
  e.g., `switch(v1){ case 2: ... }` → `switch(2){...}`

Lastly, to find bugs stemming from imprecise data object, type, and value recovery (e.g., Binary Ninja [119], Ghidra [74]), we implement the following *data-level* mutators:

- **String Literals:** Replacing with a randomly-chosen string literal; or flipping one or more bytes:
  e.g., `char *v0="Global";` → `char *v0="0xFFFFal";`
- **Numerical Literals:** Replacing with a random number; or flipping its sign or one or more bytes:
  e.g., `(v1/55)+(0xFF*v2);` → `(v1/-55)+(0x00*v2)`
- **Numerical Typecasts:** Replacing with a random numerical type (e.g., `int`, `short`, `float`, `long`):
  e.g., `(short) v3/25);` → `(float) v3/25);`

Preventing Semantically-invalid Mutations: To avoid the risk of semantically-invalid mutations that lead to runtime crashes when executing generated binaries, BIN2WRONG's source mutators are designed to operate **conservatively**—deliberately avoiding injecting, deleting, or moving variable *declarations*. Without such safeguards, BIN2WRONG rapidly encounters semantics-related errors from missing or erroneously-placed declarations. We further build our mutators around AST-node-specific guardrails, such as placing `continue` or `break` statements only within loop bodies. While we see opportunities for more guardrails—for example, deliberately injecting source code that will not be optimized-out by the corresponding optimization flags selection—we posit that the runtime costs of additional checks likely outweighs their benefits, and that mutation quality ultimately does not hinder BIN2WRONG's overall performance, as shown by its strong results in our evaluation (§ 5).

Supported Constructs and Flexibility: While BIN2WRONG supports common source constructs—expressions, control logic and structures, and data objects, types, and values—we see room for incorporating additional ones (e.g., `union`, `struct`, and arrays). Whereas other fuzzers inherit limitations from their bespoke, non-exhaustive AST manipulation tooling (§ 3.1), an advantage of BIN2WRONG's design is that its source mutators operate **directly on Clang's robust AST** interface [56]. Adding new mutators targeting other AST node types requires minimal engineering, as Clang's AST already provides access to these and all other AST nodes.

Our Approach: By bridging AST-level source mutations with compilation mutations, general-purpose fuzzing can **explore the expansive range of diverse source and compilation *combinations***—achieving unprecedented binary diversity for *systematic* decompiler testing.

4.2 Decompiler-agnostic Semantic Testing

Following testcase mutation, BIN2WRONG compiles the binary according to the specified compilation parameters and forwards it to the targeted decompiler. Drawing inspiration from previous works [54, 139], BIN2WRONG employs *differential testing* to detect cases where decompiler-emitted code semantics *diverge* from the original program's. Below, we outline the core techniques enabling BIN2WRONG's discovery of semantics-affecting decompiler bugs.

4.2.1 Recompilation-oriented Syntax Patching

Since small syntactical errors prevent entire programs from being recompilable, we perform minor syntax corrections on decompiled code. Our high-level recompilation-oriented syntax patching spans the following basic strategies:

- Resolving compilation-blocking variable type mismatches:
  e.g., `void* const str;` → `char *str;`
- Renaming objects that differ from their intended names;
  e.g., `void __cdecl func_1()` → `void func_1()`
- Injecting macros to resolve decompilers' custom types:
  e.g., `word32 v0;` → `typedef int32_t word32;`
- Culling, replacing, or adding externs for decompiler-introduced macros, symbols, and functions:
  e.g., `movss(a);` → `extern float movss(float a);`

While some recompilation failures are not easily solved via basic syntax patching, we see a major improvement in post-patching recompilation success, rising from 11.60% to **47.8%** on average—comparable to D-Helix's reported 45% recompilation rate for Angr [142]. Importantly, such failures do not prevent BIN2WRONG's finding of *the most* bugs in our evaluation (Table 6); and moreover, no developers reported any false-positives caused by our syntax patching. We weigh additional strategies for improving recompilation success in § 6.2.

4.2.2 Bug-finding via Differential Execution

To uncover subtle semantic bugs (e.g., Table 1), we adopt Csmith [139]'s approach of *variable*-level differential execution checking. Like other fuzzers', BIN2WRONG's generated programs serve as the *decompilers'* inputs and are designed to be fully self-contained, requiring no external inputs. Each program deterministically exercises its logic based solely on internal control and data flows, ensuring reliable and repeatable semantic comparison across original and decompiled forms. Accordingly, we modify BIN2WRONG-generated testcases' source functions to initialize a suite of "placeholder" globals, which eventually assume their values from the mutated testcase's *local* variables. Post-decompilation, we instrument all globals in the original and recompiled programs to self-report value-dependent checksums. After executing both, if the recompiled program's checksum *differs* from the original's, we flag it as a *semantics-affecting* defect in the decompiled code.

By focusing solely on decompiler-emitted C code, BIN2WRONG extends support to *any* C-targeting decompiler. In contrast, D-Helix's [142] symbolic-execution-based approach needs ***per-decompiler*, *per-instruction* semantic modeling** for decompilers' internal Intermediate Representations (IRs), requiring considerable retooling to support more semantics, as evidenced by their lack of *floating-point* instructions (Table 2), and moreover, its estimated **40 days' time** to support *new decompilers*. BIN2WRONG avoids invasive bug-detection mechanisms, extending semantic correctness testing to *all* C decompilers—**both open- *and* closed-source**—whilst being the first to achieve systematic, unified mutation across all major dimensions of binary generation.

Our Approach: Utilizing the original program as *the correctness oracle* allows for decompiler-*agnostic* testing, eliminating any need for impractical tailoring to decompilers' dissimilar internal IRs—whilst enabling **practical testing of open- *and* closed-source decompilers**.

4.2.3 Post-fuzzing Manual Bug Analysis

Like other fuzzers [29], BIN2WRONG offloads bug post-processing to manual analysis. We spent about 10 minutes manually minimizing each bug-exposing testcase, in-line with the duration reported by DecFuzzer's authors [54], before deduplicating them into distinct *unique* bugs. While conventional fuzzers benefit from a rich ecosystem of automated fault localization tools (e.g., [87]), no analogous tools exist for binary decompilers; hence, we relegate fault localization to the best-equipped domain experts—decompilers' own developers—and promptly report all bugs we find.

5 Evaluation

Our evaluation of BIN2WRONG is guided by the following fundamental questions:

- **Q1. Testing Depth:** Is BIN2WRONG more effective at exercising decompilers' internals?
- **Q2. Bug Discovery:** Does BIN2WRONG reveal more decompiler semantic correctness bugs?
- **Q3. New Results:** Where do decompilers struggle in handling source and compilation diversity?

5.1 Experimental Setup

We evaluate BIN2WRONG alongside state-of-the-art decompiler fuzzers Cornucopia and DecFuzzer across seven highly popular decompilers: the free and open-source Angr [132], R2Ghidra (Radare2+Ghidra) [1], Reko [49], Relyze [85], RetDec [6], and Rev.Ng [24]; as well as the commercially-sold decompiler Binary Ninja [108]. We omit D-Helix [142] as it unfortunately only supports two of our seven decompilers; as well as DSmith [20] as its source diversity is far more constrained than DecFuzzer's, excluding basic increment/decrement operators, jumps, and many common numerical data types [19]. As BIN2WRONG is built atop AFL++ v4.09c [29], we configure it in grey-box mode for the five decompilers supportive of its QEMU-based coverage tracing [16]—Binary Ninja, R2Ghidra, Reko, RetDec, and Rev.Ng—and coverage-agnostic black-box mode for Angr and Relyze.

We configure DecFuzzer's and Cornucopia's compilation parameters according to their respective papers: DecFuzzer with GCC and `-O0`, and Cornucopia with Clang and its full optimization suite. Per DecFuzzer's procedure [54], we seed all fuzzers with a corpus of Csmith-generated C programs (10 in total). Because Csmith omits certain constructs—most notably string literals—we manually augment its generated seed programs to include these elements. Following [43], we repeat all experiments for five trials; and compute Mann-Whitney U's statistical test at p=0.05 significance in comparing BIN2WRONG to Cornucopia and DecFuzzer (with statistically-significant p-values shown **bolded**). We perform all experiments on Ubuntu 22.04 machines, each with an Intel Core i9-12900K CPU and 64GB RAM.

5.2 Q1: Decompiler Testing Depth

In the following sections, we weigh BIN2WRONG's effectiveness in enabling in-depth decompiler testing through its impact on binary diversity and decompiler code coverage.

5.2.1 Binary Diversity

Rigorously testing decompilers demands binaries that *maximize* internal diversity. To assess BIN2WRONG's diversity, we measure binary similarity scores against Cornucopia and DecFuzzer using three industry-standard diffing algorithms:

DiffTool	BIN2WRONG Binary Diffing Scores per Dimension(s) of Source, Compiler, Optimization							BIN2WRONG-ALL Relative Mean Diffing Score Δ			
	ALL THREE	SRC+COM	SRC+OPT	COM+OPT	ONLY SRC	ONLY COM	ONLY OPT	over Cornucopia	MWU p	over DecFuzzer	MWU p
BinDiff	0.627	0.544	0.332	0.623	0.321	0.539	0.326	10.398 ×	**0.009**	17.189 ×	**0.011**
Radiff2-M	0.490	0.368	0.096	0.489	0.086	0.366	0.094	9.119 ×	**0.010**	16.941 ×	**0.007**
Radiff2-L	0.572	0.437	0.120	0.571	0.107	0.436	0.116	7.131 ×	**0.009**	16.089 ×	**0.011**

Table 3: Comparison between BIN2WRONG's mean binary diffing scores across all mutation dimension(s) for each diffing algorithm; and BIN2WRONG's overall scores relative to state-of-the-art decompiler fuzzers Cornucopia and DecFuzzer.

(1) Zynamics' BinDiff [143]; **(2)** Radiff2's Eugene W. Myers' $O(ND)$ Diffing Algorithm [62] (**Radiff2-M**); and **(3)** Radiff2's Levenshtein's Edit Distance [53] (**Radiff2-L**). We configure each to generate 1,000 testcases for each of their 10 Csmith-generated seed programs, totaling 10,000 testcases per competitor. We compute all three diff scores per generated binary relative to its seed binary, and report mean score across all comparisons. Table 3 shows the five-trial mean diversity per BIN2WRONG's supported mutation configurations—source, compiler, optimization, and all combinations thereof—alongside those of Cornucopia and DecFuzzer.

Results: Overall, BIN2WRONG-generated programs achieve **7.13–10.39**× and **16.08–17.18**× binary diversity relative to Cornucopia and DecFuzzer, respectively. In our ablation study of BIN2WRONG's full mutation modes, we see that mutating across *all* dimensions—source, compiler, *and* optimizations (column "ALL THREE" in Table 3)—yields the highest binary diversity across all three diffing algorithms, underscoring that **systematic, unified mutation *maximizes* binary diversity**.

5.2.2 Decompiler Code Coverage

As prior work shows [27], higher code coverage increases the likelihood of finding semantics-affecting defects. To determine whether BIN2WRONG's high-diversity inputs yield greater decompiler code coverage, we measure the coverage of BIN2WRONG, Cornucopia, and DecFuzzer on all coverage-tracing-compatible decompilers: Binary Ninja, R2Ghidra, Reko, RetDec, and Rev.Ng. For tracing coverage, we utilize the AFL-QEMU-Cov [28] tool, as it supports both open- and closed-source decompilers; however, because AFL-QEMU-Cov does not support Reko, we instead use AFL++'s built-in AFL-Showmap [29] utility to trace Reko's code coverage. We report the mean edge coverage results across five 24-hour trials per competitor, as shown in Table 4.

Decompiler	BIN2WRONG's Relative Increase over Cornucopia				over DecFuzzer			
	Δ COV	MWUp	Δ BIN	MWUp	Δ COV	MWUp	Δ BIN	MWUp
Bin.Ninja	1.091 ×	**0.008**	8.189 ×	**0.008**	1.215 ×	**0.008**	123.694 ×	**0.011**
Reko	0.989 ×	**0.008**	4.035 ×	**0.008**	0.973 ×	**0.008**	18.335 ×	**0.012**
R2Ghidra	1.344 ×	**0.012**	1.294 ×	0.421	1.451 ×	**0.008**	42.522 ×	**0.011**
RetDec	1.341 ×	**0.008**	0.798 ×	0.222	1.704 ×	**0.008**	26.201 ×	**0.007**
Rev.Ng	1.073 ×	**0.008**	16.836 ×	**0.008**	1.395 ×	**0.008**	297.763 ×	**0.011**
GeoMean:	**1.16** ×		**3.56** ×		**1.32** ×		**59.61** ×	

Table 4: BIN2WRONG's mean coverage (COV) and ratio of coverage-increasing binaries (BIN) relative to competitors.

Results: BIN2WRONG achieves mean **1.16**× and **1.32**× code coverage relative to Cornucopia and DecFuzzer, respectively, with all improvements showing statistically-significant p-values (< 0.05). Although BIN2WRONG shows statistically-significant lower coverage on Reko, it demonstrates substantially higher binary *quality*—the ratio of coverage-*increasing* binaries to total binaries generated—with a mean **3.56**× and **59.61**× relative to Cornucopia's and DecFuzzer's, respectively. This indicates that **BIN2WRONG's binaries exercise considerably more decompiler internals** compared to those generated by prior, *un*-systematic decompiler fuzzers.

Decompiler	Coverage-increasing Binaries by Mutation Configuration						
	ALL THREE	SRC +COM	SRC +OPT	COM +OPT	ONLY SRC	ONLY COM	ONLY OPT
Bin.Ninja	73.93%	0.04%	22.31%	3.26%	0.00%	0.00%	0.45%
Reko	82.47%	0.00%	16.64%	0.88%	0.00%	0.00%	0.00%
R2Ghidra	79.32%	0.02%	20.59%	0.07%	0.00%	0.00%	0.00%
RetDec	77.44%	0.00%	22.52%	0.03%	0.00%	0.00%	0.01%
Rev.Ng	68.56%	0.08%	30.96%	0.39%	0.00%	0.00%	0.00%
Mean:	**76.34%**	**0.03%**	**22.61%**	**0.93%**	**0.00%**	**0.00%**	**0.09%**

Table 5: BIN2WRONG's mean distributions of coverage-increasing binaries across all mutation dimension(s).

Furthermore, in an ablation study measuring the coverage impacts of different mutation configurations (Table 5), we observe that mutating source, compiler, and optimization *altogether* consistently produces the most coverage-enhancing binaries. Consequently, **by maximizing binary diversity, BIN2WRONG achieves the highest-overall coverage** across both open- and closed-source decompilers.

5.3 Q2: Decompiler Bug Discovery

We assess BIN2WRONG's effectiveness in identifying *semantic decompilation errors* across seven free and commercial decompilers: Angr, Binary Ninja, R2Ghidra, Reko, Relyze, RetDec, and Rev.Ng. We perform a subsequent manual root cause analysis to deduplicate all fuzzers' uncovered runtime divergences into their *unique* semantics-affecting decompiler defects. We report all identified decompiler correctness errors (Table 6) to their respective developers and maintainers.

Results: Overall, BIN2WRONG uncovers a total of **48** semantic decompilation bugs, **42** of which are uniquely found by BIN2WRONG alone, with **30** confirmed by their respective developers. Comparatively, mutation-restricted approaches Cornucopia and DecFuzzer reveal far fewer bugs—ten and zero, respectively—demonstrating the advantages of **BIN2WRONG's high-diversity, high-coverage systematic binary mutation** in thorough decompiler defect discovery. While § 5.2 suggests many of BIN2WRONG's binaries cover much of the same underlying decompiler logic—a common

Decompiler	Total Bugs Found, Confirmed, and Unique per Approach								
	BIN2WRONG			Cornucopia			DecFuzzer		
	BUGS	CONF	UNIQ	BUGS	CONF	UNIQ	BUGS	CONF	UNIQ
Angr	9	9	8	2	2	1	0	0	0
BinaryNinja	11	11	11	0	0	0	0	0	0
Reko	6	6	4	3	2	1	0	0	0
R2Ghidra	2	2	1	1	1	0	0	0	0
Relyze	7	N/A	6	2	N/A	1	0	0	0
RetDec	11	N/A	10	2	N/A	1	0	0	0
Rev.Ng	2	2	2	0	0	0	0	0	0
Total:	**48**	**30**	**42**	**10**	**5**	**4**	**0**	**0**	**0**

Table 6: Total decompiler bugs found (BUGS), total confirmed (CONF), and total unique (UNIQ) per each testing approach. N/A = instances where our correspondence went unanswered.

phenomenon in fuzzing as a whole—BIN2WRONG's broader strength is in its surfacing of subtle semantic bugs triggered by diverse source, compiler, optimization, and format *combinations*. Thus, we reason that BIN2WRONG's higher bug discovery is more directly related to its higher binary diversity (Table 3), rather than its higher code coverage (Table 4).

5.4 Q3: Analysis of Uncovered Bugs

While prior works categorize decompiler bugs into broad high-level classes (e.g., "Type Recovery" [54]), none delve into the specific *low-level causes*—or their prevalence—behind these critical failures. In the following, we conduct a comprehensive analysis of the semantics-affecting decompiler defects uncovered by BIN2WRONG, identifying their distinct source-related and compilation-related origins, supported by case studies on unique bugs discovered by BIN2WRONG.

5.4.1 Causes of Source-related Defects

Among the 48 semantics-affecting bugs discovered by BIN2WRONG, we identify **data recovery** as the most frequent error source (**68.75%**), followed by **expression** recovery (**20.83%**) and **control** structure recovery (**10.42%**).

Data Object, Type, and Value Recovery: Of the 33 data recovery bugs, we identify two involving incorrectly-recovered data *objects*: the first stems from Binary Ninja erroneously interpreting the `truncf()` function as taking multiple arguments instead of one [58]; while the second arises from Reko misordering function arguments, despite recovering them correctly otherwise. Table 7 presents a breakdown of the remaining 31 data-related bugs, categorized by *type* and *value* errors across integer, float, and string variables and literals. Although decompiler performance varies across data constructs, BIN2WRONG reveals several type recovery issues specifically related to **floating-point** data, which we discuss below.

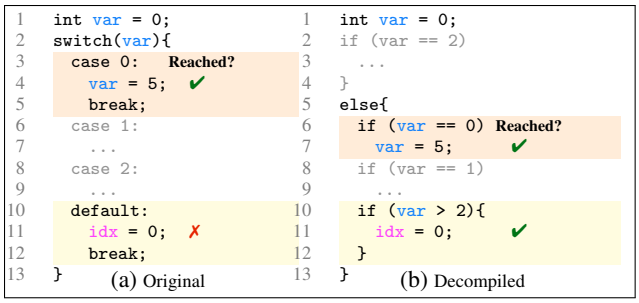
Case Study: Floating-point Recovery. Figure 3 shows a BIN2WRONG-found error in floating-point recovery affecting Binary Ninja, Angr, and Reko. In binaries, floating-point values follow the IEEE-754 format, with instructions like `movss` for single-precision and `movsd` for double-precision, distinct from those used for integers. Although decompilers

	Integers				Floats				Strings			
	Value		Type		Value		Type		Value		Type	
	VAR	LIT	VAR	LIT	VAR	LIT	VAR	LIT	VAR	LIT	VAR	LIT
Angr	1	3	2	1	0	0	0	1	0	0	0	0
Bin.Ninja	0	0	1	2	0	0	0	1	0	1	0	0
Reko	0	0	0	0	0	1	0	0	0	2	0	0
R2Ghidra	0	1	0	0	0	0	0	0	0	0	0	0
Relyze	1	1	1	1	0	0	0	0	0	2	0	0
RetDec	1	4	2	0	0	0	0	1	0	0	0	0
Rev.Ng	0	0	0	0	0	0	0	0	0	0	0	0

Table 7: Summary of BIN2WRONG-uncovered data *type* and *value* bugs spanning variables (VAR) and literals (LIT).

accurately recognize floating-point *instructions* in disassembly (e.g., line#2 in Figure 3), they often fail to convert the hexadecimal representation of floating-point values *back* to their original form; instead, they output the *hex* form directly, incorrectly interpreting these values as integers rather than recovering them as floating-point numbers. These issues highlight the critical need to consider **diverse data constructs**, underscoring limitations of approaches like DecFuzzer, DSmith, and D-Helix which fail to support floating-point data (§ 3.1).

```
1  movsd xmm0,[rbp];
2  double v0 = 1.0;
```
(a) Original



```
1  int64_t v1 =
2  0x3FF0000000000000;
```
(b) Decompiled

Figure 3: Erroneous type recovery of float-point data as integers, affecting Angr, Binary Ninja, and Reko.

Expression and Control Recovery: We analyze the eight expression-related semantic errors identified by BIN2WRONG and categorize them into two groups. Four involve misrecoveries of **individual arithmetic operators**: incorrect handling of the modulo operator and interpreting signed comparisons as unsigned (Binary Ninja); unnecessary multiplication symbols (Reko); and reversing arithmetic operators to their opposites (RetDec). Our remaining four errors arise from mishandled parsing and refinement of **data-affecting instruction sequences**, including: inaccurate propagation of modulo results (Angr); erroneous omission of instructions preceding inlined function code (Binary Ninja); extraneous operations (Relyze); missed constant-affecting operations (RetDec); and functions that fail to parse correctly (both Reko and RetDec).

Of the five bugs arising from control structure recovery, only one involves loops (R2Ghidra), while the remaining four are related to `switch-case` structures (2×Binary Ninja, 2×Rev.Ng). Figure 4 presents a BIN2WRONG-uncovered bug exposing `switch-case` recovery challenges uniquely faced by commercial decompiler Binary Ninja.

Case Study: Switch-Case Logic Recovery. In programs with `switch-case`s, Binary Ninja's medium-level intermediate representation (IR) accurately translates `case` statements into semantically-equivalent nested `if-else` statements, preserving the intended logic. However, during translation to higher-level IR, Binary Ninja incorrectly *breaks* these into separate `if` statements. Although the conditions—the original `case` values—remain correct, this restructuring makes

(a) Original (b) Decompiled

Figure 4: Incorrect switch-case recovery, making the original "case 0" and "default" blocks erroneously reachable.

multiple code blocks *reachable*, leading to divergent execution and incorrect program outputs. Binary Ninja's developers classified this bug as **High Severity**, indicating the need for a substantial overhaul of their core control-flow restructuring—underscoring the critical role of **diverse control constructs** in BIN2WRONG's systematic decompiler correctness testing.

5.4.2 Causes of Compilation-related Defects

We further examine the influence of different compilers, executable formats, and optimization flags on decompilation defects. Table 8 details the compilation parameters for all of BIN2WRONG's 48 uncovered decompiler bugs.

	Binary Formats & Associated Compiler(s)						# Opts		
	ELF				PE	Mach-O			
	CLANG	GCC	TCC	ICX	MSVC	APPLE	0	1	2+
Angr	9	7	7	9	4	9	9	0	0
Bin.Ninja	8	7	4	8	4	8	8	1	2
Reko	2	2	2	2	2	2	2	0	0
R2Ghidra	4	4	5	4	3	4	6	0	0
Relyze	7	5	5	6	3	0	7	0	0
RetDec	9	7	6	7	5	8	10	0	1
Rev.Ng	2	2	2	2	2	0	2	0	0

Table 8: High-level summary of the compilation parameters for all BIN2WRONG-discovered semantic bugs.

Optimization-dependent Bugs. Although most bugs are not directly caused by compiler optimizations, we observe that various optimizations are key to exposing intricate edge cases. We find three such bugs (2×Binary Ninja, 1×RetDec) from combinations of **two or more** optimizations, where decompilers produced only partial code and missed significant logic. Additionally, one bug, triggered only by the `-O1` optimization level, led to errors in loop logic recovery (in Binary Ninja). We detail the latter example below, shown in Figure 5.

```
while (v0!=11) { v0++ };
```
(a) Unoptimized code.

```
while (v0!=0xFFF5) { v0-- };
```
(b) Optimized & decompiled.

Figure 5: Binary Ninja bug stemming from the `-O1` optimization negating the loop constraint, causing divergent `v0` values in the original and decompiled programs post-loop-execution.

Case Study: Optimized Loop Recovery. Shown in Figure 5 is a `while` loop with counter incremented on each iteration, breaking only on count `11`. When compiled with `-O0`, the binary closely resembles this original structure; however, with `-O1`, the compiler replaces `11` with `-11` and the increment operation with a *decrement*. As negative numbers are stored in two's complement, Binary Ninja incorrectly recovers only this form, deviating from the original loop's semantics. BIN2WRONG caught this via the different `v0` values seen in the original and decompiled programs *post*-loop-execution (i.e., `11` with `-11`, respectively). This issue reiterates the importance of considering **diverse optimizations**—testing decompilers' ability to handle *each* effectively.

Compiler- and Format-dependent Bugs. We identify **eight** bugs uniquely stemming from a *single* executable format (ELF). However, these bugs are triggered by different compilers: four occur only in GCC-compiled binaries, one appears solely in TCC-compiled binaries, and the remaining span two or more compilers. Interestingly, we see the vast majority of bugs span *multiple*—but not all—executable formats and compilers: 14 appear in compilers *other* than GCC, 7 in ones other than Clang, 17 in ones other than TCC, 24 in ones other than MSVC, 10 in ones other than ICX, and 10 in ones other than AppleClang. Figure 6 shows an example bug that eludes PE binaries yet appears in both ELF *and* Mach-O formats.

```
mov r8, z
mov rdx, y
mov rcx, x
func(x, y, z);
```
(a) PE convention & code.

```
mov rdi, x
mov rsi, y
mov rdx, z
func(z, y, x);
```
(b) Mach-O & ELF decompiled.

Figure 6: Call convention bug in Reko on Mach-O & ELF binaries (right) versus the analogous PE form (left).

Case Study: Calling Convention Recovery. In PE binaries, Microsoft's x64 conventions enforces that the first, second, and third integer arguments of a function are passed via registers `rcx`, `rdx`, and `r8`, respectively. Yet for ELF and Mach-O, AMD64's System V ABI instead passes these via `rdi`, `rsi`, and `rdx`, respectively. Shown in Figure 6, Reko's call recovery succeeds on PE binaries, yet *fails* on *non-PE* binaries' conventions, resulting in incorrect argument ordering. Ensuring decompilers' accuracy with these subtle differences reinforces the need to explore **both *ELF* and *non-ELF*** formats.

```
0x100 → 0x200
0x200 → 0x4142
mov rsi, [0x100]
char *s ="AB";
```
(a) Clang convention (one-level indirection) and original code.

```
0x100 → 0x150
0x150 → 0x200
0x200 → 0x4142
mov rax, [0x100]
mov rsi, [rax]
int64_t s =0x200;
```
(b) TCC convention (two-level indirection) and decompiled code.

Figure 7: TCC-specific string literal recovery bug in Reko.

Case Study: Compiler-specific String Recovery. Figure 7 depicts a compiler- *and* source-related bug in Reko. While most compilers store the string's direct memory address, allowing retrieval with a single dereference, TCC introduces an

extra indirection—a pointer to an address holding the actual location of the string, requiring *two* dereferences to access it. This approach presents challenges for decompilers, as seen in Reko, which retrieves only the *first* level of the memory address, leaving the second dereference unresolved. As a result, Reko fails to recognize the additional indirection, obscuring the true content of the string literal—and the program's intended semantics. Such defects demonstrate how binary semantics are uniquely influenced by **variations in both source *and* compilation**, highlighting BIN2WRONG's strengths over prior approaches that largely overlook such diversity.

6 Discussion

Below we discuss potential limitations of this work and our prototype decompiler fuzzer, BIN2WRONG.

6.1 Responses from Decompiler Developers

Developers of Angr, Binary Ninja, R2Ghidra, Reko, and Rev.Ng promptly **confirmed all of BIN2WRONG's uncovered issues as valid** decompilation bugs. Unfortunately, our attempts to contact developers of RetDec and Relyze went unanswered. Fortunately, most developers responded and quickly resolved many of our reported bugs, underscoring the importance of these fixes on the reliability of their tools.

We see that Binary Ninja is the only decompiler whose developers disclose severity scores of publicly-reported bugs, classifying eight of BIN2WRONG's found defects as follows: three *low* severity, four as *medium*, and one as *high* severity. These errors spanned *all three* of Binary Ninja's internal stages: one in its medium-level intermediate language (IL) generation, two in high-level IL, and five in final C code generation. BIN2WRONG's discovered high-severity bug (Figure 4) drew significant attention in particular, **prompting a total overhaul** of Binary Ninja's core control-flow structuring techniques. This bug was later featured in a blog post detailing the efforts taken to improve the soundness of Binary Ninja's decompilation—**further highlighting BIN2WRONG's real-world impacts** in uncovering critical semantic errors in even mainstream, commercially-sold decompilers.[1]

6.2 Reliance on Recompilation

BIN2WRONG's differential testing (§ 4.2.2) relies on *recompiling* decompiled code, with minor patching applied to fix common decompiler syntax errors. As BIN2WRONG's post-patch recompilation rate averages 47.8%—in-line with D-Helix's own 45% post-patching recompilation rate for Angr [142]—many syntax errors remain unresolvable by our current patches. We observe **84.03%** result from undeclared identifiers, **7.51%** from incompatible type conversions (e.g., pointers → integers), **6.24%** from extraneous arguments, **1.49%** from extraneous symbols (e.g., code comments), and **0.52%** from patch conflicts (e.g., BIN2WRONG adding `extern` within expressions). While more advanced program repair will improve recompilation, we posit its overhead will greatly reduces BIN2WRONG's total throughput. Thus, as research suggests *faster* fuzzing is better [63], we prioritize speed over 100% recompilation. Interestingly, the remaining **0.21%** of issues stem from *compiler* errors, typically with Clang or ICX crashing under certain optimization sets. Given their infrequency, we consider identifying and culling these specific conflicts outside our current scope.

6.3 Other Potential Binary Dimensions

Binary obfuscation—such as control-flow flattening, opaque predicates, and virtual-machine-based obfuscation—are often employed to hinder decompilers, typically to protect intellectual property or complicate reverse engineering [23, 107]. BIN2WRONG currently deliberately excludes such techniques, as contemporary decompilers tend to delegate deobfuscation tasks to specialized tools and plugins [35, 109]. However, BIN2WRONG easily supports incorporating obfuscation with minor adjustments, though we leave the exploration and requisite reevaluation of this to future work.

While we also considered linkers in BIN2WRONG's mutation space, our investigation found no prior decompiler bugs where the linker was the true root cause of semantic recovery errors. All linker-related issues we found were limited to syntactic or format-specific parsing failures—e.g., malformed headers or symbol resolution issues that simply prevented the binary from being fully analyzed at all (e.g., [64, 67, 83]). We believe this is unsurprising, as linkers must conform to OS-level specifications (e.g., System V ABI), and thus typically do not touch control/data semantics. As such, we scoped linking out of BIN2WRONG's design, though we anticipate this could be explored in future work focusing on malformed binaries or toolchain robustness.

6.4 Search Space and Bug Discovery Cost

While BIN2WRONG's combined source/compiler/format/optimization search space currently spans 6 compilers, 3 formats, 5,183 optimizations, and dozens of source constructs—easily amounting to trillions of unique binary generation configurations—BIN2WRONG's goal is not to exhaustively search this space, but to sample it broadly and systematically. Inspired by mutation-based fuzzers like AFL++ [29], we find that even simple, random mutations across multiple dimensions are highly effective at uncovering semantic bugs missed by prior tools limited to one or two axes (Table 2). BIN2WRONG's novelty thus lies in unifying diverse mutation dimensions into a single framework—showing that breadth alone, when systematically applied, surfaces impactful bugs that dimension-isolated fuzzers cannot reach. While we envision opportunities to more directly target distinct elements

[1] https://binary.ninja/2024/06/19/restructuring-the-decompiler.html

of this search space that hinder decompilation (e.g., specific source and optimization combinations guaranteed to produce interesting machine code), we leave this to future work.

7 Related Work

Below we discuss recent related research in the areas of binary decompilation, as well as the use of program generation and mutation in other applications of automated testing.

7.1 Recent Advancements in Decompilation

Several works are leveraging advances in machine learning to enhance the recovery of variable *type* information: Coda [30] employs neural networks, while Slade [5] and ReSym [135] utilize large language models. Machine learning is also seeing use in improving recovery of variable *names*, further boosting the human readability of decompiled code. DIRE [51], DIRTY [21], and TYGR [141] all utilize neural networks, whereas VarBERT [79] incorporates additional pre-training on human-written source code to produce more intuitive variable names. Many efforts are also enhancing restructuring and optimization of decompiler-generated *code*—particularly for `gotos`: Phoenix [18], Rev.Ng [24,33], and DREAM [137] aggressively cull `gotos`, while SAILR [15] instead introduces compiler-specific heuristics for eliminating only *spurious* ones. Though these recent advancements largely exist as separate from mainstream decompiler platforms, we expect that future efforts will bridge the gap between academically-sourced decompilation enhancements and industrial decompilers. We foresee BIN2WRONG playing a key role in enabling automated semantic testing of decompilers—and accelerating discovery of their bugs—as these platforms continue to evolve with increasing sophistication each year.

7.2 Program Generation and Mutation

A cornucopia of program generation and mutation techniques have emerged from the field of compiler fuzzing: Csmith [139], Rustsmith [88], and YARPGen [55] randomly generate grammar-conforming programs, while GrayC [27] mutates existing ones via Clang's AST API. More recently, Whitefox [138], GoFuzz [32], and Fuzz4All [134] instead use LLMs to explore more diverse source code constructs. As BIN2WRONG builds upon the program generation and mutation popularized by compiler fuzzing, we expect future synergistic approaches to extend BIN2WRONG's to other compiled languages. For instance, incorporating other language-specific AST APIs will help BIN2WRONG test emergent decompilers targeting non-C code, such as Go [41] and Rust [59].

7.3 Grey-box Fuzzers

BIN2WRONG's overall design inherits many design advantages from its core grey-box fuzzer, AFL++ [29]—which itself is one of many mainstream general-purpose fuzzers seeing large-scale adoption today [31]. Yet, standard grey-box fuzzers are not built to find semantic bugs such as decompilation recovery errors, and instead only look for crashing signals (e.g, `SIGSEGV`). While semantic bug-finding is not a new concept [55, 139], to our knowledge, BIN2WRONG is the first system to extend AFL++ with this capability in fuzzing decompilers. We anticipate these components of BIN2WRONG could likely be repurposed for similar semantics-related bug domains (e.g., compiler fuzzing, transpiler fuzzing).

8 Conclusion

Current decompiler testing approaches broadly overlook how source code, compilers, optimizations, executable formats, *and combinations thereof* collectively shape binary executable code. In this work, we show that giving equal consideration to these factors yields significantly more diverse binaries, enabling far more effective testing of decompilers' correctness. Beyond attaining the highest-overall code coverage across seven free and industrial decompilers, our prototype BIN2WRONG reveals the most semantic errors of all decompiler testing approaches—the vast majority of which remain undetectable by prior state-of-the-art methods. At the time of writing, **30 out of 48 decompiler errors found by BIN2WRONG are confirmed by developers**, with several prompting major changes in real-world decompilers.

By embracing principles that make conventional mutation-based application fuzzing successful—namely, maximizing testcase diversity through pursuing as broad of mutation as possible—we show that complex decompiler semantic errors are easily discovered in as little as 24 hours. We thus envision an era where holistic, automated techniques help improve the accuracy of today's many critical binary analysis tools—facilitating faster and more reliable completion of the downstream tasks that rely on these tools' precision.

HEC: Equivalence Verification Checking for Code Transformation via Equality Saturation

Jiaqi Yin* Zhan Song* Nicolas Bohm Agostini† Antonino Tumeo† Cunxi Yu*

*University of Maryland, College Park †Pacific Northwest National Laboratory
{jyin629,cunxiyu}@umd.edu

Abstract

In modern computing systems, compilation employs numerous optimization techniques to enhance code performance. Source-to-source code transformations, which include control flow and datapath transformations, have been widely used in High-Level Synthesis (HLS) and compiler optimization.

While researchers actively investigate methods to improve performance with source-to-source code transformations, they often overlook the significance of verifying their correctness. Current tools cannot provide a holistic verification of these transformations. This paper introduces HEC, a framework for equivalence checking that leverages the e-graph data structure to comprehensively verify functional equivalence between programs. HEC utilizes the MLIR as its frontend and integrates MLIR into the e-graph framework. Through the combination of dynamic and static e-graph rewriting, HEC facilitates the validation of comprehensive code transformations.

We demonstrate effectiveness of HEC on PolyBenchC benchmarks, successfully verifying loop unrolling, tiling, and fusion transformations. HEC processes over 100,000 lines of MLIR code in 40 minutes with predictable runtime scaling. Importantly, HEC identified two critical compilation errors in mlir-opt: loop boundary check errors causing unintended executions during unrolling, and memory read-after-write violations in loop fusion that alter program semantics. These findings demonstrate HEC practical value in detecting real-world compiler bugs and highlight the importance of formal verification in optimization pipelines.

1 Introduction

In the post-Moore era, the pressing need to enhance the runtime performance of computing systems has driven extensive research into optimization strategies. Source-to-source transformations, such as control flow and datapath transformations, have been widely used to advance computing efficiency. Control flow transformations optimize parameters like unrolling and tiling factors to enhance hardware parallelism and performance [3, 45, 55]. Furthermore, there is significant interest in datapath and gate-level transformations [11, 16, 24, 56]. These combined efforts highlight a multi-faceted approach to optimize computing efficiency in various areas, including HLS [14, 15, 27] and compiler optimization [26]. However, the stability and correctness of these transformations are often not guaranteed. It is essential to ensure the equivalence between the programs before and after transformations.

Existing verification approaches typically focus on a single aspect of verification, thus failing to provide a comprehensive framework for verifying multi-domain transformations. For example, Polycheck [7] and ISA [2] attempt to verify equivalence for affine problems, devoted to control flow transformations. Furthermore, Samuel et al. [18] have developed verification methods specifically for datapath transformations in RTL code. These verification tools are limited in scope, and unable to offer comprehensive equivalence checking for both control flow and datapath transformations simultaneously.

As an emerging technique in compiler optimization [12,46], hardware design automation [9, 10, 16, 48, 49, 54, 58], and theorem proving [4, 5, 21, 23], e-graph can represent multiple equivalent expressions within a single graph data structure. This capability enables possibilities of validation between optimized code against its original version. In this work, we propose HEC, a formal equivalence checking framework based on e-graph rewriting. HEC is designed to provide a holistic verification of codes through equality saturation. HEC combines static rewriting rules for datapath transformations with dynamic rewriting capabilities for control flow transformations. The main contributions of HEC are summarized as follows:

- Introducing HEC, an e-graph based verification framework taking MLIR codes as inputs and performing equivalence checking. It simultaneously verifies control flow and datapath transformations, ensuring holistic equivalence checking of multi-domain transformations with equality saturation.
- Designing a hybrid ruleset to combine static rewriting rules with dynamic rewriting capabilities within the e-graph infrastructure, enabling the framework to adapt to runtime-dependent transformation parameters and accommodate diverse transformation patterns.

```

10  }
11 }
```

Listing 4: Variant D

Figure 1: Variants B, C, and D achieve equivalence with the baseline (Listing 1) through loop hoisting, De Morgan's laws, and loop tiling, respectively. This multifaceted transformation, encompassing both datapath and control flow aspects, highlights the challenges in code verification. HEC offers a hybrid, combined solution to address this challenge.

- Introducing a robust graph representation to model MLIR input code, encapsulating both control flow and datapath structures. This representation unifies variable renaming, loop decomposition, and operation tracking, serving as an interface for integration with the e-graph framework.
- Demonstrating the scalability and efficiency of HEC through comprehensive evaluations on PolyBenchC benchmarks. Specifically, HEC can process over 100,000 lines of MLIR code in 40 minutes.
- Identifying two types of compilation errors introduced by the MLIR compiler with `mlir-opt`, in PolyBenchC [40,50] benchmark suite.

2 Motivating Example

Unified datapath/control flow verification: Code transformation is a critical aspect of code optimization, encompassing both control flow transformations and data path transformations. Typical control flow transformations include loop unrolling, tiling, and fusion, etc [19, 42, 47, 59]. Additionally, numerous studies focus on optimizing the computation graph at the operator level for datapath optimization [16, 17, 24, 56]. For instance, Jia et al. [24] optimize deep neural network (DNN) computations through graph substitution. These code optimizations underscore the necessity for rigorous verification of code transformations. In this section, we illustrate the challenges associated with code transformation verification using the example presented in Figure 1.

Listing 1 presents the baseline code that iterates over two vectors, each of length 101. For each pair of elements `a` and `b`, the loop performs the `NAND(a, b)` operation. In Listing 3, a datapath transformation is demonstrated using De Morgan's law, resulting in the `OR(a', b')` operation. Listing 2 and Listing 1 are functionally equivalent through loop hoisting, where the variable `%true` is moved inside the loop body. Similarly, Listing 4 and Listing 1 are equivalent via loop tiling, where the loop on Line 4 in Listing 1 is split into two loops.

However, conventional verification frameworks, including PolyCheck [7] and ISA [2], focus on only one aspect of verification. A holistic verification approach is essential to ensure the correctness and reliability of code transformations across all optimization levels, including control flow and datapath transformations. Individually verifying each transformation layer may overlook complex dependencies and interactions that can lead to subtle bugs or functional discrepancies.

Fortunately, e-graphs [53] enable the simultaneous representation of multiple equivalent program expressions, effectively managing dependencies and interactions between control flow and datapath transformations. They support bidirectional rewriting rules, allowing transformations to be applied flexibly while maintaining equivalence across optimization levels. Additionally, e-graphs offer a compact representation of equivalence classes, reducing computational overhead and enhancing scalability for large codebases. These advantages collectively motivate the development of a novel e-graph based verification approach. In this paper, we introduce how the four variants in Figure 1 are integrated into the e-graph.

Challenges: Although e-graphs provide prominent merits for efficient verification, conventional term rewriting still poses challenges when integrating control flow transformations. For example, loop tiling in Listing 4 creates a new loop variable `%arg2`, and the loop body (lines 6 to 9) replaces all instances that originally consume `%arg1` with the newly created variable `%arg2`. Additionally, the tiling factor (e.g.,

3 in Listing 4) is unknown until the compilation of the e-graph. Consequently, it is challenging to develop a static term rewriting pattern that can universally represent all tiling scenarios across diverse input codes. To effectively incorporate code equivalence checking within the e-graph framework, the rewriting rules must also include information that is only determinable at runtime, such as the specific tiling factor, variable names generated during transformation, and loop bounds that depend on input parameters. In these complex scenarios, *dynamic rewriting* rules must be tailored to the specific characteristics and requirements of the input code. Static rules alone are insufficient to handle runtime-dependent factors, which can vary significantly across different codebases and transformation instances. By customizing dynamic rules, HEC can accurately capture and verify intricate control flow transformation patterns, ensuring robust and reliable code equivalence checking even in highly sophisticated code structures. A more detailed discussion of the presented challenges and dynamic rewriting is provided in Section 4.2.

To this end, we propose HEC, a formal equivalence verification framework utilizing e-graphs with a hybrid approach of static and dynamic rewriting. The integration of both static and dynamic rewriting rules within e-graph ensures robust verification of multi-domain source-to-source transformations. In the following sections, we demonstrate how the different variants from Listing 2 to Listing 4 are verified to be equivalent to Listing 1 using various approaches: HEC graph representation, static rewriting, and dynamic rewriting.

3 Background

3.1 Source-to-Source Equivalence Checking

Code equivalence checking is a critical challenge in software engineering, which involves confirming that two code segments, despite having different syntactic or structural forms, exhibit identical behaviors under all operational conditions. This verification ensures that transformations made for optimization, refactoring, or adaptation do not inadvertently alter the functional output or introduce undefined behavior.

Consider two programs, P_A and P_B, that operate on a common input set I. P_A produces a set of possible outputs O_A, while P_B yields an output set O_B, both corresponding to the input set I. P_A and P_B are deemed functionally equivalent if and only if their output sets are identical for all possible inputs in I. This relationship can be formally expressed as:

$$\forall I, \quad O_A(I) = O_B(I).$$

This equation asserts that for every input I, the output $O_A(I)$ of program P_A must exactly match the output $O_B(I)$ of program P_B, thereby affirming their functional equivalence.

Some studies attempt to establish program equivalence checking across various domains [2, 7, 25, 41, 43, 52]. Weilei et al. [7] introduced PolyCheck, a system designed to verify the equivalence of affine programs and their transformations through dynamic analysis. However, the applicability of PolyCheck is fundamentally limited to affine transformations, thereby restricting its use in broader code transformations. Similarly, other frameworks, such as ISA [2], suffer from restricted transformation coverage. Generally, these frameworks are sensitive to the format of the input code, and none can comprehensively provide equivalence checking that spans data path and control flow transformations simultaneously.

3.2 Multi-Level Intermediate Representation

MLIR [29] (Multi-Level Intermediate Representation) is a compiler infrastructure within the LLVM [28] project. Developed to address the complexity of generating efficient code for diverse hardware targets, MLIR facilitates the co-design of high-level optimizations and hardware-specific transformations. By providing a unified interface for different levels of abstraction, from high-level algorithmic constructs down to low-level hardware instructions, MLIR supports various domain-specific optimizations. Its modular design allows developers to define custom dialects and transformations, making it highly adaptable to various computing paradigms.

Some studies focus on optimizing and transforming the MLIR infrastructure to enhance HLS and code generation. For instance, CIRCT [13] converts MLIR to RTL code, serving as an open-source HLS tool. Cheng et al. [11] propose a MLIR based code optimization explorer based on the e-graph to address the phase-ordering problem [32]. Tools such as HeteroCL [26] and ScaleHLS [57] transform MLIR into HLS C, while other projects like SODA [3] and POLSCA [61] convert it into LLVM IR. Despite these developments, there is a lack of frameworks capable of supporting transformation verification for MLIR.

3.3 Equality Saturation

An e-graph (equivalence graph) is a data structure that compactly represents a congruence relation over expressions [37, 38, 46]. Widely utilized in compiler optimizations, program analysis, and formal verification, e-graph efficiently manages large sets of equivalent expressions by sharing common sub-expressions, allowing it to store an exponential number of expressions in linear space.

An **e-graph** $\mathcal{G}$ is formally defined as a tuple $\mathcal{G} = (N, E, \phi)$:

- N is a finite set of nodes (also called **e-nodes**). E-nodes N represent individual expressions or sub-expressions.
- $E \subseteq N \times N$ is an equivalence relation on N, partitioning N into equivalence classes known as **e-classes**. E-classes are the equivalence classes induced by E. Nodes within the same e-class are considered equivalent under the equivalence relation E. Here E has the property of closure under

congruence [36, 37] which ensures that the equivalence relation is preserved under the application of operators.

- $\phi : N \to \Sigma_k \times N^k$ is a labeling function that maps each node to an operator and a list of child nodes, where:
  - Σ_k is the set of operators of operands number k.
  - N^k denotes an tuple of k child nodes from N.

E-graphs have been used to power the optimization technique called **equality saturation**, which is an optimization process that exhaustively applies a set of rewriting rules to an initial expression within an e-graph until no new equivalence can be added. Formally, the following are defined:

- $\mathcal{G} = (N, E, \phi)$ denotes an e-graph,
- $R = \{(l_1, r_1), \ldots, (l_m, r_m)\}$ is the rewriting ruleset,
- g_0 is the initial expression encoded in $\mathcal{G}_0$.

The process involves three main steps. First, construct $\mathcal{G}_0$ from the initial expression g_0. Second, for each pair $(l_i, r_i) \in R$, identify matches within $\mathcal{G}_t$ and add the equivalences $[l_i]_E \sim [r_i]_E$ to form $\mathcal{G}_{t+1}$ via term rewriting [22]. Finally, iterate until $\mathcal{G}_{t+1} = \mathcal{G}_t$, indicating that no further changes occur. A detailed example of e-graph exploration is shown in Figure 2.

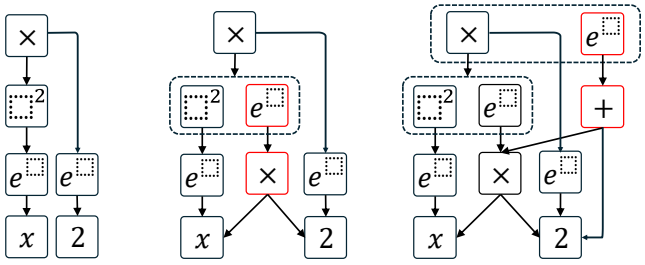

Figure 2: The e-graph rewriting for the expression $(e^x)^2 \times e^2$. **Left**: Initial e-graph. **Middle**: E-graph after applying the rewriting rule $(e^x)^2 \times e^2 \Rightarrow e^{2x} \times e^2$. **Right**: E-graph following the rewriting rule $e^{2x} \times e^2 \Rightarrow e^{2x+2}$. Dotted boxes represent e-classes; arrows show connections between e-nodes and their e-classes. Newly added e-nodes are highlighted in red.

Equality saturation has sparked research interests including compiler optimization [46], hardware design automation [16, 48, 54], theorem proving [4, 5, 21, 23], and more [8, 39, 44, 51, 56]. E-graph is supported by SMT solvers, such as Z3 [20, 21], and Willsey et al. developed an advanced e-graph framework **egg** for equality saturation [53, 60]. In this work, HEC incorporates the egg for e-graph implementation.

Formally, the functional equivalence of two programs P_A and P_B can be defined by representing programs within a shared e-graph $\mathcal{G} = (N, E, \phi)$ and verifying that their corresponding e-nodes $n_A, n_B \in N$ reside within the same equivalence class. Specifically, the e-graph exhaustively applies a comprehensive set of rewriting rules R to capture all possible code transformations. If, after saturation, n_A and n_B can be united in the same e-class, then programs P_A and P_B are deemed functionally equivalent. This approach transforms program equivalence checking into determining e-class membership within the e-graph, thereby ensuring that P_A and P_B exhibit identical behaviors across all inputs I.

4 Proposed Approach

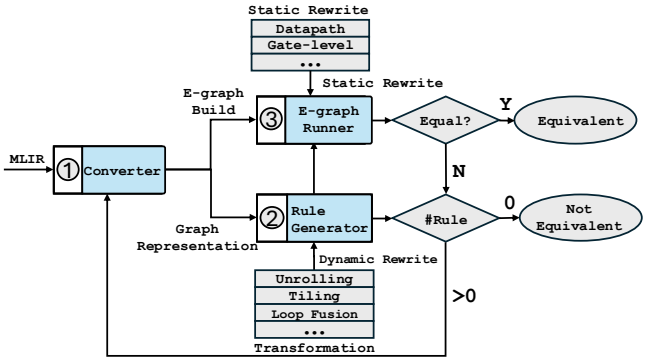

Figure 3: Overview of the HEC Framework: Initially, the input MLIR code is converted into a graph-based representation through dataflow analysis (step ①). This graph representation serves as a foundation for constructing the e-graph. The dynamic rules (step ②) are specifically designed to handle complex loop transformations that are not suitable for static rewriting. Finally, the e-graph runner (step ③) employs a hybrid ruleset that includes both static datapath rewriting and dynamic rewriting.

Here we provide an overview of HEC. To enhance versatility and avoid confinement to any specific programming language, HEC utilizes MLIR as its front-end input language. Figure 3 offers a comprehensive overview of the HEC approach. The core functionality of HEC lies in the verification of input code after datapath and control flow transformations, leveraging the e-graph with a hybrid static/dynamic rewriting ruleset.

HEC accepts MLIR as input language and any framework capable of generating MLIR code can serve as the front end, such as Polygeist [35] and IREE [1]. HEC incorporates a converter that processes the input MLIR code into a graph representation, acting as an interface for MLIR and the e-graph runner. Details of this graph representation are elaborated in Section 4.1, corresponding to step ① in Figure 3.

A major challenge within the HEC framework is to manage control flow transformations, such as loop unrolling and tiling. Standard e-graph rewriting techniques typically struggle to accurately represent these transformations. To address this issue, we have developed a dynamic rule generator (step ②) that creates rewriting rules at runtime to handle control flow transformations. This enables the creation of custom rewriting

rules tailored to each unique code input. The dynamic rule generation process is elaborated in Section 4.2.

Moreover, HEC incorporates static datapath rewriting rules. In Section 4.3, we present the e-graph based verification flow and the collaboration between static and dynamic rules, which are associated with step ③ in Figure 3. Additionally, we provide a detailed example to illustrate the process.

4.1 MLIR graph representation

Integrating the input MLIR code into the e-graph data structure requires translating the code into a graph representation. This translation process (step ①) involves two primary tasks to ensure the correctness of the mapping between the MLIR code and the graph representation. First, it needs to collect all necessary information to construct the e-graph, including dialects, operations, data type information, and other relevant metadata. Second, this involves explicitly representing loop transformation structures to ensure the graph accurately captures essential loop parameters like start, end, step, and the loop body. The generated graph representation functions as a bridge between MLIR, the e-graph runner, and the rule generator. Both the e-graph runner and the dynamic rule generator use the graph representation as input for further process.

Task 1 – The essential information encapsulated in graph representation closely mirrors the structure and characteristics of MLIR operations. We designed this representation akin to an Abstract Syntax Tree (AST), where the graph nodes correspond to individual MLIR operations. Each node comprehensively encapsulates critical information, such as the operator's name, input terms, data types, and dimensions. The interconnections between nodes are depicted as graph edges.

To construct the graph representation, we need to establish a one-to-one mapping between variable names and computation nodes. According to MLIR syntax, multiple variables may share the same variable name within their respective scopes. To address this issue, we rename all variables based on their global order of appearance in the input MLIR code. For example, if a variable %1 exists in multiple loop scopes, the variable in the subsequent loops will be renamed according to its appearance order. Similarly, all computation nodes are indexed based on their order of appearance. For example, the load operation in line 6 of Listing 1 is shown in Listing 5.

```
1 Vertex Name: Affine_Load_1
2 Dtype: i1
3 Dimension: 1
4 Input Edges: %bv, %arg1
5 Output Edges: %2
6
7 Edge Name: %2
8 Source Vertex: Affine_Load_1
9 Target Vertices: Arith_Andi_0
```

Listing 5: The graph representation attributes for the load operation and the term %2 in Listing 1 (line 6). In this example, the load operation is indexed based on its order of appearance, and is assigned an index of 1

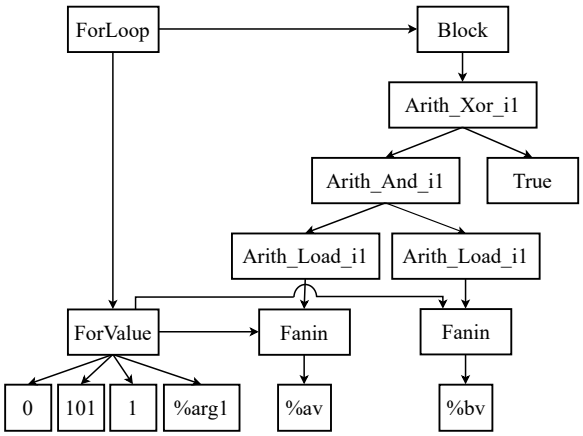

Figure 4: The dataflow graph for Listing 1

Task 2 – The second challenge involves accurately representing *for* loop constructs within our graph representation. To address this, we decompose each *for* loop into two primary components: a *loopvalue* component and a *block* operation. A visualization of Listing 1 is provided in Figure 4. Specifically, the structure of a *for* loop is represented as follows:

- The *loopvalue* component encapsulates the loop parameters, including the loop start value, end value, and increment step. All operations that use the loop variable as input will consume the *loopvalue* component instead.
- To differentiate loop variables that share the same start, end, and step values, the *loopvalue* component includes the variable name as an additional input. This differentiation is not necessary for common datapath nodes such as *add*.
- The *block* operation represents the loop body. Specifically, the inputs to the *block* operation consist of the output terms from isolated operations performed within the loop body. Isolated output terms are those not consumed by any other operations within the block scope. For example, only %4 is isolated in Listing 1. The other output terms, from %1 to %3, are consumed by subsequent operations, thereby making %4 the only output for the *block* operation.
- For operations that do not produce output data, such as affine.store, HEC introduces a pseudo output term to maintain operation tracking. All pseudo output terms are considered isolated.
- The sequence of operations within the *block* operation is order-sensitive, ensuring that the original operation order is preserved within the loop block.
- All hierarchical structures, including *for*, *func*, and *if* constructs, maintain similar block operations.

Another benefit of such representation is its ability to automatically unify code transformations resulting from variable

Table 1: Selection of static rewriting rules integrating into HEC to manage datapath transformations. All datapath rewriting rules are signage and bitwidth dependent.

Class	Left-hand Side	Right-hand Side
Datapath	$a \ll b$	$a \times 2^b$
	$(a \times b) \ll c$	$(a \ll c) \times b$
	$a \times b \times c$	$a \times (b \times c)$
	$(a \ll b) \ll c$	$a \ll (b + c)$
Gate-level	$\neg(a \& b)$	$\neg a \parallel \neg b$
	$a \oplus b$	$(a \wedge \neg b) \vee (\neg a \wedge b)$
	$a \oplus 0$	a
	$\neg a$	$a \oplus True$

movements without affecting data dependencies. For example, Listing 2 is transformed from Listing 1 through loop hoisting. In this transformation, the variable `%true` is moved inside the loop body. Since `%true` is consumed by the operation `arith.xori`, it is not isolated, and the block body does not track the term order. Both Listing 1 and Listing 2 correspond to the same dataflow depicted in Figure 4. The HEC graph representation automatically unifies the loop hoisting transformation before applying e-graph rewriting.

4.2 Hybrid E-graph Rewriting

In this section, we introduce the HEC hybrid rewriting rule sets, which encompass both static datapath rewriting rules and dynamic rewriting rules. We specifically focus on the dynamic rewriting rules, which are designed to handle control flow transformations.

Static Rewriting: HEC incorporates a comprehensive suite of static rewriting rules, including 62 bitwidth-dependent datapath rewriting rules. A selection of these static rewriting rules is presented in Table 1. These static rules are specifically designed to rewrite the input program at the operator level using Boolean algebra and standard arithmetic algebra, enabling efficient datapath transformations.

For example, as illustrated in Listing 3, the framework performs `OR(a', b')` operations for the input operands. Here, the NOT operation `NOT(a)` is expressed as `XOR(a, True)` through the rewriting rule $\neg a \Leftrightarrow a \oplus \texttt{True}$. Similarly, the operations in Listing 1 form `NAND(a, b)`. These two code segments collectively constitute the left-hand side and right-hand side of the rewriting rule $\overline{a \& b} \Leftrightarrow \overline{a} \| \overline{b}$, after which the two code segments are unified into the same e-class.

Why we need dynamic rewriting: Pre-defined static rewriting rules provide robust support for datapath transformations, but they face significant challenges when applied to control flow transformations. To illustrate these challenges and to highlight the need for dynamic rewriting rules, we present a simple example.

```
%av, %bv: memref<101xi1>

%true = arith.constant true
affine.for %arg1 = 0 to 100 step 2 {
%1 = affine.load %av[%arg1] : memref<101xi1>
%2 = affine.load %bv[%arg1] : memref<101xi1>
%3 = arith.andi %1, %2 : i1
%4 = arith.xori %3, %true : i1
%5 = affine.apply affine_map<(d0) -> (d0 + 1)>(%arg1)
%6 = affine.load %av[%5] : memref<101xi1>
%7 = affine.load %bv[%5] : memref<101xi1>
%8 = arith.andi %6, %7 : i1
%9 = arith.xori %8, %true : i1
}
affine.for %arg2 = 100 to 101 {
%10 = affine.load %av[%arg2] : memref<101xi1>
%11 = affine.load %bv[%arg2] : memref<101xi1>
%12 = arith.andi %10, %11 : i1
%13 = arith.xori %12, %true : i1
}
```

Listing 6: Unrolling variant with Listing 1

```
(block
(forcontrol
    (forvalue 0 101 1 %arg1)
    (block
        (arith_xori_i1 (arith_andi_i1 (load_i1 (fanin %av
            (forvalue 0 101 1 %arg1))) (load_i1 (fanin
        %bv (forvalue 0 101 1 %arg1)))) (
        arith_constant_i1 1))
    )))
```

Listing 7: Rewriting rule lhs corresponding to Listing 1

```
#map = affine_map<(d0) -> (d0 + 1)>
(combine
(forcontrol
    (forvalue 0 100 2 %arg1)
    (block
        (arith_xori_i1 (arith_andi_i1 (load_i1 (fanin %av
            (forvalue 0 100 2 %arg1))) (load_i1 (fanin
        %bv (forvalue 0 100 2 %arg1)))) (
        arith_constant_i1 1))
        (arith_xori_i1 (arith_andi_i1 (load_i1 (fanin %av
            (apply (map0 (forvalue 0 100 2 %arg1))))) (
        load_i1 (fanin %bv (apply (map0 (forvalue 0
        100 2 %arg1)))))) (arith_constant_i1 1))
    ))
(forcontrol
    (forvalue 100 101 1 %arg2)
    (block
        (arith_xori_i1 (arith_andi_i1 (load_i1 (fanin %av
            (forvalue 100 101 1 %arg2))) (load_i1 (
        fanin %bv (forvalue 100 101 1 %arg2)))) (
        arith_constant_i1 1))
    )))
```

Listing 8: Rewriting rule rhs corresponding to Listing 6

Consider the MLIR code shown in Listing 6, which is an unrolled version of Listing 1 with an unrolling factor of 2. To establish the equivalence between these two codes, the e-graph runner requires a rewriting rule of the form $lhs \Leftrightarrow rhs$, where the left-hand side (lhs) and right-hand side (rhs) are provided in Listings 7 and 8, respectively. However, constructing static rewriting rules to capture such transformations presents several challenges: (1) The number of operations within the *block* operation (line 5 in Listing 8) varies according to the unrolling factor. Static e-graph rewriting rules necessitate a predetermined number of input parameters prior to e-graph runner compilation, making it difficult to accommodate varying operation counts; (2) The isolated dataflow structures need to be isomorphic (line 5 in Listing 7 compared to lines 6, 7, and 12 in Listing 8). Assessing the isomorphism of these

Table 2: Selection of dynamic rewriting integrated into HEC to address control flow transformations. The pattern and transformation are interchangable if they meet the conditions.

	Left-hand Side	Right-hand Side	Condition

Unrolling	for **m1** to **n2** step **k2**:
	`Loop-body-2`
		for **m1** to **n1** step **k1**:
		`Loop-body-1`
		for **m2** to **n2** step **k2**:
		`Loop-body-2`
			1. $\lceil(\mathbf{n2}-\mathbf{m1})/\mathbf{k2}\rceil == \lceil(\mathbf{n2}-\mathbf{m2})/\mathbf{k2}\rceil + \lceil(\mathbf{n1}-\mathbf{m1})/\mathbf{k1}\rceil \times (\mathbf{k1}/\mathbf{k2})$
			2. `Loop-body-1` is **k1/k2** times replication of `Loop-body-2`

Tiling	for **%1** = **m1** to **n1** step **k2**: `Loop-body`	for **%1** = **m1** to **n1** step **k1**: for **%2** = **%1** to **n2** step **k2**: `Loop-body`	1. $\mathbf{k1} == f * \mathbf{k2}$ (f is the tiling factor) 2. $\mathbf{n2} = \min(\mathbf{\%1}+\mathbf{k1}, \mathbf{\%2})$

Fusion	for **m** to **n** step **k1**:
	`Loop-body-1`
	for **m** to **n** step **k2**:
	`Loop-body-2`
		for **m** to **n** step **k1** $\times$ **k2**:
		`Loop-body-3`
			1. `Loop-body-3` is **k2** times replication of `loop-body-1` plus **k1** times replication of `loop-body-2`
			2. No memory RAW violation across `Loop-body-1` and `Loop-body-2`

Coalesing	for **%1** = **m1** to **n1** step **k1**: for **%2** = **%1** to **n2** step **k2**: `Loop-body`	for **%3** = 0 to **n1** $\times$ **n2**: **%1**=(floordiv **%3 n2**) **%2**=(mod **%3 n2**) `Loop-body`	1. The reference of **%1**, **%2** is replaced by (floordiv **%3 n2**) and (mod **%3 n2**), respectively.

dataflow structures is challenging simply using static rewriting rules; (3) Loop unrolling introduces new variables, and their metadata (such as variable names and data types) is collected at runtime. For example, the loop variable %arg1 is created during the unrolling process in Listing 6. Since this runtime-collected information must be determined prior to compilation, creating static "unrolling" e-graph rewriting rules that accommodate all unrolling scenarios becomes impractical. In complex scenarios like loop unrolling, where the unrolling factor and variable metadata can vary dynamically based on input code, static rewriting rules prove insufficient. Therefore, dynamic rewriting rules must be customized to handle such variability. These challenges collectively prompt us to develop dynamic rewriting rules, generated at runtime, to effectively handle complex control flow transformations.

Dynamic Rewriting: To overcome the limitations of static rewriting, HEC generates dynamic rewriting rules at runtime, tailoring them to each unique code input to achieve high adaptability across diverse scenarios. In Step ②, the dynamic rule generator leverages the pre-defined transformation patterns to assess computation nodes for applicable transformations. Once suitable nodes are identified, HEC creates new dynamic rewriting rules based on the graph representation.

Using loop unrolling transformations as an example to demonstrate our verification approach, we establish the transformation criteria shown in Figure 5, which are used to determine whether a code segment qualifies as an unrolled variant. These criteria define the requirements for *for* loops to be recognized as equivalent to loop unrolling transformations. For instance, the loops in lines 4 and 15 of Listing 6 satisfy the conditions outlined in Figure 5, indicating their eligibility for the loop unrolling transformation pattern and confirming their equivalence to those in Listing 1. Additionally, we introduce

```
1 affine.for %arg1 = m1 to n2 step k2:
2   // Loop-body-2
```

Transformation Pattern Condition:

$\lceil(n2-m1)/k2\rceil == \lceil(n2-m2)/k2\rceil + \lceil(n1-m1)/k1\rceil \times (k1/k2)$

```
1 affine.for %arg1 = m1 to n2 step k2:
2   // Loop-body-2
```

Figure 5: Loop unrolling transformation pattern: the code segments at the top and bottom can be interchanged if they satisfy the required conditions in the middle.

a leading operator, *combine*, to bind the two loop operations (line 2 in Listing 8). Here, we assume that all integrated rewriting rules and transformation patterns are correct. Whether the input code meets the transformation pattern conditions is automatically verified using the Z3 SMT solver [20, 21].

HEC analyzes the graph representation illustrated in Section 4.1 to assess the eligibility of each `for` loop. For each eligible loop, HEC constructs a dynamic rule $lhs \Leftrightarrow rhs$. For instance, Listing 7 and Listing 8 show the *lhs* and *rhs* of dynamic rewriting rules in Listing 6 unrolling, respectively. A selection of dynamic rewriting patterns is shown in Table 2.

Similarly, Listing 4 is verified to be equivalent to Listing 1 through dynamic rewriting. Specifically, the *for* loop in line 4 of Listing 4 is identified as an eligible computation node for loop tiling, and customized dynamic rewriting rules for tiling are established to achieve equivalence with Listing 1.

Extensibility: HEC supports extensibility through a systematic approach for incorporating new transformation patterns. For control flow transformations, users must formalize the transformation pattern along with its correctness conditions (similar to those in Table 2), while datapath transformations require the corresponding static rewriting rules. To ensure soundness, HEC employs a dual validation strategy: static dat-

apath transformation rules are derived from mathematically proven algebraic identities such as De Morgan's laws and arithmetic associativity, making them sound by construction, while dynamic rules for control flow transformations undergo formal verification using the Z3 SMT solver to ensure mathematical correctness. For instance, the loop unrolling condition specified in Table 2 is mathematically verified to guarantee preservation of the iteration space, thereby maintaining semantic equivalence between the original and transformed code.

HEC limits Z3 usage to verifying dynamic rule pattern conditions rather than incorporating it into entire saturation process, thereby avoiding scalability bottlenecks. Our testing confirms that the dynamic rule generation, including Z3 checks, typically completes in under one second, a negligible fraction of the overall verification runtime, which is predominantly consumed by e-graph saturation.

4.3 HEC Verification Runner

```
%0 = arith.index_cast %arg0 : i32 to index
affine.for %arg2 = 0 to %0
  %1 = affine.load %arg1[%arg2] : memref<?xf64>
```

```
#map1 = affine_map<()[s0] -> (((s0 floordiv 2) floordiv 3) * 6)>
#map2 = affine_map<()[s0] -> ((s0 floordiv 2) * 2)>
#map3 = affine_map<()[s0] -> ((s0 floordiv 2) * 2 + ((s0 mod 2) floordiv 3) * 3)>

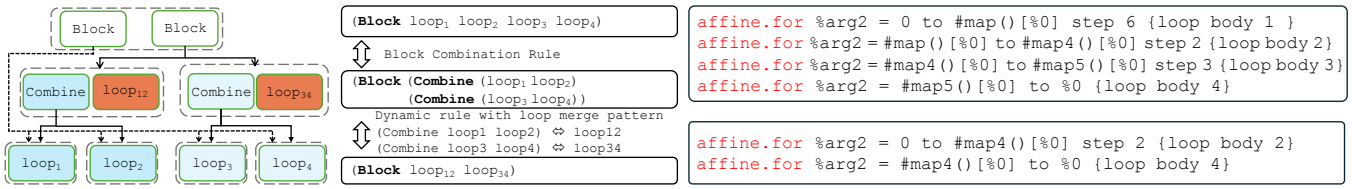
affine.for %arg2 = 0 to #map1()[%0] step 6
  %1 = affine.load %arg1[%arg2] : memref<?xf64>
  %2 = affine.apply affine_map<(d0) -> (d0 + 1)>(%arg2)
  %3 = affine.load %arg1[%2] : memref<?xf64>
  %4 = affine.apply affine_map<(d0) -> (d0 + 2)>(%arg2)
  %5 = affine.load %arg1[%4] : memref<?xf64>
  %6 = affine.apply affine_map<(d0) -> (d0 + 1)>(%4)
  %7 = affine.load %arg1[%6] : memref<?xf64>
  %8 = affine.apply affine_map<(d0) -> (d0 + 4)>(%arg2)
  %9 = affine.load %arg1[%8] : memref<?xf64>
  %10 = affine.apply affine_map<(d0) -> (d0 + 1)>(%8)
  %11 = affine.load %arg1[%10] : memref<?xf64>
affine.for %arg2 = #map1()[%0] to #map2()[%0] step 2
  %1 = affine.load %arg1[%arg2] : memref<?xf64>
  %2 = affine.apply affine_map<(d0) -> (d0 + 1)>(%arg2)
  %3 = affine.load %arg1[%2] : memref<?xf64>
affine.for %arg2 = #map2()[%0] to #map3()[%0] step 3
  %1 = affine.load %arg1[%arg2] : memref<?xf64>
  %2 = affine.apply affine_map<(d0) -> (d0 + 1)>(%arg2)
  %3 = affine.load %arg1[%2] : memref<?xf64>
  %4 = affine.apply affine_map<(d0) -> (d0 + 2)>(%arg2)
  %5 = affine.load %arg1[%4] : memref<?xf64>
affine.for %arg2 = #map3()[%0] to %0
  %1 = affine.load %arg1[%arg2] : memref<?xf64>
```

Figure 6: MLIR Nested Unrolling Case Study: The bottom MLIR code is produced by applying nested unrolling with factors of 2 and 3 to the top MLIR code.

In this section, we will elaborate more details about e-graph verification runner and use a specific example to illustrate the verification process.

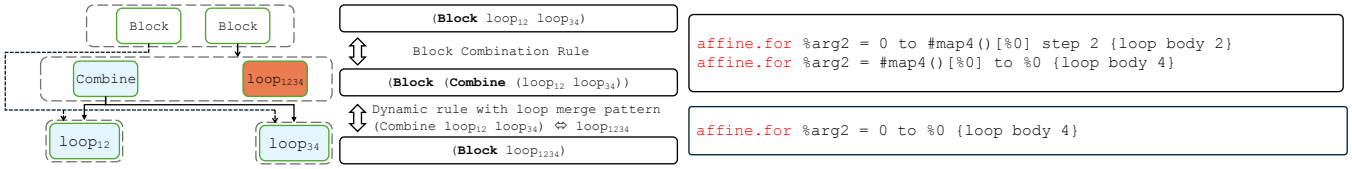
Initial E-graph Construction: HEC takes the graph representation as input. It gathers functional information and constructs the corresponding e-graph. The algorithm for e-graph construction is detailed in Algorithm 1. Before construction, it builds the topological order for each operation based on the dependence relationship. Subsequently, HEC incrementally inserts operation nodes into the e-graph following the topological order of the graph nodes. Specifically, operations are inserted into the e-graph from the leaf nodes to the root nodes to ensure that child nodes are processed beforehand. Each insertion generates an identifier representing the e-nodes and connects these e-nodes with their respective input identifier.

Algorithm 1 E-graph Construction



Input: Vertex list V from parsing netlist
Output: : E-graph G_e
Initialize *vmap* as empty HashMap
for each node v in TopoSort(V) **do** ▷ From leaf to root
  $in_id \leftarrow []$
  for each input i for node v **do**
    in_id.pushback($vmap[i]$) ▷ All children are inserted
  end for
  $id \leftarrow G_e$.insert(v, in_id) ▷ Insert v to e-graph
  $vmap[v] = id$
end for

HEC Verification: To demonstrate the verification procedure, we use the example shown in Figure 6. The bottom MLIR code presents a nested loop unrolled with factors of 2 and 3, derived from the top MLIR code. The verification process is depicted in Figure 7. For simplicity, the *for* loop structures in Figure 4 are simplified to single-loop operations.



Initially, the ruleset includes only the predefined static rules without any dynamic rules. If the differences between the two MLIR codes fall within the scope addressable by static rewriting rules, the e-graph runner reports the codes as functionally equivalent. However, if the MLIR codes involve control flow transformations, the e-graph runner cannot affirm equivalence. In such cases, the graph representation is forwarded to the rule generator to apply the control flow transformation patterns.

Figure 7a illustrates the e-graph exploration during the initial iteration. The rule generator analyzes the graph representation and creates dynamic rules for candidate operations. HEC then creates a pseudo *combine* node to bind candidates *for* loop operations. The *combine* nodes are created automatically for each pair of candidate nodes of dynamic rules. Finally, HEC unifies the e-classes of *combine* node and the fused loop operations using dynamic rewriting rules. For example, the pairs of *for* loop structures from lines 5–17 and lines 21–27 in the unrolled MLIR code of Figure 6 (indicated by dotted lines in Figure 7a) are eligible for the loop unrolling transformation pattern. The e-graph runner creates a pseudo *combine* node as their parent e-node and builds dynamic rules to merge the *combine* node with $loop_{12}$ into the same e-class (indicated by solid lines). Consequently, $loop_1$/$loop_2$ and $loop_3$/$loop_4$ are merged into two loops named $loop_{12}$ and $loop_{34}$, respectively. The MLIR codes for both the original loops and the unrolled version are displayed on the right side of Figure 7a.

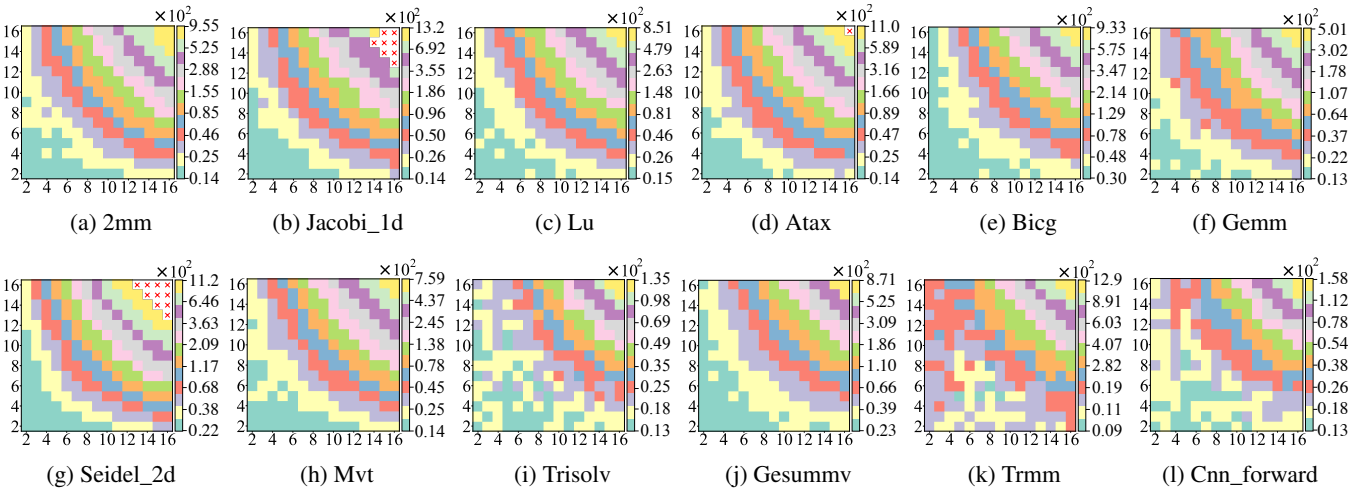
However, the e-graph runner is still unable to ascertain the equivalence between the two input codes. An additional iteration is necessary for confirmation. Similar to the approach in

(a) In the first iteration, HEC inserted pseudo *Combine* nodes to bind leaf $loop_1/loop_2$ and $loop_3/loop_4$. Then, the original sub-expression, indicated by a dotted line, is transformed into a new expression, represented by a solid line. Following this, the e-graph runner implements dynamic rules for $loop_1$/$loop_2$ and $loop_3$/$loop_4$ (highlighted by light blue nodes), merging them into $loop_{12}$ and $loop_{34}$ (illustrated with dark red nodes). However, HEC cannot verify the equivalence in the first iteration.

(b) In the second iteration, the rule generator introduces a new rule, merging $loop_{12}$ and $loop_{34}$ into $loop_{1234}$, similar to the procedure in the initial iteration. Subsequently, the e-graph runner validates the equivalence between the two input MLIR codes.

Figure 7: E-graph verification for the motivating example provided in Figure 6. The e-graph operates through two iterations, with the rule generator introducing dynamic rules to the e-graph runner during each iteration. Each *loop* operator represents a *for* loop structure, as depicted in Figure 4, for brevity purposes.

the first iteration, the rule generator proposes a new dynamic rule for merging $loop_{12}$ with $loop_{34}$ into a single $loop_{1234}$. The illustration of the second iteration is shown in Figure 7b. Consequently, the two MLIR codes in Figure 6 are unified into the same e-class. It is worth noting that Figure 7b shows only one possible verification path for clarity. In practice, the e-graph simultaneously explores multiple combination patterns, such as merging $loop_2$ and $loop_3$ into $loop_{23}$, which could lead to alternative paths like $loop_1$, $loop_2$, $loop_3$, $loop_4$ $\rightarrow$ $loop_1$, $loop_{23}$, $loop_4$ $\rightarrow$ $loop_{123}$, $loop_4$ $\rightarrow$ $loop_{1234}$. The e-graph's congruence closure property ensures that all valid transformation sequences leading to equivalent programs are automatically discovered and unified within the same e-class. If the e-graph runner still cannot determine the equivalence and the rule generator fails to create new dynamic rules for further evaluation, HEC will conclude that the input MLIR codes are not equivalent. It is important to note that both the e-graph verification runner and the rule generator utilize the graph representation as their input. During each iteration, HEC is equipped with an inverter, which converts the e-graph back into the graph representation to facilitate further processing in the subsequent iteration. Besides, the verification flow is fully automated. HEC offers an interface for adding control flow transformation patterns, facilitating broader equivalence verification through an expanded set of rewriting rules and verification patterns.



Completeness and Soundness: HEC, like any verification system based on rewriting rules, is inherently incomplete with respect to the universe of all possible code transformations. If an equivalence exists but requires a transformation rule not included in our framework, or if the saturation process is terminated due to computational limits before full exploration is complete, HEC may fail to establish equivalence even when it exists, resulting in false negatives (flagging equivalent programs as nonequivalent).

HEC guarantees soundness through a dual validation mechanism that ensures it will never produce false positives (declaring two programs equivalent when they are not). For static datapath transformation rules, soundness is achieved by deriving rules from mathematically proven algebraic identities such as De Morgan's laws and arithmetic associativity, making them sound by construction. For dynamic control flow transformation rules, pattern conditions are formally verified using the Z3 SMT solver to ensure mathematical correctness.

5 Evaluation

The experiments were conducted on a system equipped with an Intel(R) Xeon(R) Gold 6418H CPU. This CPU has 48 physical cores, operates at a maximum speed of 4000 MHz, and the system has 1024 GB of RAM. We implemented transformations on selected benchmarks using the official MLIR compiler, `mlir-opt`, with LLVM version 18.0.0.

There are many existing transformation validation tools in the literature, including CompCert [30, 31], Alive/Alive2 [33, 34], PolyCheck [7], and MLIR-TV [6], each providing verification capabilities at different levels of the compilation stack. CompCert focuses on C-level compiler correctness, Alive/Alive2 target LLVM IR optimizations, PolyCheck handles affine code transformations for C-level compilation, while MLIR-TV is designed for MLIR-level verification. Among these tools, only MLIR-TV provides verification at

the MLIR level, which is most relevant to our work. However, according to our testing, MLIR-TV fails to support the affine dialect and lacks coverage for affine operations that are central to high-level synthesis and the transformations evaluated in our benchmarks. This limitation renders a direct comparison with HEC is challenging.

Table 3: List of benchmarks.

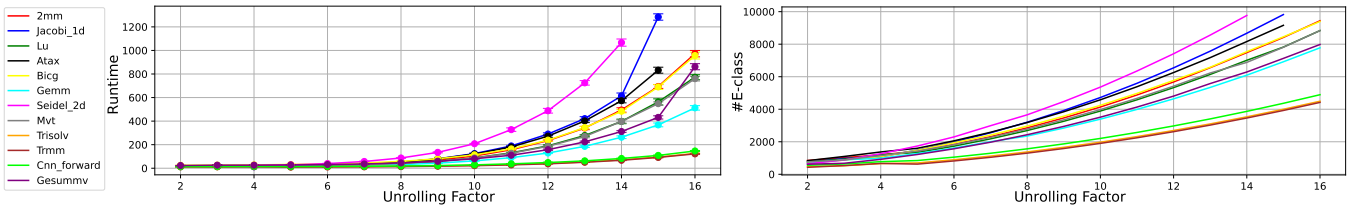
Benchmark	Description	Complexity
GEMM [40]	General Matrix Multiply	$O(n^3)$
LU [40]	LU Decomposition	$O(n^3)$
2MM [40]	Two Matrix Multiplications	$O(n^3)$
ATAX [40]	Matrix Transpose Vector Multiplication	$O(n^2)$
BiCG [40]	Biconjugate Gradient Method	$O(n^2)$
GESUMMV [40]	SUM of Matrix Vector Multiplications	$O(n^2)$
MVT [40]	Matrix Vector Transpose	$O(n^2)$
TRISOLV [40]	Triangular Solver	$O(n^2)$
TRMM [40]	Triangular Matrix Multiply	$O(n^3)$
CNN_Forward [50]	CNN Forward Function	$O(n^7)$
Jacobi 1D [40]	Jacobi 1D iterative method	$O(n \cdot t)$
Seidel 2D [40]	Gauss-Seidel method	$O(n^2 \cdot t)$

5.1 Control Flow Transformation Verification

We evaluate the performance of HEC using the loop unrolling and tiling transformations on the MLIR benchmark. Specifically, we verify the equivalence between the input code within the selected benchmarks, reporting the end-to-end runtime, the number of dynamic rules implemented, and the number of e-classes. The benchmarks used in this evaluation are selected from Polybench [40] and are enhanced with an additional benchmark, CNN-Forward, from Polybench-NN [50]. We utilize Polygeist [35] to convert the C code into MLIR, focusing specifically on the kernel portions for evaluation. These benchmarks are implemented as low-level kernels to facilitate hardware acceleration. The benchmarks, including description and time complexity, are shown in Table 3.

Comprehensive results are provided in Table 4, where all selected results have been successfully verified. The benchmarks for Seidel_2d and Jacobi_1d exhibit a specific type of error, classified as a **Loop Boundary Check Error**, which will be discussed in detail in Section 5.4.

First, HEC consistently verifies the correctness of transformations within one minute for most cases, except for nested unrolling. Second, the tiling transformation, which primarily adjusts loop parameters without altering code size, shows stable results across various tiling factors (represented as T2 to T64). Additionally, the number of e-classes has a significant impact on verification runtime, particularly in cases of nested unrolling. In these cases, the size of the e-graph predominantly determines the duration of verification.



5.2 Unrolling Verification Runtime

Since the unrolling transformation increases code size, unlike loop tiling, we specifically evaluate the verification runtime for nested unrolling as a scalability test. We assess the runtime performance of HEC across various nested unrolling factors. The results are illustrated in Figure 8, where each sub-graph is a heatmap. The x and y axes of the heatmap represent unrolling factors from 2 to 16. The color of each pixel indicates the verification runtime by seconds, as detailed by the colorbar on the right. Cases marked with an "X" indicate that they either exceeded the time limit.

Figure 8 shows that the verification runtime for most benchmarks completes within 20 minutes. E-graph saturation dominates the runtime, accounting for over 90% in runtime.

Table 4: Runtime, dynamic rule numbers, e-classes numbers comparison under various tiling (T), unrolling setup (U) configurations. For benchmark Jacobi_1d and Seidel_2d, mlir-opt tool generates the Loop Boundary errors, which will be elaborated in Section 5.4. Note that these are standard benchmarks used widely in MLIR-based compilation evaluations.

(a) Runtime (b) Number of e-class

Figure 9: Runtime and e-graph complexity w.r.t nested unrolling complexity under the same unrolling factors.

Additionally, we present detailed results in Figure 9 for the diagonal data sample from Figure 8. In this figure, the x-axis denotes the nested unrolling data sample (specifically, the unroll_k_unroll_k, where k is the unrolling factor), and the y-axis displays the runtime and the number of e-classes.

This runtime is exponential rather than linear. Firstly, unrolling transformations modify code size, introducing scalability challenges, which are not present in other transformations like tiling and loop fusion. Secondly, the diagonal data sample involves nested unrolling, where the code size increases quadratically with each increase in the unrolling factor. This quadratic growth in code size significantly impacts runtime. Notably, it is uncommon for implementations to adopt such large unrolling factors due to the substantial increase in chip area it entails. From the perspective of power, performance, and area (PPA), such high unrolling factors are generally avoided, making the case of nested unrolling particularly rare.

5.3 Datapath Transformation Evaluation

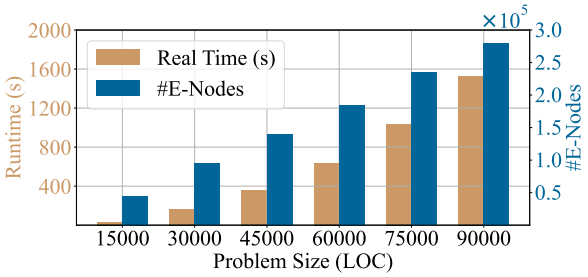

Figure 10: Runtime and e-nodes number for HEC across representative problem sizes ranging from 15,000 to 90,000 LOC.

HEC is designed to manage both static and dynamic transformations. In this section, we focus on the datapath transformation capabilities of HEC. Specifically, we generated over 150 benchmarks incorporating various datapath transformations. These benchmarks vary in size, measured by lines of code (LOC), to assess the framework scalability for datapath transformation. We conducted experiments to measure both the runtime and the number of e-nodes generated for different benchmark sizes. The results are illustrated in Figure 10. In this figure, the x-axis represents the problem size measured in the sum of LOC for input benchmark, with representative datapoints ranging from 15,000 to 90,000, while the y-axis depicts the runtime (left) and the number of e-nodes (right).

Notably, all verification tasks were successfully completed within a 40-minute timeframe. For instance, the largest benchmark, encompassing 108,012 LOC, required a verification runtime of 2,305 seconds. This indicates that HEC maintains consistent performance even as the problem size increases significantly. Additionally, the analysis of the number of e-nodes reveals a linear growth trend with respect to LOC, as illustrated in Figure 10. This linear relationship suggests that the complexity of the e-graph structure scales predictably with the size of the input code, ensuring manageable computational overhead. Together, these findings highlight the capability of HEC to efficiently verify large-scale benchmarks while maintaining structural integrity and performance.

5.4 Mining Bugs in PolyBenchC MLIR

The MLIR affine dialect [1] provides a suite of standard optimization transformations. We selected the representative kernels to showcase the application of these transformations. We will highlight two representative cases where the optimized HLS programs fail to preserve semantic equivalence with the original programs, and our tool has successfully detected and reported these discrepancies as bugs. In the following sections, we will elaborate on these two cases as case studies.

Case study 1: Loop Boundary Check Error: We begin with an example in Listing 9 and its unrolled version (Listing 10), which is unrolled by a factor of 2 using `mlir-opt`. The two code segments appear equivalent. The first loop in Listing 10 from lines 9 to 13 handles the majority of the operations, while the second loop from lines 16 to 18 processes the remainder. Together, both loops make up the entire code shown in Listing 9. However, this transformation contains a flaw in the loop boundary checks. Specifically, if we consider the scenario where `%0` equals 5, Listing 9 will not execute since the loop start value (15) exceeds its end value (10). In contrast, Listing 10 executes once for the second loop spanning from line 16 to line 19. This error occurs with all values of `%0` less than 10.

Our tests indicate that these bugs are not confined to the specific case study presented. In general, for any loop defined with start and end conditions, `mlir-opt` preserves semantic equivalence only when the loop end value is guaranteed to exceed the loop start value. If this guarantee is not met and the loop is unrolled by a factor of k, the transformed loop may inadvertently alter the loop boundaries, causing unintended iterations. For instance, such errors are observed in the

Listing 12: Memory RAW violation: Loop fusion

Jacobi_1d and Seidel_2d benchmarks listed in Table 3.

Case study 2: Memory Read-After-Write Violation: Listing 11 and Listing 12 illustrate another instance of semantic non-equivalence following a transformation—loop fusion. In the provided code, the divergence in memory state between the two functions arises from differences in the execution order of the loop body operations after loop fusion. In the first function, two separate loops handle the operations: the first loop copies values from one element to the next, and the second loop increments these values. As a result, the final state of the array consists of the original element `%arg0[0]` followed by incremented versions of this element for all subsequent indices. Specifically, the array becomes `%arg0[0]`, `%arg0[0] + 1`, `%arg0[0] + 1`, ..., `%arg0[0] + 1`, with every element after the first set to `%arg0[0] + 1`. However, in the fused version, each iteration of the single loop performs both copy and increment operations adjacently. This introduces a dependency violation on the increment operation of the previous iteration, leading to a linearly increasing sequence based on the first element. Finally, the array becomes `%arg0[0]`, `%arg0[0] + 1`, `%arg0[0] + 2`, ..., `%arg0[0] + 10`. Such transformations in the loop structure affect not only the computational dependencies but also the overall memory state of `%arg0`, resulting in non-equivalence of the final output across the two function versions.

In these case studies, we identify two types of transformation errors introduced by the `mlir-opt` compiler. Code unrolling leads to additional loop body executions, while loop fusion transformation changes the sequence of data dependencies, both affecting the intended behavior and memory state. Relying on `mlir-opt` for code transformations without subsequent equivalence checks can result in various adverse outcomes. Minor issues might include data corruption, while more severe implications could lead to complete system failures, potentially disrupting critical operations and compromising system integrity. Although code transformations can enhance performance, the improper application of these transformations without equivalence checking can introduce errors that disrupt control flow and alter semantic behavior.

6 Conclusions

This paper introduces HEC, a novel equivalence checking tool. HEC leverages the dynamic rule generation to effectively verify complex control flow transformations. By integrating both static datapath rewriting rules with dynamic, code-specific rules, HEC provides a flexible verification solution. Our experimental results demonstrate its efficiency, verifying various code transformations within an efficient runtime. Finally, HEC successfully identifies a few critical compilation errors, covering functional incorrectness and data hazard violations.

Abstract

To tame the rapidly rising cost of memory in servers, hyperscalers have begun deploying memory deduplication features, such as Kernel Same-page Merging (ksm), for some of their services. Nonetheless, ksm incurs a datacenter tax significant enough to notably degrade performance of co-running applications, which hinders its wider and more aggressive deployment. Meanwhile, the server-class CPU has started to integrate various on-chip accelerators to effectively reduce datacenter taxes. One of such accelerators is Data Streaming Accelerator (DSA), which can offload the two most taxing functions of ksm, page comparison and checksum computation, from CPU. In this work, we demonstrate that ksm offloading these two functions to DSA (DSA-ksm) can reduce the performance degradation of co-running applications caused by ksm from 1.6–5.8× to 1.0–1.6×. However, we uncover that DSA-ksm, which naïvely replaces CPU-based functions with their DSA-based counterparts, yields significantly lower rates of memory deduplication than ksm due to the long latency of offloading these functions through on-chip PCIe. To address this shortcoming, we redesign ksm to exploit DSA's batching capability (Para-ksm). It facilitates a given function to operate on multiple pages per offload, rather than a single page as ksm does, thereby amortizing the long offloading latency. Compared to ksm, Para-ksm increases the amount of memory deduplication per CPU cycle used for ksm by 31–50% while decreasing the performance degradation to 1.3–2.7×.

1 Introduction

Memory technology scaling has stagnated, while the memory manufacturing cost has steadily increased, leading to a rise in the cost per bit [28]. At the same time, hyperscale applications demand increasingly larger memory capacities. These make memory account for 30–50% of the total hardware cost of a server [18, 38]. Meanwhile, virtualization techniques, such as Virtual Machines (VMs) and containers, are widely employed by hyperscalers to provide performance scalability and isolation for serving hyperscale applications. However, they often inefficiently use the given memory capacity, as they duplicate code and data across VMs and containers. Past work shows that redundant or duplicated memory pages consume 11%–86% of memory capacity, depending on the applications and operating systems [2, 21].

OS memory deduplication features, such as Kernel Same-page Merging (ksm), have been shown to effectively utilize memory capacity by significantly reducing duplicated memory pages [20, 31]. For example, Meta employs ksm to reduce memory pressure caused by running many Instagram worker processes on each server with limited memory capacity [35]. Nonetheless, recent work has reported that ksm not only imposes a high datacenter tax (*e.g.*, consuming 14–65% of total CPU cycles in our evaluation), but also pollutes the cache hierarchy, both of which are significant enough to degrade the performance of co-running applications [14]. Especially, page comparison (memcmp) and checksum computation (xxhash) in ksm are the two most taxing functions, collectively accounting for 38% of the CPU cycles consumed by ksm according to our analysis (§3).

To effectively reduce rising datacenter taxes, the latest server-class CPU has started integrating various on-chip accelerators capable of offloading common functions in the low levels of the datacenter software stack from CPU cores. For example, four on-chip accelerators have been integrated into the Intel Xeon Scalable Processor since its 4th generation. Compared to comparable off-chip accelerators, such as SmartNIC (SNIC) connected to CPU via off-chip PCIe [9, 19, 23–25], these on-chip accelerators offer several advantages, including reduced offloading latency, streamlined memory management, improved virtualization support, owing to their tight integration with CPU through on-chip PCIe and other supporting

subsystems [40]. One of such on-chip accelerators is Data Streaming Accelerator (DSA), integrated to offload data movement and transformation functions, including memory copy, memory comparison, and checksum computation.

In this work, we not only explore the unique capabilities of DSA for `ksm` but also redesign `ksm` to efficiently offload `memcmp` and `xxhash` from CPU, significantly reducing the datacenter tax and performance degradation of co-running applications. We make the following specific contributions.

Contribution-1: Identifying opportunities in offloading `ksm` to DSA (§3–4). First, we demonstrate that offloading `memcmp` and `xxhash` to DSA, with a specific operating mode, can reduce the CPU cycle consumption for these functions by 6.6× and 6.0×, respectively, while obviating cache pollution. Although CPU may use non-temporal load instructions such as `MOVNTDQA` to prevent these functions from polluting the cache hierarchy, we show that they incur even more CPU cycle consumption than temporal load instructions. Second, we present `DSA-ksm`, which directly replaces CPU-based `memcmp` and `xxhash` with their DSA-based counterparts in `ksm`, reducing the performance degradation of co-running applications incurred by `ksm` from 1.6–5.8× to 1.0–1.6×. Nonetheless, we also uncover that these DSA-based functions take nearly 3× longer to return their results than their CPU-based counterparts although they yield CPU to other application processes during that time. Such long offloading latency makes `DSA-ksm` offer notably lower rates of memory deduplication than `ksm`. Lastly, we identify that leveraging the DSA's batching capability, which allows `memcmp` and `xxhash` to operate on multiple pages per offload, can significantly amortize the offloading latency (*e.g.*, by 81–83% with a batching size of 8), but it requires a significant redesign of `ksm`.

Contribution-2: Redesigning `ksm` to efficiently exploit the DSA's batching capability (§5). `ksm` scans pages to find those that can be merged while maintaining two Red-Black (RB) trees: stable and unstable trees, which store pointers to merged and previously scanned pages, respectively. It first picks a candidate page and compares it with pages in these trees (named tree pages) using `memcmp`. Then, based on the result of comparing the candidate and current tree pages, it determines the next tree page to compare with the candidate page and whether to compute the checksum of the candidate page using `xxhash`. That is, `ksm` is inherently a serial algorithm, and, consequently, `DSA-ksm` cannot exploit the DSA's batching capability, which requires selecting multiple tree pages to compare with the candidate page or multiple candidate pages to compare with a tree page. To tackle the shortcoming of `DSA-ksm`, we propose `Para-ksm`, a significant redesign of `ksm` that allows `memcmp` and `xxhash` to operate on multiple pages in parallel (or offload these functions to DSA for multiple pages in a batch). Specifically, we explore two algorithms: `Para-ksmC`, which compares multiple candidate pages with a single tree page, and `Para-ksmT`, which speculatively compares a single candidate page with multiple tree pages concurrently. However, we focus on `Para-ksmC` in this work, as we find that `Para-ksmT` significantly wastes DSA resources due to its speculative nature. `Para-ksmC` increases the amount of memory deduplication per CPU cycle used for `ksm` by 31–50% while decreasing the performance degradation of co-running applications incurred by `ksm` from 1.6–5.8× to 1.3–2.7×.

2 Background

2.1 Memory Deduplication

Memory deduplication has been developed to consolidate duplicate pages in memory, thereby improving memory utilization of a given memory capacity. One widely adopted implementation of memory deduplication is Kernel Same-page Merging (`ksm`), a feature integrated into Linux since kernel version 2.6. `ksm` is a Content-Based Page Sharing (CBPS) approach that scans the anonymous memory regions of processes to identify pages with the same contents, merges them, and subsequently reclaims the freed space.

The `ksm` daemon, `ksmd`, operates on the memory regions specified by the `madvise` system call and is controlled through parameters exposed in `sysfs` under `sys/kernel/mm/ksm`, such as `pages_to_scan`, `sleep_millisecs`, and `max_page_sharing` [37]. The key data structures of `ksm` are two Red-Black (RB) trees: stable tree and unstable tree. The stable tree stores pointers to all merged pages. If a process modifies a merged page, the Copy-on-Write (CoW) mechanism creates a copy of the page. In contrast, the unstable tree keeps pointers to scanned pages that have not yet been merged. Henceforth, we refer to the pages pointed to by the stable and unstable trees as *stable tree pages* and *unstable tree pages*, respectively. Both trees sort and organize the tree pages based on their contents, using the page content as the index to insert and look up a given page.

Figure 1 illustrates a single `ksm` scan over an advised memory region. During the scan, `ksmd` sequentially selects each

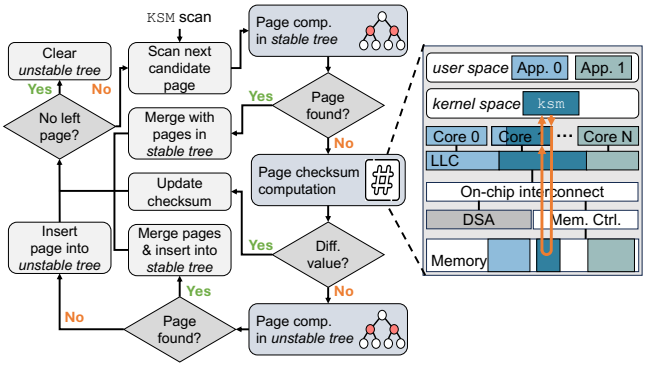

Figure 1: `ksm` scan process (left) and page checksum computation running on CPU (right).

candidate page and searches for a matching page in the stable tree. If a match is found, the candidate page is merged into the stable tree, and its memory region is freed. If no match is found in the stable tree, `ksmd` computes a checksum of the candidate page's content and compares it with the checksum from the previous scan. A mismatch between these two checksums indicates that the page has been modified between two scans, prompting `ksmd` to proceed to the next candidate page. If the checksums match, `ksmd` searches for a matching page in the unstable tree. If a match is found, the candidate page is inserted into the stable tree, the matched page is removed from the unstable tree to free the associated memory region, and the attribute of the candidate page is changed to read-only with CoW protection. If no match is found, the candidate page is inserted into unstable tree for future scans.

2.2 Data Streaming Accelerator

Hardware architecture. Figure 2 overviews the architecture of DSA. A CPU core interacts with DSA by directly submitting work descriptors to ❶ memory-mapped registers of DSA, referred to as portals. A work descriptor encapsulates the key information required to set up the offloading operation, such as the operation type, one or more source memory region addresses, and the completion record address. The operational unit of DSA is ❷ Group, comprising Work Queues (WQs) and Processing Engines (PEs). The number of WQs and PEs within a group is flexibly configurable by a user through the software interface of DSA. ❸ The Group arbiter dispatches the descriptors at the heads of WQs to available PEs, considering the relative priority of WQs set for QoS control. Upon receiving a work descriptor, ❹ a PE reads and operates on one or more source memory regions specified in the work descriptor through the cache-coherent on-chip interconnect, and updates the destination memory region if necessary and the completion record in host memory. The virtual address is used to access host memory, assisted by ❺ the on-device Address Translation Cache (ATC). ATC handles the address translations, sends requests to the IOMMU on the CPU, and handles page faults in coordination with the OS. This new feature allows both CPU and DSA to access shared memory regions in the virtual address space without memory pinning.

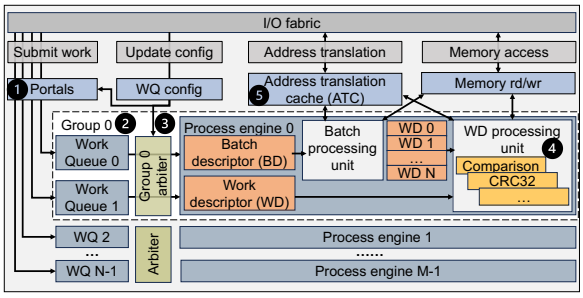

Figure 2: Architecture overview of DSA.

Software stack. The Intel Data Accelerator Driver (IDXD) is a kernel-mode driver responsible for initializing and managing DSA [10]. It provides two interfaces: a character device (`cdev`) interface for data-plane operations and a `sysfs` interface for control-plane configuration. In user space, applications can use the `libaccel-config` library to configure DSA and submit work descriptors to portals, exposed as `cdev` through `mmap`. However, there is no dedicated library existing for kernel-space DSA configuration and usage.

3 Opportunity in Offloading `ksm` to DSA

Prior work has reported that `ksm` incurs significant CPU cycle consumption when invoked [4, 14], disrupting the execution of co-running applications. In this section, we first break down the CPU cycles consumed by `ksm` to identify its CPU-intensive functions. Second, we demonstrate the potential of offloading these CPU-intensive functions to DSA.

3.1 CPU-intensive Functions of `ksm`

To show the considerable CPU cycle consumption by `ksm`, we pick a period that `ksm` co-runs with `Redis` on a CPU core. When `ksm` is invoked, we measure not only the overall CPU utilization but also the CPU utilization contributed by `ksm` and `Redis` separately. Figure 3 (left) shows that `ksm` increases CPU utilization by 14–65%, which is significant enough to degrade `Redis` performance when co-running.

Delving into the CPU utilization by `ksm`, we analyze the breakdown of CPU cycles by each function of `ksm`. Figure 3 (right) shows that `memcmp` and `xxhash`—which compares two pages and computes a 32-bit checksum value of a page—consume 21% and 17% of CPU cycles, respectively. These two functions perform simple operations compared to other functions of `ksm`. However, as they operate on thousands of pages per invocation, they collectively account for 38% of the CPU cycles consumed by `ksm`. Moreover, to operate on these pages, `memcmp` and `xxhash` need to bring them into the cache hierarchy, which incurs cache pollution [14, 15]. Although non-temporal or cache-bypassing load instructions, such as `MOVNTDQA`, can be used to implement these two functions, they are known to give lower bandwidth and higher latency

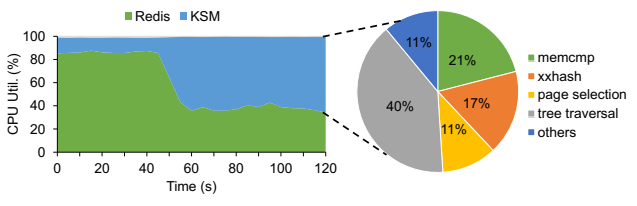

Figure 3: A snapshot of CPU utilization in a system where `CPU-ksm` co-runs with `Redis` under the YCSB-d workload and a detailed breakdown of CPU cycles consumed by `ksm`'s functions.

```
u32 dsa_xxhash(src, PAGE_SIZE, 0){
   struct dsa_hw_desc desc = { };
   struct dsa_completion_record comp;

   // ① Descriptor preparation
   desc.opcode = DSA_OPCODE_CRCGEN;
   desc.src_addr = src;
   desc.xfer_size = PAGE_SIZE;
   comp.status = 0;
   desc.completion_addr = (uintptr_t)&comp;
   desc.flags = IDXD_OP_FLAG_RCR|IDXD_OP_FLAG_CRAV;

   // ② Descriptor submission
   enqcmd(wq_portal, &desc);

   // ③ Descriptor completion check
   wait_for_interrupt(&comp.done);
   wake_up(ksm);
   return comp.result
}
```

Figure 4: Pseudo-code of DSA-based `xxhash` using asynchronous mode.

than temporal load instructions, proportionally consuming more CPU cycles. In contrast, DSA can perform these two functions while consuming far fewer CPU cycles than CPU without causing cache pollution.

3.2 Comparison between CPU and DSA: CPU Cycle Consumption

Among many DSA native operations, we can use 'Comparison' and 'CRC Generation' to implement `memcmp` and `xxhash`, respectively. Figure 4 depicts the pseudo-code of DSA-based `xxhash`. ① A CPU core first prepares a 64B work descriptor specifying (1) 'CRC Generation' as the operation to perform, (2) the address of a source page for checksum computation, (3) 4KB as the transfer size, (4) the address to write the checksum value as the completion record, and other fields. ② Then the CPU core submits the work descriptor to DSA by executing a single instruction, `ENQCMD`. When DSA receives the work descriptor, its processing engine directly operates on the source page without transferring the page into the cache hierarchy. After completing the checksum computation, it writes the checksum value to the completion record address. DSA supports two operating modes: synchronous and asynchronous modes. In synchronous mode, after submitting a work descriptor to DSA, the process continuously polls the completion record address until it receives the value returned by DSA. ③ In asynchronous mode, however, the process yields the CPU core to another process instead of polling, and it resumes execution upon receiving an interrupt, *i.e.*, a notification of work completion, from DSA.

Figure 5 compares the CPU cycle consumption by DSA-based `memcmp` and `xxhash` in kernel space with that of CPU-based counterparts. 'CPU-t' and 'CPU-nt' denote CPU-based `memcmp` and `xxhash` implemented using temporal and non-temporal load instructions, respectively. To avoid cache invalidation overhead from non-temporal loads, the associated pages are placed at random memory addresses and are not present in the CPU cache hierarchy. 'DSA-s' and 'DSA-a' represent DSA-based `memcmp` and `xxhash` implemented using synchronous and asynchronous modes, respectively. Our findings from Figure 5 are as follows. First, DSA-a-based `memcmp` and `xxhash` consume 6.6× and 6.0× fewer CPU cycles than their CPU-t-based counterparts, respectively, as they consume CPU cycles only for preparing and submitting a work descriptor and retrieving the completion record. Second, CPU-nt does not cause cache pollution as DSA, but it consumes 1.1–3.2× more CPU cycles than CPU-t. We use `MOVNTDQA` as CPU-nt in kernel space, which requires full FPU state, thereby increasing CPU cycle consumption compared to CPU-t. Lastly, DSA-s-based `memcmp` and `xxhash` consume CPU cycles comparable to their CPU-t-based counterparts, respectively. Since they do not reduce a meaningful amount of CPU cycle consumption compared to their CPU-t-based counterparts, we use DSA-a-based `memcmp` and `xxhash` to implement DSA-based `ksm` in this work.

4 `DSA-ksm`: CPU-DSA Cooperative `ksm`

We have demonstrated that `memcmp` and `xxhash` consume a significant number of CPU cycles when `ksm` is invoked, and that they can be offloaded to DSA to considerably reduce the CPU cycle consumption compared to those executed by CPU. Since DSA-based `memcmp` and `xxhash` decrease the consumption of CPU cycles without incurring cache pollution compared to their CPU-based counterparts, they can significantly reduce the performance degradation of co-running applications (§6). In this section, we present CPU-DSA cooperative `ksm` (`DSA-ksm`), where DSA performs `memcmp` and `xxhash` (collectively referred to as data-plane functions hereafter) while CPU executes the remaining control-plane functions (*e.g.*, a function selecting the next candidate page to scan) to minimize the performance degradation of applications co-running with `ksm`. This work differs from prior approaches that offload these data-plane functions to off-chip PCIe accelerators [7, 14], because it not only exploits innovations in the on-chip PCIe accelerator ecosystem [40] but also advances the `ksm` algorithm to fully capitalize on the capability of DSA.

Workflow. We first implement DSA-based `memcmp` and `xxhash` using the APIs provided by the IDXD driver (§2.2) and then build a kernel-space library integrating these func-

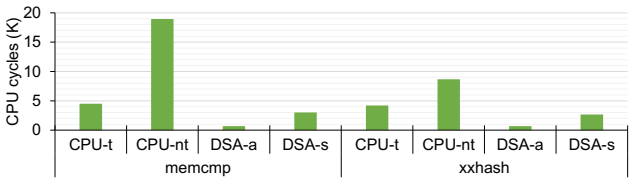

Figure 5: CPU cycle consumption of CPU and DSA-based `memcmp` and `xxhash`.

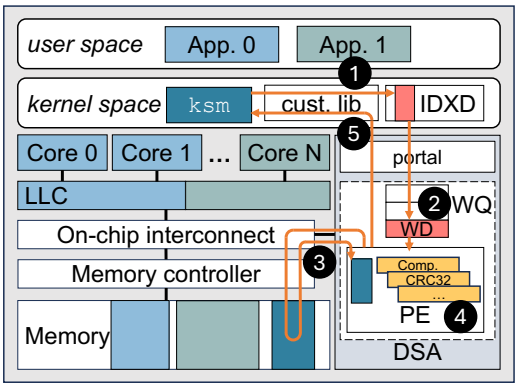

Figure 6: DSA-ksm workflow.

tions, enabling them to be invoked directly from ksm running in the kernel space. In contrast to prior work [7, 14], DSA-ksm leverages DSA's virtual memory support, eliminating the need for memory pinning and virtual-to-physical address translation, thereby simplifying kernel integration and reducing overhead.

Figure 6 depicts the workflow of DSA-ksm. To execute either memcmp or xxhash, ❶ DSA-ksm invokes the corresponding function from the library, first preparing a work descriptor that includes the virtual addresses of memory pages to operate on. ❷ Subsequently, it submits the work descriptor to a work queue (WQ) through a DSA portal. After the successful submission, the process sleeps to yield the CPU core to another process (*e.g.*, a co-running application) until it receives an interrupt from DSA. Receiving the work descriptor from the WQ, a processing engine (PE) ❸ reads the page(s) specified in the work descriptor from host memory into its internal buffer and ❹ conducts the operation specified in the work descriptor. As soon as DSA completes the operation on the entire page(s), ❺ it writes the completion record comprising the result to the corresponding address and sends an interrupt, which wakes up the process. Then, resuming the execution, the function reads the completion record and returns the result to DSA-ksm. To minimize the performance cost of handling interrupts, we choose to sleep for a fixed amount of time, wake up, and poll the completion record, observing that the completion latency exhibits little variance.

Alleviation of long offloading latency. Although DSA-based memcmp and xxhash considerably decrease the consumption of CPU cycles without incurring cache pollution compared to their CPU-based counterparts, we find that using DSA decreases the memory deduplication rate. Figure 7 shows that when the batch size is 1 (submitting one work descriptor per offload), DSA-based memcmp and xxhash present 2.6× and 2.7× longer latency than CPU-based counterparts, respectively. The increased latency is attributed to the time taken to submit a work descriptor and receive the notification of completion, denoted by 'submission' and 'waiting', respectively. While the waiting latency includes the execution time of a given function in DSA, both submission and waiting latencies for offloading a function operating on a 4KB page are dominated by the communication time between the CPU core and DSA over on-chip PCIe [11]. Compared to SNIC-based offloading over off-chip PCIe [14] , DSA still achieves lower latency (*e.g.*, 6μs versus 17μs for xxhash), as off-chip PCIe incurs longer round-trip latency [40] and additional RDMA stack overhead.

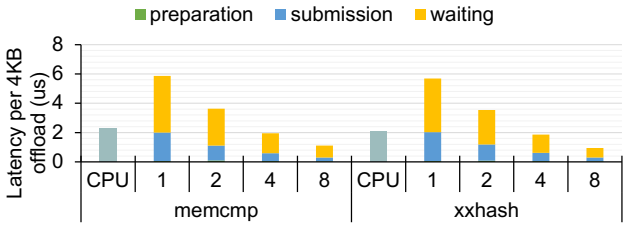

Figure 7: Latency of memcmp and xxhash running on CPU and DSA with varying batching size.

To reduce the latency, instead of submitting a work descriptor one at a time, we can submit a batch descriptor (BD) to DSA [17], which specifies the starting address of an array of work descriptors and the number of work descriptors in the array. The memory regions that these work descriptors specify for DSA to operate on do not need to be contiguous. The batch descriptor is submitted to a WQ through a portal in the same way as a work descriptor. However, receiving the batch descriptor, a batch processing unit fetches all the work descriptors in the array in a single PCIe transaction, forwards them to the processing unit for execution, and writes the completion records of the work descriptors in another PCIe transaction.

Figure 7 demonstrates that larger batch sizes decrease the average processing latency per work descriptor. For instance, a batch size of 8 offers 81% and 83% lower latency than the batch size of 1 for memcmp and xxhash, respectively. This notable latency reduction is primarily attributed to the reduced cost of (1) communication between CPU and DSA for submitting work descriptors and receiving completion records over PCIe, and (2) context switching between the ksm process and the application process. Note that the PCIe communication latency is dominated by other overheads rather than data transfer time when the data-transfer size is small [17]. To benefit from DSA's batching capability, ksm should be able to select multiple tree pages to compare with the candidate page or multiple candidate pages to compare with a tree page. However, it is not designed to do so as it is a serial algorithm.

5 Para-ksm

DSA batch processing effectively amortizes the long latency of offloading functions from CPU (§4), increasing the rate of memory deduplication. However, the vanilla ksm implementation inherently lacks parallelism to leverage DSA batch processing. To address this shortcoming, we propose Para-ksm,

a parallelized ksm optimized for efficient batch processing. Para-ksm significantly accelerates the deduplication process by batching data-plane functions associated with candidate page and further exploring batching strategies for tree page.

5.1 Sequential Processing in ksm

memcmp and xxhash are used to identify matching pages during the searches in stable and unstable trees, and to verify whether page contents have been modified between scans. We identify two **B**ottlenecks that impede the parallel processing of these data-plane functions: **(B1)** single candidate page selection and **(B2)** ordered comparisons in tree search, which stem from the properties of the trees employed by ksm.

Single candidate page selection. As illustrated in Figure 1, ksm selects one candidate page at a time from the advised memory region. It then searches for the matching page by sequentially comparing candidate page with tree pages and computes a checksum of its content if necessary. This design naturally leads to the sequential execution of data-plane functions, significantly limiting parallelism. The root cause lies in the rebalancing process of the RB trees used in ksm. An RB tree, as a type of self-balancing binary search tree (BST), maintains balance by performing recoloring and/or rotations after each node insertion or deletion, keeping a longest-to-shortest path ratio of at most two. This rebalancing ensures efficient search operations in the RB tree with a time complexity of $O(\log N)$, where N is the number of nodes in the tree. However, rebalancing prevents batch processing of candidate pages because inserting even one candidate page can modify the tree structure, invalidating comparisons already performed for other candidate pages in the same batch.

Ordered comparisons in tree search. ksm manages the memory pages using two RB trees, unstable tree and stable tree, which store pointers to pages and organize them in a ***lexicographical*** order based on page contents. This ordering enables efficient binary searches within the trees to find matching pages by avoiding unnecessary comparisons. However, since each comparison determines the next search direction, comparisons along the search path must be performed sequentially. For example, DSA-ksm typically needs to submit four separate WDs sequentially to complete a search in a four-level RB tree, as the selection of the tree page in each WD depends on the previous comparison result returned by DSA. As shown in Figure 7, this sequential approach can result in higher latency per function than CPU-based counterparts, compromising the memory-saving performance of DSA-ksm.

5.2 Para-ksmC: Candidate Page Batching

To eliminate **B1**, Para-ksm enhances vanilla ksm by incorporating candidate page batching and redesigning tree search and insertion (Para-ksmC). Para-ksmC selects N consecutive candidate pages from the advised memory region, groups them into a single batch, and conducts data-plane functions over the batch in a parallelized manner. These parallelized memory comparisons and checksum computations are offloaded to DSA using batch descriptors to exploit DSA's batch processing capabilities. As the batch processing of xxhash functions on candidate pages is straightforward, this section focuses on how Para-ksmC supports and leverages batch processing of memcmp functions in the renovated search and insertion design. In particular, we use unstable tree search and insertion as an example in this section, since the operations in the stable tree are structurally identical.

5.2.1 Search in Para-ksmC

Para-ksmC selects 256 consecutive memory pages to build a candidate page batch based on a thorough parameter search (§6.5). Since candidate pages are pre-allocated before ksm execution and their volume is typically sufficient, Para-ksmC does not wait to accumulate a full batch of 256 candidate pages. If fewer pages remain during a ksm scan pass, Para-ksmC immediately offloads all remaining pages to the DSA, avoiding unnecessary delays. Before starting the tree search, Para-ksmC creates a search_result for each candidate page in the batch, which encapsulates the addresses of candidate page as well as the addresses of its predecessor and successor in the tree. The predecessor and successor of a candidate page are defined as follows:

$$predecessor(x,S) = \max\{s \in S \mid s < x\} \quad (1)$$

$$successor(x,S) = \min\{s \in S \mid s > x\} \quad (2)$$

, where S is the set of compared tree pages.

The addresses of predecessor and successor are initialized as NULL in search_result. Para-ksmC leverages a key **P**roperty of RB trees: **(P1)** rebalancing does not alter the predecessor or successor of a candidate page. Based on **P1**, Para-ksmC uses search_result to track the addresses of predecessor and successor, as each candidate page is always inserted as a child of either its predecessor or successor. This approach eliminates repeated searches for a proper insertion spot after tree rebalancing caused by other candidate pages from the batch. Further details on the usage of search_result are provided in Section 5.2.2.

Figure 8 illustrates how Para-ksmC performs tree search in a three-level tree as an example. For simplicity, numerical values in nodes represent page contents, and the arrows indicate

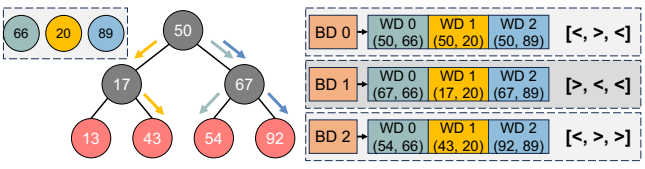

Figure 8: Search in Para-ksmC.

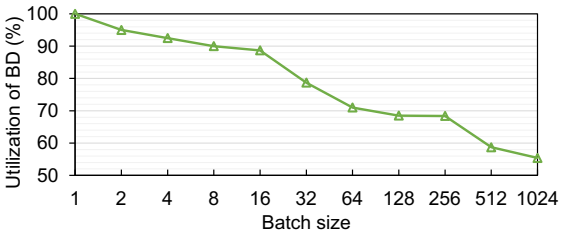

Figure 9: Utilization of BD in Para-ksmC with varying candidate page batch sizes.

search paths for candidate pages, with each path highlighted in the same color as the corresponding candidate page. The search starts at the root node. Para-ksmC prepares a list of WDs, each containing the address of a candidate page and the address of a tree page pointed to by the root node. A BD is then created to point to the WD list and submitted to DSA for batch processing of memcmp functions. Based on the comparison results returned from DSA, the WDs are updated with the addresses of the next selected tree pages for further comparisons with candidate pages. The search for each candidate page terminates when a matching page is found or when a leaf node is reached. During the search, predecessor and successor addresses in the search_result are dynamically updated based on comparison outcomes. If the encountered tree page is smaller than the candidate page, predecessor address is updated to the address of the tree page; if larger, successor address is updated. If the tree page and candidate page are the same, both successor and predecessor addresses are set to the address of this matching tree page. While Para-ksmC offloads memcmp operations to DSA efficiently in a batching manner, it preserves the original comparison paths of CPU-ksm to maintain correctness, without altering the tree traversal logic.

Unlike CPU-ksm, which interleaves page comparison and tree insertion for each page, Para-ksmC decouples the two stages by first conducting comparisons and then inserting pages in the batch, achieving similar per-page comparison and insertion times as CPU-ksm. To enable this, Para-ksmC processes all candidate pages in the batch simultaneously by deferring tree operations, such as insertion or deletion, until searches for all candidate pages in the batch are complete. This approach removes the dependency on sequential candidate page selection, preventing tree rebalancing from interfering with the search paths of other candidate pages within the batch. However, this design introduces a potential issue dubbed ***comparison skewness***. More specifically, during the search, the number of comparisons required for different candidate pages within the same batch can vary notably, leading to underutilization of BD and diminishing the benefits of batch processing. For example, in a batch of three candidate pages, one candidate page may find its matching page after five comparisons, while the other two require ten. As a result, Para-ksmC submits ten BDs to complete the comparisons for the entire batch, even though only two WDs remain in the WD list after the fifth BD. We examined the BD utilization on memcmp functions across various batch sizes, where utilization is defined as the ratio of the number of WDs in the list to the preset candidate page batch size. Figure 9 presents the utilization of BD when Para-ksmC co-runs with Graph500 (§6). The utilization remains above 90% when batch sizes are below 16. However, as the batch size increases, utilization drops sharply, falling below 60% at the batch size of 512. This underutilization of BD indicates an increasing skewness in larger batches, reducing the benefits of batch processing on DSA and highlighting the need for a careful batch size selection to maximize the effectiveness of Para-ksmC.

5.2.2 Insertion in Para-ksmC

After completing the search for all candidate pages in the batch, Para-ksmC proceeds to insert them into the unstable tree. Para-ksmC tracks the predecessor and successor of each candidate page in the search_result (§5.2.1) and uses a hash table to group search_results based on the hash value of the predecessor address as shown in Figure 10. We leverage another property of RB trees: **(P2)** two candidate pages either share the same pair of (predecessor, successor) or have distinct non-overlapping pairs. By **P2**, we know that the search_results in the same group share the same successor. After adding all search_results into the hash table, Para-ksmC traverses the hash table to insert candidate pages as outlined in algorithm 1.

If a group in the hash table contains only one search_result, the candidate page is inserted as either the left child of successor or the right child of predecessor, using the addresses recorded in search_result. Since groups have disjoint (predecessor, successor) pairs, inserting a candidate page in one group does not affect insertions in other groups. For groups with multiple search_results, Para-ksmC sorts them in descending order based on the content of candidate pages pointed to by each search_result, using the CPU-based memcmp function. If the same pages are found in the group, they are merged and inserted into stable tree directly,

Algorithm 1: unstable tree insertion in Para-ksmC.

```
for group ∈ hash_table do
    if len(group) > 1 then
        compare_and_reorder(group)
        update_succ(group)
    for search_result ∈ group do
        cand_page = search_result[0]
        (pred, succ) = search_result[1]
        if pred.right == NIL then
            pred.right = cand_page
        else
            succ.left = cand_page
        Rebalance the tree.
```

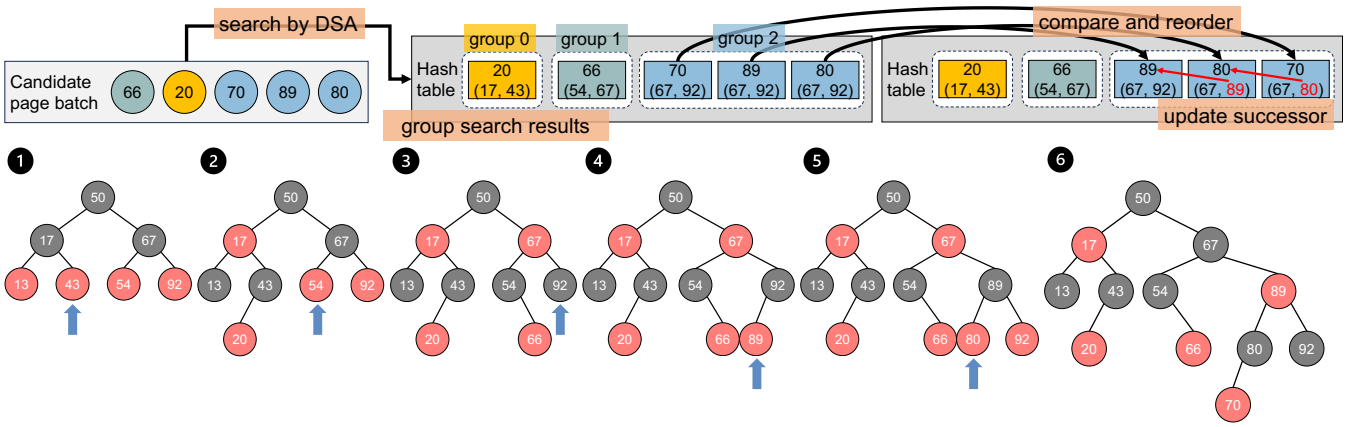

Figure 10: Insertion in `Para-ksmC`. Blue arrows point to the insertion locations in unstable tree.

and their corresponding `search_results` are removed. The successor address in each remaining `search_result` is then updated to the candidate page address in the preceding `search_result` in the sorted group. This intra-group sorting and successor update ensure that `search_result` records the correct predecessor and successor, remaining unaffected by any rebalancing triggered by earlier insertions. Figure 10 (lower) illustrates a step-by-step example of candidate page insertion into unstable tree in `Para-ksmC`. After each candidate page insertion, the unstable tree rebalances through recoloring (e.g., ❶ to ❷) and/or rotation (e.g., ❹ to ❺). Nonetheless, with our careful design, `Para-ksmC` can always identify the correct insertion point for each candidate page regardless of how the tree structure is changed.

5.3 `Para-ksmT`: Tree Page Batching

To mitigate **B2**, `Para-ksm` introduces ***speculative page comparison*** for batched tree pages (`Para-ksmT`). Instead of waiting for each comparison result to select the next tree page to be compared with candidate page, `Para-ksmT` speculatively compares the candidate page with tree pages across the next M levels and offloads all comparisons in a single BD as shown in Figure 11. Specifically, `Para-ksmT` performs an M-level inorder traversal starting from a specified node to aggregate tree pages. ❶ The inorder traversal ensures that tree pages

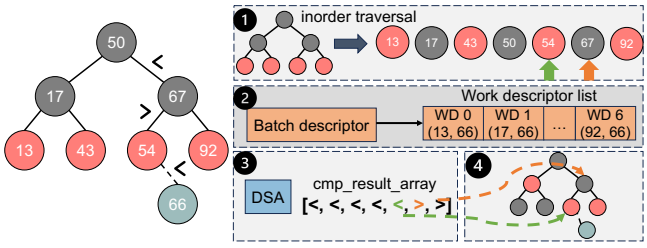

Figure 11: Search and insertion in vanilla `ksm` (left) and `Para-ksmT` (right). Green and orange arrows point to the predecessor and successor, respectively.

are visited in ascending order based on their contents, and their addresses are stored sequentially in a `tree_page_array`. `Para-ksmT` creates a WD list, where each WD includes the candidate page address and a tree page address from `tree_page_array` in sequential order. ❷ A BD pointing to the WD list is then created and submitted to DSA to execute `memcmp` functions in one offload. Upon completion, ❸ the comparison results are retrieved from the completion record and stored in the `cmp_result_array` in the same order as the WDs in the WD list. Since `cmp_result_array` preserves the same order as `tree_page_array`, predecessor (successor) is easily located in `tree_page_array` by the index of the last negative (first positive) result in the `cmp_result_array`. If predecessor (successor) is not found, `Para-ksmT` checks the left (right) child of the smallest (largest) tree page and inserts candidate page if a spot is available. If both exist, `Para-ksmT` checks the right child of predecessor and/or the left child of successor and inserts candidate page if the child is absent. If no spots are available for insertion, `Para-ksmT` continues the search on the subtrees until reaching the leaf nodes. Figure 11 (right) illustrates an example search and insertion in `Para-ksmT`. With M set to three, `Para-ksmT` speculatively compares the candidate page with seven tree pages in the next three levels in parallel and offloads seven page comparisons in a single BD to DSA. In contrast, `DSA-ksm` requires three sequential page comparisons and submits three separate WDs to DSA.

While `Para-ksmT` leverages batch processing, its memory deduplication rate remained limited. Our evaluation indicates that `Para-ksmT` achieves 9.2% of `CPU-ksm` 's deduplication rate, slightly higher than `DSA-ksm`. This underwhelming performance is caused by the overhead of unnecessary comparisons introduced by speculative page comparisons, resulting in a significant waste of DSA computation resources. After traversing M levels, `Para-ksmT` offloads $2^M - 1$ page comparisons to DSA while `DSA-ksm` only offloads M page comparisons. That is, only M out of $2^M - 1$ comparisons contribute to identifying duplicate pages. In addition to extra computation in DSA, speculative traversal also incurs extra data move-

Table 1: Hardware and software configurations.

Hardware	Description
CPU	Intel® Xeon 8460Y+ CPUs @2.0 GHz, 40 cores and 2.625 MB LLC per core, Hyper-Threading disabled
Memory	8-Ch. w/ 8 32GB DDR5-4800 DRAM modules

ment. Our evaluation shows that when $M = 6$, this results in an extra 2% of system DRAM bandwidth consumption. Moreover, `Para-ksmT` lacks support for batch processing of `xxhash` functions, further restricting its effectiveness compared to `Para-ksmC`. We consider `Para-ksmT` a complementary optimization to `Para-ksmC`, potentially beneficial in environments with abundant computational resources to handle offloaded functions. However, due to the limited availability of DSA devices in our setup, the following sections focus on evaluating `Para-ksmC`.

6 Evaluation

6.1 Evaluation Setup

System Setup. Table 1 summarizes the hardware and software configurations used in our experiments. CPU core frequency is locked at 2.0 GHz, and hyper-threading (HT) is disabled to ensure consistent performance measurements across runs. The on-chip DSA is configured with one group consisting of a 64-entry WQ and four processing engines. Candidate page batch size in `Para-ksmC` is set to 256 based on the evaluation in Section 6.5. We reproduce `STYX` [14] on NVIDIA BF-3 [26] for a comparison with `Para-ksmC`.

Workloads. We evaluate three representative workloads: `Liblinear` [6], `Graph500` [36], and `Redis` [30] with Yahoo! Cloud Serving Benchmark (`YCSB`) [5]. `Liblinear` is a widely used library for large-scale linear regression, processing datasets with millions of instances and features. We run the Support Vector Regression (SVR) from `Liblinear` on the `SUSY` dataset [39]. `Graph500` is a high-performance computing benchmark designed to stress memory subsystems with its graph generation and traversal. We use `Graph500` to generate a graph of scale 23 and edge factor of 16, and run breadth-first search (BFS) on it. `Redis` is a high-performance, in-memory Key-Value Store (KVS) database widely adopted in real-world applications requiring low-latency data access. `YCSB` is a benchmarking framework to evaluate the performance of KVS databases, providing four workloads: (a) `update heavy` (50% read and 50% update), (b) `read heavy` (95% read and 5% update), (c) `read only` (100% read) and (d) `read latest` (95% read and 5% insert), with a uniform distribution for key values.

Methodology. We launch 40 VMs, each assigned one virtual core (vCPU) and 6 GB RAM, pinned to a dedicated physical core. For `Liblinear` and `Graph500`, each VM runs the workload independently. For `Redis`, we organize the 40 VMs into 10 groups, each comprising 3 VMs as `Redis` clients and 1 VM as the `Redis` server to handle the requests. Given the memory-intensive nature of `Redis` client operations, we employed Intel's Cache Allocation Technology (CAT) [12] to partition the LLC. Specifically, one cache way is reserved for each `Redis` server, while the remaining cache ways are shared among the clients to minimize interference between client and server processes. We configure the vanilla `ksm` running on CPU (`CPU-ksm`) and `Para-ksmC` to achieve comparable memory savings and provide a fair evaluation of their impact on the co-running workloads.

6.2 Application Performance

We adopt execution time as the performance metric for `Liblinear` and `Graph500`, and 99th-percentile (p99) latency for `Redis`, as user-serving datacenter applications like `Redis` must meet strict tail latency requirements [22, 27]. Figure 12 shows the performance degradation of `Liblinear`, `Graph500`, and `Redis` on systems that deploy `CPU-ksm`, `DSA-ksm`, `STYX`, and `Para-ksmC`, normalized to a system without running `ksm` (`no-ksm`). Performance degradation refers to the increase in execution time for `Liblinear` and `Graph500`, or the increase in p99 latency for `Redis`, compared to `no-ksm`.

On average (geometric mean), `CPU-ksm` incurs 3.3× performance degradation over `no-ksm`. `YCSB` workloads on `Redis` experience higher degradation, with an average of 3.7×, while `Liblinear` and `Graph500` have an average of 2.1× execution time increase, as the tail latency is more sensitive to the CPU contention caused by the intensive data-plane functions running on the CPU. In contrast, `DSA-ksm`, `STYX` and `Para-ksmC` incur 1.3×, 1.4× and 2.1× performance degradation compared to `no-ksm`, respectively. That is, `DSA-ksm`, `STYX` and `Para-ksmC` reduce the performance degradation by 2.5×, 2.4× and 1.6× compared to `CPU-ksm`. Both `DSA-ksm` and `Para-ksmC` alleviate CPU contention by offloading data-plane functions (*i.e.*, `memcmp` and `xxhash`) to DSA, freeing CPU cycles for co-running applications and reducing the cache pollution as shown in Section 6.3. `Para-ksmC` exhibits higher performance degradation than `DSA-ksm` because it retains intra-group page comparisons on the CPU and incurs additional overhead (*e.g.*, successor update) during search and insertion (§5.2).

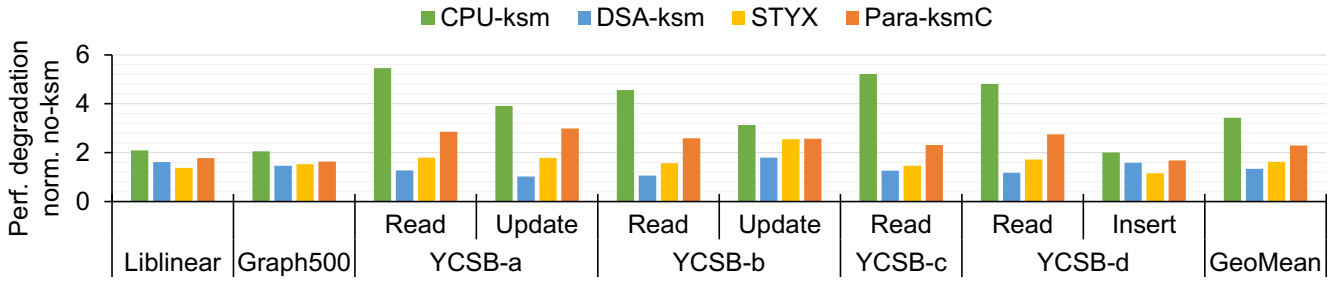

Figure 12: Workload performance degradation under CPU-ksm, DSA-ksm, STYX and Para-ksmC, normalized to no-ksm.

6.3 Impact on CPU Resource

To disclose how DSA-ksm and Para-ksmC mitigate the impact of CPU-ksm on the co-running applications, we investigate their CPU cycle consumption and LLC miss rates of server CPU in the system.

6.3.1 CPU Cycle Consumption

Both DSA-ksm and Para-ksmC conserve the server CPU cycles by offloading the CPU-intensive data-plane functions to DSA. We identify the intervals during which ksm and application co-run on a server CPU core and measure the server CPU cycles consumed by ksm within these intervals. The total CPU cycles consumed by ksm are summed and divided by the total server CPU cycles during co-running periods to calculate the average CPU utilization. The reported values for YCSB workload are geometric averages across four YCSB workloads.

Table 2 shows that CPU-ksm consumes significant CPU cycles when it co-runs with applications, with an average CPU utilization of 48%, consistent with our observations in Section 3.1. On average, DSA-ksm and Para-ksmC reduce the CPU utilization of ksm by 85% and 36%, respectively, compared to CPU-ksm. STYX achieves a comparable level of CPU cycle reduction as DSA-ksm, as both approaches succeed in offloading the memcmp and xxhash from host CPU. The saved CPU cycles can be used for applications, reducing the performance degradation caused by the deduplication feature. Para-ksmC consumes more CPU cycles than DSA-ksm because it does not offload intra-group memcmp to DSA and performs extra operations (*e.g.*, hashing on search_results and successor update) to ensure correct insertion in trees. Despite the higher CPU cycle consumption than DSA-ksm, Para-ksmC delivers more effective and efficient memory deduplication, as demonstrated in Section 6.4.

Table 2: CPU utilization of CPU-ksm, DSA-ksm, STYX and Para-ksmC when they co-run with different workloads.

	Liblinear	Graph500	YCSB	GeoMean
CPU-ksm	44.5%	39.2%	51.7%	48.2%
DSA-ksm	5.8%	5.2%	8.5%	7.3%
STYX	5.4%	5.7%	5.4%	5.5%
Para-ksmC	37.6%	29.8%	29.8%	31.0%

6.3.2 LLC Miss Rate

By offloading data-plane functions, DSA-ksm and Para-ksmC not only conserve CPU cycles but also alleviate cache pollution. We evaluate the cache pollution by measuring the LLC miss rates of the server CPU every second while running CPU-ksm, DSA-ksm, STYX, and Para-ksmC.

Table 3 reports the average LLC miss rates across workloads. CPU-ksm leads to 7%–114% higher LLC miss rate than no-ksm as ksm brings cold pages into CPU caches for comparison or checksum calculation when invoked. Liblinear and Graph500 exhibit smaller LLC miss rate increases as they are more memory-intensive than Redis. DSA-ksm and Para-ksmC reduce the LLC miss rate by 28% and 18% on average compared to CPU-ksm. The reduction is achieved because DSA reads data directly from host memory to its processing engines, bypassing the CPU cache hierarchy when executing the offloaded functions (❸ in Figure 6). However, cache pollution is not fully eliminated in DSA-ksm and Para-ksmC, as only the two dominant data-plane functions, memcmp and xxhash, are offloaded, while control-plane functions remain on the CPU.

6.4 Deduplication Performance

After evaluating the impact on application performance and CPU resources, we focus on the deduplication performance of the memory deduplication feature in this section. Specifically, we examine the deduplication effectiveness and efficiency of

Table 3: LLC miss rate of systems (no-ksm, CPU-ksm, DSA-ksm, STYX and Para-ksmC).

	Liblinear	Graph500	YCSB	GeoMean
no-ksm	52.5%	8.9%	20.7%	21.3%
CPU-ksm	56.4%	11.9%	42.5%	30.5%
DSA-ksm	52.2%	9.0%	22.9%	22.1%
STYX	53.5%	9.5%	21.7%	21.9%
Para-ksmC	52.7%	10.4%	28.4%	25.0%

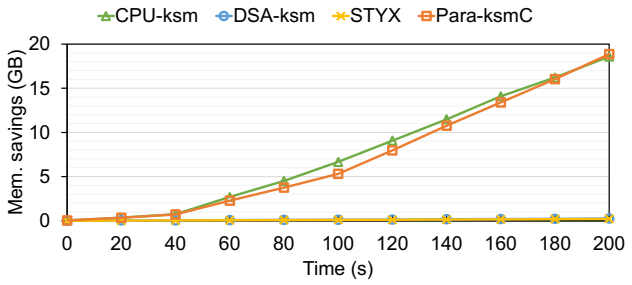

Figure 13: Memory saving under `CPU-ksm`, `DSA-ksm`, `STYX` and `Para-ksmC` when `Liblinear` runs.

`CPU-ksm`, `DSA-ksm`, and `Para-ksmC`.

6.4.1 Deduplication Effectiveness

Deduplication effectiveness is measured as memory saving achieved at a given time while the deduplication feature co-runs with workloads. Although metrics like the number of scanned or saved pages can reflect the deduplication progress, memory savings offers a more direct and comprehensive measure of deduplication effectiveness, as it captures both the amount and usefulness of eliminated duplicate pages. We pick a 200-second window during which the deduplication feature runs alongside the workload and measure the memory savings every 20 seconds.

Figure 13 shows the memory saving over the selected period using `Liblinear` as a representative workload, reflecting similar trends observed across other workloads. `DSA-ksm` achieves only 12% of `CPU-ksm`'s memory saving after the first 20 seconds, with the gap widening over time. The deduplication effectiveness of `DSA-ksm` is hindered by the long execution time of DSA-based `memcmp` and `xxhash` functions (Figure 7), resulting from the communication overhead between CPU core and DSA. `STYX` exhibits slightly lower deduplication effectiveness than `DSA-ksm` in the same window, due to even longer offloading latency that further delays memory savings. Although both `DSA-ksm` and `STYX` eventually converge toward the memory savings of `CPU-ksm`, their short-term effectiveness is constrained by offloading inefficiencies. The limited deduplication effectiveness of `DSA-ksm` highlights the necessity of exploiting the batching capability of DSA to amortize the offloading overhead.

`Para-ksmC` achieves memory savings comparable to `CPU-ksm` by redesigning `ksm` and leveraging the batching capability of DSA. During the period, `Para-ksmC` delivers 20% less memory savings than `CPU-ksm` after the first 100 seconds and eventually narrows the gap to under 1% by the end. The significant improvement in deduplication effectiveness of `Para-ksmC` over `DSA-ksm` stems from the redesign of vanilla `ksm` that enables `memcmp` and `xxhash` to operate on multiple pages in parallel. This software enhancement allows functions to be offloaded to DSA in a batch, substantially reducing offloading overhead and consequently boosting deduplication effectiveness.

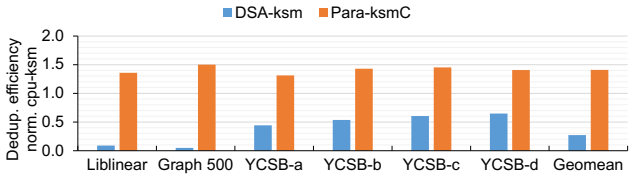

Figure 14: Deduplication efficiency of `DSA-ksm` and `Para-ksmC` normalized to `CPU-ksm` across workloads.

6.4.2 Deduplication Efficiency

Deduplication efficiency is defined as the memory savings per 1K CPU cycles consumed by the deduplication features (*i.e.*, `CPU-ksm`, `DSA-ksm`, and `Para-ksmC`). This metric offers a more comprehensive evaluation by accounting for both CPU cycle consumption and memory savings, reflecting how efficiently deduplication features utilize CPU cycles. Similar to Section 6.4.1, we select a 200-second window during which the deduplication features and user applications run concurrently. The deduplication efficiency is calculated by dividing the total memory savings by the CPU cycles consumed by the deduplication features during this period.

Figure 14 presents the deduplication efficiency of `DSA-ksm` and `Para-ksmC` normalized to `CPU-ksm` across workloads. `DSA-ksm` achieves only 5%–65% deduplication efficiency compared to `CPU-ksm`. This reduced efficiency is primarily because `DSA-ksm` offloads each function individually in DSA asynchronous mode. Excessive context switching and CPU-DSA communication overhead overwhelm the CPU cycle savings from function offloading, leading to lower overall efficiency. In contrast, `Para-ksmC` achieves 1.3×–1.5× higher deduplication efficiency than `CPU-ksm`. Its superior efficiency over `DSA-ksm` is attributed to the batch processing on DSA, which consolidates multiple functions into a single BD instead of processing individual WDs. Batch processing amortizes the submission overhead across multiple functions, reduces the frequency of context switches, and minimizes the software overhead for checking completion records. Although `Para-ksmC` introduces additional operations to vanilla `ksm`, the benefits of batch processing outweigh these overheads, yielding significantly higher efficiency.

6.5 Impact of Batch Size

In this section, we investigate how the deduplication performance of `Para-ksmC` changes under different batch size configurations. We measure the memory saving every 20 seconds and CPU cycles consumed by `Para-ksmC` over a 160-second period during which `Para-ksmC` co-runs with `Graph500`.

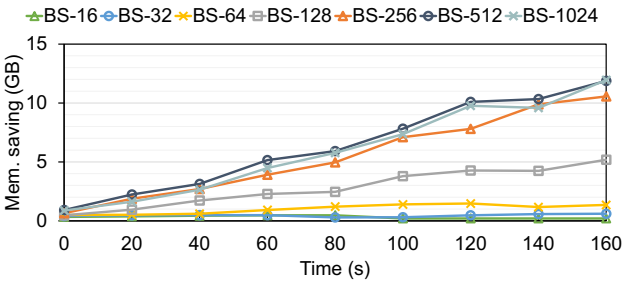

Figure 15: Memory saving achieved by `Para-ksmC` under varying batch sizes (BS) while co-running with `Graph500`.

Figure 15 shows memory saving achieved by `Para-ksmC` with batch size ranging from 16 to 1024, where 1024 is the maximum batch size supported by DSA. As the batch size doubles from 16 to 256, `Para-ksmC` achieves 3.0×, 2.2×, 3.9× and 2.1× increases in memory savings over the preceding batch size. However, beyond the batch size of 256, the improvements plateau, with only 1.1× and 1.0× higher memory savings as the batch size doubles from 256 to 512 and 512 to 1024, respectively. Two factors drive this plateau. First, DSA 's limited function processing capability becomes a bottleneck for larger batches, increasing the latency of DSA-based functions and degrading deduplication performance. Second, the comparison skewness issue, as shown in Figure 9, exacerbates the underutilization of BD at large batch sizes, reducing the overall efficiency of batch processing. We also calculate the deduplication efficiency of `Para-ksmC` across various batch sizes normalized to the efficiency achieved at a batch size of 16, as shown in Figure 16. The deduplication efficiency rises steadily up to 2.2× at a batch size of 256, then slightly declines at larger batch sizes. This decline results from DSA's processing limitations and the effects of comparison skewness, as discussed above.

7 Related Work

Memory deduplication. Memory deduplication has proven to be an efficient technique for reducing server memory requirements, particularly in virtualization environments [7, 8, 29, 31, 32]. Numerous software and hardware techniques have been proposed to enhance the performance and scalability of `ksm`, the widely used memory deduplication mechanism.

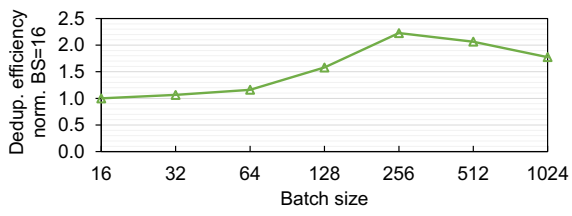

Figure 16: Deduplication efficiency of `Para-ksmC` across different batch sizes, normalized to the efficiency at the batch size of 16, while co-running with `Graph500`.

On the software side, UPM [29] enhances `ksm` by using user-provided hints to identify memory regions likely to contain duplicates, thereby improving accuracy and reducing overhead. XLH [21] extends the memory deduplication process by introducing cross-layer I/O-based hints, enabling earlier identification and exploitation of page-sharing opportunities. CMD [4] classifies pages into different groups and performs comparisons only between pages within the same group, thereby minimizing futile comparisons. However, these software techniques still rely on the CPU for data-plane functions, and thus cannot eliminate CPU overhead. `Para-ksm` enhances `ksm` by introducing greater parallelism, offering an orthogonal approach that can be combined with the aforementioned software techniques.

On the hardware side, PageForge [34], a pioneering design, integrates a dedicated hardware component into the memory controller to execute `memcmp` and leverages the Error Correcting Code (ECC) engine to perform `xxhash` functions. Although PageForge reduces CPU overhead, it requires complex and challenging modifications to memory controller hardware that are infeasible without vendor support. In contrast, `Para-ksm` can operate seamlessly on processors with on-chip DSA accelerators without any hardware modification.

Kernel function offloading. Kernel function offloading has been popular for its success in alleviating CPU workload by shifting intensive OS functions and stacks to specialized hardware accelerators, such as GPUs, FPGAs, SmartNICs (SNICs), and dedicated processors. PCIe-based FPGAs and SNICs stand out as promising candidates for offloading due to their flexible programmability. LineFS [16] offloads distributed system functions, while FlexTOE [33] offloads the TCP stack to SNICs. Pigasus [41] employs FPGA-based SNICs to accelerate the intrusion detection and prevention systems (IDS/IPS), two demanding stateful network functions. Performance-related kernel functions are offloaded to FPGAs in a prior work [1] and hXDP [3] offloads Linux's eXpress Data Path programs written in eBPF to FPGAs.

Specific to memory deduplication, Catalyst [7] employs GPUs to accelerate computationally intensive functions from `ksm`, while STYX [14] harnesses the capabilities of RDMA-capable SNICs to mitigate the overhead of `ksm`. However, as a non-coherent off-chip device accessed over PCIe, STYX introduces longer offloading latency, requires memory pinning,address translation, and involves substantial kernel modifications (∼1300 LoC). In contrast, `Para-ksm` utilizes a coherent on-chip DSA, achieving lower offloading latency without the need for memory pinning, and integrates more easily into the OS (∼300 LoC). Compared to another recent work [13], which only offloads `memcmp` to DSA and uses the CPU to filter comparisons to offset offloading latency, `Para-ksm` achieves lower CPU utilization by offloading both

memcmp and xxhash, and improves deduplication throughput by redesigning ksm and leveraging the batching capability of DSA. Recent work [15] on CXL Type-2 devices demonstrates efficient kernel function offloading with reduced communication overhead enabled by the cache-coherent CXL interconnect. However, the current implementation of genuine CXL Type-2 devices relies on a resource-constrained FPGA for computation, which is less capable than DSA and requires extra programming effort. Furthermore, Para-ksm's software enhancements to ksm are adaptable to existing hardware acceleration techniques for memory deduplication, offering the potential for higher throughput and improved efficiency.

8 Conclusion

In this paper, we first identified the CPU-intensive functions, memcmp and xxhash, in the memory deduplication feature, ksm, and demonstrated the potential of offloading them to the on-chip accelerator DSA to reduce CPU cycle consumption. Second, we proposed DSA-ksm, which directly replaces CPU-based memcmp and xxhash with DSA-based counterparts in ksm. While DSA-ksm significantly reduced the performance degradation on the co-running applications incurred by ksm, it offered notably lower rates of memory deduplication than ksm due to long offloading latency. We found that DSA's batching capability can effectively amortize this latency by enabling memcmp and xxhash to operate on multiple pages per offload. Based on this observation, we lastly proposed Para-ksm, which redesigns ksm to replace its sequential processing of memcmp and xxhash on a single page with parallel processing on multiple pages, enabling the Para-ksm to fully leverage DSA's batching capability. We showed that Para-ksm increased the amount of memory deduplication per CPU cycle by 31-50% compared to ksm while decreasing the performance degradation of co-running applications incurred by ksm from 1.6–5.8× to 1.3–2.7×.

A Artifact Appendix

Abstract

This artifact provides instructions for reproducing the key experimental results reported in the paper. Specifically, it covers two key sets of experiments: (1) application performance degradation on systems running `CPU-ksm`, `DSA-ksm`, and `Para-ksmC`, normalized to a system without `ksm` (`no-ksm`) (Figure 12); and (2) memory deduplication performance, including both deduplication effectiveness (Figure 13) and deduplication efficiency (Figure 14).

Scope

The artifact enables validation of two main claims: (i) offloading data-plane functions of `ksm` to DSA (`DSA-ksm` and `Para-ksm`) significantly reduces performance degradation of co-running applications; and (ii) after an elaborated redesign of `ksm`, `Para-ksm` leverages DSA's batching capability by processing multiple pages per offload, effectively amortizing offload latency. Compared to vanilla `ksm`, `Para-ksm` achieves comparable memory deduplication effectiveness while significantly improving deduplication efficiency.

Contents

The artifact includes: (i) a `README.md` file containing instructions for building and installing the kernel with `Para-ksm` support, and for running the experiments using provided scripts; (ii) the `linux-paraksm` directory containing the Linux kernel source code modified with the `Para-ksm` implementation; and (iii) the `scripts` directory containing scripts to reproduce experimental results and generate the corresponding figures.

Hosting

The artifact is hosted on GitHub at https://github.com/ece-fast-lab/ATC-2025-Paraksm.git, on the `main` branch. Users can obtain the artifact by cloning the repository and checking out the latest commit (`98716ac`) to reproduce the results.

Requirements

The experiments require a server with 4th-generation (or newer) Intel Xeon Scalable Processor equipped with DSA accelerator. The `Para-ksm` implementation is based on Linux kernel version 6.2.15 and has been tested on Ubuntu 18.04.6 LTS. QEMU-KVM version 2.11.1 is used for virtual machine management, with guest VMs running Ubuntu Cloud 22.04.

A.1 Installation

Clone the artifact repository as follows:

```
$ git clone https://github.com/ece-fast-lab/ATC
    -2025-Paraksm.git
```

The Linux kernel source code with `Para-ksm` implementation can be found in `linux-paraksm` directory. Follow the instructions in `README.md` to build and install the kernel. A system reboot is required to use the compiled kernel.

A.2 Experiment workflow

After installing the kernel, experiments can be executed as follows:

```
$ cd /scripts/fig12-14/
$ bash run.sh
```

The `run.sh` script executes all benchmarks by default; specific experiments can be selected by commenting or uncommenting lines within the script. All generated results will be automatically saved. The figures (Figure 12, 13 and 14) can be plotted and saved as PNG files by running `plot.sh` in the `/scripts/fig12-14/` directory. Additional details are provided in the `README.md` file in the root directory.

DSA-2LM: A CPU-Free Tiered Memory Architecture with Intel DSA

Abstract

Tiered Memory is critical to manage heterogeneous memory devices, such as Persistent Memory or CXL Memory. Existing works make difficult trade-offs between optimal data placement and costly data movement. With the advent of Intel Data Streaming Accelerator (DSA), a CPU-free hardware to move data between memory regions, data movement can be up to 4× faster than a single CPU core. However, the fine memory movement granularity in Linux kernel undermines the potential performance improvement. To this end, we have developed DSA-2LM, a new tiered memory system that adaptively integrates DSA into page migration. The proposed framework integrates fast memory migration workflow and adaptable concurrent data paths with well-tuned DSA configurations. Experimental results show that, compared to three representative tiered memory works: MEMTIS, TPP and NOMAD, DSA-2LM can achieve 20%, 30% and 16% performance improvement under real-world applications.

1 Introduction

Data-intensive applications such as data processing, machine learning and graph processing are experiencing rising memory demands. It couples with the increasing cost of DRAM and limited DRAM capacity have made memory a major expense. Non-DRAM memory devices, such as Compute Express Link (CXL) [33, 40, 50]/Non-volatile Memory (NVM) [37], appear as a larger memory tier with a low per GB price. However, these technologies expose higher latencies than main memory, potentially degrading performance if data is sub-optimally placed in memory hierarchy.

To place hot/cold data in the correct fast/slow tier, the architecture of tiered memory involves three primary stages: detecting hot data, selecting data to be migrated, and executing the data migration. NOMAD [44] presents that a significant amount of time is consumed by page copying during the memory migration process. Despite the implementation of MEMTIS [29], which effectively mitigates page copying using histogram algorithm [29], the measured migration time spent on copying remains around 49%. One solution is to enhance the accuracy of the data hotness detection. Nonetheless, achieving high precision is associated with substantial CPU overhead. Even when tasks are offloaded to hardware solutions such as processor event-based sampling (Intel PEBS [48]), the performance degradation is still recorded at 20% [44]. This is attributed to the increased frequency of migration, which consumes CPU resources (11% CPU overhead in Graph500 [34]) and occupies additional bandwidth, interfering with applications, negatively impacting overall end-to-end performance.

A promising way to reduce CPU bottleneck is to offload overhead to hardware accelerators such as the Intel Data Streaming Accelerator (DSA). DSA can transfer data between memory regions without involving CPU and now ships as a standard feature in 4/5th generation Intel Xeon processors [24]. Its benefits are twofold. First, each page-copy request requires submitting only a small descriptor to work queue (WQ), which takes only a few cycles to complete [10]. This eliminates most of the CPU overhead, even in systems that rely on CXL and CPU interactions. Second, DSA provides a bandwidth of about 32 GB/s per device, comparable to four CPU cores [19]. Modern servers typically include four DSA devices per socket, delivering a combined bandwidth of up to 110 GB/s. Hence, DSA is well-suited for tiered memory.

However, using DSA effectively requires careful design. First, current kernel support for DSA relies on the traditional Direct Memory Access (DMA) interface, introducing large overhead for buffer preparation and (un)mapping. It is inadequate for fine-grained page movement. Second, DSA outperforms CPU-based copying only when there is sufficient concurrency to hide high invocation latency, so asynchronous task partitioning and dispatching must be carefully planned to maximize performance by utilizing the multiple cores provided by the CPU socket. Finally, DSA performance is sensitive to many configurations and requires tuning. We address this by developing an adaptive algorithm for different page types, with dynamic batch sizes and WQ settings.

Based on DSA hardware, we design DSA-2LM (DSA-based two-level memory), a new tiered memory system in Linux kernel with flexible interfaces (§3.2). While inheriting hotness detection and page migration logic via `kmigrated` of MEMTIS [29], DSA-2LM introduces several DSA-specific designs. These designs contain fast memory migrating workflow (§3.3) and adaptable concurrent data migration (§3.4) with well-tuned batch size and number of WQs. It avoids

CPU involvement in the critical data copying path, enabling aggressive CPU-free migrations.

To evaluate the performance of DSA-2LM framework, we choose five widely used applications and use traces of industry workloads. The evaluation environment is a commercial pre-market CXL system. The DSA-based acceleration of page copying allows the system to take full advantage of page migration, thereby improving its responsiveness to changes in memory access patterns. Experimental results show that, compared to three representative page management schemes: MEMTIS [29], TPP [33] and NOMAD [36], DSA-2LM achieves up to 81.7%, 52.9% and 15.6% performance improvement under real-world applications. DSA-2LM is available at https://github.com/madsys-dev/DSA-2LM.

2 Motivation and Challenges

2.1 Tiered Memory and Applications

The memory demand of data-intensive applications such as graph processing and machine learning continues to increase [28]. In Microsoft Azure, memory costs ∼50% of the total server costs [30]. ML models are rapidly growing, and are expected to grow 50× in the next five years [33]. With rapid data growth, memory hierarchy should be redesigned.

Tiered memory fulfills the requirements of data-intensive applications. It uses a two-level hierarchy with a fast, expensive tier and a slow, cost-effective tier [15]. It frequently accesses data in the fast tier, moves less-accessed data to slow tier, and maintains an exclusive data placement. Emerging memory technologies such as high bandwidth memory, CXL memory [8, 32, 40, 43, 51], NVM [47], and NVMe SSDs introduce solutions that challenge the traditional memory hierarchy. For example, CXL [8] integrates various memory devices under a single interface, offering larger storage capacities and narrowing the performance gap. It guided researchers to explore state-of-the-art systems like TPP [33], MEMTIS [29], NOMAD [44], and Nimble [46], each designed to optimize data access across different memory tiers.

2.2 Tiered Memory Top-down

Trade-off between CPU and hotness detection algorithm. Both hardware-based and software-based access tracking involve CPU usage [35, 39], a critical performance bottleneck for tiered memory systems. There is no one-fit-all hotness detection algorithm [45]. Achieving high precision and finer monitoring granularity for detecting hot pages requires tiered memory systems to either shorten the monitoring interval or increase the number of counters, both of which demand additional CPU resources.

Interference between migration and applications. To adapt to dynamically changing workloads, tiered memory requires to frequently migrate data between the fast and slow tiers, leading to data copying overhead. The extra CPU utilization for monitoring and migration will interfere with application performance [23], thus a well-designed tiered memory system may not be the best choice. As shown in Figure 1, increasing the sampling interval results in higher CPU utilization and more page migrations, which can degrade application performance eventually.

Page copy is still a problem for tiered memory. One of the critical challenges is the significant CPU overhead associated with page migration and memory copying. This issue has been explored in previous tiered memory works [27, 29, 44]. Nimble reports 30% in the page migration phase. Our empirical tests further highlight this challenge, particularly in scenarios involving mixed workloads (e.g., co-location [17]) and hot start (e.g., serverless [31]). The core reason for this overhead is the CPU's involvement in memory copying, which leads to CPU stalls. To address this, we explore solutions such as offloading memory copy, which could alleviate the CPU's burden and improve system performance.

Figure 2 shows the function sampling results of kernel migrating process captured by perf [2] on MEMTIS. The proportion of migrating pages is 72.87%, while getting page info from index (i.e., `get_pginfo_idx`, which involves kernel's reverse mapping mechanism and update page access statistics) is 29.82% and memory copying (`migrate_page_list`) is 34.43%. About 73.51% of processor cycles in migrating pages are spent on copying pages.

Huge Pages are commonly found in tiered memory. Transparent Huge Page (THP) is utilized to enhance performance in applications [38], such as cloud [20] and database [21]. Most tiered memory works enable THP, so we measure the processing of TPP. Results show that Huge Pages will be the majority if THP [3] is enabled. For PageRank [22] workload, during the demotion, there are 1249067 4KB Pages and 8670 2MB Huge Pages. Thus Huge Pages account for 78.0% memory.

2.3 Observations of DSA

DSA [24] in Intel 4/5th (Sapphire/Granite Rapids) Xeon CPUs can enhance data copy and transformation. DSA hardware comprises interfaces for host communication, work queues (WQs) for descriptor storage, processing engines (PEs) for task execution, and arbiters for quality of service [25]. DSA devices appear as single root complex integrated endpoints, compatible with PCIe. Users submit 64B descriptors via MMIO portals; these include operation details like operation type, address, and batching list. Descriptors are stored in WQs, which can be either a dedicated WQ for single-client use or a shared WQ for multiple clients without synchronization.

DSA's address translation cache interacts with the IOMMU, supporting coherent shared memory with CPU cores, eliminating the need for memory pinning. The software architecture includes the Intel Data Accelerator Driver (IDXD) [7] for DSA

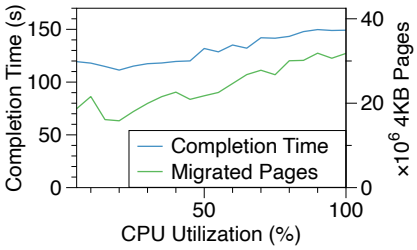

Figure 1: Analysis of hotness detection.

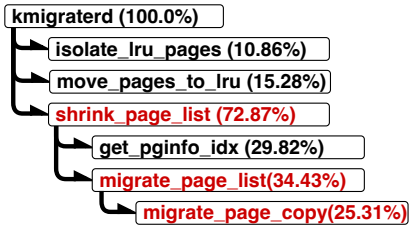

Figure 2: Profiling of migrate process.

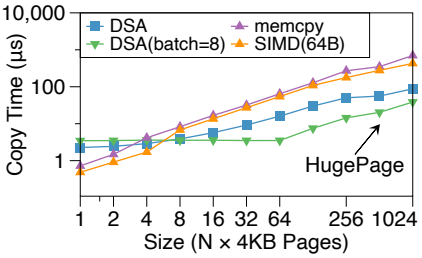

Figure 3: DSA/Memcpy comparisons.

management [19]. Applications exploit `libaccel-config` API to use DSA in user space, and IDXD allows WQ portal address exposed to user space via `mmap`.

The performance of DSA is higher than CPU. While copying data between local/remote NUMA nodes, a DSA can attain a bandwidth of up to 32 GBps, whereas an individual CPU core achieves a maximum bandwidth of only 9 GBps. Moreover, the time required for data copying with a DSA is consistently less than that of a CPU when the size of the data exceeds 32 KB. Furthermore, memory copying increases CPU utilization, leading to interference with ongoing tasks due to significant contention for CPU resources [42].

Not all memory copy sizes benefit from DSA. Figure 3 shows that using DSA performs higher performance than CPU copying when the transfer size is above 32 KB, where each descriptor is submitted and completed before sending another. The submitted descriptors are processed in a pipelined fashion [25], so CPU copying is faster than DSA in small transfer size (< 32 KB). As the transfer size increases, the submission overhead of DSA can be disregarded, thereby showcasing its performance advantage compared to CPU copying.

Number of WQs and batch size of DSA. Figure 4/5 shows that the number of WQs significantly influences maximal throughput. The number of WQs is positively correlated with increased throughput. The throughput attains its maximum when configured with four WQs. Users should carefully consider transfer size, as it affects scalability differently.

The DSA-facilitated batching of descriptors serves to reduce the cost associated with offloading. As shown in Figure 6, the performance improvement plateaus as the batch size reaches 8. Additionally, DSA enhances throughput in a non-linear manner, and it depends on the transfer size.

2.4 DSA v.s., DMA

DMA and DSA operate at different abstraction levels. DMA provides a general interface that various underlying engines, such as DSA or Host Bridge can support, and these interfaces abstract memory operations, letting developers work without dealing with complex hardware drivers [49]. Directly manipulating DSA driver functions (i.e., IDXD) offers less abstraction. However, this approach balances ease of use with advanced functionality and performance. Utilizing DSA directly, without dependence on the DMA interface, presents two principal advantages:

Elimination of memory pinning overhead. Most devices using DMA cannot tolerate page faults, requiring guest buffers to be pinned in host memory and mapped in the IOMMU page table before DMA access. Consequently, DMA becomes problematic in tiered memory scenarios, a major limitation, especially when hosting multiple virtual machines. In contrast, DSA supports the use of either physical or virtual addresses. The use of virtual addresses that are shared with processes running on the CPU is called shared virtual memory. Therefore, address translation does not require IOMMU page table mapping or memory pinning.

Significant performance improvement. In the submitting descriptor phase, DSA shows better performance than DMA. In DSA-2LM, the DSA descriptors are designed as per-cpu variables, so there is no dynamic descriptor (de)allocation. In contrast, using DMA interfaces should wait for the descriptor to be ready. We measure single copy operation for one 4KB page shown in Figure 7. DMA operation spends an extra 88*ns* in total to (un)map DMA buffer, prepare memory copy and submit DMA request. In contrast, only 6*ns* time is required to submit DSA descriptor. The major expensive phase is waiting for the completion of each DMA/DSA operation. According to evaluations in Section 2.3, utilizing features such as DSA batching and multi-channel DSA utilization further boost performance compared to the previous generation DMA engines such as Crystal Beach DMA (CBDMA) and Intel I/O Acceleration Technology. DSA provides 2.1× greater throughput on average and up to 8× higher throughput than CBDMA [25].

2.5 Challenges and Design Principles

Above all, there are three primary challenges: (1) How to directly use DSA in kernel-space for migrating pages and cooperating with tiered memory system (2) How to let both 4KB Page and 2MB Huge Page enjoy the benefit of DSA, and (3) How to dynamically choose appropriate batch size and number of WQs for each descriptor to maximum performance without harming application performance. Thus, we should redesign the tiered memory system considering the features of DSA from three aspects.

Use DSA directly for page migration in kernel space. Utilizing the CPU for page migration will increase CPU footprint, thereby affecting the performance. Section 2.3 shows that using DSA can alleviate CPU overhead and exhibit superior performance in page migration. For in-kernel program-

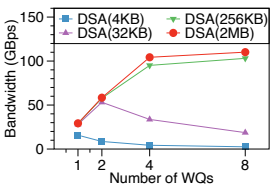

Figure 4: The effects of different number of WQs.

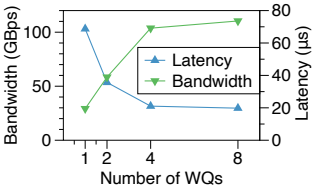

Figure 5: The bandwidth and latency of multi-WQ.

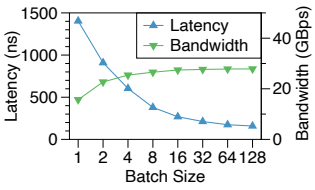

Figure 6: The effects of batch size.

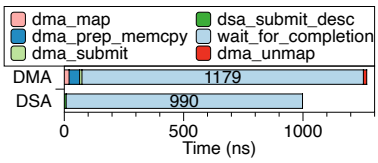

Figure 7: The performance breakdown of DSA and DMA.

ming, we bypass DMA interface and directly use physical address in submitted descriptors. Our evaluation confirms that using DSA in kernel space does not trigger any page fault.

Use asynchronous mode of DSA properly. Handling hardware interrupts in user space can be tricky. Intel officially recommends using `UMONITOR/UMWAIT` instructions after submitting descriptors to reduce power consumption of the CPU core [11, 25, 49]. However, this approach does not achieve true asynchronous mode, as the CPU cannot schedule other tasks while in a low-power state. Intel DTO [1] adopts the `sched_yield` syscall to proactively relinquish the CPU to avoid busy polling, but this sacrifices some responsiveness. Hence, such user-space programming models are not applicable in kernel space. DSA-2LM must carefully design and utilize the advantage of handling interrupts in kernel space, achieving genuine and efficient asynchronous waiting.

Aggregate data path for both small/large size page migration. Section 2.3 presents that only large-sized page migration can benefit from DSA. Naive design is using two separate data paths for page migration. For 4KB Pages, DSA-2LM uses the original `copy_page` method. For 2MB HugePages, DSA-2LM uses DSA-oriented copying functions. A separate data path means extra overhead and small-sized pages cannot benefit from DSA. We need a new data path with adaptable algorithm to aggregate small and large pages.

Carefully tuning parameters for DSA. As we discuss in Section 2.3, using different values of batch size and number of WQs will significantly influence the copying rate. For a page list to be migrated, we should tune the value of parameters to maximize performance. So we need to know the performance changes and adjust the parameters dynamically according to the page number and each page size in the page list.

3 Design of DSA-2LM

3.1 Architecture Overall

DSA-2LM consists of three steps: track page access using hardware performance counter, choose hotness pages, and migrate pages in the background with DSA (Figure 8). (1) DSA-2LM uses the page histogram mechanism, which is the same as MEMTIS [29], to record the access of pages. It samples memory access in the page granularity using PEBS, and updates the hotness distribution of all allocated pages periodically. (2) DSA-2LM ensures that the size of the hot set is

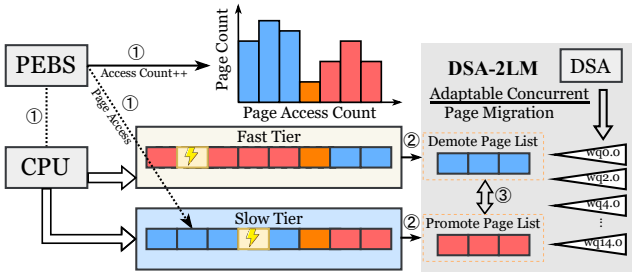

Figure 8: DSA-2LM overall.

maintained near the capacity of the fast tier, thereby enabling the fast tier to accommodate all hot pages. It chooses hot/cold pages according to its access count higher/lower than the thresholds T_{hot} and T_{cold}. These thresholds are dynamically adjusted to fit into the total pages. Then selected hot/cold pages are moved to promotion/demotion page list. (3) The per-node kernel threads responsible for migration perform the migration operation including demotion and promotion. Such a kernel thread will be woken up periodically in a time interval (e.g., 200 ms). DSA-2LM decides to migrate pages according to the available space in the fast tier. It detects the status of DSA, and it migrates the page list using available DSA devices in the kernel space. DSA-2LM uses an adaptable concurrent migration algorithm to copy page lists that include 4KB Pages and 2MB Huge Pages.

Compared to MEMTIS, DSA-2LM inheriting its hotness detection algorithm, page placement strategies and relying on the `kmigrated` kernel thread for page migration. Additionally, DSA-2LM improves MEMTIS's sampling algorithm to consistently utilize the most recent samples, thus avoiding using outdated samples. Crucially, DSA-2LM introduces several key improvements that are specific to DSA. Inspired by Nimble [46], DSA-2LM introduces a concurrent page migration strategy. DSA-2LM applies the DSA adaptive migration algorithm to optimize page copying. Because DSA is CPU-free, DSA-2LM shortens the wake-up interval of the kmigrated thread, adopting a more aggressive migration strategy without incurring extra overhead.

3.2 Implementation in Kernel

An extra moudle is implemented under the `misc/exp` directory, which exposes two new APIs: `dsa_multi_copy_pages` and `dsa_copy_page_lists`. The functionality of DSA-2LM

can be toggled via a sysAPI interface, and various statistical parameters are presented through `procfs` for monitoring purposes. The state-of-the-art tiered memory systems like MEMTIS [29] and TPP [33] are based on the 5.x kernel. To ensure compatibility with existing systems, the overall implementation is based on Linux kernel version 5.13/5.15. The modifications to the memory management subsystem and DSA acceleration module implementation comprise approximately 2K LoC, while the backporting of the IDXD and IOMMU drivers from kernel 6.4 introduces around 8K LoC.

3.3 Migration Workflow

DSA-2LM creates a migration kernel thread for each memory tier to handle promotion and demotion operations in the background. The system maintains two lists: a promotion list containing hot pages for the slow tier and a demotion list containing cold pages for the fast tier.

Whenever processing a memory access sample, DSA-2LM compares the page's hotness factor (H_i) to the threshold T_{hot}. If the page is determined as hot, it is moved to the promotion list. Also, the migration kernel thread periodically performs cooling by halving a page's access count for every N sampled events. This process can cause some pages to transition to cold states, in which case they are moved to the demotion list.

In the slow tier, the migration thread checks for hot pages and determines if there is available space in the fast tier. If both conditions are met, it promotes hot pages to the fast tier. Conversely, when the available memory in the fast tier drops below a predefined free-space threshold (set at 3% of the fast tier's total size for future page allocations and promotions), the demotion operation is initiated.

This demotion process involves selecting victim pages from the fast tier. Initially, cold pages ($H_i \leq T_{\text{cold}}$) are demoted back to the slow tier. It stops until sufficient free space is reclaimed. Otherwise, cold pages are demoted until the necessary free space is achieved. This strategy allows DSA-2LM to retain as many cold pages as possible within the fast tier.

3.4 Adaptable Concurrent Migration

After promotion/demotion page list is prepared, the migration thread uses DSA to copy pages containing mixed 4KB Pages and 2MB Huge Pages.

Before migrating (see Algorithm 1), the total number of available WQs must be initialized. `limit_chans` specifies the total number of available DSAs used for page migration and should be configured properly according to configurations (typically a power-of-two value with DSA-2LM defaulting to 8). In DSA-2LM, each DSA device enables four PEs and one WQ, so DSA device and WQ are one-to-one. DSA-2LM enumerates each WQ, updating the count of available WQs when DSA-2LM is initialized first or `limit_chans`/`dsa_state` are updated through sysfs API.

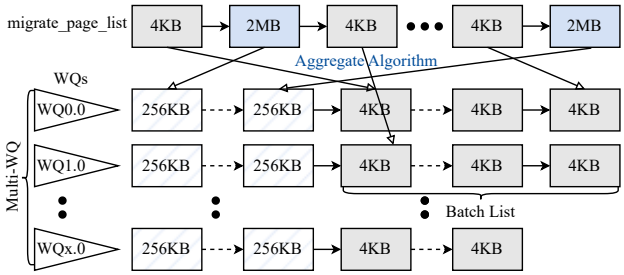

Figure 9: Workflow of adaptable page migration.

Algorithm 1 DSA Migrate Page List

Input: *page_list*: 4KB and 2MB mixed page pair lists to be migrated (A page pair include source/destination page)

1: get `idxd_desc/dsa_hw_desc/dsa_completion_record/completion` pointers from per-cpu `struct` variables
2: **repeat**
3: *nr_base_pages* ← 0
4: **for** each unsolved *page_pair* in *page_list* **do**
5: **if** *page_pair* is THP/HugePage **then**
6: *transfer_size* ← 2MB / `limit_chans`
7: **for** each available WQ *i* **do**
8: Prepare a `memmove` DSA descriptor for (*page_pair*, *transfer_size*, WQ *i*)
9: Submit a DSA descriptor
10: **else**
11: *nr_base_pages* ← *nr_base_pages* + 1
12: *batch_size* ← *nr_base_pages* / `limit_chans`
13: *batch_list* ← ∅
14: **for** each unsolved 4KB *page_pair* in *page_list* **do**
15: Prepare a `memmove` DSA descriptor *desc* for *page_pair*
16: *batch_list* ← *batch_list* ∪ *desc*
17: **if** number of *batch_list* fits *batch_size* **then**
18: Choose a WQ *t* in round robin
19: Prepare a `batch` DSA descriptor for (*batch_list*, *batch_size*, WQ *t*);
20: Submit a DSA descriptor
21: *batch_list* ← ∅
22: **for** each available WQ *i* **do**
23: Yield and wait for WQ *i* completion
24: **until** each page pair in *page_list* has been migrated

Aggregate data path. When the page order is greater than 3 (i.e., 32 KB), utilizing DSA for copying pages achieves lower latency compared to using the CPU. For non-contiguous pages, we employ batch processing to reduce additional overhead. In case of contiguous pages, such as 2MB Huge Pages, we leverage multi-WQ parallel copying to enhance efficiency.

Combining these strategies altogether, Figure 8 and Algorithm 1 show the workflow of handling the promotion/demotion page list. In the first pass, DSA-2LM picks the 2MB Page and splits it into `limit_chans` (e.g., 8) subpages whose size is 2MB / `limit_chans` (e.g., 256 KB), and assigns subpages to each WQ in round robin. In the second pass, DSA-2LM calculates the average transfer size (i.e., `batch_size`) for each WQ based on the remaining 4KB Pages, and distributes them into batch lists in each WQ. According to the "shortboard effect", DSA-2LM balances the total transfer size submitted to each WQ so that the difference among WQs does

not exceed the size of a single 4KB page. If the `batch_size` is less than two in a corner case, DSA-2LM directly submits the remaining 4KB pages to each WQ.

Concurrent migration with both batch and multi-WQ. According to `limit_chans` of batch lists, DSA-2LM initializes the necessary DSA data structures for processing memory copy, including `idxd_desc`, `dsa_hw_desc`, and `dsa_completion_record`. These data structures are created as per-cpu global variables in the initialization phase, to avoid the preparation overhead that exists in DMA processing.

Subsequently, for each WQ, DSA-2LM submits DSA descriptors, ensuring any errors encountered are handled appropriately. Since adopting asynchronous mode, DSA-2LM leverages the Linux kernel's `completion` mechanism to await completion of copy requests. Once the `status` field in the `dsa_completion_record` is set by hardware, it triggers an MSI-X interrupt that awakens the `idxd_wq_thread`, which then scans all pending DSA descriptors. For each completed descriptor, `idxd_wq_thread` invokes the corresponding callback function, thereby signaling the `completion`. Consequently, the migration thread is unblocked from `wait_for_completion_timeout` and proceeds with the subsequent operations. DSA-2LM sets a timeout for each submitted descriptor, and returns fails if it occurs. This workflow significantly enhances the efficiency and speed of page copying operations in the kernel.

4 Evaluations

4.1 Evaluation Configurations

Hardware configuration. Our testbed is a dual-socket server equipped with 4th Gen Xeon Platinum CPU (48×2 physical cores), where each socket has 1 TB (256 GB×4) DDR5 DRAM. One of the sockets is connected to a 64 GB ASIC-based Montage Technology CXL device. We disabled Intel Hyper-Threading and fixed the CPU frequency to 3.2 GHz. We set CPU affinity for workloads and used only 32 cores of one socket. Similar to prior works, we used a DRAM NUMA node (load/store: 112 ns) and a CPU-less node with CXL memory (load/store: ∼300 ns), and THP [16] is enabled. DSA-2LM can also support two NUMA nodes without CXL. We configured the CXL-attached memory to `system-ram` mode. It allows load/store access to CXL memory in kernel space.

Software configuration. We use different methods to equitably constrain the fast tier. For AutoNUMA, TPP and NOMAD, we changed the kernel boot argument (memmap GRUB option [5]) to limit the fast tier size. The fast tier size is set as 16/32 GB. For MEMTIS, we used a memory `cgroup` interface to control the size of the fast tier. The ratios of fast/slow tier memory size were established from 1:2 to 1:16. The proportion of the fast tier size was adjusted from 33% (1/3) to 5.9% (1/17) of the resident set size (RSS) for each benchmark.

Workload	RSS	Description
Graph500	68.0 GB	Graph generation and breadth-first search of some random vertices [18].
PageRank	12.3 GB	Compute the PageRank score with an iterative method [18]. (Twitter dataset [26])
XSBench	63.4 GB	Monte Carlo neutron transport algorithm [41].
BTree	38.3 GB	In-memory index lookup benchmark [4].
Pandas	20.2∼92.6 GB	Data processing with six different queries [12].

Table 1: Workload characteristics.

4.2 Performance of Copy Pages

Two distinct workloads A/B, are employed to assess the impacts of our adaptable copying algorithm. Workload A comprises 1023 4KB pages and a single 2MB huge page, with the smaller 4KB pages constituting the bulk of the workload. Conversely, workload B is characterized by a high page intensity, consisting of 1000 4KB pages and 24 2MB huge pages.

As shown in Figure 10, we measure the bandwidth of continuous page migration with three strategy: 1) CPU: only use CPU to copy pages; 2) DSA (raw): migrating 4KB page with CPU and 2MB page with DSA; and 3) DSA (opt): use adaptable concurrent migration proposed in Section 3.4. For workload B, the bandwidth of DSA-2LM (106.3 GBps) is 14.38/2.19× higher than CPU/DSA (raw) implementations. We conclude DSA-2LM can easily saturate the bandwidth (the peak bandwidth in our evaluation platform is ∼110 GBps).

4.3 Performance Breakdown

We repeat to capture the result of function samples in kernel mode by perf and Figure 11 shows the results. The overall proportion of migrating pages in is dropped from 39.0% to 4.24%, which is only 2.51% compared with the original overhead. This proves that our approach can effectively reduce CPU overhead in the migration data path.

Figure 12 shows copying duration in real-time during the execution of Graph500. The application completes in 142s, with a total copying time of 14.9s when employing CPU-based migration. Conversely, using DSA-based methods DSA-2LM for page migration reduces the total copying time to 1.39s, representing only 9.3% of the baseline duration. In the results reported in DSA-2LM, the copying time accounts for only 0.97% of the execution time, whereas it comprises 10.5% in the context of original tiered memory.

4.4 Real-world Applications

We evaluate five representative workloads in Table 1. Since MEMTIS and TPP limit fast-tier memory size in different ways, it is difficult to reserve the same fast-tier memory size. For a fair comparison, we presented them in separate figures.

The upper part of Figure 13 compares DSA-2LM with TPP, NOMAD, and AutoNUMA. We successfully applied DSA to other state-of-the-art tiered memory systems using similar approaches, denoted as TPP+, NOMAD+, and AutoNUMA+ in Figure 13. We set the fast tier as 16/32 GB.

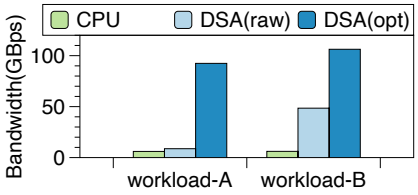

Figure 10: The performance of adaptable copying algorithm.

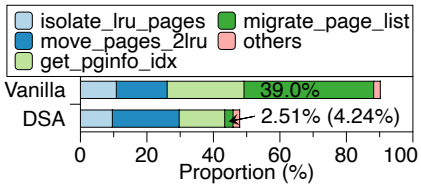

Figure 11: The perf breakdown in DSA-2LM.

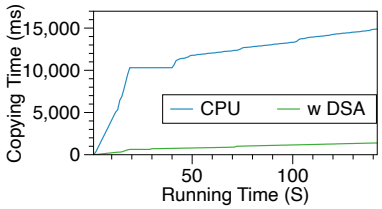

Figure 12: CDF of copying time.

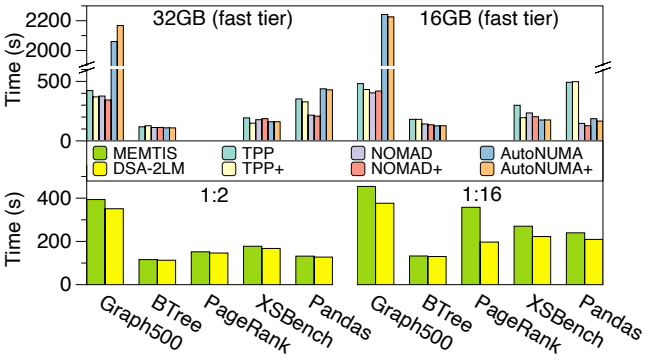

Figure 13: Performance with different applications.

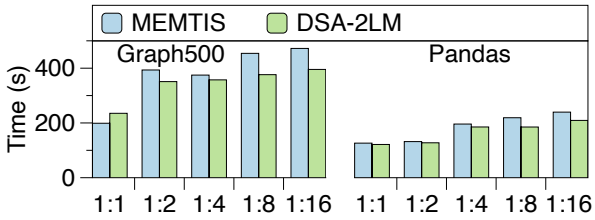

Figure 14: Performance with different ratio.

Note that PageRank's RSS is less than 16 GB, so it is excluded from this comparison. For TPP, Graph500 and XSBench show performance improvements of 14.5%/11.5% and 29.8%/53.9% respectively for the 32/16 GB configuration. For NOMAD, the baseline already outperforms TPP in the majority of cases across four workloads. When DSA is integrated with NOMAD, two-thirds of the cases show 4%∼16% performance improvements. This enhancement is attributed to the increased page migration efficiency, which effectively reduces the migration window and consequently decreases the probability of transactional migration failures. For AutoNUMA, since it employs a more conservative page placement strategy, DSA integration generally yields minimal performance changes. In Pandas, AutoNUMA+ achieves performance improvements of 2.0% and 12.1% for the 32 GB and 16 GB configurations, respectively.

The bottom part of Figure 13 compares DSA-2LM against MEMTIS. When the ratio of fast/slow tier is 1:2, DSA-2LM outperforms MEMTIS in all evaluated benchmarks by 2.5∼12.0% for five applications. When increasing the ratio to 1:16, the performance enhancement averages 28% across all benchmarks. In the best case, DSA-2LM achieves a 1.8× speedup compared to MEMTIS. This significant improvement occurs because the fast tier memory can only accommodate a small subset of hot pages, causing the hottest page set to change rapidly. DSA-based fast page migration enables better adaptation to these dynamic access pattern changes.

We measure Graph500/Pandas as represented applications for further case analysis (Figure 14). When the ratio is 1:1, the performance increase is insignificant. When the ratio is 1:8, the completion time can decrease by 20.68% in Graph500. The effects of DSA will be better with the ratio increasing.

5 Related Works

Compatibility with other tiered memory systems. Nomad [44] employs Transactional Page Migration (TPM), abandoning the page copy if the page is modified during migration. Since DSA can speed up page migration by 5∼10×, which significantly reduces the migration window and consequently decreases the probability of TPM failures. In the case of Colloid [42], the key insight is balancing access latencies across different memory tiers. Then it determines the direction of page migration based on global access latency. In this context, page migration is still necessary, and our work is orthogonal to Colloid. Additionally, recent works like NeoMem [52] have been able to offload the page placement strategy to hardware as well. It would be interesting to integrate DSA-2LM with NeoMem to achieve a fully CPU-free solution.

Intel accelerator use cases. Recent research has demonstrated the effectiveness of Intel accelerators in optimizing storage, networking, and virtualization. For instance, AnolisOS leverages "Memory Fill" capability to pre-zero memory pages, reducing VM startup latency in large-memory configurations by offloading page-zeroing from CPUs to DSA [6, 9]. The Intel IAA plugin for RocksDB provides accelerated compression/decompression in RocksDB [14]. For storage and networking, DSA accelerates CRC/DIF generation and memory comparison through specialized hardware pipelines while maintaining data integrity [13, 19]. DSA-2LM is the first work to utilize DSA in tiered memory.

6 Conclusion

This paper introduces DSA-2LM, an efficient tiered memory system using DSA. It exploits the hardware capabilities of DSA to design an aggregation algorithm for adaptable data paths. DSA-2LM leverages batch/multi-WQ approaches for concurrent migration. Results on the real CXL platform show that applications benefit significantly from DSA.

Abstract

Approximate Nearest Neighbor Search (ANNS) plays a key role in database and AI infrastructure. It exhibits extremely high memory intensity with a ∼1:1 compute-to-memory access ratio. Commodity Processing-in-Memory (PIM) hardware such as UPMEM is promising for overcoming the memory wall in ANNS. However, its reuse of the system DDR bus prevents the CPU and PIM cores from accessing memory simultaneously. This necessitates batch scheduling in existing systems, which, in turn, leads to severe underutilization in two scenarios: 1) inter-batch, where PIM remains idle while the CPU is copying data, and 2) intra-batch, caused by uneven load distribution of PIM cores in a batch.

This paper proposes an efficient PIM-capable ANNS system named PIMANN. We observe that each PIM core has an additional, undocumented, and little-known control interface (originally used for control commands like launching PIM kernels), which could be retrofitted for fine-grained arbitration of DDR bus access. Thus, PIMANN can break the traditional batching scheduling paradigm and adopt a fine-grained, per-PIM-core scheduling paradigm. With this key idea, PIMANN introduces 1) persistent PIM kernel technique to eliminate the idle state between two batches, and 2) per-PU query dispatching technique that dispatches queries based on the real-time load of PIM cores. Experiments show that PIMANN can boost throughput by 2.4-10.4× compared to existing ANNS systems on CPU or GPU. The implementation of PIMANN is available at https://github.com/cds-ruc/PIM-ANNS.

1 Introduction

Nearest Neighbor Search (NNS) finds top-k vectors closest to a query vector in a dataset. Approximate Nearest Neighbor Search (ANNS) balances speed and accuracy, making it suitable for massive high-dimensional data where exact NNS is costly. ANNS has wide applications in various scenarios, including information retrieval tasks such as search [59] and recommendation [66] (e.g., image-based search [7] and content retrieval [19]), or assist large language models through retrieval-augmented generation (RAG) [48].

ANNS is characterized by extremely high memory intensity [34]. The core of ANNS lies in maintaining in-memory data structures to quickly identify potential neighbors. Currently, mainstream ANNS algorithms rely on traversing data points within their respective data structure (i.e., cluster-based [36] or graph-based [68]), resulting in an extremely low compute-to-memory access ratio, close to 1:1.

Constrained by the von Neumann memory wall [53], current ANNS systems based on CPUs [35] or GPUs [71] are increasingly unable to meet the growing demand in both volume and performance [40]. While CPUs can provide TB-scale memory capacity to store large volumes of vectors, their limited DRAM bandwidth (approximately 200 GB/s) limits vector retrieval performance. Existing work [14] shows that modern CPUs, with SIMD instructions equipped, can typically process 5 billion vector operations per second (with a compute bandwidth of around 500 GB/s), far exceeding DRAM bandwidth. On the other hand, while GPUs offer substantial computing capability and high-bandwidth memory, their limited memory capacity (even a recent high-end GPU like H100 has only 100 GB) prevents them from handling storage requirements for billions of vectors with thousands of dimensions.

Processing-in-Memory (PIM) is a classic approach to overcoming the memory wall by performing computations directly within memory, eliminating the need for extensive data transfers between memory and processors. With the release of UPMEM [65], the world's first commercially available real PIM hardware in 2022, this technology is finally no longer limited to software simulations [5, 6, 10, 11, 15, 18, 20, 23, 26, 29, 31] or FPGA verification [4, 5, 32, 37] and is ready for public real use [42, 47, 57]. UPMEM modules can be plugged into general-purpose servers via DIMM interfaces, functioning like DRAM. Each module integrates two levels of memory (WRAM and MRAM) and incorporates over one hundred

† These authors contributed equally.

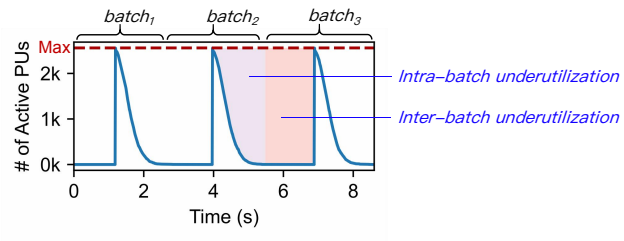

Figure 1: The active PU count over time in a PIM-capble ANNS strawman system. *The red dashed line shows the maximum PU count (2560). In an ideal case, the blue line should closely follow the red dashed line as much as possible.*

RISC-based processing units (PUs[1]), with each PU capable of supporting up to 16 parallel threads. Equipped with 20 UPMEM modules, a single server can provide a total of 2,560 PUs (supporting over 40,000 threads) and deliver an aggregate memory bandwidth of 2 TB/s.

However, due to the architectural differences between UPMEM and CPU/GPU, simply shoehorning existing ANNS systems into UPMEM can only achieve 18.2% of the hardware's theoretical throughput cap (see §2.3), and the number of active PUs is zero for more than 65% of the time (Figure 1). We analyze that this under-utilization stems from the deficiency of **batching paradigm** (§2.3), including the following two key factors:

- *Inter-batch under-utilization, caused by batches' gang scheduling.* Due to UPMEM's reuse of the system DDR bus, it currently does not natively support concurrent memory access by both the CPU and PUs; see §2.2. As a result, existing applications [8, 9, 16, 25, 27, 30, 38, 43, 51, 54] typically rely on batching paradigm, where the CPU first copies all necessary data to UPMEM, and then gang-schedules all PUs to run. This leads to a gap between two batches where PUs are unable to perform computations.
- *Intra-batch under-utilization, caused by PU load unbalance within a batch.* Although UPMEM enjoys a strong aggregated multi-core performance, its single-core capability is rather weak. Unlike CPUs, where multiple cores can access each other through the shared memory architecture, UPMEM hardware restricts PUs from mutual access. Thus, uneven load distribution among PUs may cause some straggler PUs to become the performance bottleneck for the entire batch.

To this end, we propose PIMANN, an ANNS system designed to fully harness UPMEM's potential. Its core idea is breaking the traditional batching scheduling paradigm and adopting a fine-grained, per-PU scheduling paradigm. We observe that the necessity of existing batch gang-scheduling arises from the hypothesis that CPU and PUs can only communicate at the boundary of batches due to their mutually exclusive access to the shared DDR bus. Under this paradigm, once a PIM kernel (i.e., a batch of tasks) is launched, it must be assumed that the PU always retains control of the shared bus until the kernel completes. However, this constraint could be relaxed, with *our key observation that each PU has an additional, undocumented, and little-known control interface (originally used for launching and synchronizing PU programs), which could be retrofitted for fine-grained arbitration of DDR bus access*.

With this key idea, we propose *persistent PIM kernel* (§4.2) to address inter-batch under-utilization. persistent PIM kernel allows continuous sending of individual ANN requests to different PUs for computation in runtime. Unlike the original batch gang-scheduling approach, where there is a pause between two batches, our approach ensures that UPMEM remains uninterrupted throughout the entire process. Specifically, by modifying the UPMEM driver, persistent PIM kernel carefully coordinates the access to the corresponding memory (i.e., MRAM) by either the CPU or PU through each PU's control interface. Due to the limited shared bus bandwidth (∼0.41 GB/s), the CPU or PUs may experience prolonged data stalls when attempting to gain bus control while the other is holding it. To minimize this data stall, PIMANN employs coroutine techniques on the CPU, which hides the bus acquisition time and parallelizes data transmission and computation.

To cope with intra-batch under-utilization, PIMANN introduces *per-PU query dispatching* (§4.3) to dispatch queries to individual PUs based on their real-time load to achieve well load balance. Since PUs follow a share-nothing architecture, PIMANN employs a selective replication data placement scheme, which replicates hot clusters across multiple PUs. With the help of fine-grained per-PU scheduling, PIMANN enables 1) live adjusting data placement without downtime based on the updated hotness information, and 2) dynamically dispatching queries to different replicas based on the real-time load of PUs.

Our evaluation on off-the-shelf UPMEM shows that, PIMANN can improve the throughput by up to 10.4× compared with Faiss-CPU [22] and by up to 2.4× compared with a PIM-capable ANNS system based on the batching paradigm. Compared to a pure-GPU-storage system, Faiss-GPU [22], PIMANN can also improve the throughput by up to 3.7×.

2 Background and Motivation

2.1 Approximate Nearest Neighbor Search (ANNS)

By 2030, humanity will enter the YB-scale data era, with more than 90% being unstructured [33]. ANNS is the primary method for retrieving useful information from massive unstructured data. ANNS has wide applications in various

[1]This component is referred to as the data processing unit (DPU) in UPMEM. Here we call it PU to avoid ambiguity with smart NICs.

scenarios. Initially, they were used in traditional information retrieval tasks such as search [59] and recommendation [66] (e.g., image-based search [7] and content retrieval [19]). In recent years, as large language models (LLMs) have emerged as a new frontier of artificial intelligence, ANNS has become a core infrastructure to carry knowledge for LLMs. Through retrieval-augmented generation (RAG) [48], they assist LLMs in retrieving credible, accurate, and timely knowledge, helping to mitigate hallucinations [64].

ANNS exhibits an extremely high memory intensity. First, ANNS needs to repeatedly read large volumes of vectors from memory, causing massive memory access. For example, Alibaba handles approximate searches on billions of data points [69], while Microsoft performs approximate queries on datasets with hundreds of billions of entries [1]. Second, ANNS have an extremely low compute-to-memory access ratio. Typical ANNS algorithms rely on maintaining in-memory data structures to quickly identify potential neighbors. Currently, ANNS algorithms can be broadly classified into two categories, cluster-based [36] and graph-based [68]. Both rely on traversing data points within their respective data structure (i.e., clusters or graphs), resulting in a compute-to-memory access ratio close to 1:1.

In this paper, we explore ANNS systems on UPMEM, with a specific focus on cluster-based algorithms, which are well-suited to UPMEM's massive parallel threading capabilities. Specifically, we focus on the Inverted File with Product Quantization (IVFPQ) algorithm, as it incorporates the Product Quantization (PQ) technique on standard cluster algorithms to further reduce computational overhead. Another category of ANNS algorithms (graph-based methods) are not suitable for UPMEM, because they introduce significant communication overhead when implemented on PIM architectures. This limitation is caused by the constrained communication bandwidth on commodity UPMEM systems—only 0.41 GB/s (from our test results) for both inter-PU and CPU-PIM data transfers. In fact, to the best of our knowledge, there are no existing implementations of graph-based ANNS on PIM devices.

Figure 2 shows an example of the IVFPQ algorithm, which includes two phases: the offline phase and the online phase.

Offline Phase: The offline phase is responsible for preparing the dataset for efficient search by building a cluster-based index. This phase includes two steps: ① Inverted File (IVF) and ② Product Quantization (PQ).

① The IVF step partitions the whole dataset into C clusters using methods such as K-means. Once the clusters are formed, ② the PQ step calculates the residuals, which are defined as the differences between each data point x and its corresponding cluster centroid c. It then compresses these residuals by dividing the residual vectors into M subvectors and then encoding them using a codebook. Each encoded point serves as an identifier that has a one-to-one mapping with a specific codeword in the codebook. In practical implementations, the identifiers are often encoded as 8-bit unsigned

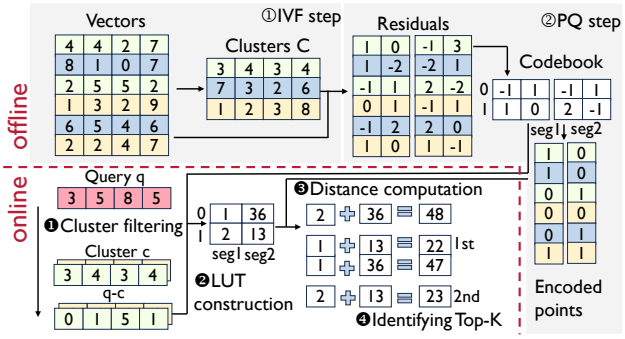

Figure 2: IVFPQ example.

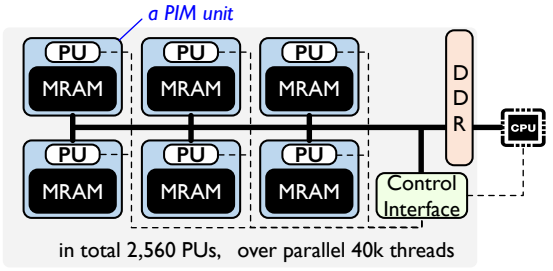
integers (uint8), enabling a compression rate of $\frac{4D}{M}$.

Online Phase: Given a query vector q, the online phase includes 4 steps to find k vectors closest to q. ❶ Cluster filtering, which finds *nprobes* clusters that are closest to q by computing the distances between their centroids and q. ❷ Look-up table (LUT) construction. The LUT serves to store pre-computed data, significantly optimizing the search process by converting computing to memory lookups. Specifically, each element LUT$[j][i]$ represents the distance between the j-th vector in the codebook B_i, where i denotes the i-th segment of residual vectors. To derive the distance from q to a given data point x, one can refer to and sum up the values in LUT as follows:

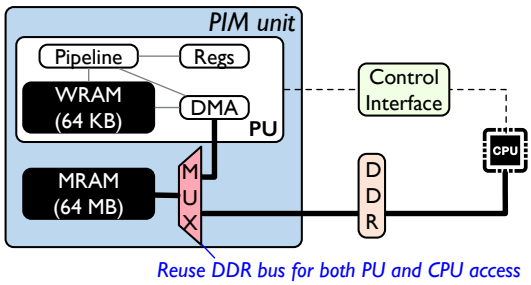
$$L_2(q,x) = L_2(q-c,r) = \sum_{i=0}^{M-1} \text{LUT}[e_i][i],$$

where r and e. denote the residual and encoded vectors of x, respectively.



❸ Distance computation. Leveraging LUTs, the distances from q to all data points within the filtered clusters are calculated. ❹ Identifying Top-K, which sorts all computed distances and selects the k vectors with the shortest distances as the approximate nearest neighbors.

2.2 Commodity PIM hardware architecture



Processing-in-Memory (PIM) is a classic way to deal with the famous "memory wall" problem [6]. For a long time, various PIM architectures have been proposed [17]. However, prior to the release of UPMEM in 2022, these PIM architectures were confined to simulations or FPGA-based verification. UPMEM marked a significant milestone as the world's first commercially available real-world PIM hardware, bridging the gap between theoretical concepts and practical applications. Consequently, our work mainly focuses on leveraging UPMEM to build ANNS system.

In this section, we mainly introduce the following three hardware features of UPMEM.

Multi-core architecture. Figure 3a shows the architecture of the UPMEM-capable system and inner-UPMEM-DIMM

(a) Architecture of UPMEM-capable system.

(b) Inner-PIM-unit details.

Figure 3: Architecture of UPMEM-capable system and inner-PIM-unit details. *The bold line represents DDR bus, and the dashed line represents control interface.*

details. UPMEM are connected to the CPU through DIMM slots. An UPMEM DIMM is made up of 64 PIM units. As shown in Figure 3b, each unit has two main components: a memory bank (MRAM) and a general-purpose processing unit (PU) integrated with the bank. Each PU is a 32-bit in-order RISC-V core featuring a 14-stage pipeline and supporting up to 16 hardware threads. With 20 UPMEM DIMMs, a single server can harness a total of 2,560 PUs, accommodating over 40,000 threads and achieving an aggregate memory bandwidth of 2.5 TB/s. Due to limitations in hardware fabrication, PUs in the current generation of PIM hardware have the following three issues: 1) PU only offers integer-native ALUs; float-related operations are implemented via software. This causes UPMEM to have a much slower FLOPS compared to integer operations. 2) All PUs adhere to a share-nothing architecture, meaning that each PU can only access data stored in its local memory bank. Currently, any communication between PU has to go through the host CPU.

Two-level memory hierarchy. Each PIM unit contains two levels of memory internally, including 1) Working RAM (WRAM), and 2) Main RAM (MRAM). WRAM acts as the faster cache, made of SRAM, with a size of 64KB. MRAM has a substantially larger storage capacity (64MB), but it has slower access speeds compared to WRAM. PU cannot directly access MRAM; it must first bring data from MRAM to WRAM via the on-chip DMA engine.

Bus sharing on MRAM. MRAM receives access from both the CPU and the PU. The CPU is used for sending/collecting task data, while the PU is for PIM computing. Nevertheless, the DIMM-PIM architecture (such as UPMEM), which plugs PIM devices into DIMM slots, inherently lacks the support for simultaneous memory access by the host CPU and the PUs. Specifically, as shown in Figure 3b, each PIM unit reuses the DDR bus for both the PU and host CPU access. Due to the constraints of existing DDR bus protocols, which require deterministic latency behavior [61], simultaneous memory access by the CPU and PU is not feasible. This is because shared access alters the memory access latency, violating the strict timing guarantees of DDR protocols. To address this limitation, UPMEM hardware employs a multiplexer (MUX) for manual access arbitration. Specifically, MUX is a two-state register, namely CPU-side or PU-side, allowing exclusive access to the MRAM by the CPU or the PU, respectively. The state of MUX is controlled by the CPU through the *control interface*. With this design, it simplifies the integration of PIM into traditional systems while adhering to the requirements of DDR bus protocols.

2.3 Motivation

Batching paradigm of current PIM programming model. The PIM programming model adheres to an accelerator model, similar to that of GPUs. Programmers prepare an execution program (referred to as a *kernel*) along with its data in advance and then launch it on the PIM device. The CPU communicates with PIM via the *control interface*, by sending commands such as starting/synchronizing kernels or querying the status of the running kernel (Figure 3b).

Currently, PIM-capable programs [12, 13, 39, 46, 49, 51] typically follow the batching paradigm. This paradigm stems from the limitation that the CPU can only interact with PIM's MRAM at kernel boundaries—either before launching a kernel or after it completes. This restriction arises with the hypothesis that, once PUs are activated, PUs will retain the bus control until the kernel terminates. Thus, the CPU can not read/write PIM's MRAM when PUs are running.

This batching paradigm includes three steps; see Figure 4. First, the CPU gets a buffer ready, filling it with a set of tasks (i.e., a batch) meant for each PIM unit, and sends the buffer to all PIM's MRAM. Next, the CPU launches the PIM kernel, prompting the PIM units to start working on their assigned tasks and generate computing results. Lastly, the CPU collects all the running results and moves them into the host memory.

Impact of batching paradigm on ANNS. We investigate the deficiency of existing batching paradigm on ANNS. We implement a strawman ANNS system based on Faiss [22], by storing clusters on MRAM and offloading the distance computation step (❸ in the Online Phase) to PIM's PUs. Figure 5 shows their performance on the SPACE-1B dataset [3]. We can observe that:

- *Achieving only 18.2% of the theoretical performance.* Figure 5a shows the computing performance of Faiss-CPU

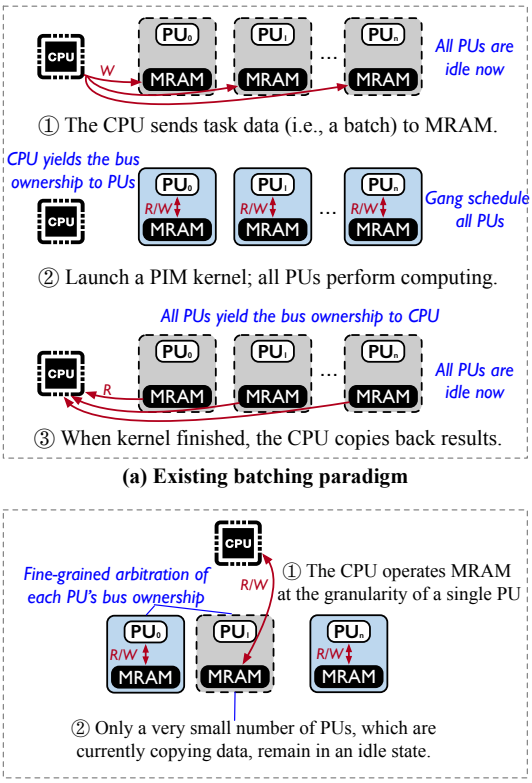


Figure 4: Comparision of existing batching paradigm and PIMANN's per-PU scheduling paradigm.

and PIM-capable strawman system. We observe that: 1) for the strawmen system, the throughput of PIM, although with tens of thousands of threads, is comparable with that of a standard CPU. 2) PIM's performance is far from being fully utilized. If fully leveraged, PIM has the potential to achieve more than 5.5× the throughput. Further analysis reveals that there are two types of under-utilization as follows.

- *Inter-batch under-utilization.* Figure 1 shows the number of active PUs across time. Between two batches, there is a period of over 1.21s during which the number of active PUs is zero. This period accounts for 65% of a single batch's duration. This is because, during this time, the CPU is copying the results of the previous batch from MRAM while transferring the input for the next batch to MRAM. Since the CPU and PUs cannot access the shared bus simultaneously, PUs cannot be activated.
- *Intra-batch under-utilization.* In batch scheduling, a batch of queries is distributed among the PUs. Figure 5b shows the number of tasks assigned to each PU. As shown in this figure, imbalanced workloads across PUs may cause some PUs to idle while others are overloaded, delaying the completion of the entire batch.

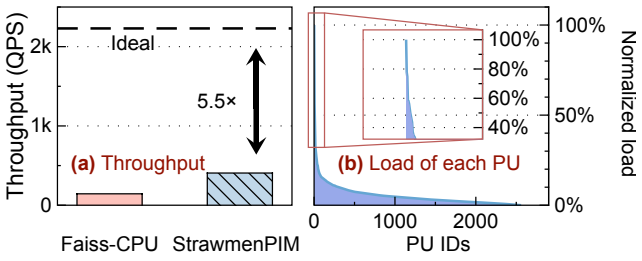

Figure 5: Motivation. *(a) The throughput of a standard CPU ANNS system (Faiss-CPU) and a strawmen PIM-capable system (StrawmenPIM). The dashed line denotes the ideal performance of UPMEM. (b) The load of each PU. The load values are normalized by the heaviest PU.*

3 Key Idea & Challenges

Key Idea: Per-PU scheduling with fine-grained arbitration. Traditional PIM systems use batched gang scheduling where CPUs and PUs operate MRAM alternately, leading to the inefficiencies of inter/intra-batch underutilization (§2.3). These issues are rooted in the assumption that PUs retain control of the shared bus for the entire duration of the PIM kernel's execution, from launch to completion. Differently, this assumption is broken with our key observation that: each PU in UPMEM has an additional control interface (originally used for control commands), which could be retrofitted for sending custom control messages to fine-grainedly coordinate the access of PU and CPU. Building on this insight, we propose a per-PU scheduling paradigm (Figure 4b) by manipulating the ownership of each PU unit's MRAM, determining whether it is currently being read/written by PU/CPU.

Per-PU scheduling offers two advantages. First, it eliminates the idle state between two batches (Figure 1), effectively handling inter-batch underutilization. Each PU can be in one of two states: either performing computation or waiting for the CPU to copy data. Second, without gang scheduling, it enables dynamically dispatching each query to different PUs based on their real-time loads, thus achieving good load balance and avoiding intra-batch underutilization.

Challenges. However, achieving per-PU scheduling is not easy. First, the native driver does not allow reading from or copying data to PIM when PIM is running. Second, due to the limited read/write bandwidth between the CPU and the PU's MRAM, switching a PU's state may cause the CPU to experience a long stall. Third, although per-PU scheduling can dynamically send queries based on the current load of each PU, PUs do not share the same memory space. Therefore, an efficient data placement scheme needs to be designed to pre-distribute clusters across the PUs.

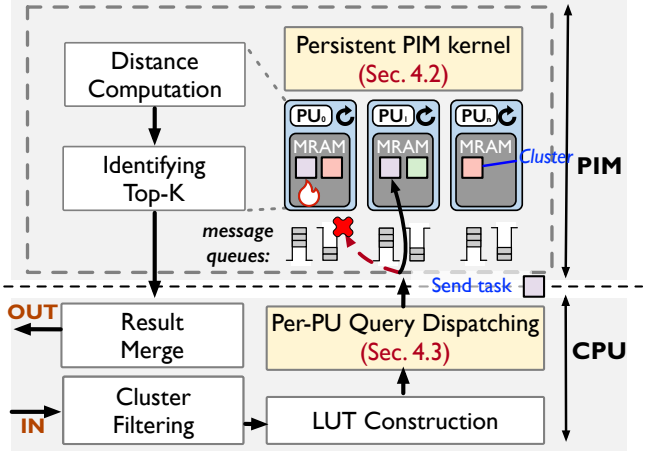

Figure 6: Overview of PIMANN. *This figure shows the workflow of an ANNS query in PIMANN. It supposes PU_0 is overloaded. Our per-PU query dispatching will dispatch this query to the replica on PU_1.*

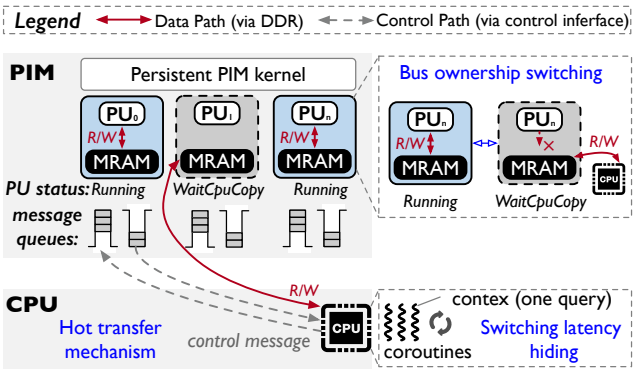

Figure 7: Design of persistent PIM kernel. *Each PU contiguously pulls tasks from the message queue and performs computation. The input/output data of tasks are transferred via the hot transfer mechanism, involving multiple bus ownership switches.*

4 PIMANN Design

4.1 Overview

PIMANN architecture. Figure 6 shows the architecture of PIMANN. PIMANN offloads the most parallelizable distance computation step (see §2.1) of the entire IVFPQ process to UPMEM, while the other steps are still executed by the CPU. Each PU stores multiple IVF clusters and performs the corresponding distance computations.

To mitigate inter-batch underutilization, PIMANN introduces the *persistent PIM kernel* (§4.2), which launches a persistent kernel enabling continuous query processing without idle states between batches. Each PU can independently receive queries from the CPU continuously.

However, due to bus sharing, the native UPMEM driver does not support copying data to/from PIM when PIM is running. Based on our observation that the additional control interface can be retrofitted for fine-grained bus arbitration, we implement a *hot transfer mechanism* to transfer data between the CPU and PU when PIM is running (§4.2.1).

With bus arbitration, each PU can dynamically switch between two states: *Running* (performing computation) or *WaitCPUCopy* (waiting for the CPU to copy data). These two states correspond to the ownership of the shared bus being held by either the PU or the CPU. We discuss how to switch two states safely and efficiently in §4.2.2.

To optimize energy efficiency during idle periods (i.e., when no queries are being processed), we also support transitioning from the persistent kernel to the normal kernel.

To mitigate intra-batch underutilization, we propose *per-PU query dispatching* (§4.3). With the help of bus arbitration, we can dispatch queries to individual PUs based on their real-time load. However, as PUs follow a share-nothing architecture, different PUs cannot access each other's MRAM. Thus, we must tailor an efficient data placement scheme, pre-allocating each PU's clusters in advance. PIMANN leverages a selective replication for data placement (§4.3.1), replicating high-popularity clusters among PUs. It also detects hotness shifts and dynamically adjusts data placement without shutting down the PIM (§4.3.2).

4.2 Persistent PIM kernel

Different from the existing batching paradigm which launches a separate PIM kernel for each batch of queries and lets the CPU copy data between two kernels, PIMANN only launches one persistent PIM kernel for all ANNS queries during system initialization. In this kernel, since we allow dynamic arbitration of per-PU bus during runtime, each PU can independently perform computation or data copying. Thus, the persistent PIM kernel design eliminates the idle copying time introduced by batch gang scheduling.

The main workflow of each PU continuously loops through the following steps:

①Dequeue an ANNS request from the message queue.
②Wait for CPU to copy the task data (e.g., LUT) to MRAM.
③Switch to the *Running* state and perform computing.
④Switch to the *WaitCPUCopy* state.
⑤Wait for the CPU to copy the computing results.

Step ①②⑤ require data transfer from the CPU to the PU while PUs are in the running state; step ③④ require switching the PU's state (i.e., switching ownership of the shared bus). Therefore, we have designed the hot transfer mechanism (§4.2.1) and bus ownership switching scheme (§4.2.2), respectively.

4.2.1 Hot transfer between CPU and PIM

Next, we discuss how CPU and PUs transfer data to each other when PUs are running. This hot transfer mechanism includes two parts, with control and data paths separated: 1) The control path uses a custom *message queue*, implemented through the PU's control interface link and isolated from the DDR bus. 2) The data path allows the CPU to directly read/write MRAM via the DDR bus (but requires holding the bus ownership).

Control path: Message queue implemented on the control interface. To achieve fine-grained per-PU scheduling, the most fundamental function lies in the ability of CPU-PU communication when PIM is running. By carefully reading through the UPMEM driver, we notice that the CPU's read and write access to the WRAM is routed through an additional, undocumented control interface link (§2.2), completely bypassing the DDR bus. This hardware characteristic allows us to implement a message queue directly on WRAM for communication between the PU and the CPU.

This message queue has two limitations, which should be considered when designing our system. First, the message queue has a limited capacity (in the order of a few tens of bytes), In comparison, a common data structure in an ANNS query, LUT, has a typical size of 32 KB. To this end, we only store necessary metadata (e.g., query ID) or small control messages (e.g., ownership switching) in this queue. Other large messages (e.g., LUT) are directly written to MRAM. Second, as PIM does not have the ability to interrupt the CPU, PIMANN maintains dedicated CPU threads to poll all message queues of PUs to get notifications from PIM.

Data path: Exposing MRAM to CPU. The native UPMEM driver does not support exposing MRAM to the CPU for direct read and write operations during PIM execution. We perform a thorough analysis of the driver and make the following two modifications: 1) exposing MRAM to CPU when PIM is running (enabling the CPU to directly read/write MRAM), and 2) constructing a mapping table that maps all variable symbols to their corresponding MRAM addresses (finding where should the CPU read/write).

For 1), all MRAM are viewed as multiple device files in the operation system, and mapped in the virtual memory space. We can obtain the base address of mmap files by implanting a recording function in the PIM startup path. Considering UPMEM adopts memory-level parallelism [44], all writes to MRAM should perform a transpose operation on the data to ensure that the data can be correctly transmitted to the same chip [44].

For 2), the main challenge is the lack of mapping from variable symbols to offsets in the mmap files. Our solution is as follows: before starting the PIM, we first use the standard MRAM copy interface (`dpu_copy_to`) to access the corresponding variables once, recording the corresponding addresses and caching them in the user program.

It should also be noted that the bandwidth of directly writing MRAM by CPU in the running state seems to be relatively low (0.41 GB/s). The reason is that: different from batching paradigm which could easily exploit the bank-level parallelism (8 PUs), our fine-grained per-PU scheduling means that data can be copied to only one PU's MRAM at a time. Although per-8PU scheduling could achieve higher bandwidth, we abandon this approach for two main reasons. First, per-8PU scheduling incurs computation redundancy: if a cluster is split into 8 slices, each slice needs to maintain its own top-k queue, resulting in 8x computation redundancy. Second, per-PU scheduling already has a negligible data transfer time: Although per-PU may suffer from a relatively lower bandwidth, in our implementation, the time taken to copy data is negligible (please refer to the purple bar in Figure 15).

4.2.2 Per-PU bus ownership switching

In this subsection, we present how we safely and efficiently switch the state (i.e., bus ownership) of each PU in PIMANN.

Switching ownership safely. As stated in §2.2, the bus ownership is controlled by the MUX registers; we expose the mapping of each PU units' MUX registers to userspace. Each MUX has two states: CPU-side and PU-side. If there is an inconsistency between the memory access and the MUX state, it may cause abnormal access by either the CPU or PU.

Thus, we next show how PIMANN ensure this consistency. We discuss two cases of PU state switching respectively: 1) *WaitCPUCopy→Running* (i.e., MRAM access ownership switching from CPU to PU), and 2) *Running→WaitCPUCopy*, reversely. The first case corresponds to the CPU copying the LUT table to the PU, and waiting for the PU to start the distance calculation. The second case occurs after the computation finishes, where the PU waits for the CPU to perform result aggregation.

For *WaitCPUCopy→Running*, in PIMANN, the CPU sends an ownership transfer message to the queue after completing the copy operation. Thus, the PU only needs to poll the message queue to receive the message, after which it can safely access the MRAM and perform computation.

For *Running→WaitCPUCopy*, since the PU itself cannot switch its MUX, it sends a message to the CPU via the queue. Upon receiving this message, the CPU switches the MUX and sends an ack message back to the PU. At this point, the PU can enter the WaitCPUCopy state safely.

To reduce the software stack overhead, PIMANN caches the MUX state for each PU in userspace. The interface for checking the MUX state directly reads from the cache. When switching a PU bus ownership, both the actual MUX state and its cached copy are updated simultaneously. Since only the CPU can modify the MUX state, cache inconsistency is not a concern.

Ownership switch in pairs. In our implementation, we discover a strange phenomenon: when the CPU directly accesses the MRAM of a certain PU, it sometimes causes the

tasks on the adjacent PU to malfunction. This lead us to a reasonable speculation: two adjacent PUs may share a physical MUX register. It may be due to the special hardware circuit design of UPMEM that there is only one control interface for the MUXes of two adjacent PUs. We later confirm this speculation through experiments. As a result, we determine that the minimum switching granularity of PIMANN is two adjacent PUs. Thus, even if the current query only involves one PU, it is necessary to simultaneously switch the ownership of two adjacent PUs, resulting in a resource waste of the other adjacent PU.

To address this limitation and minimize resource waste, we propose the optimization of pairwise cluster slicing to ensure that adjacent PUs are always invoked simultaneously. Specifically, instead of assigning a single IVF cluster to a PU, each cluster is sliced into two smaller *cluster slices* and adjacent PUs are allocated segments from the same cluster. This ensures that when one PU in a pair is active, its neighboring PU is also active, thus maximizing hardware resource efficiency. We will refine this slicing strategy in the section of load balancing design (§4.3).

Hiding the switching latency. The per-PU bus ownership switching may experience significant latency if the required MUX ownership is not immediately available. The reasons are twofold. First, PU's computing capability is weak. The clock frequency of PU is only O(100) MHz, so the task execution time of a single PU may be relatively long. If the PU is still executing a task, the switching time also includes the wait for the ongoing computation to complete, which can be substantial, reaching up to several milliseconds.

Second, the CPU-PIM communication latency is high. Even if the PU already releases the ownership, the CPU side cannot obtain it immediately. Instead, it has to poll the message queue on WRAM through a bandwidth-limited interface [2]; it takes 0.9 ms to poll the message queue of one rank (64 PUs). Thus, naively blocking the CPU thread is inefficient.

To mitigate this, we employ a coroutine-based optimization that allows the CPU to switch execution contexts to other tasks while waiting for ownership switching, thus hiding the switching latency. Specifically, our coroutine scheduling prioritizes tasks based on the two following principles. 1) Immediate ownership availability: coroutines associated with PUs whose bus ownership is already set to CPU side are prioritized for execution. 2) Predictive scheduling: for PUs whose MUX state is on the PU side, our scheduler estimates when the MUX state will switch based on the fixed execution time of PU tasks. Coroutines likely to have their ownership status become available soon are given higher priority. This estimation leverages the deterministic nature [28] of UPMEM's in-order RISC cores, which have no caching or speculative execution.

4.3 Per-PU query dispatching

The design of the persistent PIM kernel enables us to dispatch queries to individual PUs based on their real-time load, thereby addressing intra-batch underutilization. However, since each PU follows a share-nothing architecture, different PUs cannot access each other's MRAM. As a result, it is crucial to design an appropriate data (i.e., cluster) placement strategy. A naive approach, such as random assignment of clusters to PUs, often leads to significant load imbalances due to variations in cluster popularity.

To this end, PIMANN employs a *selective replication data placement* scheme. This scheme selectively replicates hot clusters across multiple PUs. In this section, we discuss: 1) how to choose clusters to replicate in §4.3.1, 2) how to live adjust the data placement when hotness shifts in §4.3.2, and 3) how to dispatch queries between replicas to achieve well load balance in §4.3.3.

4.3.1 Selective replication data placement

The selective replication data placement includes the following three steps.

Replicating high-popularity clusters. Clusters are replicated based on their popularity, which is quantified as the product of cluster size (s_i) and access frequency (f_i), because popularity is determined by the query time of a cluster and the query time is proportional to its size and its access frequency. The number of replicas for a cluster is determined by dividing its popularity ($p_i = s_i * f_i$) by the average PU load. Formally, for a high-popularity cluster i, its number of replicas $replica_count_i = p_i / p_{avg}$. where $p_{avg} = \frac{\sum_i p_i}{n}$, n denotes the cluster count.

Slicing clusters for less memory fragmentation. As the size of MRAM is not necessarily an exact multiple of the cluster size, the previous strategy may lead to significant memory fragmentation. To address this problem, we divide clusters into smaller slices of uniform size. Specifically, MRAM is partitioned into fixed-length slots, each capable of holding one slice. This approach simplifies data allocation and minimizes memory fragmentation, especially given the variety in cluster sizes and dynamic insertion or deletion of clusters in online adjustment (§4.3.2).

Placement of cluster slices. Cluster slices are placed to ensure balanced utilization across PUs. Considering the constraint of pairwise bus ownership switching, we group adjacent PUs and distribute slices evenly among PU pairs, ensuring that the two adjacent PUs are always active simultaneously. We define a heat upper limit for each PU pair. The heat upper limit is a hyperparameter tradeoff the time spent on generating the placement with the degree of load balancing. Within this upper limit, all cluster slices are greedily assigned to maintain balanced workload distribution. In our practice, this simple greedy strategy can already achieve a well load balance; please see the evaluation section.

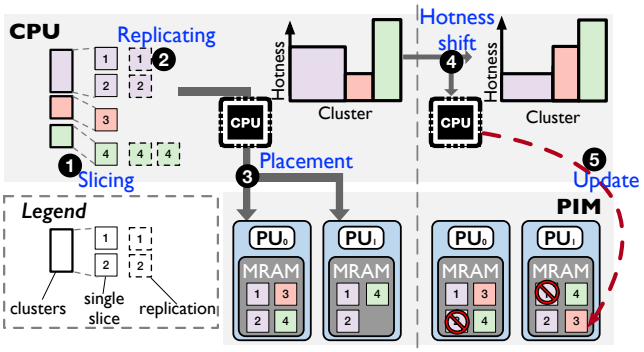

Figure 8: Design of per-PU query dispatching.

4.3.2 Live adjustment of data placement

Over time, cluster hotness may shift, necessitating real-time adjustments to the data placement. Fortunately, the per-PU scheduling design of the persistent kernel enables us to redistribute clusters without shutting down the PIM.

Hotness shifting detection. We use a lightweight monitoring mechanism that tracks cluster access frequency in real time. Specifically, each cluster is assigned a frequency counter that increments when a query involves the cluster. We define a time window and threshold used to detect significant changes in cluster popularity. For example, within the past 1,000 queries (pre-defined time window), if the ratio of a cluster's access frequency compared to the previous time window exceeds a factor of 2 (pre-defined threshold), whether the change is an increase or a decrease, it is considered that the cluster's heat has changed significantly.

Adjustment strategy based on updated hotness. 1) For increased cluster hotness, additional replicas are created on underutilized PUs based on the updated hotness. Queries are then dynamically redirected to these new replicas. 2) For decreased cluster hotness, we remove redundant replicas to free up MRAM space; we prioritize the removal of replicas on heavily loaded PUs. Freed memory slots can be reallocated to clusters with increasing hotness.

4.3.3 Online request dispatching

We maintain a mapping table that records the cluster ID to PU IDs (i.e., all replicas) on the host side. The dispatcher always selects the replica with the lightest current load to send the request. The load of PUs are denoted by the queue depth of message queues.

5 Evaluation

5.1 Experimental Setup

The experiments are conducted on a server equipped with UPMEM modules. The server features two Intel Xeon Silver 4210 processors, providing a total of 20 physical cores running at 2.4 GHz. It is configured with 128 GB of DDR4 memory distributed across 4 DIMM slots. The UPMEM setup consists of 20 DIMM modules, containing a total of 2,560 PUs running at 400 MHz. Each PU supports 16 threads. The server runs Ubuntu 22.04 with kernel version 5.15. The host program is developed using the GCC 11.4.0 compiler, while the PIM program is built with UPMEM SDK 2024.2.0, based on Clang 12.0.0. Additionally, we use an NVIDIA RTX A6000 for evaluating GPU-based ANNS systems.

Competitors:We compare PIMANN with the following ANNS systems.

- Faiss-CPU [22]: It is a popular approximate nearest neighbor search library developed by Meta.
- PIMANN-Batch: There exists one UPMEM baseline system named DRIM-ANN [12], which leverages the batching paradigm, but this work does not provide open-source code. Therefore, we rigorously implemented it according to its paper and named it PIMANN-Batch in our paper.
- Faiss-GPU [22]: It is the GPU-capable version of Faiss, which stores all vectors in GPU memory and performs their computations directly on the GPU.

As for FPGA-based systems [34, 70], because they are not open source, and work [34] requires a customized IP core, for which we do not have the necessary experimental setup, we are unable to include a comparison with these systems.

Datasets: We use the following two large-scale datasets for evaluation:

- SIFT-1B [62]: It consists of 1 billion 128-dimensional vectors encoded into 32 segments.
- SPACE-1B [3]: It consists of 1 billion 100-dimensional vectors encoded into 20 dimensions.

Metrics: We compare different solutions based on: throughput (QPS), latency, and tail latency under the same recall@10. Here, recall@10 refers to the recall calculated for the top 10 items returned by ANNS systems. For Faiss-GPU, we also compare the QPS/Watt to evaluate the energy efficiency of different systems. And we compare the QPS/$ to evaluate the cost efficiency.

Unless otherwise specified, we use the following default experimental configuration: selective replication defaults to using all MRAM memory; the number of clusters in IVF is set to 4096; the number of coroutine is 4; the slice size is 100 K; the default dataset is SPACE-1B; the default achieved recall@10 is 0.9.

5.2 Performance vs. Recall

We evaluate the throughput and latency of PIMANN, Faiss-CPU and PIMANN-Batch. PIMANN significantly outperforms the other two in all cases.

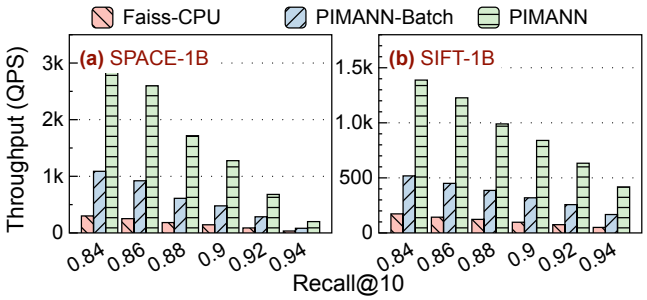

Figure 9: (Exp #1) Throughput under different recalls.

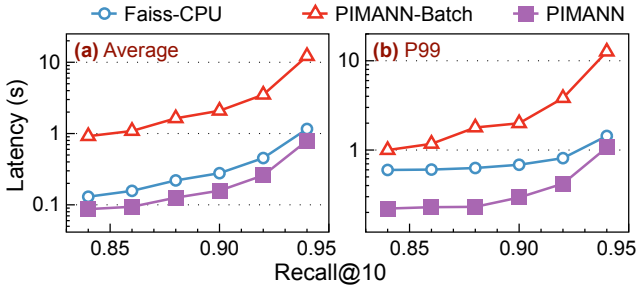

Figure 10: (Exp #2) Latency under different recalls. *(a) Average latency, (b) Tail latency*

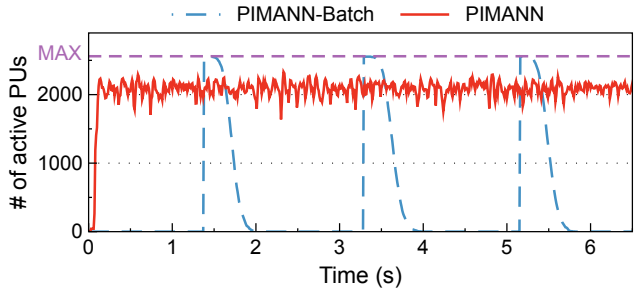

Figure 11: (Exp #3) The number of active PUs over time.

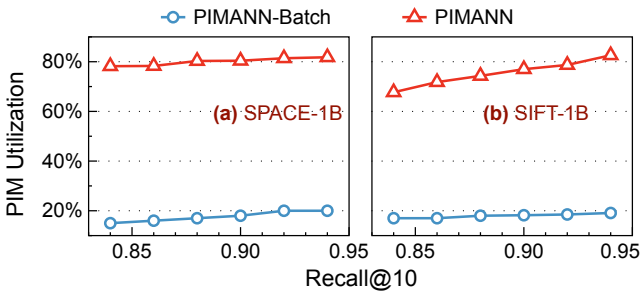

Figure 12: (Exp #3) PIM utilization of different systems. *Utilization is defined as the integral of the number of active PUs over time.*

Exp #1: Overall throughput. Figure 9 shows the throughput of PIMANN, Faiss-CPU, and PIMANN-Batch on SPACE-1B and SIFT-1B. We can make the following observations:

1) The throughput of PIMANN-Batch is 2.4-3.7× higher than that of Faiss-CPU. This is because batch takes advantage of the High Memory Bandwidth of UPMEM.

2) Compared with PIMANN-Batch, introducing per-PU scheduling (PIMANN) can further boost throughput by 2.4-2.9×. This is because PIMANN eliminates inter-batch under-utilization caused by batch gang scheduling, and alleviates intra-batch under-utilization caused by PU load imbalance within a batch. As a result, the QPS of PIMANN improves by 5.9-10.4× compared with that of Faiss-CPU.

3) For cases with low recall (≤ 0.88), the QPS of all three systems on SPACE-1B is higher than on SIFT-1B; for cases with high recall, the opposite is true. This is because, in low-recall cases, fewer clusters need to be queried on SPACE-1B compared to SIFT-1B to achieve the same recall rate, whereas in high-recall cases, the reverse holds true.

Exp #2: End-to-end latency. Figure 10 shows the average latency and the P99 tail latency of Faiss-CPU, PIMANN-Batch, and PIMANN under different levels of search recall requirements, ranging from 0.84 to 0.94. We can find that PIMANN exhibited significantly superior performance compared to CPU and PIMANN-Batch.

Compared to Faiss-CPU, although PIMANN-Batch is equipped with high-parallel UPMEM and enjoy a 2.4-3.7× throughput boost (Exp #1), its average latency is approximately 7.1 to 10.5× higher and its tail latency is about 1.7-8.8× higher, mainly due to the additional inter-batch blockage latency. In contrast, PIMANN eliminates this additional latency by enabling fine-grained bus sharing, reducing average latency by 32-43% and tail latency by 26-63%. The independent per-PU scheduling enables the independent scheduling of tasks, reducing the end-to-end per-query latency.

5.3 PIM utilization

Exp #3: PIM utilization. In this experiment, we revisit our motivation to investigate the PIM utilization of different systems. Figure 11 shows the number of active PUs over time. An active PU refers to a PU that is currently executing computing tasks. Here the used dataset is SPACE-1B; the recall rate is 0.9; other cases share a similar conclusion.

As shown in Figure 11, the number of active PUs in PIMANN (the red line) remains basically stable over time, achieving a utilization around 80%. This stability is achieved because PIMANN overcomes the limitations of batch scheduling. When the CPU receives a query task and completes the corresponding stage, it can immediately send the task to the PU. After the PU finishes the task, it can promptly return the result to the CPU and wait for new tasks. The PU remains active from the time it receives a task until it completes the task. In contrast, in PIMANN-Batch, the number of active PUs exhibits periodic fluctuations (the blue dashed

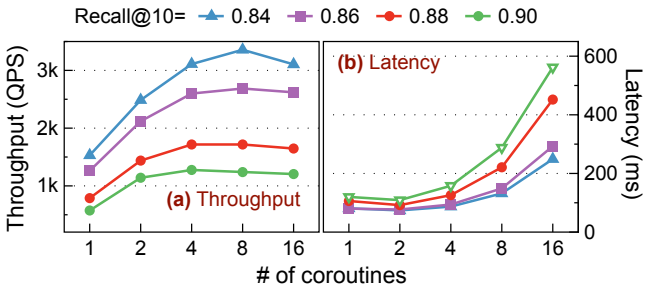

Figure 13: (Exp #4): Effectiveness of coroutine-based bus ownership switching.

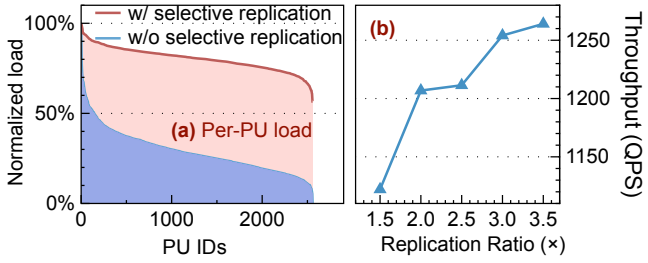

Figure 14: (Exp #5): Effect of per-PU dispatching. *(a) Per-PU load w/ or w/o selective replication, (b) Throughput with different capacity budgets.*

line). At the start of each batch, when all PUs are initially active, the number of active PUs peaks. Later, during the data copying phase between batches, all PUs yield the bus ownership and become inactive. Additionally, within a batch, due to the imbalanced task load among PUs, some PUs complete their tasks early and enter a waiting state, further reducing the number of active PUs.

Furthermore, we integrate the number of active PUs over time, and based on this, calculate the PIM utilization rates of the two systems under different datasets and recall conditions; please see Figure 12. Under all datasets and all recall rates, PIMANN can achieve 65-83% of the PIM utilization, far surpassing the batch paradigm (∼20%). This shows the effectiveness and efficiency of PIMANN's designs. The persistent PIM kernel technique eliminates the idle state between batches. On the other hand, the per-PU dispatching technique makes the load of each PU sufficiently balanced.

5.4 Techniques

Exp #4: Coroutine-based bus ownership switching. Figure 13 shows the performance with different coroutine counts. We can see that: 1) Compared to PIMANN without coroutine optimization (i.e., coroutine count=1), PIMANN with this optimization can yield around 3× better throughput. A moderate coroutine count can slightly reduce request latency, as coroutines help hide the latency associated with shared bus ownership switching. 2) However, an excessive number of coroutines increases the system's scheduling overhead, which negatively impacts both throughput and latency.

Exp #5: Effect of selective replication. Figure 14a shows the impact of selective replication technique in per-PU dispatching of PIMANN. Compared to the system without replication, which causes a single PU to become a bottleneck, PIMANN can use the replication technique to prevent hotspot clusters from concentrating on a few PUs, achieving better load balancing. Figure 14b shows the throughput under different memory capacity budgets, and throughput increases with the budget.

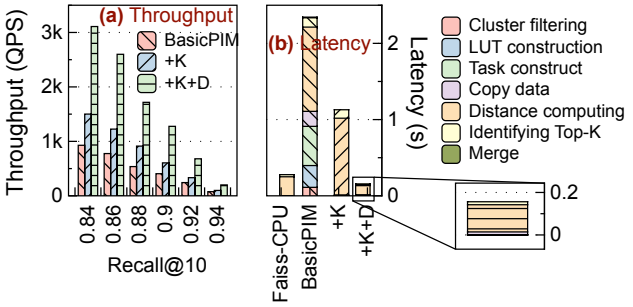

Figure 15: (Exp #6): Contributions of techniques. *(a) Throughput, (b) Latency breakdown of a query. Design techniques are cumulative. BasicPIM: a version of PIMANN-Batch w/o selective replication; K: persistent PIM kernel; D: per-PU query dispatching.*

Exp #6: Contributions of individual techniques. Figure 15 shows the contribution of each individual technique to the end-to-end performance. We only show the result of SPACE-1B, while SIFT-1B shares a similar conclusion.

We evaluate the throughput (Figure 15a) and latency breakdown (Figure 15b) of the system by gradually adding the persistent PIM kernel (abbr. as K) and the per-PU query dispatching technique (abbr. as D) to a baseline version of PIMANN-batch (called BasicPIM, which forbids the selective data replication optimization).

From Figure 15, we can observe that: 1) in all cases, both techniques have achieved positive performance gains. Specifically, the persistent PIM kernel technique has increased the throughput by 30% to 70%; by introducing the per-PU query dispatching, it further increases the throughput by 88% to 112%. 2) The persistent PIM kernel technique reduces the time in all stages except for distance computation, since it overcomes the inter-batch wait time of batch scheduling. 3) By introducing per PU query scheduling, distance computation time is also greatly reduced. The main reason is that this technique leads to a more balanced load distribution between PUs.

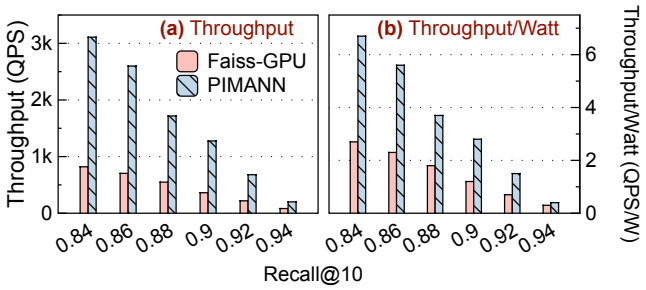

Figure 16: (Exp #7) Comparision with GPU-based system. *(a) Throughput, (b) Power Efficiency.*

Table 1: (Exp #8): Cost efficiency comparison of different solutions.

Solution	Price ($)	QPS	QPS/$
Faiss-CPU	1,500	144	0.096
Faiss-GPU	9,685	478	0.049
PIMANN	5,473	1,276	0.233

5.5 Comparison with GPU-based systems

Exp #7: Comparison with Faiss-GPU. We compare PIMANN and Faiss-GPU in terms of performance and power efficiency on the SPACE-1B dataset; see Figure 16. It is worth noting that there is a huge gap in peak computing resources between UPMEM and GPU. The GPU is equipped with 10,752 cores and has a computing power of up to 38.7 TFLOPS, while UPMEM can only achieve an integer processing capacity of 1 TOPS [65]. In terms of power consumption, the total power consumption of UPMEM is 462W [24]. In contrast, the power consumption of the RTX A6000 GPU is approximately 300W. The current high power consumption of UPMEM is mainly influenced by hardware fabrication, but it can be significantly reduced with future PIM designs. However, even with such a large power gap, as shown in Figure 16, the throughput of PIMANN is still 2.4 to 3.7× compared with that of the GPU, and the power efficiency is increased by 1.6 to 2.5× compared with that of the GPU. It is worth noting that Faiss-GPU requires storing all vectors in the GPU memory, so PIMANN has a much better capacity scalability.

5.6 Cost efficiency

Exp #8: Cost efficiency. As shown in Table 1, we evaluate the cost-effectiveness of three solutions using QPS/$. PIMANN outperforms both Faiss-CPU and Faiss-GPU. Compared to Faiss-CPU, PIMANN's price is higher, but its throughput is significantly improved, leading to a 2.4× increase in cost-effectiveness. Compared to Faiss-GPU, PIMANN achieves both the lower price and the higher throughput, resulting in a 4.8× improvement in cost-effectiveness.

6 Discussion

Available for the next generation of UPMEM: Our approach is fundamentally decoupled from specific architectural implementation details of the UPMEM platform. Instead, it leverages intrinsic hardware capabilities that are inherent to the underlying PIM infrastructure. Consequently, potential architectural modifications to UMPEM would not necessitate revisions to our proposed design.

The core of our methodology relies exclusively on the standardized control interface exposed by each PU. As it serves as the fundamental mechanism through which the host CPU issues critical control commands like launching PIM kernels, it is guaranteed to persist across future iterations of the UMPEM platform.

Other PIM architectures: We evaluate our framework on the UPMEM platform, which is the first commercially available real-world PIM hardware. And we observe that other PIM architectures [41,45,52,56,58] also exhibit similar characteristics to UPMEM. In future work, we will evaluate our framework on these platforms as conditions permit.

7 Related Work

We organize the related work into two types: 1) with similar goal and different mechanism, which uses other hardware to optimize ANNS systems, and 2) with different goal and similar mechanism, which uses PIM for other applications.

ANNS systems built on CPU, GPU, or FPGA. Faiss [22] and Milvus [67] are two widely used open-source vector databases. Both support CPU and GPU, but they are also restricted by the memory capacity.

DiskANN [35] and HM-ANN [60] all expand the memory of a single machine to support vector storage with a larger capacity. DiskANN extends DRAM with SSDs, forming a two-layer memory structure consisting of DRAM and SSD. It modifies the neighbor pruning algorithm of nodes, enabling free control over the scale of edge pruning, and adapts to the poor random access performance of SSDs through techniques such as cache prefetching. HM-ANN expands memory using heterogeneous memory and maps the hierarchical design of HNSW onto the memory hierarchy. The upper layer is placed on DRAM, and the bottom layer is placed on heterogeneous memory.

CAGRA [55], BANG [40] and RUMMY [71] use GPU to build ANN systems. CAGRA has designed a new indexing algorithm to make full use of the parallel processing capabilities of the GPU: it first calculates the kNN graph [21], and then prunes and reorders based on the kNN graph to build the index. However, the expensive GPU memory limits the scale of vectors. BANG focuses on graph-based ANNS, which requires much more memory than cluster-based systems. To extend GPU memory, BANG uses a storage structure similar to that of DiskANN. It stores compressed vectors in the

GPU video memory and the full set of vectors in DRAM for full distance computation. RUMMY solves the problem of redundant and inefficient data transmission between video memory and memory through techniques such as pipeline rearrangement.

Apart from CPUs and GPUs, there are also works that use FPGAs and SmartSSDs to build ANN systems. FANNS [37] achieves lower costs and power consumption than GPU through multi-stage automatic tuning, but it is still limited to a single card. DF-GAS [70] extends vector retrieval to multiple FPGAs, improving memory access efficiency through data prefetching and latency optimization. It also enhances query performance by enabling parallel searches that integrate both the entire graph and its subgraphs. Vstore [50] utilizes computable SSDs to complete graph-based approximate retrieval. SmartSSDs [63] are extended to multiple computable SSD devices. It has designed a multi-disk task scheduling strategy to ensure load balancing and a search pruning strategy to reduce unnecessary computations. CXL-ANNS [34] uses the CXL link protocol to connect memory pools and adopts caching and prefetching techniques to reduce the impact of the high latency of the CXL pooled memory.

Other systems using emerging PIM hardware. Numerous explorations have been made to build applications in different fields on PIM. 1) In the field of databases, PID-Join [51] utilizes PIM to implement the join operator and proposes a method for rapid communication among PIM nodes. Work [8] utilized PIM to address large table scan. Work [9] used PIM for query compilation. PIM-tree [38] designed an ordered index for PIM systems. 2) In the field of programming library, TransPimLib [27] provided a library of transcendental functions, such as trigonometric functions, logarithms, powers, etc. PID-Comm [54] proposes a framework for collective inter-PE communication designed for PIM-enabled DIMMs. 3) In the field of machine learning, work [16] implements two CNN algorithms, eBNN and YOLO3, on UPMEM. 4) In the field of scientific computing, UPMEM BLAST [43] deploys a molecular biology software on UPMEM. SparseP [25] provided a sparse matrix-vector multiplication library.

8 Conclusion

This paper presents PIMANN, an ANNS system designed to fully exploit the potential of UPMEM. By introducing the persistent PIM kernel and per-PU dispatching techniques, PIMANN effectively addresses the inefficiencies of traditional batching scheduling in PIM-based ANNS systems. The experimental results demonstrate its superiority in terms of throughput, latency, and resource utilization compared to existing CPU-based, GPU-based, and batching-paradigm-based solutions. PIMANN not only provides a promising approach for accelerating ANNS on PIM hardware but also offers valuable insights for future research in the intersection of memory-centric computing applications.

Acknowledgement

We appreciate our shepherd and anonymous reviewers' constructive comments for improving the quality of this paper. This work is supported by Beijing Natural Science Foundation (Grant No. 4254083), National Natural Science Foundation of China (Grant No. U23A20299), PCL-CMCC Foundation for Science and Innovation (Grant No. 2024ZY1C0030) and Kuaishou.

A Artifact Appendix

Abstract

The artifact consists of the C++ code of PIMANN and baseline systems used in evaluation. For ease of experiment reproduction and result visualization, we also provide runner scripts and plotter scripts accordingly. It is intended for validating the claims made in the paper and facilitating further research on Processing-in-Memory (PIM) hardware.

Scope

At a high level, the artifact allows its users to validate the following major claims in the paper:

- *Major Claim 1:* PIMANN outperforms baselines in terms of query throughput and latency. (Exp #1,#2,#7,#8)
- *Major Claim 2:* PIMANN overcomes batch scheduling limitations via fine-grained per-PU scheduling. (Exp #3,#6a)
- *Major Claim 3:* PIMANN's techniques synergistically improve performance.(Exp #4,#5,#6b)

Contents

The artifact contains source code, scripts, and README files. Below, we explain the contents aside from the README.

Source codes. The major part of source codes are well documented, facilitating further research.

```
common/              # shared files for both DPU and host programs
dpu/                 # DPU kernel functions
host/                # host programs interacting with DPU kernels
third-party/
   ├── upmem-2024.2.0-Linux-x86_64/  # modified UPMEM-SDK
   └── faiss_upmem/                  # modified FAISS
AE/                  # test scripts and plotting scripts
main.cpp             # main program entry point
```

Figure 17: Directory structure of our project.

Scripts. The scripts directory contains runner scripts for running experiments and plotter scripts for visualizing the results. Scripts directly reproducing the experiments (i.e., AE scripts) in the paper are in the ae subdirectory. Scripts not in the ae subdirectory serve as building blocks of the AE scripts, such as running a single experiment.

Hosting

PIMANN's artifact repository is hosted on GitHub at PIM-ANNS on the main branch. The first usable commit version is the initial commit (af44d9f). However, due to possible future bugfixes and updates, please always use the latest commit.

Requirements

Hardware Requirements: To run this project, a server equipped with UPMEM hardware (`https://www.upmem.com/`) is required.
Software Requirements: Additionally, we also need setup the following software environment.

- UPMEM-SDK: This project uses a modified version of UPMEM-SDK based on the 2024.2 release.

```
cd third-party/upmem-2024.2.0-Linux-x86_64
cd src/backends
bash ./install.sh
```

- FAISS: The IVFPQ index algorithm reuses portions of the FAISS codebase. For better UPMEM compatibility, we provide a modified version of FAISS based on: `https://github.com/facebookresearch/faiss`. Install like FAISS.

```
cd third-party/faiss_upmem
cmake -B build .
make -C build -j faiss
make -C build install
```

- Boost library: This project utilizes Boost's coroutine library. Thus, please install the libboost with the following commands.

```
sudo apt-get update
sudo apt install libboost-all-dev
```

Experiment workflow

Building PIMANN from source

Please simply use the CMake building system.

```
cmake -B build .
cd build
make -j
```

Hello-world example

To verify that everything is prepared, you can run a hello-world example that verifies PIMANN's functionality, please run the following command:

```
bash AE/hello_world.sh
```

It will run for approximately 1 minute and, on success, output something like below:

```
yyyy-mm-dd hh:mm:ss
json_path: PIMANN/config.json
query path is dataset/space/query10K.i8bin
query_num: 10000, dim: 100
searching SPACE1M, nprobe = 11
The command ./main 11 completed successfully
```

If you can see this output, then everything is OK, and you can start running the artifact.

Run all experiments

We provide convenient scripts for running either all experiments collectively (#1) or individual experiments selectively (#2).

#1: Running the all-in-one script. We provide an all-in-one AE script for running all experiments end-to-endly:

```
AE/run_all.sh
```

This script will run for approximately 8 hours and store all results in the "AE" directory.

#2: Running specific experiments. If you wish to replicate only specific experiments, we provide nine separate scripts corresponding to different experimental settings. These scripts, located in the `AE/exps/expX.sh` files (where X = 1, 2, ..., 8), can be used to reproduce all the figures presented in our paper. The name of all scripts (i.e., `expX.sh`) are aligned with those presented in our main paper.

If you want to run individual experiments, please refer to these script files and the comments in them (which describes the relationship between experiments and figures/tables).

Estimated running hours of experiments are shown in Table 2.

Table 2: Estimated time of all experiments

Experiment Description	Time(hours)
Exp #1: Overall throughput	1.5
Exp #2: End-to-end latency	1.5
Exp #3: PIM utilization	1.5
Exp #4: Coroutine	1.0
Exp #5: Selective replication	0.5
Exp #6: Individual techniques	1.0
Exp #7: Comparison with Faiss-GPU	0.5
Exp #8: Cost efficiency	0.2

Plot all figures & tables

We provide two alternative ways to visualize the experimental results.

#1: (Recommended) All-in-one jupyter notebook for Visual Studio Code users. Please install the Jupyter extension in VSCode. Then, please open AE/figures/plot.ipynb. Please activate the virtual environment (.venv/bin/python) by running the following commands.

```
source .venv/bin/activate
```

Then, you can run each cell from top to bottom. Each cell will plot a figure or table (see Figure 18). Titles of these figures and tables are consistent with those in the paper.

#2: Traditional python plotting scripts.

We provide a traditional plotter script. Please run it in the AE directory:

```
cd AE/figures
python3 plot.py
```

The command above will plot all figures and tables by default, and the results will be stored in the AE/figures directory (Figure 19). So, please ensure that you have finished running the all-in-one AE script before running the plotter.

The plotter further allows users to specify particular figures or tables to generate by providing supplementary command-line arguments. For example:

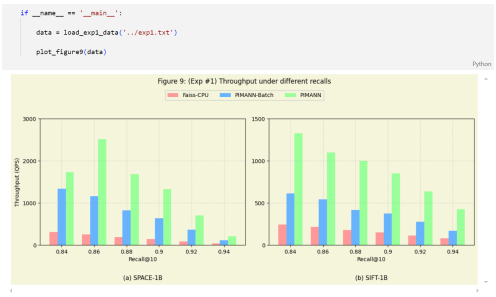

Figure 18: Visualizing results with the all-in-one Jupyter notebook.

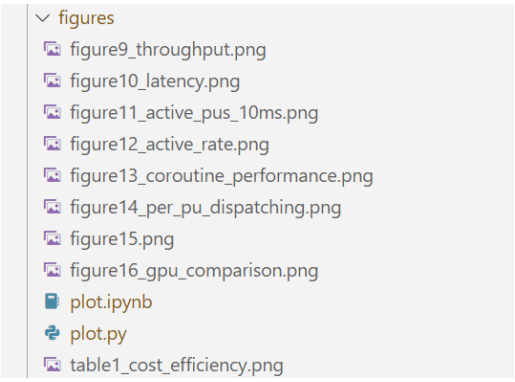

Figure 19: Visualizing results with the conventional script.

```
python3 plot.py exp1 exp2
```

Please refer to plot.py for accepted arguments.

```
python3 plot.py help
```

SwCC: Software-Programmable and Per-Packet Congestion Control in RDMA Engine

Hongjing Huang[†], Jie Zhang[†], Xuzheng Chen, Ziyu Song, Jiajun Qin, Zeke Wang[*]

Department of Computer Science, Zhejiang University, China

Abstract

Many data centers adopt Remote Direct Memory Access (RDMA) to allow data center applications to achieve low latency and high throughput, while keeping minimal CPU overhead. The upper-layer applications keep evolving rapidly, and thus need congestion control algorithms (CCAs) that exist in the NIC hardware also to react correctly and timely, especially for a burstier ML workload. Even worse, the data center network will increase the line rate to 400 Gbps, even 800 Gbps soon. Therefore, how to reduce control loop delay for various CCAs becomes crucial to the performance of various applications. However, RDMA's hardwired CCA is not able to satisfy such a requirement.

To this end, we design and implement SwCC, an RDMA engine with on-NIC RISC-V cores that allows software-programmable and per-packet congestion control. To avoid the performance degradation caused by introducing the programmable RISC-V cores, SwCC carefully designs the 1) RISC-V core memory subsystem, 2) engine architecture, and 3) interaction between the RISC-V core and other NIC resources. Besides, SwCC provides a set of rich software APIs, allowing developers to deploy new CCAs with minimum engineering efforts. We prototype SwCC using the Xilinx U280 FPGA. Experimental results demonstrate that SwCC achieves performance comparable to current commercial RDMA NICs (Mellanox ConnextX-5). Both SwCC and ConnectX-5 reach 3.1 µs control loop RTT and need 512B packet size to reach line-rate traffic (100 Gbps). In terms of flexibility, SwCC allows to use the C language to implement nearly all kinds of existing CCAs, e.g., rate-based CCAs, window-based CCAs, and credit-based CCAs. The potential ASIC design of SwCC can easily scale to higher network bandwidth.

1 Introduction

Modern data centers urge their networks with low latency and high bandwidth utilization while keeping low CPU utilization. In recent years, many mainstream data centers have adopted RDMA to reduce CPU overhead and network latency. Among all RDMA technologies, RDMA over Converged Ethernet (RoCE [33]) is the most widely deployed in modern data centers such as Microsoft Azure [8, 24, 28], Alibaba Cloud [20], and Google Cloud [40]. RoCE relies on Priority Flow Control (PFC) [32] to ensure the network lossless [20, 87, 88]. However, PFC introduces issues such as head-of-line blocking, congestion spreading, and PFC deadlocks [25, 28, 29, 56, 73]. To essentially prevent the activation of PFC, developers propose various CCAs to optimize network performance by effectively managing traffic and reducing congestion, thereby inherently preventing the activation of PFC. According to the location of RDMA congestion control (CC) logic, we mainly identify four types of CC solutions.

ASIC-based NIC CC solutions, such as DCQCN [88], IRN [56], implement the CC logic on the ASIC-based NIC. These solutions adjust network transmission within tens of nanoseconds after congestion notifications reach the NIC, significantly reducing control loop latency. However, CCAs are tightly coupled with the NICs and can not be optimized or upgraded after manufacturing. When a better CCA is introduced, it takes years to deploy it in real commodity NICs. Therefore, these solutions cannot keep up with the rapid iterations of data center CCAs. For example, at least 11 CCAs [1, 2, 6, 21, 22, 44, 54, 76, 81, 82, 86] have been proposed in 3 years, while only 7 Mellanox NICs [47–53] are released in recent 10 years.

CPU-based CC solutions. To facilitate the rapid deployment of new CCAs, people place the CC logic in CPUs, leveraging software flexibility and programmability to enable fast deployment of various CCAs. CPU-based CC solutions, such as Soft-RoCE [62], implement the CC logic on the CPU to enable the flexible deployment of various CCAs, allowing dynamic adjustments to transmission bandwidth based on diverse congestion signals. However, compared with deploying CC logic in the NIC, these solutions usually have a high control loop delay due to the long latency from PCIe and layered software (tens of microseconds higher). Considering RDMA's micro-second latency, such a high delay could

[†]Contributes equally
[*]Corresponding author

greatly degrade the network performance when congestion occurs. In our experiment that runs two flows with DCQCN [88] on a dumbbell topology, we observe that a high control loop delay would significantly increase the time needed to drain the switch queue. Compared with NIC-based CC solutions, running CCAs in the host CPU can increase the switch queue draining time by 7.8× (Subsection 3.2).

Naive FPGA-based SmartNIC CC Solutions. To enable programmability while keeping low control loop delay, developers place the CC logic in SmartNICs to avoid PCIe latency and complicated host software layers. Tonic [4] and NanoTransport [5] place the CC logic on FPGA-based SmartNICs. These approaches offload transport logic in the SmartNIC and allow users to update the NIC transport logic using hardware description language (HDL). However, FPGA programming requires much more engineering effort and a much longer development cycle, making it hard to keep pace with the rapid iteration of CCAs.

SoC-based SmartNIC CC Solutions. To address the programmability issue, NVIDIA BlueField-3 [60] offers Programmable Congestion Control (PCC) [63] to run CCAs in a RISC-V processor named datapath accelerator (DPA), which allows users to deploy the CCAs using software programming. Though this provides high programmability, it is hard to ensure performance with wimpy DPA, because the CC controller is triggered in a long interval and can not be triggered each time when receiving a packet. Besides, PCC only allows developers to adjust per-flow rates and cannot support credit-based or window-based CCAs, and PCC only supports a small subset of CCAs (as shown in Figure 2). Therefore, PCC results in low flexibility.

In summary, none of the existing solutions can provide both high flexibility and high programmability while maintaining a low control loop delay. To this end, we design and implement SwCC, an RDMA engine that allows software-programmable and per-packet congestion control. SwCC integrates an on-NIC RISC-V processor to allow flexible and fast deployment of CCAs while keeping software programming. The main **challenge** is that naively integrating a programmable RISC-V processor into the RDMA engine will cause severe performance degradation (as observed in NVIDIA BlueField-3 PCC [63]). To this end, SwCC carefully design the 1) memory subsystem by exploiting the data access pattern of different CCAs, 2) engine architecture to allow the core to run at a high frequency, and 3) interaction between the RISC-V core and other NIC resources to reduce required CPU cycles when running CCAs in the RISC-V core.

We prototype SwCC on an Xilinx U280 FPGA. Experimental results demonstrate that SwCC achieves comparable performance to current commercial RDMA NICs (Mellanox ConnextX-5): 1) 3.1 µs/3.4 µs control loop RTT, and 2) 512-bytes/512-bytes packet size to achieve line-rate traffic (100 Gbps). SwCC supports rate-based, window-based, and credit-based mainstream CCAs to ensure flexibility. We implement representative CCAs such as TIMELY, DCQCN, and HPCC using only 102, 140, and 148 lines of code, respectively. We believe that the potential ASIC design of SwCC can easily scale to a higher network bandwidth.

2 Background

An end-to-end CC algorithm involves the collaboration between the sender and the receiver. The receiver is usually responsible for notifying the sender of the congestion with meta information such as credits [19, 57] and congestion notification packets (CNP) [86, 88]. The CC controller on the sender side reacts to the congestion and reallocates network resources such as sending rate, and congestion window, depending on the specific algorithm. Different CCAs 1) use different CC signals, 2) trigger the CC controller at different times, and 3) reallocate network resources with different strategies when the CC controller is triggered.

2.1 What CC Signals to Use

CC controller on the sender side relies on CC signals to be aware of the network congestion. Different CCAs use very different signals, which can be categorized into four classes.

ECN: CCAs such as DCQCN [88], TCD [86], and ACC [81] use explicit congestion notification (ECN). The receiver would send congestion notification packets (CNPs) to notify the senders of the network congestion.

RTT: CCAs, such as TIMELY [55], Swift [40], BBR [11], Copa [7], and Bolt [6], allows the senders to proactively measure the link RTT to be aware of the network congestion. The RTT value can indicate the degree of the queuing along the link, which is caused by network congestion.

INT: CCAs, such as HPCC [42], PowerTCP [1], and Poseidon [76], utilize INT (In-band Network Telemetry) to obtain precise link load. When a sender sends a packet to a receiver, the switches along the path insert metadata indicating the current loads of the packet's egress port. The receiver copies these metadata to the ACK packet and sends the ACK to the sender, which then adjusts its transmission accordingly.

Token: CCAs, such as pHost [19], NDP [27], Homa [57], and ExpressPass [14], use credits to avoid network congestion. The available sender credit of a flow is the total tokens received from the receiver minus the transmitted bytes. Usually, each transmitted packet piggybacks the credit in the ACK.

2.2 When to Trigger the CC Controller

CCAs use events to trigger the CC controller. Different CCAs generate events at different times. The events can be mainly categorized into sending packet events, receiving packet events, and timer/counter events. The sending/receiving packet events are generated when sending/receiving packets. Note that the above events may not generated for all kinds of packets. For example, some CCAs [40, 42, 55] only need to generate receiving packet events for ACK packets. Timer/-counter events are generated periodically or when the counter

Table 1: Comparison of CC Solution in Different Locations

Solution	Control Loop Delay	Flexibility	Programmability
CPU-based CC [62]	23 μs	High	High
ASIC-baesd NIC CC [33]	3.1 μs	Low	Low
Naive FPGA-based SmartNIC CC [4]	3.3 μs	High	Low
SoC-based SmartNIC CC [63]	3.5 μs	Low	High
SwCC	3.3 μs	High	High

reaches a threshold. One CCA may adopt one or multiple kinds of events to trigger the CC controller. For example, credit-based CCAs usually generate sending packet events to trigger the CC controller to decrease the credit and generate receiving packet events to trigger the CC controller to increase the credit.

2.3 How to Adjust Data Transmission

CC controller limits the data transmission in three main ways:
Window: Previous works [1, 6, 40, 42, 76, 82] adopt a per-flow congestion window to allow for 1) tracking each inflight packet/segment, and 2) reacting to network congestion in a fine-grained manner. Window-based CC is quite complicated, especially in the presence of selective acknowledgments.
Rate: Instead of tracking each packet/segment, previous works [54, 55, 75, 81, 82, 88] adopt a more coarse-grained approach to limit packet sending rate. They only adjust the sending rate of each flow. For example, TIMELY [55] measures the flow RTT and adjusts the sending rate according to the RTT gradient.
Credit: Previous works [14, 19, 27, 57] use credits as permissions to send data. The credit of a flow is the total number of received tokens minus the number of transmitted bytes and the credit calculation consists of simple addition/subtraction.

3 Motivation

An ideal RDMA NIC should offer 1) low control loop delay to let CCAs react to congestion timely; 2) high flexibility to enable various kinds of CCAs; and 3) high programmability to allow developers to program easily without knowing much hardware details. However, the existing solutions fail to meet all the requirements as shown in Table 1. In the following, we present the detailed design and the corresponding limitations of each kind of solution.

3.1 ASIC-based NIC Solution

RDMA NICs such as Mellanox Connect-X series [50] are widely deployed in nowadays datacenters. They offload the congestion control logic to the NIC ASIC area to save host CPU usage. Running CCAs in the NIC greatly brings low control loop delay as it avoids PCIe traversals for control signals. However, ASIC-based solutions are far behind the rapid evolution of the CCAs, because one special RDMA NIC usually only supports one or a few CCAs with configurable settings. For example, Mellanox CX series NICs only support DCQCN. However, CCAs are evolving rapidly. From 2021 to 2023 alone, 11 new CC algorithms were presented [1, 2, 6, 21, 22, 44, 54, 76, 81, 82, 86] to improve the CC performance for different scenarios. At the same time, commercial NIC hardware requires years of development. Mellanox releases only seven CX series NICs [47–53] since 2012. It's impossible for commercial NICs to always keep pace with the evolving CCAs.
Limitation: ASIC-based NIC solutions provide low control loop delay but have low flexibility and low programmability. Even worse, ASIC-based NIC usually only supports adjusting CCA parameters through firmware updates, and upgrading to a new CCA is nearly impossible for currently off-the-shelf ASIC NICs.

3.2 CPU-based CC Solution

To enable fast deployment of new CCAs, Soft-RoCE [62] runs CCA logic in host CPU software. It implements the RDMA transport on top of the Linux network stack. Users can use software programming languages to implement their CCAs, providing high flexibility and programmability. However, running CCA logic in the software significantly increases the control loop delay. As Table 1 shows, Soft-RoCE needs nearly an order of magnitude higher control loop delay than running CCAs in the hardware NIC. Compared with running CCAs in ASIC-based NIC, Soft-RoCE introduces severe overheads: PCIe traversal, software stack, and kernel switching.

The high control loop delay is harmful to the performance of CCAs. To illustrate the potential impact of control loop delay, we conduct an experiment in our testbed. We connect two sender servers and one receiver server to a P4 switch. Each server is equipped with an FPGA NIC running DCQCN [61]. We first let one sender establish a stable flow to the receiver and then let the other sender establish a new flow to the receiver. The control loop delay is measured from the generation of the CNP packet to when the sender receives it. We manually delay the processing of the CNP packet to obtain different control loop delays. Figure 1 shows the time to drain the switch queue when congestion occurs. We observe that a high control loop delay would significantly increase the time needed to drain the switch queue. Compared to NIC-based CC solutions, running CCAs in the host CPU can increase the draining time of the switch queue by 7.8×.
Limitation: CPU-based CC solution provides high flexibility and high programmability. However, the overheads from PCIe traversals and software context switching significantly increase control loop delay, thus degrading CC performance.

3.3 Naive FPGA SmartNIC-based CC Solution

To keep low control loop delay while enabling multiple kinds of CCAs, researchers offload transport protocols on FPGA SmartNICs. For example, Tonic [4] proposes a Verilog-programmable transport layer in hardware. NanoTransport [5] proposes a programmable hardware transport layer using the

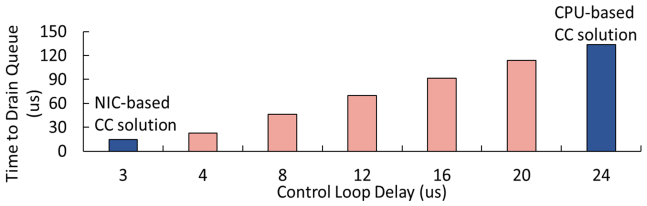

Figure 1: Effect of control loop latency on queue draining time.

P4 language. Thus flexibility is guaranteed because such a programmable transport allows developers to implement CCAs according to their needs. Low control loop delay is also guaranteed because the transport runs in the NIC and the CC control signals do not need to traverse the PCIe interconnect or kernel stack.

Limitation: However, offloading transport to FPGA exposes one severe limitation: hardware programming offers low programmability. Developers have to write hardware description languages (HDLs) such as Verilog and Chisel. Implementing a CCA using HDL requires much more engineering effort. Developers have to know hardware details well and fix timing problems. Besides, debugging is very difficult when using FPGAs to implement CCAs.

3.4 SoC SmartNIC-based CC solution

NVIDIA BlueField-3 SmartNIC allows the offload of CCAs to the RISC-V processor of the SoC SmartNIC, called programmable congestion control (PCC [63]). PCC allows developers to write a C-style program to run on the NIC RISC-V processor. NIC periodically generates events and notifies the user's CC program to adjust the data transmission rate. Conceptually, PCC keeps a low control loop delay while providing high flexibility and programmability.

However, the cache and memory system of the datapath accelerator (DPA, i.e., RISC-V cores) in BlueField-3 are inadequate to support running PCC efficiently. Because DPA has poor cache/memory performance and weak single-thread performance, DPA is suitable for simple workloads with high parallelism (using its 256 concurrent threads) [13]. However, CCAs need to fetch many packet-related data (i.e., fields in the packet header) and QP-related data (e.g., per-QP credit) from memory, so its poor cache (L1: 10 ns)/memory (300 ns) incurs high overhead to process each packet. For example, at a 100 Gbps line rate, a 1 KB packet arrives every 89 ns, well below the memory access latency (300 ns).

This cannot be easily solved by using DPA's multiple threads. CC is not a high-parallelism workload, as the packet processing of the same QP must be mapped to the same thread to avoid inter-thread communication/synchronization overhead. As such, letting DPA run CC for a small number of QPs cannot exploit the high parallelism of DPA and easily becomes a system bottleneck, especially for the CCAs triggered per packet. This is also why the **current PCC only supports rate-based CCAs**, because not every packet would trigger the CC in rate-based CCAs.

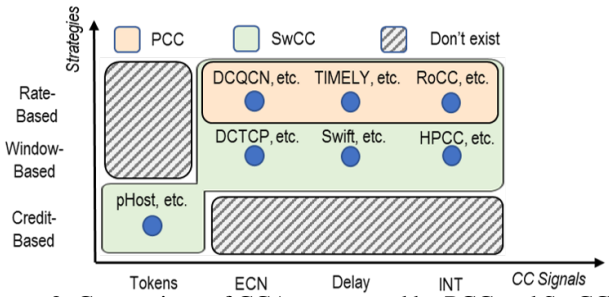

Figure 2: Comparison of CCAs supported by PCC and SwCC.

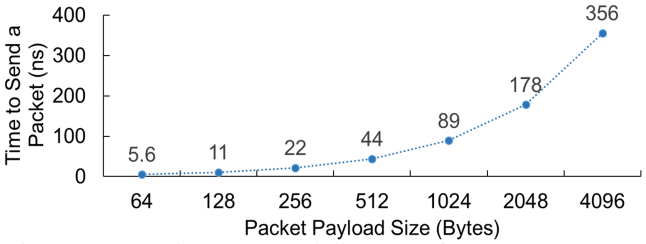

Figure 3: To achieve a network line rate of 100 Gbps, the NIC has to send a data packet within a specific duration depending on the packet size.

4 Design and Implementation

To address these limitations, we present SwCC, a NIC RDMA engine that allows flexible implementation of various CCAs through software programming without sacrificing performance. SwCC has three design goals:

Low Control Loop Delay and Short CC Controller Triggering Interval. As described in Section 3.2, control loop delay directly influences the efficiency of CCAs, SwCC aims to provide low control loop delay. Besides, SwCC must ensure a short CC controller triggering interval to support per-packet CCAs at a high network bandwidth. To be more specific, we have to allow triggering CC controller upon sending/receiving a packet. As shown in Figure 3, under the 100 Gbps line rate, the packet arrival interval is only 89 nanoseconds for 1 KB packets. Therefore, the frequency of the CC controller should be as high as possible, and the required cycles for processing each packet should be as low as possible.

High Flexibility. To support various kinds of CCAs, SwCC must allow developers to use different kinds of CC signals (§Section 4.3.1) and use different kinds of data transmission strategies (§Section 4.2.2). Besides, SwCC should allow triggering the CC controller flexibly (§Section 4.3.2).

High Programmability. To keep pace with the fast evolution of CCAs, SwCC must provide an easy-to-program interface to allow developers to focus only on the high-level CC algorithms, rather than on low-level hardware details.

To this end, we design and implement SwCC, an RDMA engine that allows software-programmable and per-packet congestion control. SwCC integrates an on-NIC RISC-V processor to allow flexible and fast deployment of CCAs while keeping software programming, thus providing flex-

ibility. However, this introduces significant processing overhead compared to hardwired solutions. Our key idea is to carefully design the interaction between the RDMA engine and the RISC-V core, so as to enable the user CC program running in the RISC-V processor to access and control the NIC resources at a very low cost. To do so, we rely on careful co-design from both hardware and software perspectives. As such, we have ensured 1) **low control loop delay** because the CCAs are running in the NIC RISC-V core; 2) **short CC controller triggering interval** due to the carefully designed hardware/software interaction mechanism; 3) **high flexibility** because we expose enough hardware resources to the RISC-V processor; and 4) **high programmability** because users can program the RISC-V core with a high-level software programming language.

4.1 SwCC Design Overview

Figure 4 provides SwCC system overview. The hardware part mainly consists of 1) RX path logic; 2) TX path logic; 3) "WQ Handler" module that processes WQEs, sending data packets to the TX CC and packets without data to the "Header Fabricator"; 4) "DMA" that performs address translation and reads/writes data to the host memory; 5) QP-aware memory subsystem that maintains the per-queue-pair QP context.

Along the RX path, SwCC consists of 1) "RX Parser" that parses incoming packets; 2) "Packet Retransmission" that handles go-back-N retransmission; 3) "Packet Filter" that generates events to trigger the RX CC core according to the user configuration; 4) "RX CC" that runs CCA logic related to dealing with RX events.

Along the TX path, SwCC consists of 1) "TX CC" that runs CCA logic related to whether to allow transmitting a packet; 2) "Header Fabricator" and "Packet Fabricator " that fabricate the header and the complete packet.

SwCC software consists of a rich set of APIs allowing easy programming. These APIs allow users to define 1) when to trigger the CC controller flexibly, 2) what extra header fields should be carried in each packet as needed, and 3) how to let the CC core interact with hardware efficiently. In the following, we present the detailed design of SwCC, organized in a manner that shows how it guarantees our design goals.

4.2 How to Keep Low Control Loop Delay and Short CC Controller Triggering Interval.

To keep a low control loop delay, we put a programmable CC controller (RISC-V core) that runs CCAs in the NIC engine. This greatly reduces CC controller response time to network congestion as it avoids the long PCIe wire latency, which could contribute up to 90% wire-to-wire response time for flows with small packets [59].

However, naively integrating a RISC-V processor into the NIC leads to low single-core performance due to the power/-form factor limitation of the NIC, as evidenced by the case of NVIDIA PCC. To keep a short CC controller triggering interval, we 1) strive to increase the CC controller hardware frequency as much as possible; 2) strive to reduce the required number of CPU cycles when the CC controller processes each event.

4.2.1 TX/RX Separated Multi-Core

Integrating more cores in the CC controller can linearly increase the CC processing capability, thus allowing a short CC triggering interval. Instead of naively adopting a multi-core design in the CC controller, we propose a TX/RX separated multi-core design, which runs the TX and RX logic of CCAs in different CC controller RISC-V cores.

Such a design is guided by our observation that **most CCAs can be clearly partitioned into a TX function and an RX function**, in both the programming perspective and logic perspective. In the RX function, when the CC controller is triggered by an event, the CC controller adjusts the context of the current queue pair, such as the congestion window and credits. In the TX function, the CC controller usually decides whether to send a packet or not, according to the context of the current queue pair.

Based on this observation, the proposed TX/RX separated multi-core lets each core only deal with either TX or RX function, so as to reduce processing latency. In case of enough hardware resources for $2N$ cores in the NIC, we let half of them process the TX function and the other half process the RX function. Each queue pair corresponds to a specific TX CC core and a specific RX CC core, according to the result of the queue pair number (QPN) mod N. This avoids consistency issues as the same queue pair would not be processed by different RX CC cores or TX CC cores.

The main benefit of TX/RX separated multi-core is that a single core would only deal with a subset of CC logic and thus only need to access a subset of the NIC resources. For example, the RX CC core only needs to be connected to the RX port, and the TX CC core only needs to be connected to the TX port. Compared to a fully connected data path, TX/RX separated multi-core can greatly reduce the required hardware resources to construct the data path. As such, the design can meet the timing constraints more easily. In our FPGA prototype, TX/RX separated multi-core can increase the design frequency by up to 16% (§Section 5.3). We believe that the conclusion still holds when applied to an ASIC-based design of SwCC.

4.2.2 QP-aware Memory Subsystem

A traditional memory subsystem relies on a large cache with a sophisticated pre-fetching mechanism to provide upper-layer applications with low-latency memory accesses. However, due to form factor and power constraints, the cache size in the NIC is usually limited, and the pre-fetching mechanism is much wimpier compared with traditional host server CPUs. And a NIC cache usually has much higher latency than the server CPU cache (an order of magnitude higher) as observed in NVIDIA BF3 [13].

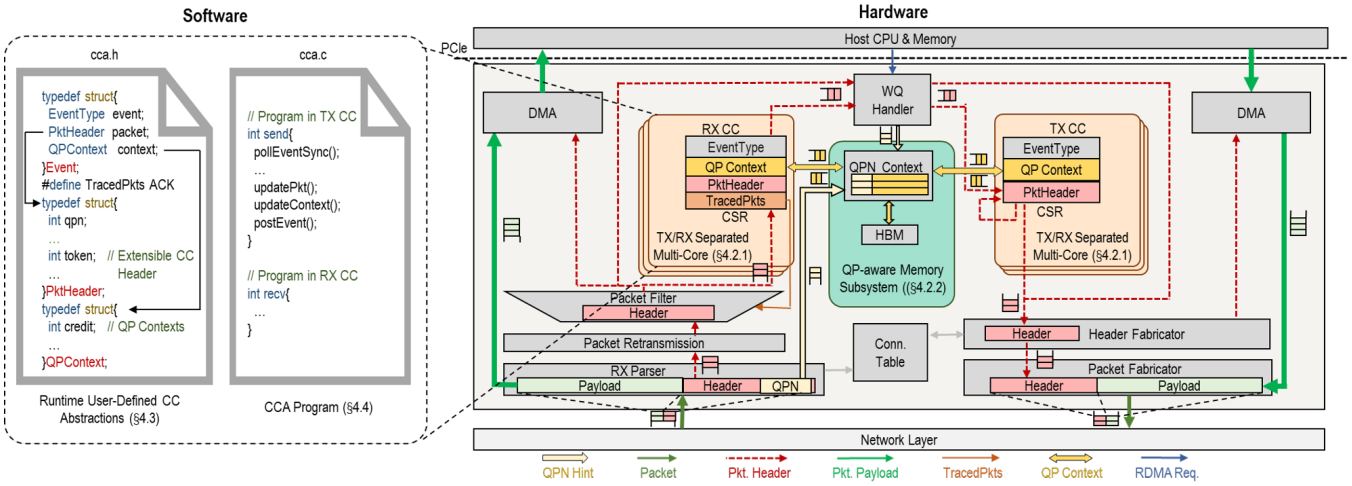

Figure 4: Overall architecture of SwCC.

Instead of trying to construct a powerful and general memory subsystem, we exploit the underlying data access pattern in the NIC CC core and construct our memory subsystem accordingly, based on the following observation. When receiving a packet, the packet is first processed by the RX-related logic, such as header parsing and retransmission logic. Then the CC controller is triggered to run CC logic. When running CC logic, the RX core needs to access QP-related context, such as per-QP credits, and packet-related information, such as returned tokens.

Inspired by this, we propose QP (Queue pair)-aware memory subsystem to forward the QP contexts and user-specified packet header to the CC core's control & status registers (CSR) before the CC core is triggered. What's more, before the packet is processed by the RX-related logic, we use the QPN as a hint to prefetch the QP context from off-chip DRAMs to the on-chip memory region. As such, it overlaps the DRAM access latency and RX-related logic processing, minimizing the time of forwarding QP context to the CC core's CSRs. To do so, we introduce four hardware-software co-designed mechanisms (described below) and revamp the data access process based on them.

QP Context Table. In SwCC, we do not design a traditional cache that organizes data in cache-line granularity, uses memory address to index each cache slot, and uses host DRAM to back on-chip SRAM. Instead, we use both on-chip SRAM and off-chip DRAM to store QP contexts. The on-chip SRAM is organized as a 4-way set-associative cache, with each cache line storing all the contexts of a QP. Each slot is 128 bytes[1] and the total size of the QP context table is 128 KB, which can store QP contexts of up to 1K QP. The swap-in/out process follows a simple LRU algorithm. Unlike traditional RNICs, which use host DRAM to back on-chip SRAM, SwCC uses on-NIC DRAM, which offers much lower access latency (1200 ns vs. 100 ns) and incurs significantly lower swapping overhead.

CSR-based Fast Path. Although the data organization differs from that of traditional caches, the QP context table still has a relatively high latency given the power/form factor constraints. Instead of letting CC cores access the QP context table at runtime, we let hardware write the corresponding QP contexts into the core's control & status registers (CSRs) in advance. The standard RISC-V ISA sets aside a 12-bit encoding space for up to 4,096 CSRs [66]. In each SwCC CC core, we leverage 64 CSRs[2] that have been reserved in the RISC-V ISA sets. Before the CC core is triggered to execute the RX or TX function, the NIC hardware would write the incoming event type, and QP contexts into the reserved CSRs using a user-configurable manner in advance. For the RX CC core, the header of the received packet that triggers the RX function would also be written into the CSR registers. During the execution of the TX/RX function, the CC cores directly operate on the CSR registers instead of the QP context table. Reading data from CSRs to general-purpose registers (GPRs) only takes one cycle since implementing 64 one-cycle CSRs (256 bytes in total) is easy even under power/form factor constraints. As such, the CC core execution time is greatly reduced as high NIC cache access latency is removed.

Prefetch with QPN Hint. When an event is scheduled to run on an RX CC core, the NIC hardware has to write the QP context into the CC core's CSRs. However, it's likely that the QP's slot is not in the QP context table, as the on-chip table size is limited and the number of concurrent QPs could be numerous. In this case, the QP context table has to fetch the QP contexts from the backed off-chip DRAM and the CC core has to be stalled for dozens of cycles due to the long off-chip DRAM access time. As such, we use QPN as a hint to prefetch the QP contexts from off-chip DRAM in advance.

In the RX path, when a packet enters "RX Parser", the packet QPN would be extracted and forwarded to the QP

[1]We choose 128 bytes because the per-QP contexts of most CCAs can fit in this size.

[2]The 64 CSRs include 32 CSRs for writing QP context, 16 CSRs for writing packet header, and 16 CSRs for writing event type and other configurations.

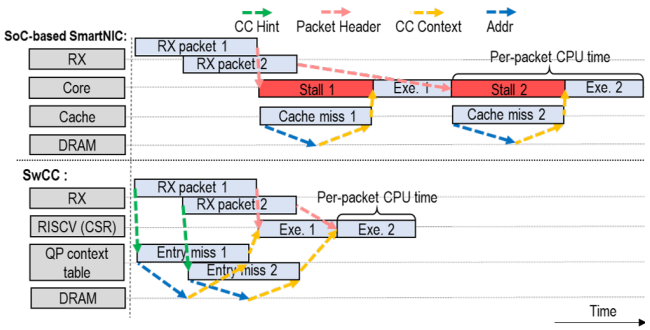

Figure 5: Comparison of Soc-based SmartNIC and SwCC when processing packets.

context table to prefetch the QP contexts from the backed DRAM if the QPN's contexts are not in the table. Before the packet's corresponding event runs on the RX CC core, it has to go through "RX Parser", update the packet sequence number (PSN) in the "Connection table", and go through "Packet Filter". Processing the above logic takes around 60 nanoseconds. Considering that a DRAM access time is very close to this value, forwarding the QPN in advance allows the QP context table to hide the stall penalty caused by long-latency DRAM access.

In the TX path, when a sending packet request from the user/RX core enters the "WQ Handler", the request QPN would be forwarded to the QP context table for prefetching. This also helps to hide QP context table miss penalty as the "WQ Handler" has to slice large messages into small packets and the processing time could be up to dozens of nanoseconds.

Consistency Guarantee. Although different QPs are mapped to different CC cores, it is likely that a TX CC core and an RX CC core concurrently access the QP context of a particular flow. As such, the QP context table must provide a consistency guarantee. We implement locking purely in hardware, without requiring atomic instructions in the software. The core is triggered by hardware only when the QP context entry to be processed is not owned by other cores. Once triggered, the QP context entry is owned by this core, and the hardware manages the entry ownership. Each entry has a lock bit to indicate whether it is owned by a core. When triggering a core with an event, the hardware checks the lock bit; if occupied, it tries other events; otherwise, it triggers the core and sets the lock bit. When the core finishes execution, the hardware clears the lock bit. This mechanism works for two reasons. First, each event follows a run-to-completion model, so a core does not require ownership after processing. Second, the core processes events one by one, with each event having only one corresponding QP context entry, ensuring no complicated lock dependencies.

Summary. With the above four hardware-software co-designed mechanisms, SwCC is able to reduce as many as possible CC core stalls due to the long off-chip memory access time. Figure 5 illustrates how the packet events are processed when there is a miss in the on-chip cache/QP context table. In SoC-based SmartNIC, the RX packet has to be pre-processed by the RX hardware pipeline before triggering CC core execution. The cache miss would incur the stall of the core. In SwCC, we prefetch with a QPN hint to hide on-chip QP context table misses within the RX packet pre-processing. As such, the real RISC-V core cycles used for each packet event are minimized, thus a short CC controller triggering interval is guaranteed.

4.3 How to Keep High Flexibility

SwCC should provide developers with the ability to implement various kinds of CCAs, i.e., developers can decide 1) what signals to use, 2) when to trigger the CC controller, and 3) how to adjust data transmission in the CC controller.

As described in § 4.2.1, we place a multi-core RISC-V processor as the CC controller to allow developers to implement their custom logic on how to adjust data transmission. In the following, we present how developers can decide what signals to use and when to trigger the CC controller in SwCC.

4.3.1 Using Different CC Signals in SwCC

SwCC allows developers to leverage different CC signals to provide as much flexibility as possible. As discussed in §Section 2, CC signals can be mainly categorized into 1) ECN, 2) delay, 3) token, and 4) INT signals.

Extensible CC Header. To support the above CC signals, we propose the extensible CC header, a customized header sitting after the RoCEv2 BTH header. To use the extensible CC header, developers can add their own fields in the definition of a structure `PktHeader`. The first four fields (QPN, RDMA opcode, pktLength, and ECN) in the `PktHeader` are common for all kinds of CCAs, and developers can add their own fields, such as tokens, after the fixed four fields. Each packet in SwCC would carry the user-defined extensible CC header. The size of the extensible CC ranges from 0 to 64 bytes, as 64 bytes are enough for all mainstream CCAs (for example, HPCC [42] has 42B). In the RX path, when receiving a packet, the QPN and opcode in the BTH header, the packet length and ECN signal in the IP header would be extracted to the first four bytes of the structure `PktHeader`. The user-defined extensible CC header would also be placed in the following position of the structure `PktHeader`. The RX CC core can read the `PktHeader` structure to get all the required information. In the TX path, the TX CC core can write data into the structure `PktHeader`, and the hardware would

be responsible for padding the data into the packet header. The position of the `PktHeader` in the packet header is shown in Figure 6.

Compatibility. Different CCAs have different deployment requirements. If the chosen CCA does not utilize the extensible CC header and thus does not require the remote side to provide custom metadata/signals, the remote side can be an existing commercial NIC. Otherwise, the remote side must be a SwCC-enhanced NIC. For non-INT CCAs, the switch simply treats the extensible CC header as part of the RDMA packet payload, and there is no switch deployment requirement. For INT-based CCAs, we currently need to use programmable switches to add INT metadata in the extensible header, as existing switches can only add INT metadata at the end of the packet.

The extensible CC header allows developers to implement ECN-based, token-based, and INT-based CCAs. To support delay-based CCAs, SwCC implements a hardware timer and exposes the timer as a CSR to all CC cores. CCA logic in the CC core can read this CSR to get the hardware time and use it to implement their delay-based CC logic. As such, SwCC can support all four kinds of CCAs and SwCC allows developers to decide what CC signals to use flexibly.

4.3.2 Selective Triggering

To allow developers to flexibly trigger the CC controller, we design a "Packet Filter" module that sits between the "RX Parser" and RX CC cores. Instead of letting each incoming packet generate an event and trigger the CC controller, the "Packet Filter" only generates events for the user-specified packets.When a packet arrives, the "Packet Filter" checks the opcode field in the packet header and determines whether to generate an event to trigger the RISC-V core. As such, developers can decide whether to trigger the CC controller at runtime.

The "Packet Filter" recognizes the RDMA opcode in the BTH header of the incoming packet. The opcode consists of 8 bits, where opcode[7:5] indicates the RDMA transport service type (e.g., Reliable Connection) and opcode[4:0] indicates the packet type (e.g., Send, Recv, Read, Write, etc.). In addition to the opcodes defined by the RoCEv2 standard, developers can adopt unused 0x18-0x1F opcodes to define their own packet types [34]. When implementing a CCA, developers must specify which RDMA opcodes will trigger an event by setting a 32-bit one-hot value. During system initialization (i.e., after the CCAs are programmed to the RISC-V core), the RISC-V core updates one of its CSRs using the one-hot value. The value of this CSR is connected as an input of the "Packet Filter" module, which would trigger the events according to this input. By blocking unnecessary packet events, selective triggering allows the CC controller to focus on processing user-specified events. As such, SwCC achieves its design goal of letting developers decide when to trigger the CC controller flexibly.

4.4 How to Keep High Programmability

SwCC provides a rich set of programming APIs (Table 2) to help developers to deploy their CCAs. We take a simple credit-based CCA as an example and show how to use these APIs to implement the CCA. The CCA has two functional parts: sender-side TX function and receiver-side RX function.

On the sender side, the TX function checks if the remaining credit is larger than the length of the to-be-sent packet. If the credit is enough, the TX function would notify the NIC hardware to construct and send this packet out. Otherwise, the request would be deferred.

On the receiver side, the RX function increments the credit if it has received an ACK packet. If the received packet is a data packet, the RX function would generate a send packet event to notify the NIC hardware to send an ACK packet to the remote sender. The CCA defines four bytes in the extensible CC header to store the returned credits in the ACK packet.

```
/* Selective processing */
#define TracedPkts (ACK | WRITE_REQ | READ_RESP)
/* Extensible packet headers */
typedef struct{
  int qpn;          /*Static*/
  int opcode;       /*Static*/
  int pktLength;    /*Static*/
  int ecn;          /*Static*/
  int returned_credit;
}PktHeader;
/* Extensible QP context */
typedef struct{
  int total_credit;
}QPContext;
/* Program running in the TX CC cores*/
int send(){
  int credit;
  Event e;
  while(true){
    /* Poll for new packet arrivals and read events from CSR */
    pollEventSync(&e);
    /* Update the credit when sending a packet */
    if(e.context.total_credit > e.packet.pktLength){
      credit = e.context.total_credit - e.packet.pktLength;
